CONTENTS

Frederic C. Bartlett (1886–1969) was a distinguished British psychologist who spent most of his career at Cambridge University. He is chiefly known today for his book Remembering: A Study in Experimental and Social Psychology, *which laid the foundation for schema theory.*

INTRODUCTION

Frederic C. Bartlett (1886–1969) was a distinguished British psychologist who spent most of his career at the University of Cambridge. He was trained as an experimental psychologist and became the most prominent English psychologist of his generation through the influence of his writings, his work on applied problems, and the great students he trained who continued work in his tradition. He is chiefly remembered today for his 1932 book, *Remembering: A Study in Experimental and Social Psychology*, which laid the foundation for schema theory and pioneered the study of memory distortions. Bartlett was knighted in 1948 for his great accomplishments, which are described briefly below.

BIOGRAPHICAL DETAILS

Early Life and Education

Bartlett was born in Stow-on-the-Wold, a small country town in Gloucestershire. His father was a successful businessman who made shoes and boots, but the educational opportunities in town were slim. A severe illness when he was 14 years old made it impossible for him to attend a boarding school, so young Bartlett stayed in Stow and educated himself with the aid of his family (his father had a great library) and friends. He eventually took a distance course at the University of London and settled on psychology, logic, sociology, and ethics as topics of study. He received an MA from London in 1911 and continued to Cambridge, where he came under the influence of W. H. R. Rivers, Cyril Burt, and C. S. Myers. He obtained his doctorate with first-class honors in 1914, just as Burt decided to leave Cambridge. Myers then offered Bartlett Burt's vacated position, so Bartlett stayed in Cambridge.

The First World War and Bartlett's Development

The First World War broke out soon after Bartlett took up his position at Cambridge. Most of Bartlett's colleagues left to aid the war effort, but poor health prevented him from joining them. However, the absence of people senior to him thrust him into the role of leading the psychological laboratory. He threw himself into teaching and began writing a book based on his dissertation, although it would not appear for many years. Much of his research during this time focused on practical problems driven by the war, such as detecting weak auditory signals in noise (to help with the problem of detecting German submarines). His war work eventually culminated in a book, *The Psychology of the Soldier* (1927).

After the war, Rivers and Myers returned to Cambridge and became Bartlett's associates. However, in 1922 Rivers died suddenly and Myers retired, so Bartlett became director of the Cambridge Laboratories and built them into a research powerhouse over the years. In the 1920s Bartlett's research turned to social anthropology, an early interest, and he wrote *Psychology and Primitive Culture* (1923). His international reputation expanded and he came to know distinguished psychologists from around the world.

REMEMBERING

In 1932 Bartlett published his great book, which is still in print today. *Remembering* actually grew out of his dissertation experiments begun in 1913, so the gestation period was nearly 20 years. The book

introduced a very different tradition for studying memory from the scientific methods of Ebbinghaus with their emphasis on careful control and measurement of memory in rather unnatural conditions. Bartlett's methods were casual, almost anecdotal, compared with those of Ebbinghaus, yet he uncovered powerful truths about remembering that reverberate through the field even today. Bartlett tested people under fairly relaxed conditions and his 'data' consisted largely of verbal reports with which he sprinkled his writing. (*See* **Ebbinghaus, Hermann**)

The early chapters of *Remembering* actually consist of studies of perceiving. The great middle part of the book is directly concerned with memory. The last section of the book deals with social and anthropological factors in cultural transmission. The general thrust of the book is to emphasize the constructive nature of cognition. Perceiving, remembering, and all of thinking involve the individual as part and parcel of the cognitive process. For example, in perceiving an ambiguous stimulus that is briefly presented, one's past background and experience determine what is perceived as much as (or even more than) the stimulus that is presented.

Bartlett devised two methods to study remembering: repeated reproduction and serial reproduction. In his most famous work he read a native American folk tale, *The War of the Ghosts*, to his British participants and then later tested their memories. This bizarre and supernatural story was usually read twice, aloud. In the repeated reproduction technique Bartlett would have his listeners recall the story after an interval of about 15 min. Next he would test their memory for the story at various later times, but with no further presentations of the story. Thus, repeated reproduction involves the same individual repeatedly reproducing the story, as the name implies. Bartlett's interest centered on how people remembered the story and how their memories would change over time and repeated retellings.

Not surprisingly, people remembered less about the story as time passed – their reports became increasingly short. Of more interest was the content of what they did remember and what these recollections indicated about the workings of memory. Besides becoming shorter, the stories became simpler, supernatural elements dropped out and other bizarre items would be reinterpreted. Bartlett called this process 'rationalization' because people added material to explain unnatural elements, or dropped them out altogether if they did not seem to fit the person's past experience. Rationalization over repeated retellings caused the story 'to be robbed of all its surprising, jerky and inconsequential form, and reduced it to an orderly narration' (p. 153 of the 1932 edition of *Remembering*). Bartlett also referred to the 'effort after meaning' that occurred in his perception and memory experiments, whereby people try to convert or recode elements that are difficult to perceive or understand into forms that can be comprehended. People try to impose structure and order to understand the world around them, even when their experience does not conform neatly to their prior categories.

Bartlett wrote that 'the most general characteristic of the whole of this group of experiments was the persistence, for any single subject, of the form of his first reproduction', and the use of 'a general form, order and arrangement of material seems to be dominant, both in initial reception and in subsequent remembering' (p. 83). He named this general form that people use to encode and to remember experiences a 'schema', a term now used throughout the cognitive sciences. A schema is a general organization of a story of a typical event. So, for example, many old films about the American wild west follow a schema involving 'good guys', 'bad guys', crisis, and resolution. The schema can aid encoding and retention of details that are consistent with it, but details that do not fit may be forgotten or distorted to fit the schema. In remembering *The War of the Ghosts* some English participants seemed to use the schema of a fairy tale, a genre to which they were more accustomed. Some even tacked on a moral at the end of the story.

The method of serial reproduction, the other major technique Bartlett introduced, is like the children's game of rumor or telephone. One person hears *The War of the Ghosts* (or is exposed to some other material) and recalls it after a set period. This person's recollections are then read to a second person, who recalls it in turn. This second recall is then read to a third person for later recall, and so on, through as many instantiations as desired. The changes in recall across repeated tests using the serial reproduction method are much greater than those in repeated reproduction, although Bartlett thought the same types of memory processes were at work (but in greater force). The serial reproduction technique involves a human chain, and if there were to be one weak link in the chain – someone who was wildly inaccurate in recall – then there would be no hope of a person later in the chain correcting the false memory of the material because that person would never have been exposed to the correct version. Reading through the lengthy samples that Bartlett provided in

Remembering (chapters 7 and 8) leads to agreement with his basic claims. The serial reproduction technique was later championed by psychologists studying the transmission of rumors.

The serial reproduction technique also served, Bartlett believed, as a useful analogy for the way information might be handed down from one generation to another within a society or even for the spread of ideas from culture to culture. He dealt with these issues in some detail, although with anecdotal evidence, in the last section of his book.

Bartlett's *Remembering* provides many interesting ideas and quotable passages. The book was well known at the time, but his research tradition did not really catch on. Part of the reason for this is that, in his hands, the research was more anecdotal than experimental (despite the subtitle of his book). He has been criticized for this lack of careful empirical research to document his points, and it was not until recently that a successful replication of his basic findings using the repeated reproduction technique appeared in print. Bartlett's book came to the forefront of the field when Neisser adopted Bartlett's theme of the constructive nature of cognition for his 1967 text, *Cognitive Psychology*, which helped to usher in the cognitive revolution in psychology. In the early 1970s psychologists such as Elizabeth Loftus, John Bransford and Marcia Johnson became interested in errors of memory and Bartlett's ideas were invoked and his book was once again read by a new generation.

Throughout *Remembering*, Bartlett's message ran counter to the idea that memory should be conceived of as static memory traces that are called to mind and read off in a more or less accurate fashion. Memory does not work like a video recorder, tape recorder, or computer. In his words, 'Remembering is not the re-excitation of innumerable fixed, lifeless and fragmentary traces' (1932, p. 213). Rather, 'remembering appears to be far more decisively an affair of construction rather than reproduction' (p. 205). 'It is an imaginative reconstruction, or construction, built out of the relation of our attitude towards a mass of organized past reactions or experiences' (p. 213). This credo still guides the field today in many ways.

LATER CONTRIBUTIONS

The Second World War confronted psychologists with many more practical problems to be solved. Bartlett and Kenneth Craik worked during the war on problems of skill acquisition, and Bartlett served on the Royal Air Force's Flying Personnel Research Committee, focusing his work on pilot training. They also studied related topics such as the effects of fatigue on performance. When Craik was tragically killed in an automobile accident two days before the war in Europe ended, Bartlett felt the loss keenly, because the men had become best friends as well as close collaborators.

After the war, Bartlett applied notions of skill learning to those of higher-order thinking, capitalizing on the insight that just as experts in a physical skill develop their exquisite expertise after many hours of practice, so do experts in thinking skills – problem-solving, reading X-ray graphs and so on. In 1958 he published *Thinking: An Experimental and Social Study*, which provided his insights on these topics. However, this book did not enjoy the earlier success of *Remembering*, although it too is an interesting treatise.

Bartlett retired from the chair of experimental psychology in Cambridge in 1952, but maintained his affiliation with the applied psychology unit which he had helped to found. His many students frequently called on him for advice and he continued to serve on national committees. Despite his early health difficulties, he remained generally robust in his later years, although he was bothered by hearing loss. He died after a brief illness on 30 September 1969.

CONCLUSION

Frederic Charles Bartlett wielded tremendous influence both nationally and internationally. Some commentators have remarked that this influence was out of proportion to his actual scholarly work. His contributions were good, but only one (*Remembering*) was of enduring importance. Rather, Bartlett's own charismatic character drew people to him and established his leadership, the power of his personality infecting those around him with his wit, his wisdom, his generosity, and his good nature.

Knighted, in 1948, Sir Frederic Bartlett received many other honors, including honorary doctorate degrees from seven universities in six countries. In Britain he was elected to the Royal Society in 1932 and received its Baly and Huxley medals in 1943. He was awarded the Royal Medal in 1952, the highest distinction a scientist in Britain can receive. In the USA Bartlett was elected to the American Philosophical Society, the National Academy of Sciences (as a foreign fellow) and the American Association of Arts and Sciences. Bartlett was a towering figure of twentieth-century psychology, and in recent years the study of human memory has come around to the approach he advocated so strongly in the 1930s.

Bloomfield, Leonard

Introductory article

Stephen R Anderson, Yale University, New Haven, Connecticut, USA

CONTENTS

Leonard Bloomfield (1887–1949) was an American linguist whose contributions to general linguistics as well as to the study of a number of language families make him one of the central figures in the history of this field of study. His name is virtually synonymous with the American Structuralist approach to language through the 1950s.

INTRODUCTION

Few figures in the history of linguistics stand out as prominently as incarnations of their time and place as Leonard Bloomfield. Linguistics in America from the publication of his book *Language* in 1933 until the development of Generative Grammar in the 1960s is practically identifiable with his approach. This was in part because he represented the desire of linguists to be treated seriously as pursuing a scientific discipline with its own methods, goals, and results. Edward Sapir and Franz Boas, other major figures in the history of linguistics whose activity overlapped with Bloomfield's, studied languages within the theoretical framework of anthropology or psychology. Others studied particular languages and language families for their own sake. In contrast, Bloomfield thought of himself as a linguist, studying language for its own sake. In the process, he aligned himself with contemporary positions in philosophy (positivism) and psychology (behaviorism) that were seen as paving the road to a genuinely scientific view of language, in contrast to humanistic approaches.

As a result, linguistic theory as it developed during this time was largely formed either through Bloomfield's own work or by what his students and colleagues did in the name of his views. Although a good deal of 'post-Bloomfieldian' linguistics was not particularly close to Bloomfield's own positions, it was nonetheless felt that a scientific approach to language could be largely identified with the task of working out Bloomfield's views. American structural linguistics largely *was* Bloomfieldian linguistics.

BLOOMFIELD'S LIFE

Leonard Bloomfield was born in Chicago in 1887, and moved to Elkhart Lake, Wisconsin, in 1896 when his father bought a resort lodge there. During his childhood in Wisconsin he came into contact with the Menomini people and their language, a member of the Algonquian family, which would occupy much of his later attention. His father's brother, Maurice Bloomfield, was a noted Sanskritist and no doubt had an influence on Bloomfield's subsequent interest in this language and its grammatical tradition.

Bloomfield entered Harvard in 1903, received his AB degree in 1906, and went to the University of Wisconsin for graduate study. One of the first scholars Bloomfield met there was Edward Prokosch, one of the major names in Germanic studies, who interested him in historical work within the framework of Indo-European linguistics. In 1908 he moved to the University of Chicago, where he received his PhD in 1909 for a thoroughly traditional, philologically oriented thesis: *A Semasiological Differentiation in Germanic Secondary Ablaut*.

Most of Bloomfield's academic career was spent as a teacher of German: although he practiced general linguistics within the limits of such positions, it was not until he came to Yale in 1940 that he actually held a professorship of linguistics, as opposed to German. His first job was at the University of Cincinnati, from which he moved to the University of Illinois in 1910. He was told early on that while his department was enthusiastic about promoting him, a competing candidate had the edge by virtue of having studied in Germany, and that if Bloomfield wanted to get ahead, he would have to study in Germany too. Taking this advice to heart, he spent the year 1913–1914 in Leipzig and Göttingen, studying with such notable Indo-Europeanists as Leskien and Brugmann. In the process, he rubbed elbows (quite literally) with a number of other students who would later be important names in linguistics, such as Nikolai Trubetzkoy.

In 1914 he published his first book, *An Introduction to the Study of Language*. This general survey was based solidly in the introspectionist psychology of Wundt, influential at the time but virtually the antithesis of the approach he would later champion. This book is little read today, but interesting for understanding the later development of Bloomfield's views on, for instance, morphology (inflection and word formation).

The outbreak of the First World War led to an immediate and precipitous decline in German studies in the USA, and Bloomfield no doubt had a certain amount of time on his hands as a teacher of German. During the war, he worked with a student at Illinois who spoke Tagalog, the principal indigenous language of the Philippines. This work resulted in a book *Tagalog Texts with Grammatical Analysis*, which contains an extensive grammar of the language, though one that is difficult to use as a result of Bloomfield's explicit, conscious avoidance of traditional categories and terminology in describing a system far from the familiar structure of Indo-European languages.

In 1921, he moved to Ohio State University (not having been offered tenure at Illinois, despite having studied in Germany!) where he immediately became a full professor of German. Here one of his colleagues was Albert Weiss, a major figure in the early development of behaviorism, whose views on the mind largely determined Bloomfield's own for the rest of his career. In 1927, he was invited to the University of Chicago, again in the German department. Here one of his colleagues was Sapir, in the anthropology department: the two were professional collaborators (but uneasy friends) in the emerging discipline of general linguistics.

In addition to his work on German and general linguistics, Bloomfield was also occupied during this time with comparative Algonquian studies. This was not just an escape from the rigors of Germanic linguistics. Bloomfield brought the methods of Indo-European studies to work on American Indian (and by extension, other indigenous) languages. This was unusual: others had suggested that the methodology of comparative reconstruction, developed with respect to Indo-European, was substantially dependent on the fact that several languages (Vedic Sanskrit, Gothic, Homeric Greek, Hittite, Old Church Slavonic, etc.) of the family are attested at considerable time depth, and that the same techniques would not be effective in dealing with unwritten languages. Bloomfield showed that the methodology could be applied in establishing the comparative grammar of Algonquian (especially its central branch, based on data from Fox, Cree, Menomini and Ojibwa).

The clinching demonstration of this came when, in working out the system of consonant clusters in the system ancestral to these languages, he was left with one correspondence set that did not fit any known combination of segments. For this, he postulated an additional proto-Algonquian cluster which he wrote as *çk. Later, however, as data from other languages and dialects of the family became available, it became clear that exactly the words for which Bloomfield had posited this cluster showed consistent unique reflexes across the family; and indeed other words came to light that illustrated the same correspondence set. This was widely seen as providing a dramatic confirmation of the correctness and generality of the assumptions of comparative linguistics – as dramatic, in its way, as the confirmation provided by the analysis of Hittite for the prior assumption of 'laryngeal' segments in the phonology of proto-Indo-European.

Bloomfield's role in the professionalization of linguistics in the 1930s and 1940s was tremendously important. He worked hard for the establishment of the field's distinctive institutions, especially the Linguistic Society of America, its journal *Language*, and the annual summer institutes which it organized (at the time, virtually the only occasions when linguists gathered in significant numbers). In 1940 Bloomfield was invited to Yale, after the death of Sapir (who had preceded him there as Sterling Professor of Linguistics). He never really settled in New Haven: he and his wife were both attached to Chicago, and she suffered from severe depression when they left. To this was of course added the dislocation provoked by the Second World War, but he turned this to advantage, working actively in the army's Intensive Language Program during the war years and thereby providing useful work for a new generation of descriptive linguists. In 1946, Bloomfield suffered a severe stroke from which he never really recovered. He died in 1949.

BLOOMFIELD'S VIEW OF LANGUAGE AND THE MIND

Bloomfield's first writing dealing with general issues in the study of the mind was in his 1914 book *An Introduction to the Study of Language*, but he soon lost confidence in the explanatory power of the Wundtian psychology underlying that book. That point of view was soon supplanted by an ardent embrace of the behaviorist (or 'mechanist'

as he preferred to call it) psychology of his Illinois colleague Weiss. This was already evident in his 1926 paper, 'A set of postulates for the science of language' (*Language* **2**: 153–164), intended as a fairly direct calque on a paper by Weiss laying out an axiomatization of psychology, although it also shows considerable influence of the study of the Sanskrit grammatical tradition. More important perhaps than Bloomfield's intent to emulate Weiss's point of view, the paper's terminology in referring to psychological factors is enthusiastically behaviorist in tone, as when he defines the meanings of utterances as their 'corresponding stimulus–reaction features'.

A product of his times, Bloomfield's notion of a scientific explanation was one based solely on propositions relating observable events by principles of logic and mathematics alone. Throughout his career, he repeatedly ridiculed 'mentalistic' explanations as they appeared in the supposedly scientific literature on language and linguistics. Subsequent commentators (as well as many of his contemporaries) took this to imply a rejection of the existence of a mental life, but this is not at all what he intended. Rather, he meant to reject the notion that linguistic (or any other) phenomena are causally affected by a mysterious and unobservable entity (the 'mind') whose principal property is its nonobedience to normal laws of physical causation.

Early behaviorists insisted that if the mind were to be taken seriously as an object of scientific inquiry, it must be reduced to special cases of the activity of some observable physical system. There are, of course, alternatives to this, as the 'cognitive revolution' has made clear, but for Bloomfield, an attempt to ground the study of language in the properties of mental and cognitive organization seemed like an effort to evade the constraints of rational inquiry. Considering the excesses of romanticist approaches to the nature of language, and indeed the introspectionist psychology Bloomfield himself followed in his early years, these concerns were not entirely illusory. For Bloomfield, the only sensible alternative to antirational speculation about the mysteries of the soul was a denial of the scientific relevance of anything but the material embodiment of mind.

This restriction of scientific discourse, including all talk about 'meanings' apart from the framework of observable stimuli and responses, was not, as it is commonly seen, intended to deny that minds and meanings exist, or even that they might play a central role in human life. His point, rather, was that in the present state of science we have no way of cashing these notions out in strictly observable terms, and thus that talk about them necessarily falls outside real science. He did believe that a satisfactory account of meaning would need to be based on an encyclopedic knowledge of the world and its laws, down to the last detail – something obviously well beyond the scope of linguistics or perhaps any science. This belief that meaning ultimately has a comprehensive explanation in terms of sufficiently minute details concerning (potentially observable) electrochemical events within the nervous system is just as much a matter of faith on his part as the 'mentalist' picture is for others.

A language can be seen as a system that relates sounds and meanings, and it would thus seem that some account of meaning is necessary to linguistics. For this reason, Bloomfield introduces a mechanistic picture that seems naive even by comparison with other behaviorist work, but he also denies that the difference between such a view and the mentalist one has any significance. For him, the structural properties of language can be investigated perfectly well even if meaning is simply reduced to the status of a postulate, not treated in its substance (whatever that might be). In a 1944 article, he compared his 'antimentalism' to 'a community where nearly everyone believed that the moon is made of green cheese, [in which] students who constructed nautical almanacs without reference to cheese would have to be designated by some special term, such as *non-cheesists*.'

With complete impartiality, Bloomfield maintained that the concrete properties of sound are also, strictly speaking, irrelevant to an understanding of language; and thus neither phonetics nor semantics played a role in the sort of structuralist accounts he advocated. His actual practice involved appeals to our understanding both of sound and of meaning that were not significantly different from those he opposed: he simply maintained that these matters were not essential to an understanding of linguistic systems.

Bloomfield's views on the nature of mind and cognitive organization were surely much too simplistic, as generations of commentators have maintained. Nonetheless, his repeated insistence that the methodology and results of linguistics are independent in principle of any particular theory of psychology (his or another) should be taken at face value. The radical behaviorist views he advocated had much less influence on his own practice with regard to central areas such as phonology and morphology than his pronouncements would have on his own students and their immediate successors. Bloomfield was a solid scholar in a number of

areas, and one whose intuitions about linguistic structure took him far beyond the limitations of his stated basic principles.

Brazier, Mary A. B.

Introductory article

Mary Brown Parlee, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

Mary A. B. Brazier was an authority on electroencephalography who after World War II pioneered the use of correlational techniques and high-speed computers to study brain activity and behavior. She also authored influential books and articles on the history of neurophysiology which stimulated historical interest in the brain and behavioral sciences.

INTRODUCTION

Mary A. B. Brazier (1904–1995), an authority on electroencephalography, pioneered the use of computers to study brain physiology and brain–behavior relationships. She was also an influential editor, organizational leader and historian of neurophysiology (Figure 1). In collaboration with colleagues at Harvard University and the Massachusetts Institute of Technology, she was the first to use modern high-speed computers and correlational techniques for frequency analysis to study the electrical activity of the brain in relation to behavior. Author of a classic textbook, *The Electrical Activity of the Nervous System* (see Further Reading section), she edited several volumes of Macy Foundation-sponsored conferences on brain and behavior. These brought the latest research to the attention of a broad scientific readership at a time (the late 1950s and early 1960s) when the modern cognitive and neurosciences were emerging as new sciences from their interdisciplinary roots. Brazier's influence on these fields continued through her editorship (1975–84) of the journal *Electroencephalography and Clinical Neurophysiology* (of which she was a founder in 1949) and through her leadership in the International Brain Research Organization (IBRO) and other national and international scientific organizations concerned with brain and behavior. She also authored numerous articles and two books on the history of neurophysiology in the seventeenth, eighteenth and nineteenth centuries. Prior to her move in 1940 from England to the USA, where she made her reputation as a brain researcher and historian of science, Brazier conducted award-winning research in endocrinology. In the USA she was usually the first and only woman in the post-World War II scientific circles of neurophysiologists, neurologists, electrical engineers and mathematicians among whom she traveled and thrived.

LIFE AND WORK

Mary Agnes Burniston Brown, known as 'Mollie' to her friends, was born in Weston-super-Mare, near Bristol, England on 17 May 1904, the second of two children (she had an older brother) in a Quaker family. As a child she developed what would be lifelong loves of the sea and of science, and after attending school at Sidcot she entered the all-women Bedford College of the University of London, where she studied physiology, obtaining her BSc in 1926. In 1927 she took up an appointment as a Research Fellow in the Imperial College of Science and Technology, working with Frederick Golla at the Maudsley Hospital on separation of the products of protein hydrolysis. She continued this research for more than a decade, obtaining a PhD in biochemistry from the University of London in 1930. In 1928 she married electrical engineer Leslie J. Brazier, with whom she had a son, Oliver.

Mary Brazier's research at the Maudsley Hospital focused on measurement of the electrical changes in the skin which occurred in patients with diseases of the thyroid gland. The technique for measuring these changes, which Brazier named the *impedance angle test*, proved useful for diagnosing thyrotoxicosis. It led to her receiving research awards in 1934 from the (British) Institute of Electrical Engineers and the American Association for the Study of Goiter. A few years later, also at the Maudsley Hospital, research by W. Grey Walter demonstrated the diagnostic usefulness of another

Figure 1. Mary A. B. Brazier (1904–1995). Photo supplied courtesy of the History and Special Collections Division of the Louise M. Darling Biomedical Library, UCLA.

electrophysiological measure, namely the electroencephalogram (recordings of electrical activity of the brain through the unopened scalp and skull of humans). EEGs could be used to locate tumors of the brain. This finding, together with a report that petit mal epilepsy was associated with changes in the EEG, generated considerable interest in EEGs and their potential clinical applications. References to these and other articles – more than 100 are covered – can be found in Brazier's 1958 account of the development of concepts relating to electrical activity of the brain (see Further Reading).

In 1940, with London under heavy attack, Mary Brazier and her son moved to Boston, while Leslie Brazier remained in England. With a Rockefeller fellowship she secured an appointment as a neurophysiologist at Massachusetts General Hospital (MGH), in Harvard Medical School's Department of Psychiatry, headed by Stanley Cobb (she later held appointments in the Departments of Anesthesia and Neurology). One of the earliest EEG laboratories in the USA had been established at MGH in 1937 by Robert Schwab, and Brazier soon found her way there. She remained at MGH, later heading her own Neurophysiological Laboratory, for the next 20 years. During the war she collaborated with her new colleagues in national defense research on a variety of topics, including peripheral nerve injuries, aircraft pilot selection, war neuroses, electromyograms and muscle dysfunction in poliomyelitis. Her first publication on the subject of EEGs appeared in 1942, and during the next 7 years such research became the focus of her work, including the characteristics of normal EEGs: comparison of the EEGs of psychoneurotic patients and normal adults; and the effects of blood sugar levels, anoxia and various anesthetic agents on EEGs.

The first International EEG Congress was held in London in 1947, and there Brazier was a founding member of the International Federation of Societies for Electroencephalography and Clinical Neurophysiology. In 1950, her comprehensive 178-page *Bibliography of Electroencephalography, 1875–1948* (see Further Reading) was published as the first supplement to the novel field's new (two-year-old) journal, *EEG and Clinical Neurophysiology*. It became, as three of her long-time friends and colleagues later put it, 'a guiding beacon to the then newcomers to the field'. The same would prove true of Brazier's 1951 textbook, *The Electrical Activity of the Nervous System* (see Further Reading), which went through four editions and was translated into seven languages. During this period (the late 1940s to early 1950s), in addition to her research, writing and organizational work, Brazier began to develop her thinking about the relationships between nervous activity, consciousness and behavior.

Until the end of the 1940s, most research on EEGs involved 'eyeballing' the data, and it became apparent to Brazier and others that more precise and reliable techniques were needed. In 1946, Schwab and Brazier persuaded Grey Walter to visit Boston with the automatic low-frequency analyzer he had developed for use in his EEG research. He demonstrated the Walter analyzer at MGH at a meeting of the Eastern Association of Encephalographers, and the analyzer remained in the MGH Clinical EEG Laboratory. It was used there by Brazier and others to analyze human EEGs until the early 1950s, when it was superceded by new technologies that were developed in the post-World War II ferment of excitement about cybernetics, signal analysis and communication (information) theory.

This ferment was particularly intense in the Boston and Cambridge area, with MIT mathematician Norbert Wiener at its epicenter. After the war, Wiener published two influential books based largely on his wartime work on prediction theory, namely *Cybernetics or Control and Communication in*

the Animal and the Machine (published in 1948) and *Extrapolation, Interpolation and Smoothing of Stationary Time Series* (published in 1949). Scientists and engineers in a wide range of fields regarded these texts as providing mathematically specifiable concepts (e.g. information, feedback, communication system, signal/noise) which could be used to analyze complex systems of all kinds (machine, biological, human–machine, social), including the central nervous system. Wiener's influence was particularly strong at MIT's interdepartmental Research Laboratory of Electronics (RLE), where in 1951 Walter Rosenblith established a Communications Biophysics Group to investigate sensory (primarily auditory) systems in animals and humans using the latest engineering technologies.

Beginning in 1948, when Brazier invited Wiener to speak to a group of MGH researchers in psychiatry and physiology, she became increasingly interested in using mathematical techniques developed by Wiener (autocorrelation and cross-correlation analyses, used to detect the presence of a weak signal embedded in noise) to analyze EEGs. These correlational techniques could be used both to identify naturally occurring rhythms in the brain's 'resting' state and to detect responses evoked by sensory stimulation, making them useful general tools for exploring questions about brain functioning and behavior. Stimulated by Wiener's work and his new-found interest in EEGs, Brazier and James Casby, an MIT undergraduate working in Brazier's MGH laboratory, published a paper on 'cross-correlation and autocorrelation studies of electroencephalographic potentials' in 1952. Brazier and Wiener discussed the application of these techniques to EEGs at the Third International Congress of Electroencephalography and Clinical Neurophysiology, which was held in Cambridge, Massachusetts in 1953.

'Application' of the mathematical techniques in EEG research required instrumentation, in particular devices for filtering the electrical activity recorded through EEG electrodes and 'correlators', namely machines for calculating the cross-correlations (between a stimulus presentation and brain activity, over repeated stimulus presentations) and autocorrelations (between a segment of the recorded activity and the same segment overlaid but displaced in time). (The latter technique enables the detection of cycles of unknown periodicities and small amplitudes relative to background activity.) Brazier's MGH group, which after 1951 included the then third-year Harvard Medical School student John Barlow, began a mutually fruitful collaboration with Walter Rosenblith's Communications Biophysics Group. An analog electronic correlator had been developed at the RLE in the late 1940s, and reliable, high-speed digital electronic computers were being developed by computer designers at MIT's Lincoln Laboratory, which had close ties to Rosenblith's laboratory. Both analog and digital machines could be used to perform the correlations required for the quantitative analyses of EEGs which Brazier sought, and she used both in research published in the early 1950s. When the first of a new generation of general-purpose digital computers was developed at Lincoln Laboratory in the mid-1950s (the TX-0), one of its earliest applications was in a device called the Average Response Computer (ARC-1). The latter was used in RLE's Communications Biophysics Laboratory by Rosenblith, Brazier, Barlow, Nelson Kiang and others to analyze electrophysiological recordings of nervous system activity (including EEGs). A technically detailed, first-hand account of the early history of EEG data processing by the MIT–MGH collaborators was published by Barlow in 1997 (see Further Reading). Brazier herself published a more extended overview with illustrations from her experiments on animals, normal human subjects, and neurological patients.

Interest in electroencephalography as a technique for investigating brain activity and consciousness continued to grow during the 1950s. Beginning in 1953, after Stalin's death, international exchanges between brain scientists in the West and in the former Soviet Union generated considerable excitement. Brazier participated in one of the earliest of these, namely the 1953 Laurentian Symposium on Brain Mechanisms and Consciousnesss (held in Ste Marguerite, Quebec), and in the subsequent Moscow Colloquium on Electroencephalography of Higher Nervous Activity, to which Brazier was invited as one of five US scientists. From the Moscow Colloquium, plans emerged for the formation of the International Brain Research Organization (IBRO), the first international organization to encompass all of the areas of what are now termed the neurosciences, including investigations of brain–behavior relationships. The first meeting was held in 1960, and Brazier served as Secretary General of IBRO from 1978 to 1982. Throughout her career Brazier actively promoted internationalism in brain research, not only through IBRO, but by serving successively as Treasurer, Secretary and President of the International Federation of Societies for Electroencephalography and Clinical Neurophysiology between 1953 and 1965. After her death, the International Federation established

a scientific award in clinical neurophysiology in her honor, the M.A.B. Brazier Young Investigator International Award.

The objective of Brazier's EEG research, in the words of long-time collaborators and friends, 'was to try to understand the nature of the EEG, as reflected in its statistical properties, as a signal in a communication system, i.e. the brain'. Throughout her career, Brazier continued to consider the implications of cybernetics and communication theory for brain research, sometimes contrasting models drawn from information theory with classical approaches ('deterministic models') in ways that presaged neural network models by many years. Brazier's interactions with Soviet brain scientists also influenced her research, and in the late 1950s and early 1960s she used correlational techniques to investigate EEGs in relation to the orienting, conditioning and habituation responses (phenomena of considerable interest to brain scientists working in the Pavlovian tradition). Brazier's bibliography of EEG research, published in 1950, had shown an interest in the historical background of her science, and in the 1950s she began to publish articles about the history of neurophysiology. In the 1980s she published her landmark books, *A History of Neurophysiology in the Seventeenth and Eighteenth Centuries* and *A History of Neurophysiology in the Nineteenth Century* (see Further Reading).

In 1958, the Macy Foundation sponsored the first of two invited Conferences on the Central Nervous system and Behavior, organized by Horace Magoun of the University of California at Los Angeles (UCLA). Magoun had been instrumental in establishing a brain and nervous system research unit when UCLA's School of Medicine was organized in 1950, and the unit was established as the Brain Research Institute (BRI) in 1959. Brazier's skillful editing of these conference proceedings led to a continuation of the series – now called Brain and Behavior Conferences – under the auspices of the American Institute of Biological Sciences, again with Magoun as organizer and Brazier as editor. These interdisciplinary conferences had international participation (including distinguished Soviet and East European brain scientists), and their rapid publication brought the latest research in the brain sciences to broad scientific audiences. Concurrently, between 1961 and 1965 the US Air Force Office of Scientific Research sponsored conferences on brain function. These, too, were organized by Magoun, edited by Brazier, and influential in the new field that was becoming known as 'neuroscience'. In 1961, Brazier left her MGH laboratory and her long-time MIT collaborators to join Magoun, Donald Lindsley, Louise Marshall and others at the BRI. Always impossible to pigeon-hole in a neat grid of established disciplines, Brazier was appointed professor in the Departments of Anatomy, Biophysics and Nuclear Medicine, and Physiology of UCLA's Medical School. Prior to her arrival, computers were not widely used by BRI researchers, and Brazier, who served on a National Institutes of Health (NIH) advisory committee on computers in research, led the development of a data-processing facility. Her EEG research continued at the BRI, expanding to include new clinical applications. She was active in university-wide affairs at UCLA, and also served as a consultant or advisor on several NIH and National Science Foundation committees, as well as those of national non-governmental organizations.

In 1988, with her eyesight failing, Brazier moved back to the East Coast, to the sea and to the house she had built on Cape Cod while she was living in Boston. There she gardened, sailed, traveled (at least once every year to Paris and London) and visited and corresponded with friends and family – her son Oliver and his family were nearby. She died on 9 May 1995, nine days before what would have been her ninety-first birthday.

HONORS AND AWARDS

Mary A. B. Brazier was elected to the American Academy of Arts and Sciences in 1956. In 1962 she received a Career Research Award from the National Institutes of Health, one of four scientists so honored in the first year of these awards. The University of London honored her with a doctorate (DSc, on the basis of her published works) in 1960, and she received an MD (honoris causa) from the University of Utrecht in 1976. In 1985, the British EEG Society awarded her the Grey Walter Medal. The most complete and detailed account of Brazier's life and work to date is the 1996 memorial tribute written by John Barlow, Robert Naquet and Hans van Duijn (see Further Reading).

Brazier's papers are archived in the History and Special Collections Division of the Louise M. Darling Medical Library, UCLA. Contemporary researchers are fortunate that her published work (she was the author or editor of almost 250 articles and books) speaks clearly for itself. She wrote well, and her sense of history – even when she was working within the conventional genres of scientific articles and chapters – enabled her to place her own work in an unusually broad and detailed scientific context. Reading Brazier's writings, both scientific and historical, will give contemporary

cognitive and brain scientists a richer and deeper understanding of their field and its conceptual and technical roots.

Acknowledgments

Dr John Barlow has very kindly allowed me to see some of the extensive correspondence he had with Mary Brazier's friends and colleagues while he was preparing the 1996 memorial tribute to her life and work. I thank him for doing so.

Broca, Paul

Intermediate article

Stanley Finger, Washington University, St Louis, Missouri, USA

CONTENTS

Paul Broca (1824–1880) was a French surgeon, pathologist, anatomist and anthropologist. He is remembered for localizing speech in the frontal lobes, recognizing cerebral dominance, and performing the first surgery based on localization, as well as his research on the brain and intellect, and for his insights and theories on ancient trepanned skulls.

INTRODUCTION

Paul Broca (Figure 1) was born in France on 29 June 1824 in Sainte-Foy-la-Grande, a small town near Bordeaux, to Protestant parents. Following in the footsteps of his father, he opted to study medicine. This decision led him to Paris, where he excelled in his studies and completed his medical degree in 1848. From the beginning he had a reputation for being extremely thoughtful, thorough, and for looking at medical and scientific problems from many perspectives. He was also considered a liberal – not by today's standards, but in the culture in which he lived. Broca first made a name for himself by showing that cancer cells can be spread through the blood, and with his studies on various diseases, including muscular dystrophy and rickets. His early research in pathology, coupled with his strong belief that laboratory and clinic must join forces to improve medicine, helped him to secure several desirable Paris hospital appointments, such as surgeon at the Bicêtre.

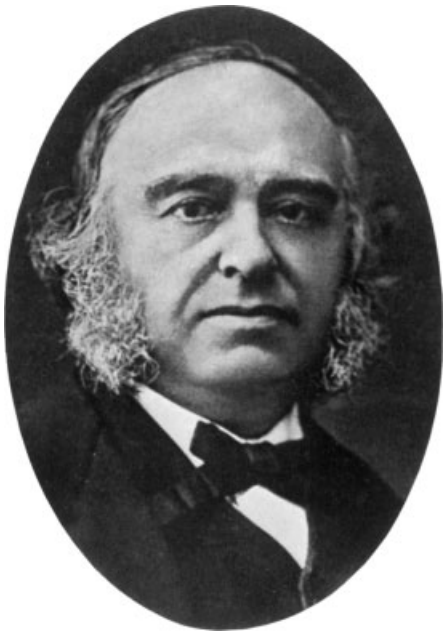

Figure 1. Paul Broca (1824–1880).

SPEECH AND THE FRONTAL LOBE

In 1859 Broca founded the world's first anthropological society, the Société d'Anthropologie. It was at the meetings of this fledgling society, where Broca served as secretary, that scientists discussed human groupings, intelligence, and the brain. It was also here that some French physicians interested in the effects of brain damage started to make the case for cortical localization of function. Two such individuals were Jean-Baptiste Bouillaud and his son-in-law Simon Alexandre Ernest Aubertin. They contended that damage towards the front of the cerebrum is more likely to disrupt speech than damage towards the back of the massive cerebral hemispheres. Others, however, including Pierre Gratiolet, disagreed, arguing that the cerebral hemispheres function as an indivisible unit.

On 12 April 1861 a 51-year-old man suffering from cellulitis and gangrene was transferred to Broca's surgical service at the Bicêtre. Described as mean and vindictive, the patient (named Leborgne) had suffered from epilepsy since youth and had been hospitalized at the age of 31, after losing his power to speak. He then developed a paralysis on the right side of his body with loss of sensitivity on the same side. Broca invited Aubertin

to examine Leborgne with him, to assess his speech and to see if he would exhibit damage to his frontal cortex when he died. Indeed, the patient was found to have great difficulty speaking. After he died an autopsy showed a chronic softening in the third frontal convolution, near the rolandic fissure of the left hemisphere. Broca first presented this patient's brain to the Société d'Anthropologie. A more detailed report was given to the Société d'Anatomie later in 1861. Broca used the French word *aphemie* (or aphemia) for Leborgne's inability to speak. It was Armand Trousseau who coined the more popular word 'aphasia' in 1864. This form of aphasia became known as Broca aphasia or motor aphasia. As for Monsieur Leborgne, since 'tan' was once of the few sounds he was able to make before he died, he was often to be called Tan in the later literature.

Broca used this case to argue for a special frontal cortical area that is responsible for fluent speech. He went out of his way to explain that this is located behind and below the one proposed by phrenologists, such as Gall and Spurzheim, who associated character and abilities with bumps on the skull and whose theories were in disrepute. Today we refer to this specialized cortical region as 'Broca's area'. Hence, two eponyms that helped make Broca famous stemmed from this one case. With the landmark case of Leborgne, Broca became fully committed to the cortical localization revolution and was looked upon as its champion. As a careful investigator, however, he worried that he might have gone too far on the basis of only a single case study. Over the next few years he was gladdened to find additional cases that were supportive of his frontal lobe localization for speech, beginning with the case of an old man named Lelong later in 1861.

CEREBRAL DOMINANCE

On 2 April 1863 Broca lectured about eight cases of loss of fluent speech. He remarked that, to his surprise, all exhibited lesions of the left hemisphere. Still, he felt that more cases were needed before he could make a definitive statement about the left hemisphere being special. The idea seemed likely to generate even more of a storm than cortical localization of function.

Broca's clearest statements and most important thoughts about cerebral dominance appeared in 1865, in an article in the *Bulletin de la Société d'Anthropologie*. In this he theorized that the left hemisphere is, in fact, dominant for language. Because it matures faster than the right hemisphere, it is better suited to take the lead. As was true with the concept of cortical localization of function, Broca was not the first to argue for this new way of looking at the brain, although his role was significant. That honor goes to Marc Dax, a physician from the south of France who wrote a memoir on the left hemisphere and speech in 1836, but never published it (he died a year later). Whether his material had indeed been presented orally at a congress in 1836, as was claimed by his son Gustave, is not certain. Broca himself could find no evidence that it was. What we do know is that the Marc Dax paper was sent to the Académie de Médecine in Paris in 1863. It was a part of a larger report by Gustave Dax which contained his own collection of cases supportive of cerebral dominance. The paper arrived and was announced by title (but not made public) just before Broca made his first tentative remark about the eight cases with left hemispheric lesions. The Dax report was then sent to a 'secret' committee, where it languished before it was severely criticized by the committee chairman (Lelut) late in 1864. Upset by the Lelut report, Gustave Dax then saw to it that both his father's report and his own data were published elsewhere. They appeared as two short but separate articles in a medical periodical in 1865, just weeks before Broca's own celebrated paper appeared in a different journal.

Today, both the Daxes and Broca are recognized for their seminal contributions to the development of the concept of cerebral dominance. For a while, however, Broca was given most – if not all – of the credit for this important discovery.

AGE, BRAIN DAMAGE AND THERAPY

In his 1865 paper on cerebral dominance, Broca was forced to deal with exceptions to the idea that the center for articulate language resides in the third left frontal convolution. One such case was that of a woman with epilepsy who was a patient at the largest Paris hospital, the Salpêtrière. This patient was probably born without a left Broca's area, but was able to learn to read, speak fairly well, and express her ideas without difficulty. Broca suggested that the healthy right hemisphere had taken over the role of the compromised left hemisphere, something that is accomplished more readily when the brain damage occurs early in life. He also postulated that a small percentage of healthy people might be born 'right-brained'. He then considered the question of why we do not see more sparing and recovery following damage to this part of the brain, postulating that one limiting factor might be that most aphasic patients also suffer

from intellectual deficiencies, limiting their ability to relearn (see below). This would be especially likely after strokes and injuries that affected more than just Broca's area in the frontal lobes.

Broca also pointed out that professionals did little to retrain their aphasic patients. He suggested teaching people with aphasia in the same way that a child learns to speak: therapy should begin with sounds of the alphabet, then words, then phrases, and eventually sentences. By working from the simple to the complex, Broca suggested, the right hemisphere might find it easier to take over from its injured counterpart on the left side. He tried speech therapy with one of his own adult patients, who was successful in relearning the alphabet and in working with syllables, but did not do well when it came to constructing longer words. Nevertheless, Broca was optimistic and expressed the hope that others would be able to devote more time to speech therapy than he had been able to do owing to his busy schedule.

SURGERY BASED ON LOCALIZATION

In 1865 Broca was elected president of the Paris Surgical Society and 3 years later he became professor of clinical surgery. In 1868 he introduced cranial cerebral topography, a technique that uses skull and scalp landmarks to localize underlying parts of the brain. Broca used his new method to open the skull in the right place and drain an abscess in a patient whose speech had become impaired after a closed head injury. Although the operation took place late in the 1860s, it was not reported until 1876. This was probably the first brain surgery to be based on the new theory of cortical localization of function.

INTELLECT, BRAIN AND RACE

Beginning in 1861, Broca also raised the possibility that the frontal lobes might serve executive functions other than speech, including judgment, reflection and abstraction. Indeed, when Leborgne's lesion was spreading throughout the frontal lobes, this patient showed signs of losing his intellect, not just his fluent speech. By arguing that the front of the brain is more 'intellectual' than the back, Broca was able to explain why there was not more relearning and recovery after large frontal lobe lesions that affect speech. He and the other localizationists who accepted this idea also had a good explanation for why some individuals with large skulls were not as intelligent as others with smaller skulls. For example, in 1873 he examined some recently unearthed Cro-Magnon specimens from central France. They had cranial capacities that far exceeded those of the modern French. To Broca and his colleagues in Paris, it was not that Cro-Magnon men and women were geniuses; they most certainly were not. Instead, the greater overall size of their crania only reflected the greater development of the more pedestrian back of the brain. Broca made precisely the same point when referring to some old exhumed Basque skulls that were sent north to Paris. They were also large relative to the skulls of modern Parisians, but this too was attributed to growth in the back of the brain, not the intellectual front.

Thus, although Broca initially believed that cranial capacity was a good physical correlate of intellect, he abandoned this view as he learned more about cortical localization of function. In addition, like many others at the time, Broca believed in multiple creations for the different human races. However, once caught up in the Darwinian revolution of 1859, he also embraced evolution, rejecting the older notion that the human groups are fixed entities, and with it the popular belief that only pure races could prosper. Moreover, he found slavery, even for people with small brains and low intelligence, inexcusable and repulsive.

TREPANATION

Broca's interest in trepanned skulls began in 1867 when he was asked to examine an Inca skull with cross-hatched cuts. This unusual cranium had recently been obtained in Peru by American diplomat-archeologist E. George Squier. Broca agreed with Squier that the cuts on the skull had been made on a living person prior to the European conquest, and that this individual had survived the operation by a few weeks. Thanks to Broca's help, this was the first case of trepanation from an ancient culture to be correctly and widely recognized as such.

Broca then became involved with the discovery of much older trepanned skulls in France. Many late Neolithic (New Stone Age) crania that had been trepanned were found, most of which are now estimated to be approximately 5000 years old (the Peruvian skull was judged to be only around 500 years old). Broca visited burial sites and unearthed some cranial specimens himself, but mostly studied the findings presented to him by others, especially one of his associates, Prunières. Broca postulated that that the openings in the Neolithic skulls had been made by scraping with a sharp stone, such as a piece of flint or obsidian,

and that the fibrous dura mater covering the brain was left intact. As for the smoothed surfaces where bone had been removed, they were the result of an extended period of healing. He further posited (from one skull in particular) that the operation was probably performed early in life.

During the mid-1870s Broca gave many talks and published a large number of papers on trepanation. One of his goals was to convince people that the holes in many of the unearthed French skulls were not due to accidents, combat, nature, or gnawing animals. Another was to associate the surgery with some sort of therapy and with the primitive mind. Broca held that the openings were not the result of surgical treatment of head wounds, since there would have been more openings over the facial areas, which were carefully avoided. Moreover, he did not see signs of fractures. Instead, he thought it more likely that the operations were done on the living to treat 'internal maladies'. After much thought, and after considering newer anthropological evidence, he suggested that the surgery might have originated as a way to treat benign infantile convulsions, such as seizures caused by fever spikes or teething. These were disorders that primitive people might have attributed to demons. Moreover, the children would have recovered anyway: an illusion of success would have been achieved, and the practice would have spread and perhaps generalized.

Broca's theory about trepanation, demonology and seizure disorders is still widely cited in books and papers on trepanation. Most researchers agree that he was probably on the mark when he suggested that the practice had something to do with medicine, the brain, and abnormal behaviors; but he was wrong to think that the operations were confined to children.

LATER YEARS

Paul Broca made his last statements about speech and the brain in 1877. At this time, he was much more interested in the family of man than in cortical localization of function. In addition, he was intrigued by the limbic lobe, a collection of brain parts then thought to be associated with olfaction, a subject on which he wrote in 1877 and 1878.

Broca died in 1880, only months after he was elected to the French Senate as a representative of science and medicine. He had been a perfectionist and a 'workaholic' who published over 500 books and articles during his intense scientific career. When he succumbed to heart disease, his wife, three children, and scientists and physicians around the world mourned the passing of a man who had contributed monumentally to many fields. In the neural and cognitive sciences he is best remembered for his theory of the cortical localization of speech, his recognition of cerebral dominance, his thoughts about intelligence and the races, and for his discoveries and insights bearing on the ancient practice of cranial trepanation.

Descartes, René

Introductory article

Stephen Gaukroger, University of Sydney, Sydney, New South Wales, Australia

CONTENTS

Descartes pursued two different approaches to the question of the nature of the mind: one via psychophysiology and one via a theory of the different properties of mind and matter, construed as different substances.

DESCARTES' LIFE AND PHILOSOPHICAL DEVELOPMENT

René Descartes was born in 1596, and entered the Jesuit college of La Flèche as a boarder at the age of 10. He left it in 1614, and, after spending a year in Paris, completed his formal education by taking a degree in civil and canon law at the University of Poitiers in 1616. From 1619 onwards, he pursued a career as a gentleman soldier, first in the army of Maurice of Nassau and then in that of Maximillian I of Bavaria, before settling down to a life of science and scholarship in the early 1620s. He worked primarily in mathematics and natural philosophy in the 1620s and early 1630s, in Paris and elsewhere, moving to the Netherlands in 1628. In the mid-1630s he developed a skeptical form of epistemology, set out in the *Discourse on Method* (1637), in the *Meditations* (1641), and finally in the *Principles of Philosophy* (1644). It is this form of pure epistemological speculation for which Descartes is now principally remembered. In 1649 he moved to Sweden, where he died early in 1650.

We can trace three different strands of interest in Descartes' development. From 1619 to the late 1620s he pursued mathematics above all else. A precocious and original mathematician, his greatest contribution was to the discipline of analytic geometry, in which lines and curves are represented by equations through the use of coordinates. What he provided was a powerful unification of arithmetic and geometry, and it was from his treatise on the techniques that he had developed in this area, the *Geometry*, that Newton and others learned their advanced mathematics later in the seventeenth century.

Descartes also pursued an active research program in natural philosophy from 1619 onwards, moving from kinematics, hydrostatics, and optics to a general Copernican cosmology in the 1630s. Some time in the middle to late 1620s, he discovered a central law in geometrical optics, the law of refraction, which was crucial in the development of better telescope lenses. In the early 1630s, in *The World*, he developed a comprehensive physical cosmology – the most important seventeenth-century cosmological system before Newton – in which the problem of how the planets can revolve in stable orbits around a central sun was solved by proposing a model in which a revolving celestial fluid carries the planets along, their distance from the sun being a function of their size.

In the 1630s, Descartes began to develop a distinctive epistemology driven by skepticism. He focused on a number of problems, such as radical skepticism, the provision of foundations for knowledge, and the exact nature of the relation between mind and body, which were either new or treated in a new way. However, Descartes explicitly warned against an insulation of philosophy from empirical questions.

THE PSYCHOPHYSIOLOGY OF COGNITION

At various stages in his career, Descartes tried to describe the nature of various kinds of intellectual or psychological phenomena in psychophysiological terms. There are three that are of particular importance: mathematical cognition, perceptual cognition, and affective states.

Mathematical Cognition

In his *Rules for the Direction of the Mind*, the relevant parts of which were completed between about 1626 and 1628, Descartes was concerned with the question how a quantitative grasp of the world was

possible. The question is how to connect the contents of the world, which consists of material objects, with the contents of the intellect, which, in the case of mathematical cognition, consists of abstract mathematical structures, which may have arithmetical or geometrical interpretations, but which are neither arithmetical nor geometrical in themselves. If a quantitative grasp of nature is to be possible, mathematics must somehow be mapped onto the material world.

Descartes' solution is to suggest that such a mapping cannot be direct: a determinate representation of the abstract mathematical structures is mapped onto a *representation* of the world. As regards the representation of the world, Descartes sets out to show how qualitative differences, such as differences in color, can be represented purely in terms of different arrangements of lines: red as vertical lines, blue as horizontal lines, green as a combination of these, yellow as diagonal lines, etc. We might think of this as a form of encoding: qualitative differences can be encoded in a very economical form, namely in terms of lines. As regards abstract mathematical structures, Descartes argued that these can be represented in terms of line lengths, or combinations of line lengths – the basic arithmetical operations of addition, subtraction, multiplication, division, and root extraction can all be performed using line lengths, for example, and geometrical operations present no problem in this respect. The contents of the intellect are represented in the 'imagination' as line lengths, and the contents of the material world are represented there as configurations of lines, and the former are mapped directly onto the latter, thus allowing a quantitative grasp of nature.

There are a number of interesting features of this account. Firstly, there is the idea that sensory information must be encoded in some way if we are to be able to engage with it cognitively. Secondly, note that the 'imagination' is a material organ (Descartes will later identify it with the pineal gland, this being the unique central, unduplicated organ in the brain, and hence ideally suited as a site for central cognitive processing), and that this, rather than the intellect, is where the cognition actually takes place. In other words, we seem to have a material site for cognition.

Perceptual Cognition

A distinctive feature of Descartes' natural philosophy is his commitment to mechanical explanation. This is evident in his physics and astronomy, but it goes further. Without appealing to vital forces of any kind, Descartes reasoned that, except in the case of the exercise of judgment and free will, which require consciousness, physiological processes – including such psychophysiological cognitive functions as visual perception, memory, and habitual and instinctual responses – can be accounted for mechanically. In the *Treatise on Man*, Descartes set out one of his most daring projects: the complete mechanization of physiology, from nutrition, excretion and respiration up to memory and perceptual cognition. His treatment of the last two is particularly ingenious.

In the case of visual perception, he argues – against a long and deeply entrenched tradition stretching back as least as far as Aristotle – that a visual image need not resemble the object perceived. Not only is there nothing in the optics or physiology of vision that requires resemblance, but the fact that the retinal image is inverted, that the retina where the visual image must be represented is a two-dimensional concave surface, that it must be transmitted through the nerves, and so on, all indicate a form of encoding of information. Descartes also shows awareness of fundamental problems of information recognition: he shows how we must employ an innate or unconscious geometry in order to be able to gauge the distance of objects, since our visual stimulation results from a light ray which cannot carry information about how far it has traveled from the object to the eye.

Descartes' account of animal cognition is very sophisticated. His aim is to show that the structure and behavior of animal bodies are to be explained in the same way as we explain the structure and behavior of machines. In doing this, he wants to show how a form of genuine cognition occurs in animals, and that this can be captured in mechanistic terms. He does not want to show that cognition does not occur, that instead of a cognitive process we have a merely mechanical one. In more modern terms, his project is a reductionist, not an eliminativist, one.

In the case of memory, Descartes offers an account in which the memory images do not have to resemble what caused them, and they do not have to be stored faithfully and separately but only in a way that enables the idea to be represented in a recognizable form. Unlike his contemporaries, who were largely preoccupied with identifying the physical location of memory storage (a favored location was in the folds of the surface of the brain, because of the large surface area such folds created), Descartes' concern is with just what is needed for recall, and he provides a rudimentary

account of how memory works by means of association.

Affective States

In the *Passions of the Soul* (1649), Descartes provided an extensive account of affective states, or passions, in which he examined how the mind and the body interact to produce such states as fear, anger, and joy. One of his primary concerns here was to argue against the idea that there are higher and lower functions of the mind, that there is a hierarchy of appetites, passions, and virtues, with the will occupying a precarious position. What Descartes opposes is the idea of a fragmentation of the soul, whereby one loses a sense of how the agent can collect himself or herself together, and exercise true moral responsibility. This is particularly important for Descartes, because he sees the crucial part of ethics to be the difficult process of forming oneself into a fully responsible moral agent – this is what the control of one's passions is ultimately aimed at – rather than the question of how such an agent should behave.

THE METAPHYSICS OF MIND

The doctrine for which Descartes is most famous is 'Cartesian dualism'. He advocates a view of the mind whereby (1) the mind is a different substance from the body, by virtue of having different essential or defining properties, and (2) the mind can exist in its own right, independently of the body, and have an identity that distinguishes it from other minds. Modern versions of dualism usually restrict their claims to the first of the above claims, substance dualism, but Descartes' advocacy of substance dualism seems to be in large part motivated by the second claim, which, because mind is not subject to the physical processes that lead to death and corruption, is tantamount to the doctrine of personal immortality.

Substance dualism requires no commitment to the capacity for independent existence of the mind. The fact that mind and matter are separate substances does not in itself require us to imagine that mind might be able to exist independently of matter: we might conceive of the mind as the 'software' that runs the cognitive parts of the body, for example, thinking of it as something quite distinct from its material realization in a particular brain, or central nervous system, while at the same time arguing that it makes no sense to talk about such software independently of its being a program.

However, Descartes' concerns seem different. As he indicates in the dedicatory letter which prefaces the *Meditations*, he is concerned to defend the doctrine of personal immortality of the soul. This doctrine had been undermined by two different kinds of philosophical conception of the mind. The first was Alexandrism, which was in effect substance dualism without personal immortality. Alexander of Aphrodisias and his followers had argued that the mind or soul is the 'organizing principle' of the body, something essentially materially realized, so that with the death and corruption of the body, it goes out of existence. The second kind of conception was Averroism, whereby the mind can be separated from the body at death, but in undergoing such separation it loses any identifying features and becomes identical with 'mind' as such. The idea here is that what distinguishes my own mind from another is a set of features it has by virtue of being instantiated – my sensations, memories, and passions are easily sufficient to mark me out from everyone else, for example, but these are dependent on my having a body – and once it becomes separated from my body, it loses anything that might differentiate me from anything else, and so becomes one with a universal mind (God).

Descartes' challenge is to steer a middle path between Alexandrism, which denies immortality altogether to the soul, and Averroism, which denies it personal immortality. It is not clear that he is able to do this. His account of such processes as mathematical cognition, perceptual cognition, and affective states presuppose that the mind is instantiated in the body, and so are compatible with Alexandrism (conceived as a minimal substance dualism). He does not describe what a disembodied soul is like except to tell us that it contemplates universals, but that is what God does, and what Averroes' single mind does: there is nothing to distinguish disembodied souls from one another in this respect.

RELEVANCE OF DESCARTES' WORK TO COGNITIVE SCIENCE

Descartes was the first person to provide a comprehensive account of a mechanized psychophysiology. Although his ideas had some followers in the succeeding two centuries, the resources available – most importantly knowledge of brain physiology – were far from adequate, and Descartes' project looked like a dead end. As these resources were acquired, from the late nineteenth century

onwards, the situation changed. There remain a number of deep philosophical problems about the nature of cognition and the mind – perceptual cognition in unintelligent animals, what is involved in memory retrieval, and so on – which Descartes, because of his limited empirical resources, was forced to focus on in a way that draws attention to some of the conceptual problems that need to be addressed if one is to orientate one's empirical investigations in a fruitful direction.

Ebbinghaus, Hermann

Introductory article

Robert R Hoffman, Institute for Human and Machine Cognition, University of West Florida, Pensacola, Florida, USA
Michael Bamberg, Clark University, Worcester, Massachusetts, USA

CONTENTS

Hermann Ebbinghaus (1850–1909) was a German psychologist whose books, research, and ideas had a great effect on early psychological theory. He is often credited with founding the experimental psychology of the 'higher mental processes'.

INTRODUCTION

Hermann Ebbinghaus was born on 23 January 1850 in the industrial town of Barmen, in the Rhine Province of the kingdom of Prussia. He studied classics, languages, and philosophy, and completed his doctoral dissertation at the University of Bonn in 1873. After working for some years as a tutor, he happened to read about the new research on psychophysics, and became inspired to study the 'higher mental processes'. In 1878, Ebbinghaus began formal experiments on memory, conducted in his home. A monograph on the work was published in 1885. Within a year he was promoted to a salaried professorship at the Friedrich Wilhelm University in Berlin. Journals that published psychological research were beginning to spring up everywhere and Germany needed a general journal. Ebbinghaus helped establish the *Zeitschrift für Psychologie und Physiologie der Sinnesorgane* (Journal for the Psychology and Physiology of the Sense Organs) and served as its editor for 22 years. In 1893 Ebbinghaus took a professorship at Breslau University in the Prussian province of Silesia. Ebbinghaus's psychology textbook appeared in 1897, and was the most popular and widely used general psychology text for many years.

Ebbinghaus was known as an eloquent lecturer and excellent teacher. He was a man with vision, a champion of the view that psychology should be emancipated from philosophy, and the higher mental processes studied experimentally.

Ebbinghaus died of pneumonia in 1909. At that year's psychology conference at Clark University (to which Ebbinghaus had been invited), Cornell University psychologist Edward B. Titchener began with a eulogy: 'As I approach the topic of this lecture, what is uppermost in my mind is a sense of irreparable loss. When the cable brought the bad news, last February, that Ebbinghaus was dead … the feeling that took precedence even of personal sorrow was the wonder of what experimental psychology would do without him.'

EBBINGHAUS'S RESEARCH

The monograph *On Memory* has three aspects: the experiments themselves, a discussion of statistical analyses of data, and some theorizing. Much of the theorizing concerns the strength and vividness of associations and the search for 'mathematical rules for mental events'. Ebbinghaus's discussion of the basic statistical methods was so clear and exact that many psychologists had their students read Ebbinghaus's book just for its discussion of statistics. Each data point that entered into his analyses was an average of the learning times (or average number of repetitions needed to reach a learning criterion) over a large number of lists. The averages were used to compute a distribution of means, and results were then described in terms of standard errors: the percentage of cases falling under a given area of the distribution.

The monograph reported 19 studies conducted in the years 1879–1880 and 1883–1884. To conduct the research Ebbinghaus first prepared a pool of 'all possible syllables' – 2300 in all (quite a few of them were words in German, English or French). A few examples are heim, beis, ship, dush, noir, noch, dach, wash, born, for, zuch, dauch, shok, hal, dauf, fich, theif, hatim, shish, and rur. Pacing himself with a metronome, and reading the lists aloud with a poetic meter, he proceeded to memorize lists of syllables. Using a set of buttons on a string, he was able to keep track of the number of repetitions

he needed in order to learn a list to the point that he could give one perfect recitation. The experiments were an ambitious project and required great effort.

Ebbinghaus led a ritualistic, almost monastic life during these experiments, learning and recalling lists every day for months on end, dozens of experiments and replications of experiments, each involving multiple trials and hour after hour of data collection and careful record-keeping. Imagine learning 84 600 syllables in 6600 lists, taking more than 830 h! Although the number of list repetitions involved for every experiment cannot be determined for some of the studies on the basis of what Ebbinghaus said in his monograph, for experiment 2 alone Ebbinghaus engaged in 189 501 repetitions of lists.

The first two experiments had the goal of showing that the variability of the average learning times over a large number of lists was within limits that would be scientifically acceptable. He emphasized that the standard errors he obtained compared favorably with the precision of measurement in the physical and biological sciences (e.g. measurements of the speed of neural conduction, or measurements of the mechanical equivalent of heat). In fact, his 'probable errors' of about 7% were more precise than the physical measurements and very close to those for the biological measurements.

The list of Ebbinghaus's findings includes many of the basic phenomena that are discussed to this day in books on the psychology of memory. His research demonstrated the viability of the method of savings or 'ease of relearning' as a means of measuring the strength of association. He demonstrated the effects of fatigue and time of day on retention; the effect of list length on the number of repetitions it takes to learn material; the 'decay of memory' as a function of the delay between acquisition and memory test (with delays spanning hours, days, weeks and even years). Ebbinghaus demonstrated the effect of 'distributed versus massed' practice. He demonstrated what came to be called the 'serial position' effect (i.e. better memory for material that falls near the beginning and near the ending of a list). Ebbinghaus also measured what would come to be called the short-term memory span – 'the number of syllables which I can repeat without error after a single reading is about seven. One can, with a certain justification, look upon this number as a measure of the ideas of this sort which I can grasp in a single unitary conscious act.'

Textbooks on general and cognitive psychology preserve a myth about Ebbinghaus, which is that he conducted experiments in which he memorized 'nonsense' syllables. It was not the syllables that were nonsense – in the examples given above, the first 10 are all meaningful in one or another of the languages Ebbinghaus knew – it was the task of learning a list of semantically unconnected items that Ebbinghaus refers to as involving an 'impression of nonsense'. Indeed, the term he preferred for his lists, *Vorstellungsreihen* (literally, 'presentation series'), could just as well be translated as 'image series', and Ebbinghaus discussed at some length how the strength and vividness of memory images should be related to the effort taken in learning them.

Another contradiction to the myth is that Ebbinghaus did not begin his studies by attempting to memorize lists of syllables. Instead, he began with a task more familiar to teachers – and to the pupils whom Ebbinghaus taught – the memorization of poetry. His preliminary trials with poetry showed that the material was learned too quickly. He found no need for multiple repetitions (meaning that he could not obtain enough data about trials and time to criterion in order to generate statistically reliable laws) and he was also concerned that the material could not be systematically and quantitatively varied (lists of numbers did not afford enough variety either); hence his eventual choice of syllable lists. However, his research did not end with the memorization of syllable lists. Ebbinghaus memorized stanzas from Byron's *Don Juan* in order to address the question of the role of meaningfulness in the associative process. Over a period of 4 days he conducted seven separate tests, each test involving the learning of six stanzas. Each test took about 20 min and involved about eight repetitions of each stanza. Given that each stanza consisted of about 80 syllables, he could compute that meaningfulness resulted in a large advantage: about one-tenth the effort in terms of the number of repetitions needed to achieve one perfect recitation. Most important to Ebbinghaus was the fact that the findings with the poetry confirmed the findings for the syllables: general laws were in operation.

INTELLIGENCE TESTING

The school board of Breslau had commissioned Ebbinghaus to generate mental tests that could be used to determine the best distribution of study hours for schoolchildren. He invented the completion method to see how well children could perceive relationships, combine information, and arrive at correct conclusions. In the task, students would have to fill in the missing letters in sentences such

as 'WH__ WILLY ___ TWO _____ OLD, HE _____ __ _ RED FARM_____'. This type of task is still used in modern intelligence and aptitude tests. Along with digit memory and a rapid calculation task, the results showed a clear effect of age and individual differences. However, only the results from the method of combinations showed a relation to the children's grades. Ebbinghaus's work on intelligence testing was thus some of the very first research on this topic. According to Woodworth, the completion method was probably a better test of intelligence than any other method available at the time. Alfred Binet was working on mental testing at the time, and Binet was encouraged by Ebbinghaus' studies of school children. The original Binet–Simon scale included Ebbinghaus's method of relearning of lists (of words) as well as the sentence completion task.

IMPACT ON PSYCHOLOGY

Ebbinghaus's monograph received mixed reviews when it was published, but American psychologist William James praised the work, pointing out the author's 'heroic efforts'. To James, 'this particular series of experiments [was] the entering wedge of a new method of incalculable reach' (p. 199). Once Ebbinghaus's work became known in the USA, other psychologists began conducting studies of learning. Ebbinghaus became a model of the experimental psychologist, whose theoretical speculations were brief and cautious but whose research was rigorous in its method and its use of statistics. He provided a model for the use of experimental logic, including the testing of alternative hypotheses by setting up experimental situations where rival hypotheses would make differing predictions, and also a sensitivity to what are today called 'experimenter bias effects' (especially important to Ebbinghaus because he was his own subject). Finally, he provided experimental psychology with a model for preparing a research report: the now-traditional ordering of introduction, methods, results, and discussion sections.

Fechner, Gustav Theodor

Introductory article

Stephen Link, University of California, San Diego, California, USA

CONTENTS

Gustav Theodor Fechner (1801–1887) was a German physicist and philosopher whose application of mathematical and scientific methods to psychological theory established the science of psychophysics and laid the foundations of experimental psychology.

INTRODUCTION

'In general, the clergy was strongly represented among our relatives, and I was also supposed to embark on this path, but somehow it turned out differently.' Gustav Fechner, son and grandson of pastors, was born on 19 April 1801 in the Saxony village of Großsärchen, now Zarki-Wielkie in Poland. At age 16 he matriculated at Leipzig University, where he spent 70 years first as a medical student, then as professor, chemist, physicist, psychophysicist, estheticist, nature philosopher, poet and satirist (Figure 1). His many theoretical and empirical discoveries enhanced the field of physics and created a basis for statistical hypothesis testing, descriptive statistics, experimental psychology and experimental esthetics.

Figure 1. Gustav Theodor Fechner (1801–1887).

LIFE AND WORKS

Following the Magisterexamen (rigorosum) at Leipzig University in 1823, Fechner spent ten years developing the theory of electricity, and his important experiments on Ohm's law that made him famous. His translations into German of books by the greatest French physicists of his day gave him the opportunity to meet them personally, to expand on their works and, in 1832, to publish the three-volume *Repertory of Experimental Physics*. These achievements led to his appointment as Professor in Ordinary at Leipzig University in 1834, the establishment of the Institute of Physics in Leipzig, and researches into the perception of color and afterimages.

In December 1839, overwork brought on by voluminous publications including the eight-volume, 7000-page *Hauslexicon* in 1837, and blindness caused by staring directly into sunlight to create vivid afterimages, led to a complete nervous collapse. Ellenberger characterized Fechner's illness as a 'sublime hypochondriasis, a creative illness from which a person emerges with a new philosophical insight and a transformation in their personality'. William James, a close follower of Fechner's work, described the illness as a 'habit neurosis'. For three years Fechner lived as a recluse, wearing a lead eye mask to prevent the pain caused by even the slightest illumination of his damaged eyes. His thoughts became uncontrollable, and his inability to consume food or liquids left him a skeleton near death.

Three years later, however, Fechner miraculously recovered. A transformation of his personality evidenced itself in his writings on the first law of the mind, 'the pleasure principle of action'. In 1846 Fechner argued that the search for pleasure and the avoidance of unpleasure were forces driving human behavior, in *Über das höchste Gut* (On the

highest good). The ideas appear fixed in *Über das Lustprincipl des Handelns* (1848). In 1848, his famous *Nanna, oder über das Seelenleben der Pflanzen* (On the soul life of plants) proposed that 'one can ask whether such a life (of animate creatures) pertains also to the plants, whether they too are animate individuals, combining in themselves impulses or sensations, or maybe more psychic experiences …. If this were so then plants along with men and animals would constitute a common contrast to stones and all things we call dead.'

Expanding on the idea of consciousness, in 1851 Fechner rendered a new version of *Zend-Avesta*, the sacred writings of the Persian prophet Zarathustra (Zoroaster). Fechner's *Zend-Avesta, über die Dinge des Himmels und des Jenseits: vom Standpunkt der Naturbetrachtung* (About heavenly things and the hereafter from the standpoint of contemplating nature) proposed that all life forms were self-aware and conscious. Even more, consciousness was in all and through all things. The Earth itself was conscious. Fechner also revealed that when he awoke on 22 October 1850 (now known as Fechner Day), he saw a relation between the body and mind, between the physical and mental, that became the basis for a new science and the first methods of mental measurement.

In particular, Fechner observed that a just noticeable difference (JND) in sensation is felt when a new stimulus increases in magnitude by a fixed proportion of the stimulus against which it is compared. For example, if a 312 g weight feels just noticeably different from a 300 g weight, then a 624 g weight will feel just noticeably different from a 600 g weight. Each JND is a unit of experience, as important to psychology as the mole is to chemistry or the quantum to physics.

Defining stimulus magnitude as a value S, and a just noticeable increment in stimulus magnitude as a value ΔS, Fechner developed the equation known as Weber's law:

$$\Delta S/S = \text{constant} \quad (1)$$

Fechner generalized this principle, and proposed that even smaller units of $\Delta S/S$ may be added together to create a measure of sensation magnitude. Letting dS represent a small increment in stimulus, Fechner created the differential equation

$$dS/S = \text{constant} \quad (2)$$

Integrating this equation adds together small relative increases in stimulation to form a total amount of sensation. The result is one of the most famous laws in psychology, relating sensation magnitude ψ to physical stimulus magnitude S, known as Fechner's law:

$$\psi = \log_e S \quad (3)$$

This formula set Fechner on a voyage of scientific discovery that marked the origin of experimental psychology.

THEORY OF MENTAL JUDGMENT

In *Elemente der Psychophysik*, published in 1860, the future of experimental psychology was set. In this two-volume, 907-page work, Fechner created the theory of judgment and methods of experimentation that still dominate psychological research. Fechner discovered that when comparing two stimuli, such as weights, a person could feel a just noticeable difference in weight but err in judging which of the two weighed more. For example, weights of 300 g and 312 g might feel just noticeably different but the 300 g weight might be judged heavier than the 312 g weight. This paradox led Fechner to propose a theory of judgment that predates the modern theory of statistical hypothesis testing.

In this regard, Fechner assumed that the sensory system is the mind's connective tunnel to the external world. A sensation or feeling such as heaviness must derive from the process of transforming into neural energy the energy of a physical stimulus. However, Fechner also assumed that the electrochemical sensory measurement system was not perfect. It suffered from the same form of inherent variability in measurement as Gauss had proposed in 1809 to affect physical measurement devices.

As shown in Figure 2, the transformation of weight to heaviness generates a Gaussian probability distribution of heaviness values. The true heaviness of a fixed 300 g weight equals $h(300)$, but because of sensory variability, the actual feeling of heaviness varies. Sometimes the weight feels heavier – and sometimes lighter – than the true heaviness of $h(300)$. Similarly, the true heaviness of a 312 g weight equals $h(312)$, but its heaviness varies according to the probability distribution shown in the upper part of Figure 2. The spread of heaviness values surrounding the mean values of $h(300)$ and $h(312)$ is characterized by the standard deviation of the Gaussian distribution, often denoted σ. Fechner suggested that this sensory variability was the basis for errors of judgment. As a theoretician, Fechner devised a theory of errors of judgment that allowed for a scientific measure of the unknown amount of sensory variability, σ.

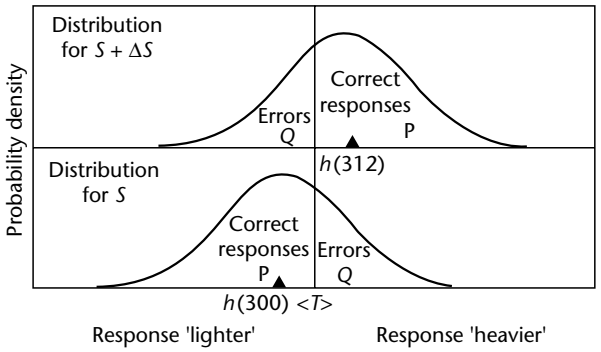

Figure 2. Fechner characterized the unseen variability within the nervous system as a Gaussian (normal) distribution. The abscissa represents heaviness, a psychological phenomenon. Two weights of 300 g and 312 g respectively generate average heaviness values of $h(300)$ and $h(312)$. The average of the two true heaviness values $h(300)$ and $h(312)$ equals T and is the threshold used (on the average) to determine which weight feels heavier.

The theory of judgment assumes that when two weights are compared, the average of the two heaviness values serves as a threshold for deciding which stimulus is heavier (or lighter). The stimulus that produces a heaviness greater than the average heaviness is judged to be the physically greater stimulus (*Elemente*, vol. 1). Converting these ideas into a mathematical form produces a measurement of the amount of variability in the nervous system in units of the physical stimulus. This extraordinary achievement, the first mental measurement, established psychology as a scientific discipline.

Figure 2 illustrates the essential features of Fechner's decision theory. Two weights of 300 g and 312 g are under comparison. On each comparison trial, the participant lifts each stimulus, experiences a sense of heaviness for each weight, and then reports which stimulus is greater in weight. According to the theory, Gaussian distributed variability perturbs the measure of heaviness. These distributions are shown in Figure 2 with heaviness means equal to $h(300)$ and $h(312)$. The threshold (criterion) for deciding which weight was heavier will change from trial to trial because the same heaviness values will not occur with each lifting of the weights. On the average, however, the threshold for deciding which weight is heavier is the average of the two mean heaviness values, equal to the value T shown in Figure 2.

The area to the right of T and under the Gaussian distribution for the heaviness of 312 g equals P. This is the probability of correctly judging the 312 g weight to be the larger weight. Also, the area Q, to the right of the criterion under the Gaussian distribution for the 300 g weight, equals the probability of an error in judging the smaller weight of 300 g to be the larger. Owing to the mirror symmetry of the Gaussian distributions with respect to T, and the requirement that areas under probability distributions must sum to 1, the values of P and Q must sum to 1.0. For a larger weight, say 324 g, the distribution of heaviness values shifts to the right. As a consequence, the threshold value T also shifts to the right, causing the value of P to increase and the value of Q to decrease.

To measure the amount of the unseen variability in the nervous system Fechner defined a measure of distance along the abscissa of Figure 2 in terms of the standard deviation, σ. Then he created mathematical tables showing how many errors of judgment occur for any value of T as measured in numbers of standard deviation units, σ. By running experiments to determine the probability of an error of judgment, and by comparing the error probability to entries of T in his tables, Fechner determined the number of standard deviation units separating T from $h(300)$. Using the Newtonian assumption that for very small differences in heaviness the function h is approximately linear, he determined that the threshold at T equaled $\frac{1}{2}(312 - 300)/\sigma$. Therefore,

$$\sigma = \tfrac{1}{2}(312 - 300)/T \qquad (4)$$

In this way Fechner measured the unseen force that resulted in errors of judgment. In this way he measured the unknown value of σ in units of the physical stimulus. In this way psychology became a science.

Elemente remained the basic work on experimental design until the 1935 appearance of R. A. Fisher's *Design of Experiments*. The theory still finds powerful applications. Thurstone developed a theory equivalent to Fechner's that yielded psychological measurement scales for such diverse stimuli as the seriousness of crimes, likeableness of vegetables and attitudes generally. The signal detection theory formulated by Tanner and Swets in 1954 allowed the value of T to vary as a function of experimenter inducements to bias judgments toward one response. Kinchla and Smyzer extended Fechner's theory in 1967 by providing a theory of visual position memory that predicted linear increases in σ^2 as a function of time.

The 'mirror effect' in recognition memory can be interpreted as a shift of Gaussian distributions of the memory strength along an abscissa of memory strength. As one distribution for memory strength shifts toward higher values, due to increased memory strength, the value of T must also shift

and the value of P in Figure 2 must increase while the value of Q must decrease. Stretch and Wixted showed that the value of T increases as word recognition memory strengthens, as Fechner's decision theory requires.

Elemente Volume 2 defines Fechner's law and describes 'inner psychophysics', the study of mind without regard to its sensory connections. The application of Weber's law, Fechner's law, and the threshold to inner psychophysics results in ideas about sleep and being awake, partial sleep, attention, and consciousness. Other chapters describe the wave scheme, relations between sensory and imagery phenomena, memory images, memory afterimages, the phenomena of sensory memory, psychophysical continuity and noncontinuity, hallucinations, illusions and dreams. Some fifty years later, Sigmund Freud commented, 'I … have followed that thinker on many important points.'

During his last 27 years Fechner created the field of experimental esthetics, continued his psychophysical investigations, and introduced ideas about descriptive statistics. In 1866 *Das Associationprincip in der Aesthetik* foreshadowed *Zur experimentellen Aesthetik* (1871) and the establishment of the field of experimental esthetics with the two-volume *Vorschule der Aesthetik* in 1876. Modern works on esthetic judgments by Beebe-Center, Hare, and Dorfman and colleagues extend and apply Fechner's and Thurstone's theories to art and emotion.

Returning to psychophysics, in 1877 Fechner published *In Sachen der Psychophysics*, in 1882 *Revision der Hauptpuncte der Psychophysik*, and in 1884 two more major experimental works. At Wilhelm Wundt's urging G. F. Lipps edited and published, posthumously, Fechner's last work *Kelletivemasslehre* (1897) a theory of data analysis that coined the term 'descriptive statistics'.

CONCLUSION

Fechner called upon the world to recognize the fundamental unity of the mind and physical reality. His many theoretical ideas changed over time and yet became foundations for a century and more of research and theory. What would psychology be without Fechner's psychophysics, without such important developments as signal detection theory, psychoanalysis, experimental memory, and attention and esthetics? Each of these mighty fields owes much to Fechner's originality of thought, integration of psychological theory with mathematics and experimental design, and firm belief that the physical and mental worlds form a single reality.

Freud, Sigmund

Introductory article

Malcolm Macmillan, Deakin University, Burwood, Victoria, Australia

CONTENTS

Sigmund Freud founded psychoanalysis between 1895 and 1900 as a therapy for neuroses but developed it as a method for investigating mental processes and as a general psychology. He applied psychoanalysis to such fields as anthropology, sociology, and literature, and it became one of the most influential of all twentieth-century systems of thought. However, neither his original theory nor the variants descended from it have been widely accepted.

BACKGROUND, UPBRINGING, EDUCATION, AND INTERESTS

Sigmund Freud was born on 6 May 1856 in Příbor, Czechoslovakia. He was Jewish, his ancestors coming from Galacia. His family moved to Vienna when he was three, where he was educated and practiced medicine. When the Nazis invaded Austria in 1938 and persecuted the Jews there, they extorted a substantial ransom before allowing Freud and most of his family to go into exile in London. He died there on 23 September 1939. As a student Freud was well above average in academic ability. He read much general literature and philosophy and became deeply interested in biology and evolution but, as a Jew, medicine was one of the few careers open to him. Initially a neurohistologist, he began his medical practice as a neurologist.

NEUROLOGY AND PSYCHOLOGY

After beginning his medical studies in 1873, Freud enrolled in extra classes in physics, zoology, philosophy, and biology and Darwinism. He conducted histological work as a student and began his adult neurohistological research in 1876. Freud explicitly related his findings to the evolutionary-developmental framework in which he conducted this work.

Neurology and Affect

In 1885 Freud went to Paris to extend his neurohistological work at the clinic of Jean-Martin Charcot, where he became interested in Charcot's work on hysteria and hypnosis. Charcot produced anaesthesias and paralyses in hypnotic subjects and showed that the symptoms so produced were identical to those of hysteria. Using the minor trauma of indirect suggestion, by for example striking the subject on the arm, he seemed to show that hypnotic and hysterical symptoms formed when the affects of traumas caused a loss of ego control. Freud called the reflection in the symptoms of ideas and sensations from the trauma 'determining quality'. Together with the effects of the intense emotional state, it became central to his theories of mind.

Libido and Affect

After returning to Vienna in 1886 Freud practiced as a neurologist. Most of those of his patients with symptoms having no organic basis had neurasthenia, a supposed nervous weakness (asthenia), rather than hysteria. Sexual problems were frequently associated with it and Freud set out to establish its exclusively sexual aetiology. By the beginning of 1893 he claimed it was adolescent masturbation. Freud also differentiated anxiety neurosis – a sudden attack of anxiety with pronounced physiological manifestations such as increases in heart rate – from neurasthenia and proposed that its cause was incomplete sexual gratification (e.g. *coitus interruptus*).

Calling both neuroses 'actual neuroses', he theorized that they were caused by defective discharge of libido, that is, of the psychological sexual energy that formed when sexual ideas were charged or invested with physiological sexual energy. The loss of libido in neurasthenia caused general weakness; its deflection into organs like the heart caused

orgasm-like anxiety symptoms. Freud eventually generalized this thesis by proposing that the affects causing hysteria and obsessional neurosis were charges of libido.

FREUD AND THE PSYCHONEUROSES

Freud had first become interested in hysteria when Josef Breuer, his Viennese medical mentor, told him in 1882 how he had used talking to treat the hysterical symptoms of the pseudonymous Anna O. (Bertha Pappenheim). Under Freud's influence, Breuer explained Anna O.'s symptoms with 'French' dissociation theory: the 'traumatic' sensations that occurred in her elementary *secondary consciousness* returned as symptoms when it did. Her talking reconnected these secondary consciousness experiences with her *primary consciousness* and, according to Breuer, caused her symptoms to disappear.

Freud's Theory of Psychological Forces

Freud himself did not find that symptoms always formed in secondary states. Many patients recalled consciously trying to forget unacceptable ideas, which were then repressed by an unconscious mechanism. Freud's evidence for this ego force was the psychological effort he had to make to overcome the resistance patients had to recalling the unacceptable ideas. Initially Freud also drew on dissociation theory: repression separated the idea from its affect, pushed it into a secondary consciousness, and kept it there. Expressing the affect under light hypnosis re-established the previously subconscious association of the idea with normal consciousness and the symptom disappeared.

Freud soon abandoned hypnosis and dissociation theory. Pathogenic ideas could not always be recalled under hypnosis and repressed ideas could be retrieved in normal consciousness when patients fully reported what came to mind as they thought about their symptoms (*free association*). Both symptom formation and symptom removal took place in the waking state and these waking state concepts explained more: in hysteria the affect might be converted into physical symptoms and in obsessions displaced on to another idea, etc.

Affect, Sexuality, and Repression

Affect became central to Freud's theorizing when he concluded that effective therapy depended on how completely patients expressed or *abreacted* the emotions they had held back when their symptoms formed.

When first treating hysteria and obsessions (the psychoneuroses), Freud did not report that the unacceptable ideas had any particular content. But, from about 1895 they were always sexual, by 1896 they were always of perverse sexual experiences into which patients had been seduced as children, usually by an adult, and by 1897 the seducer was invariably the patient's father. Few patients recalled such experiences; most of the so-called 'memories' were constructed by Freud from their fragmentary recollections. This *childhood seduction theory* thus aligned the psychoneuroses with the actual neuroses. And, in accord with *Koch's postulates* from bacteriology, each neurosis had a specific sexual cause: masturbation for neurasthenia, incomplete gratification for anxiety neurosis, unpleasant childhood seductions for hysteria, and enjoyable for obsessions. Libido, not affect, thus powered repressed ideas.

NEURONAL AND NEURONAL-LIKE THEORIZING

In 1895 Freud outlined a physiological theory particularly directed to explaining why only sexual ideas were repressed. This unpublished work, called (in English) the *Project for a Scientific Psychology*, was much influenced by the *biophysics movement*, which tried to explain living phenomena by material processes. Freud eventually abandoned the *Project*: the deductions became too complex, some assumptions, especially about consciousness, became too *ad hoc*, and he never completed the section on repression.

A Neuronal-like Theory

In the next theory, the *topographic theory* of Chapter 7 of *The Interpretation of Dreams* (1900), Freud nevertheless retained the three kinds of neurons of the *Project*: permeable Φ neurons for perception, alterable Ψ neurons for recording memories, and ω neurons for consciousness, and a group of neurons with its own store of energy to delay responses (an ego). Apparently devoid of speculative physiology, the theory was still based on a teleological reflex and drew on notions of energy in flow and the cathexis or investment of ideas by it. Primary process was located in a system unconscious (*Ucs.*) and the secondary ego functions shared between the systems preconscious (*Pcs.*) and conscious (*Cs.*). *Pcs.* and *Cs.* repressed and controlled unacceptable ideas in *Ucs.*, allowing them only a disguised *Cs.* representation. Dreams, like symptoms, were fundamentally based on repressed sexual wishes.

Freud generalized these neuronal-like proposals and aligned them with his earlier theses that aspects of everyday mental life, such as faulty recall, slips of the tongue etc. (or parapraxes), resulted from conflicts between opposing conscious and unconscious forces. He could speak equally as well in the language of wishes as of neuronal activity.

SEXUAL AND OTHER INSTINCTUAL DRIVES

It was still a mystery why sexual ideas were so important and why only they were repressed. Freud tried to solve the problem by proposing that repression was a two-stage process that selectively affected the sexual drive.

Seduction Fantasies and Phylogenesis

Freud first proposed that the seduction 'memories' were fantasies caused by a childhood sexual drive. This childhood drive had separate *oral*, *anal*, and *phallic components*, each of which sought the same objectless, or *autoerotic*, perverse *modes* of satisfaction as in the perverse adult. Sucking and biting satisfied the oral component, fecal retention and expulsion the anal, and childhood masturbation the phallic. Freud claimed that some of these activities caused orgasm-like reactions. His analysis of symptoms also required such drives. A biological process of *primary repression* repressed each component drive according to a *phylogenetically* determined timetable.

Repression proper occurred when unacceptable ideas later revived these earlier, primarily repressed modes of satisfaction. Modes of satisfaction, just like other evolutionary developmental processes, could be fixated. Uncomplicated fixations explained perversions, and excessive repression and ego regression accounted for neuroses and psychoses respectively. Thus, schizophrenia and paranoia were based, respectively, on oral and anal fixations and regression, and hysteria on excessive repression of phallic sexuality. In this theory of psychosexual development, normal adult character traits were continuations of partial fixations. For example, eating, drinking, and dependence continued the oral mode, and orderliness, cleanliness, and parsimony the anal-retentive.

Finalizing the Instinctual and Structural Theories

Freud's theory logically required an *ego-instinctual drive* to repress the sexual instinctual drive in childhood when the ego was weak. He therefore recast basic mental conflict as one between the drives for self-preservation (ego) and preservation of the species (sexual). Self-love or narcissism undermined this polarity. Partly to resolve this difficulty and partly to explain the prominence of guilt and self-punishment in severe depression, Freud announced his final instinct theory. A death instinct, Thanatos, which aimed to return living matter to the inanimate state was now in conflict with a life instinct, Eros, comprising the old ego and sexual drives. Directed inward, Thanatos explained depression; outward explained aggression.

The two new drives were incorporated into Freud's third theory, the *structural theory* of 1923. Mental life was now an interaction between the *Id*, *Ego*, and *Superego*, and the Id was the repository of Thanatos and Eros as well as of repressed ideas. The Ego had many *Cs*. and *Pcs*. functions but was partly unconscious. It was powered by a *sublimated* form of Eros and only it sensed anxiety. The Superego was entirely new. Containing standards and conscience, it scrutinized behavior, punished infringements, and repressed sexual drives when the Ego generated signal anxiety. It formed in the *Oedipal phase* when the sexual and aggressive feelings of the child toward both parents were repressed. The child then *identified* with its lost sexual object and *incorporated* its standards into its Ego where they were cathected by Thanatos to form its own, harsh Superego. In this way the Oedipus complex was dissolved.

These drives, structures, and related developmental processes virtually completed Freud's general psychological theory.

SOME PROBLEMS WITH PSYCHOANALYSIS

Although Freud's influence is undeniable, the logical and empirical deficiencies of his central ideas means that their truth is still debated.

Structural Problems

First, psychoanalysts do not agree on the functions possessed by the structures of the third theory. Second, there is little agreement on when or how the Superego forms, and Oedipal identifications deliver feminine qualities to the boy's Superego and masculine to the girl's. Third, female sexuality develops tortuously, mainly because Freud insisted on a male starting point for both sexes. Fourth, how sublimation 'purged' libido of its overt sexuality is a mystery. Fifth, although

analysts do not agree on the sources of aggression most reject Thanatos.

Sexuality

Freud's clinical evidence for the role of sexuality is weak. There is also no direct evidence for a childhood sexual drive of the kind Freud's theory required. Observation shows that the supposed component drives are not sexual and that perverse adult behaviours do not lack objects or by themselves lead to orgasm. Empirical studies of the ways character traits cluster and whether they relate to early fixations also provide only weak support to the psychosexual theory. There is also a lack of evidence for the kind of repression that Freud proposed.

Free Association

Freud claimed that free association was as reliable and objective as the microscope. He insisted that he did not influence what the patient reported. However, analyses of psychotherapy sessions show that patients produce what their therapists search for, and the same thing appears to happen in the therapies conducted by psychoanalysts of different schools.

Interpretation

Freud believed that *interpretation* of the apparently meaningless ideas obtained by free association revealed their unconscious relations and uncovered their logically meaningful connections with the causes of the problem. For him these unconscious processes had the same reality as the unobservables of physics or chemistry. Psychoanalytic methods therefore allowed for trustworthy reconstructions of patients' histories.

Freud often compared interpreting free associations to deciphering or translating unknown languages. However, the translations of different psychoanalysts agree only minimally. Partly this is because there are no interpretive guidelines, but the more basic problem has been identified as the lack of knowledge of the grammar, syntax, and lexicon of the 'language' of the unconscious. When nothing is known about it, a language cannot be deciphered.

CONCLUSION

Were free association and interpretation as reliable and objective as Freud claimed, and were his theoretical concepts soundly based, analysts would collect and interpret essentially the same data in the same way and develop the theory from agreed-upon basic concepts. None of this happens. By 1930 irreconcilable differences had emerged among psychoanalysts, a fragmentation that has accelerated. Few analysts now accept all or even most of Freud's propositions. Nor can they define psychoanalytic theory or therapy. After more than a hundred years there should also be plenty of evidence to support at least one version of psychoanalysis, but there is none that has either a strong clinical or empirical base.

CONTENTS

Norman Geschwind (1926–1984) was a twentieth-century American neurologist considered to be the father of behavioral neurology because of his research and theories concerning higher cortical functions.

INTRODUCTION

Norman Geschwind (Figure 1) is a seminal figure in behavioral neurology because of his intensive clinical investigation and anatomical research on aphasia, isolation of the speech area, apraxia, agnosia, language-induced epilepsy, anatomical asymmetries of the brain, and cerebral dominance.

Geschwind was born in New York City in 1926. After graduating from Boys High School in Brooklyn, Geschwind attended Harvard College on a Pulitzer scholarship. He graduated *magna cum laude* with a concentration in mathematics in 1947, and then obtained a degree in medicine, *cum laude*, from Harvard Medical School in 1951. He interned in medicine at Boston's Beth Israel Hospital and then was awarded a Moseley scholarship to study at the National Hospital, Queen Square, London in 1952. Upon his return to the USA, he became chief resident on the Boston City Hospital neurological service under Derek Denny-Brown. After 2 years of axonal physiology research at the Massachusetts Institute of Technology, he joined the neurology service at Boston's Veterans Administration Hospital in 1958, becoming its chief in 1963. In 1966, with support from the National Institutes of Health, Geschwind started the Aphasia Research Center. That year he was also awarded the chair of the department of neurology at Boston University and began his research on higher cortical brain functions.

Returning to Harvard in 1969, Geschwind was named the James Jackson Putnam Professor of Neurology, succeeding Denny-Brown. The Harvard neurological unit moved from the Boston City Hospital to the Beth Israel Hospital in 1975, where Geschwind remained neurologist-in-chief until his death in 1984. At Beth Israel Hospital his interests flourished, particularly in behavioral neurology, language alterations, the relationship of one side of the brain to the other, the significance of large neuronal networks and their interconnections, and the relationships between brain development and other characteristics of both health and disease, particularly autoimmune illnesses.

Geschwind received three honorary degrees, two awards, and several honorary memberships and visiting lectureships. In 1978 he accepted a joint appointment at the Massachusetts Institute of Technology as a professor of psychology. He was elected president of the Boston Society of Neurology and Psychiatry and of the American Association of University Professors of Neurology. Geschwind was considered by many to be the father of behavioral neurology, and several of his many areas of interest, which extended over a remarkably long period, are outlined below. His work extended from the reestablishment of classic, predominantly French and German, theories to the creation of new frontiers in the understanding of brain–behavior relationships.

Geschwind was a physician, educator, colleague, advisor, role model, teacher, mentor, and creative genius. He inspired countless colleagues and students worldwide because of the brilliance of his ideas and his zeal for discussing them, his passion for history, an ability to see new relationships that others ignored, his appreciation for the value of detailed clinical and pathological case studies, and a knack for synthesizing observations from daily life into his hypotheses. His legacy in the field of

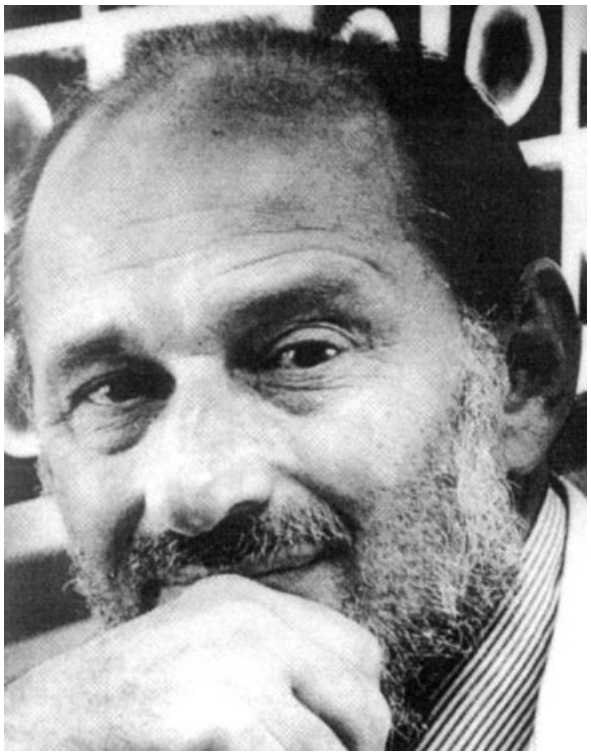

Figure 1. Norman Geschwind.

neurology is memorialized with the Norman Geschwind Prize in Behavioral Neurology, awarded annually by the American Academy of Neurology, and the annual Geschwind Visiting Professorship at the Beth Israel Deaconess Medical Center in Boston.

DISCONNECTION SYNDROMES

Geschwind's most powerful and persisting contribution to neurology was his work on disconnection syndromes in animals and humans. He resurrected the relevant German and French literature from the late nineteenth and early twentieth centuries and added new, carefully studied cases that revealed how neuroanatomy could shed light on the mechanisms of behavior.

Geschwind's interests in alexia, apraxia, and aphasia were largely responsible for the resurgence of attention of neuroscientists to brain–behavior relationships. Both alexia and apraxia provided insights into the cortical machinery of executing specific coordinated higher functions: reading, and skilled, learned movements, respectively. The role of the dominant parietal lobe in reading, writing, and praxis was further defined by these contributions, as were the effects of disconnecting left parietal input (alexia without agraphia) or output (one form of ideomotor apraxia). Although most neurologists considered apraxia to be rare, Geschwind emphasized that it was common, especially in patients with acute dominant hemisphere frontal lobe strokes. He stressed that the term should be used to describe a disorder characterized by impairment in executing a learned movement in response to a stimulus that would normally elicit the movement in the setting of intact sensation, strength, attention, and cooperation.

Geschwind revolutionized the conceptual framework of aphasic disorders. He subdivided aphasias into fluent and nonfluent groups, which largely corresponded with lesions that were anterior (nonfluent) or posterior (fluent) to the central sulcus. He then renewed interest in testing repetition, a simple maneuver that permitted identification of conduction or transcortical aphasias. Geschwind's approaches to the anatomy of language, the mechanisms underlying language dysfunction, the examination of aphasic patients, and the classification of aphasias continue to define the modern approach to examining and diagnosing patients with these disorders.

EPILEPSY

Geschwind studied the memory disorders that are commonly found in patients with epilepsy and emphasized the role of neuropsychological testing in the assessment of memory dysfunction. He was intrigued by personality changes associated with epilepsy and the schizophreniform psychosis that took many years to develop after its onset. He was concerned with elucidating the physiology of seizure triggers, language and epilepsy, behavioral changes following temporal lobectomy, and aggression in temporal lobe epilepsy (TLE). Most importantly, he described the interictal behavior syndrome of TLE. Geschwind felt strongly that psychiatrists should study TLE, because he contended that the associated personality changes might constitute the single most important condition in psychiatry. For Geschwind, TLE was a neurological model of psychiatric illness – a probe for the study of the physiology of emotion. He maintained that there was no other disorder characterized by alterations of behavior whose neurophysiological mechanisms were so well understood.

CEREBRAL DOMINANCE

Geschwind's interests in cerebral dominance, and the related topics of hemispheric asymmetries and 'handedness', grew out of his belief that the human

brain was endowed with anatomical asymmetries that could account for various aspects of cerebral dominance, such as language representation in the left hemisphere, which is found in 90% of right-handed people. Geschwind began his study of asymmetries and cerebral dominance with the temporal lobe. Together with a colleague, Geschwind cut 100 adult brains postmortem in the planes of the sylvian fissures and compared the appearance of the left and right plana temporale. In this landmark study, they found a larger left planum temporale in 65 of 100 brains, whereas in 35 brains, the plana were symmetric ($n = 24$) or the right planum temporale was larger ($n = 11$). This ratio of approximately 2:1 of left–right asymmetry was central to Geschwind's later concept of standard structural dominance.

During the early 1980s additional studies were performed and published, and Geschwind, in conjunction with his colleague Albert Galaburda, formulated a far-ranging hypothesis that integrated handedness, cerebral dominance, and autoimmune disease. The publication of this hypothesis, often called the Geschwind–Behan–Galaburda (GBG) hypothesis, stimulated innumerable additional investigations and papers, and generated considerable support and skepticism. As originally put forward by Geschwind and Galaburda, the hypothesis states, 'the most powerful factors [in determining the patterns of cerebral asymmetry] are variations in the chemical environment in fetal life and to a lesser extent in infancy and early childhood. The factors that modify cerebral dominance also influence the development of many other systems, e.g. the organs involved in immune response.'

The resistance to widespread acceptance of the GBG hypothesis derives from three sources. First, the study of the fetal origins of cerebral dominance is at odds with another influential handedness researcher and theorist, Marian Annett, who purports that the genetic theory of cerebral development is a more powerful determinant of cerebral development than the 'pathology model' of Geschwind. She argued that intrauterine factors are less important than genetic factors in determining brain structure. However, her theory and the GBG hypothesis actually complement one another. The latter approach may be able to shed light on the mechanism by which genes control cerebral development. For instance, identifying the fetal insults or factors (for example, testosterone) that modify brain structure and cerebral dominance from what would otherwise be predicted on strictly genetic grounds may provide clues to the mechanisms by which genes control normal brain development. Further, distinguishing the biologic associations of cerebral dominance and handedness may shed light on other genes that may be tightly linked with the 'right shift' gene, which according to Annett controls the development of handedness. For example, if autoimmune illness is associated with left-handedness, as was thought by Geschwind, then the search for the right shift gene could be directed toward those genes that are associated with autoimmune illness.

Second, the lack of consistency in handedness studies has resulted in a number of 'negative' studies of handedness and biological associations, casting further doubt on the GBG hypothesis. Yet many of these studies are inadequate because they do not include enough participants to demonstrate statistical significance, or they use measuring instruments that do not produce a handedness score that is proportional to the degree (for example, slightly right-handed versus strongly right-handed) and direction (left versus right) of handedness. Further, investigators often do not test the distribution of handedness scores for normality and yet use statistics for normally distributed data.

Third, and most importantly, the interpretation of the hypothesis has often been too narrow. Restatements of this hypothesis by other authors and critics often focus exclusively on the possible role of testosterone, though it is only one of many possible fetal factors. Geschwind did propose that testosterone was one of the major influences on brain development, but the essence of the hypothesis, the assertion that intrauterine factors influence fetal brain development, is a profound concept that further revises the nature–nurture argument. Conceptually, this was one of Geschwind's most insightful contributions.

Geschwind sought to increase our understanding of the interrelationships between brain structure and function. Like his other contributions, it was based on Geschwind's recognition of a connection – in this case between fetal factors, brain development, and human behavior. Though it was tragic, as pointed out by a colleague, that he died suddenly in 1984 before this opus was ever published in its complete form, neuroscientists around the world carry on his work, making new discoveries and thereby forging new frontiers made possible by Norman Geschwind.

Gibson, James J.

Introductory article

Eleanor Gibson, Cornell University, Ithaca, New York, USA

CONTENTS

James J. Gibson (1904–1979) was a leading American scholar and researcher in the field of perception. His dynamic and functional approach radically changed perceptual theories of the time and led to his own theory, the ecological approach to perception.

INTRODUCTION

James J. Gibson is known chiefly for his work on perception, which includes a novel theory that renounces the traditional view of perception as based on bare sensations that have to be supplemented by past experience or inferential processes in order to yield meaningful knowledge. He defined perception as an organism's means of acquiring information about the external world and his own relation to it, a functional view in contrast to the old, static sensation-based position, thus making him a rebel in the eyes of an older generation of perception theorists.

James Gibson was born in the American Midwest in 1904 and attended public schools in Wilmette, Illinois. He received his collegiate education at Princeton University and there obtained his PhD. He majored in both philosophy and psychology and was considerably influenced by one of his mentors, philosopher–psychologist E. B. Holt, a radical behaviorist. His first position was at Smith College as assistant professor of psychology, where he taught experimental psychology and with his students (one of whom later became his wife) performed many original experiments. Meanwhile, he began a program of research in perception. Experiments by his class on adaptation to curvature of lines in the layout, and other distortions caused by wearing prism spectacles, led him to examine the effect of inspecting curved and tilted lines without the spectacles. He found that after some seconds of inspection, there was adaptation to the curvature or tilt, and when a straight line was presented afterward, an after-effect occurred in the opposite direction. These experiments led him to the conclusion that spatial vision was not caused by stimulation of separate single receptors, but rather by larger structures such as gradients of change in the optic array – a new concept.

Wartime Research on Aviation

Early in the Second World War Gibson joined the US Army Air Corps as a research psychologist, and was assigned to a unit given the task of preparing tests for the selection of pilots and other aircrew such as bombardiers. Tests of the adequacy of spatial perception were especially important, but the research on perception of distance and orientation at that time was confined to the use of static cues such as retinal disparity, offering little for the task at hand. Gibson was sent to the Santa Ana Army Air Base in California, where he formed a film test unit. Films allowed him to study the role of motion in space perception, since it was clear that a flier needed to detect the location of other aircraft (and the ground) while in rapid movement. Gibson formulated a new approach to space perception based on information obtained from motion. He defined the role of what he named 'flow patterns' for judging the location of the flier in relation to the ground, other aircraft, and the external layout as a whole. He illustrated these flow patterns with diagrams (Figure 1); these diagrams now appear in all discussions of space perception. Not only fliers move; so do we all, moving our eyes, our heads and our positions. Other work of Gibson's during the war included research on aircraft identification, which eventually led him to a theory of perceptual learning as a process of differentiation rather than association, work that was followed up later with his wife, Eleanor Gibson.

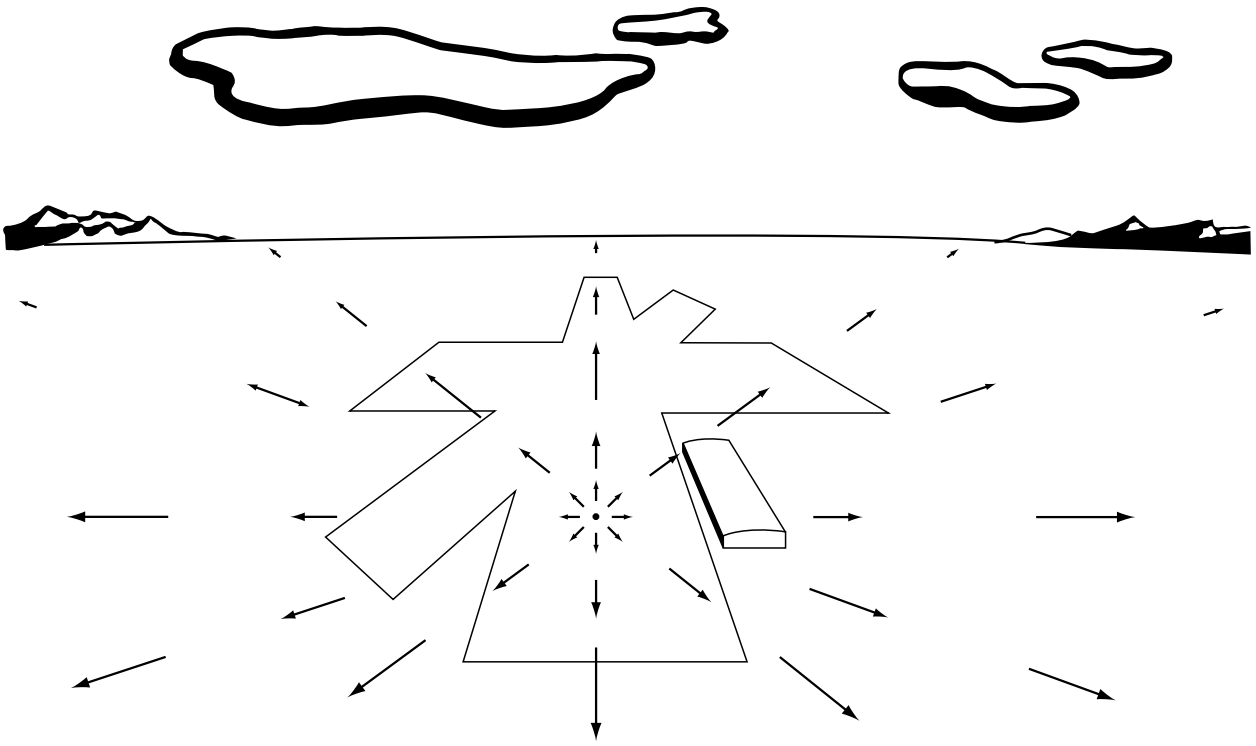

Figure 1. A flow pattern illustrating motion in an optical array when approaching a landing site.

A NEW THEORY OF PERCEPTION

Gibson's discoveries about the importance of motion as information for perceiving one's location in the spatial layout led him to reflect further on the nature of stimulation. He was by then sure that information for invariant properties of the environment must be extended over time, as well as space (which he had already discovered in the gradients that specify curvature and tilt of lines). The ground, in the natural human habitat, is also an essential ingredient in information for location and locomotion in the spatial layout. On his return from the war, Gibson began a book, *The Perception of the Visual World*, which would make these points and propose a new theory which would displace the traditional view that perception of the visual world begins with separate bits of stimulation giving rise to static, mosaic-like retinal images, and sensations, which are then supplemented by past experience and inference, to yield perception of a structured world in three dimensions. The old theory led to two views of the way the supplementation occurred, an 'empiricist' view and a 'nativist' view. Gibson's theory invoked neither one, since information for perception was rich and structured. The old research with static pictorial displays was useless and should be discarded. New research, pinning down the role of motion and dynamic displays that one directly perceived, was called for. The task for the psychologist was to find and describe the information. Three years later, when the book was finished, Gibson moved to Cornell University where he would find many graduate students to undertake the research called for.

THE PERCEPTUAL SYSTEMS

At Cornell, Gibson performed many experiments on the way motion gradients and transformations specified invariant structure in the world. Many of these experiments are described in his second book, *The Senses Considered as Perceptual Systems*. His view of perception as the work of systems emphasizes the active nature of perception, that information is obtained by perceptual systems, rather than stimulation falling passively on receptors. The book explains in detail other receptor systems besides the visual one, and shows how they cooperate in detecting the layout of the world and what is going on in it. Exploratory activity, such as looking around in visual search, and touching before seizing something or stepping on an unfamiliar surface, are examples.

According to this theory of active perception conducted by perceptual systems rather than

passive sensations, knowledge is certainly not innate, but the mechanisms of perceptual activity are to a great extent ready to go at birth. Research has shown that spontaneous activity, such as looking around and listening, is present at birth. Sensory equipment is not fully mature, as in the case of the visual system, but information about the external environment is obtained at once, and even newborns are motivated to obtain such information. This environment itself must be described in an account of what information is obtained. Gibson coined the term 'ecological optics' to refer to visual information in an ambient array, structured to specify the layout of things and the events occurring in it. Events, indeed, he considered the major source of information for perception.

THE ECOLOGICAL APPROACH

Radical as were these views, Gibson felt that he had not gone far enough in discarding the old view of perception based on a retinal image that had to be supplemented by past experience and reasoning processes.

What we actually perceive is a layout furnished with things that may or may not be useful to us and events that stir us to action. He felt that a sensory surface such as a retinal image interposed between the perceiver and this meaningful world was not of service for understanding a world full of action, including the perceiver's own. Action itself must be part of the repertoire of a perceiver, who shapes the environment by actions which are directly perceived as well as detected through the external events that they cause. The relation between exteroceptive and proprioceptive information is perceived and no inferential process is needed to detect it. Evolution has adapted us to detect proprioceptive information about our own actions and information ensuing from those actions. We are thus enabled to keep in touch with what is going on around us, allowing us to be attentive to what will happen next. The exploratory actions that are characteristic of perceiving result in perception that is prospective, heading toward the next action to be undertaken. Locomotion is a prime example. As we move towards some surface, information about the layout, where we are in it, and where we might be going are all specified at the same time. There is a reciprocity between action and perception that requires a description of both environmental structure and the perceiver's actions with respect to it.

The ecological approach to perception, as Gibson called his new view, retained the innovations expressed in his earlier books: that stimulation goes on over time, providing invariant information, with gradients over space and those carried by motion; that such information specifies structure in the world that is directly perceived; that perception is an active process of seeking this information; and that perceivers detect their own actions and their consequences.

The relation between a perceiver and the environment is thus one of reciprocity. This notion led to a new concept, that of 'affordances'. Gibson coined the word to refer to the resources of the environment with respect to their potential use to an organism, relating properties of the physical world to the functional capacities of a given organism. The 'graspability' of an object, the 'traversibility' of a ground surface, and the 'edibility' of substances are examples. When such affordances are perceived, the organism is perceiving the meaning of them. To quote a well-known sentence of Gibson's, 'The affordances of the environment are what it offers animals, what it provides or furnishes, for good or ill.' Surfaces may be 'stand-on-able' or 'fall-off-able'. They may be negative with respect to an animal's welfare as well as positive, harmful or beneficial. They may be social, such as the affordances for play, sex or communication. In any case, they are all specified in information obtainable by the perceptual systems of the animal – visual, auditory, proprioceptive and so on. They are real, as well as meaningful when they are picked up. Picking them up may involve a learning process, known as 'perceptual learning.'

It is evident that the relationship between an animal and its environment is one of mutuality, both specialized for each other, either by evolution or by alteration of the environment by acts such as the making of tools, or changing natural environments by artificial means such as heating or cooling. In either case, the relation is an invariant objective one, potentially detectable by an organism for which it has usefulness for existence or comfort. Affordances, Gibson affirmed, are the foundation of values.

Gibson's views on ecological psychology were received as a major contribution by many psychologists. One American reviewer (Restle) wrote in the journal *Contemporary Psychology*, 'This book comes forth as a major theory, as the culmination of the life's work of Jimmy Gibson, our one original irreplaceable creative genius.' Shortly after Gibson's death in 1979, friends and students, both American and European, formed the International Society for Ecological Psychology. At the time of writing, this

group continues to thrive and attract new members. It holds annual meetings and sponsors the *Journal of Ecological Psychology*.

CONCLUSION

The dean of American psychologists, E. G. Boring, wrote of Gibson's first book, 'The book's appearance becomes, in a sense, an event within a tradition: Goethe (brilliant, erudite, dogmatic, wrong); Purkinje (keen, usually right); Hering (argumatic, pedantic); and now Gibson creating the paradox of a phenomenology of vision which is both modern and American.' In the end, however, Gibson was hardly a phenomenologist, proposing an ecological psychology that included the world: a paradox, perhaps, for history.

Hebb, Donald Olding

Intermediate article

Raymond M Klein, Dalhousie University, Halifax, Nova Scotia, Canada

During his lifetime Donald Olding Hebb (1904–1985) was an extraordinarily influential figure in psychological science and behavioral neuroscience. In the middle of the twentieth century his principled opposition to radical behaviorism, his critical analyses of the shortcomings of the then dominant theories of learning and perception, and his emphasis on understanding what goes on between stimulus and response helped clear the way for a revolution in North American psychology. Hebb's view of psychology as a biological science helped rejuvenate interest in physiological psychology, and his simple and appealing neuropsychological cell-assembly proposal served as a magnet for creative scientists and a stimulus for theoretical and empirical advances. Since his death, Hebb's seminal ideas wield an ever-growing influence on scholars interested in mind (cognitive science), brain (neuroscience), and how brains implement mind (cognitive neuroscience).

Born to physician parents, in Chester, Nova Scotia, in the Maritime region of Canada, Hebb attended Dalhousie University, from which he graduated in 1925. Though he aspired to write novels, Hebb chose instead to earn a living as a public school teacher and soon became a school principal in the Province of Quebec. Hebb notes that his interest in psychology was excited by the writings of James, Freud, Watson, and Pavlov. Hebb was accepted as a part-time student to the McGill graduate program, and got a position as a research assistant with Dr L. A. Andreyev, a visiting scientist from Pavlov's laboratory. Though this led to a Master's degree, Hebb was unimpressed with Pavlov's program, and was, as he would say, 'softened up for my encounter with Kohler's Gestalt Psychology and Lashley's critique of reflexology'. Hebb went to work with Lashley at the University of Chicago; moved with Lashley to Harvard University; and in 1936 completed his PhD on the effects of early visual deprivation upon size and brightness perception in the rat. (*See* **Lashley, Karl S.**)

The first of two pivotal postdoctoral experiences was made possible when Wilder Penfield offered Hebb a fellowship at the Montreal Neurological Institute (MNI). At the MNI Hebb explored the impact of brain injury and surgery, particularly lesions of the frontal lobes, on human intelligence and behavior. From his observations that removal of large amounts of tissue seemed to have little impact on memory and intelligence, Hebb inferred a widely distributed neural substrate (Hebb, 1945).

Hebb then briefly joined the faculty at Queens University, Kingston, Ontario, Canada, where he developed human and animal intelligence tests, including the 'Hebb-Williams' mazes, which subsequently have been used in hundreds of studies to investigate the intelligence of a wide range of species, including even humans – thanks to the development of virtual versions of the mazes, making it the 'Stanford–Binet' of comparative intelligence (Brown and Stanford, 1997). Hebb's studies of human and animal intelligence led him to conclude that experience played a much greater role in determining intelligence than was typically assumed (Hebb, 1942). Though Hebb would later emphasize the contribution of heredity this was an explicit effort to reverse the pendulum of opinion on the nature/nurture issue, which Hebb thought had swung too far in the nurture direction (Hebb, 1953). Nevertheless, Hebb maintained that the question 'to what extent is a given piece of behavior dependent on one of these influences?' was nonproductive, and his cogent analysis is often summarized with the following analogy which he used to explain why:

> Is it fifty-percent environment, fifty-percent heredity, or ninety to ten, or what are the proportions? This is exactly like asking how much of the area of a field is due to its length, how much to its width. The only reasonable answer is that the two proportions are one-hundred-percent environment, one-hundred-percent heredity. They are not additive; any bit of behavior, whatever, is fully dependent on each. (Hebb, 1953 p. 44)

In 1942 Hebb left Queens University and rejoined Lashley, who had become director of the Yerkes Laboratories of Primate Biology in Florida. Although his plans to interact with Lashley and explore the effects of various brain lesions on the performance and temperament of adult chimpanzees did not materialize, Hebb's experiences at the Yerkes Laboratories were, like those at the MNI,

pivotal for the development and impending dissemination of his ideas. Instead of the effects of lesions, Hebb explored fear, anger, and other emotional processes in the intact chimpanzee. He would later say of this exposure that he 'learned more about human beings during that time than in any other 5-year period of my life except the first' (Hebb, 1980). During his time at the Yerkes, Hebb began writing a book, *The Organization of Behavior: A Neuropsychological Theory* (1949), in which he synthesized different lines of research into a 'general theory of behavior that attempts to bridge the gap between neurophysiology and psychology' (p. vii). Hebb credits 'the weekly colloquium and the persistent theoretical debate at the Yerkes Laboratories of Primate Biology' (p. viii) for providing an invaluable intellectual climate for the development and refinement of his ideas.

Hebb returned to McGill as Professor of Psychology and in 1948 was appointed chair of the department. The book he wrote while at the Yerkes Laboratories appeared in 1949. In the years after its appearance the impact of *The Organization of Behavior* was great and the influence of Hebb and his ideas grew steadily. McGill University became a North American mecca for scientists interested in the brain mechanisms of behavior, and the proposals put forward in Hebb's book led to many important discoveries and steered contemporary psychology onto a more fruitful path.

For Hebb 'the problem of understanding behavior is the problem of understanding the total action of the nervous system, and vice versa' (1949, p. xiv) and his advocacy of an interdisciplinary effort to solve this neuropsychological problem was his most general theme. Hebb's book provided a rallying point for those interested in the brain mechanisms of mind, and because there was a powerful movement in psychology to reject physiological concepts (Skinner, 1938), his book marked a turning point away from this trend. The history of attempts to explain behavior and thought is punctuated by metaphors put forward by scholars in the hope that understanding will be illuminated by reference to the properties of well-understood nonbiological entities. Psychological theory, for example, has its roots in the 'mental chemistry' of the British Associationists; hydraulic concepts figure prominently in ethological and psychodynamic conceptions of motivational influences upon behavior; and the Gestalt psychologists relied on magnetic fields to help understand perceptual organization. More recently, the cognitive revolution was inspired by the idea that the mind is like a general-purpose digital computer with inputs and outputs, storage devices, and a central processor that performs operations one at a time. Hebb shunned such metaphors and sought instead to develop a theory of human and animal behavior and thought in terms of the actual device which produces them – the neural machinery in the brain. In *The Organization of Behavior*, Hebb presented just such a neuropsychological theory.

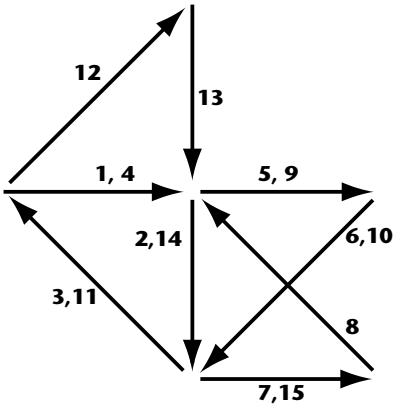

Figure 1. Schematic of Hebb's 'cell-assembly' hypothesis. 'Arrows represent a simple "assembly" of neural pathways or open multiple chains firing according to the numbers on each (the pathway "1,4" fires first and fourth, and so on), illustrating the possibility of an alternating reverberation which would not extinguish as readily as that in a simple closed circuit.' (Redrawn from Hebb, 1949, Figure 10, p. 73.)

There were three pivotal postulates. First, the connections between neurons increase in efficacy in proportion to the degree of correlation between pre- and post-synaptic activity. In Hebb's own words, from Chapter 4 of *The Organization of Behavior*: 'When an axon of cell A is near enough to excite B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased' (p. 62). In neuroscience this proposal is referred to as the 'Hebb synapse'. Speculative and hypothetical in 1949, real examples were subsequently revealed in long-term potentiation (Bliss and Lomo, 1973) and kindling (Goddard *et al*., 1969). In cognitive science this postulate, which is known as the 'Hebb rule', provides the most basic learning algorithm for adjusting the strength of connections between nodes in artificial neural network models.

The second postulate is that when groups of neurons tend to fire together they form a *cell-assembly* whose activity can persist after, and serves to represent, the original triggering event. This proposal, that the joint activation of an assembly of

cells represented a sensation or idea (see Figure 1), foreshadowed the wide adoption of distributed representation in models of natural and artificial intelligence and is considered by some (Milner, 1986) to be Hebb's most important conceptual contribution.

The third postulate is that thinking is the sequential activation of sets of cell-assemblies. In the Introduction to *The Organization of Behavior* Hebb provides this summary of the theory that is developed in the subsequent chapters:

> Any frequently repeated, particular stimulation will lead to the slow development of a 'cell-assembly,' a diffuse structure comprising cells in the cortex and diencephalon (and also, perhaps, in the basal ganglia of the cerebrum), capable of acting briefly as a closed system, delivering facilitation to other such systems and usually having a specific motor facilitation. A series of such events constitutes a 'phase sequence' – the thought process. Each assembly action may be aroused by a preceding assembly, by a sensory event, or – normally – by both. The central facilitation from one of these activities on the next is the prototype of 'attention.' … The theory is evidently a form of connectionism … though it does not deal in direct connections between afferent and efferent pathways: not an S–R [stimulus–response] psychology, if R means *muscular* response. … It does not, further, make any single nerve cell or pathway essential to any habit or perception. (p. xix)

Hebb's book was greeted enthusiastically. Oliver Zangwill (1950) noted that Hebb has 'made an original and exciting beginning' towards a framework for linking psychological phenomena with principles of nervous system organization, and Fred Attneave (1950) called it 'the most important contribution to psychological theory in recent years'. The sheer magnitude of the contribution and the degree of excitement Hebb's book, ideas and leadership would generate was not anticipated, nor was the seminal role his proposals would attain.

Hebb acknowledged that his theory was speculative and incomplete. Missing from the model, for example, was neural inhibition (Milner, 1957), a concept Hebb later incorporated (Hebb, 1959) and to which he would attach great significance (Hebb, 1980a). At this early stage in the development of theories linking brain and mind (neuropsychological theories) speculation was a virtue and incompleteness a necessity. Hebb himself noted that a primary role of our merely momentarily correct theories is to stimulate scientific discovery and that 'one's only strategy is to interest intelligent people of diverse skills, interests and knowledge, in the problems as one sees them' (Hebb, 1959). Hebb was extremely fruitful in implementing this strategy. Many important psychologists and behavioral neuroscientists of the latter half of the twentieth century trained directly with Hebb, and other scholars who came to McGill during his era benefited from their contact with him. Whole literatures on the role of early experience in perceptual development (Hunt, 1979), on sensory deprivation (Zubek, 1969), self-stimulation (Olds and Milner, 1954), the stopped retinal image (Pritchard *et al.*, 1960), the neural basis of pain (Melzack, 1996), synaptic modifiability (Goddard, 1980), and learning without awareness (McKelvie, 1987), were provoked or fostered by Hebb's proposals.

Hebb's seminal ideas of 1949 are being applied not only in neurophysiology, neuroscience, and psychology, but also in engineering, robotics, and computer science. In these diverse scientific literatures references to Hebb, the Hebbian cell-assembly, the Hebb synapse, and the Hebb rule increase each year. This widespread influence is a testament to Hebb's scientific acumen, creativity, and courage to put forth a foundational neuropsychological theory of the organization of behavior. One of Hebb's professors at Harvard, E. G. Boring, described psychology as the mid-nineteenth-century offspring of the scientific method of physiologists and the preoccupation with mind of philosophers (Boring, 1950). In the mid-twentieth century, by providing a neural implementation of the Associationists' mental chemistry, Hebb's ideas nurtured the young and developing science and laid the foundation for neoconnectionism which seeks to explain cognitive processes in terms of connections between assemblies of neurons, real or artificial.

Hebb won many honors and awards and held many positions of leadership. Among these: he was named Fellow of the Royal Society of Canada and of the Royal Society (London); he won the American Psychological Association Award for Distinguished Scientific Contribution; and he served as President of the Canadian and American Psychological Associations. For the reader interested in learning more about Hebb's life and the evolution of his ideas, his own articles (Hebb, 1959, 1980b) and those by Glickman (1996), Klein (1980), and Milner (1986) are recommended.

Helmholtz, Hermann von

Introductory article

Warren R Street, Central Washington University, Ellensburg, Washington, USA
Philip Tolin, Central Washington University, Ellensburg, Washington, USA

CONTENTS

Hermann von Helmholtz (1821–1894) was one of the most productive and versatile scientists of the nineteenth century. His experimental, theoretical, and technical accomplishments advanced the fields of optics, physiology of hearing and vision, epistemology, electrodynamics, hydrodynamics, meteorology, mathematics, music, and the emerging science of experimental psychology.

INTRODUCTION

Hermann Ludwig Ferdinand von Helmholtz was born on 31 August 1821 in Potsdam, Prussia, the most powerful of the states that merged to form the German empire in 1871. His mother, Caroline Penn Helmholtz, was a descendant of the American colonist William Penn and was a reserved, intelligent and encouraging parent. His father, August Ferdinand Julius Helmholtz, was a teacher of classical languages at the Potsdam gymnasium and an admirer of the philosophies of Immanuel Kant and Johann Gottlieb Fichte. (*See* **Kant, Immanuel**)

Helmholtz was frequently ill as a child and did not attend school until the age of seven. Bolstered by an intellectually stimulating home environment, he progressed rapidly through his studies. An inspiring mathematics teacher ignited a lifelong interest in physics and optics. In classes that did not interest him, Helmholtz sometimes ignored his assigned reading and worked on optics problems underneath his desk.

By the age of 14 years, Helmholtz had declared an interest in becoming a scientist, and at 17 years old he was admitted to the Friedrich Wilhelm Institute of Medicine and Surgery in Berlin. While physics was Helmholtz's preferred field, medicine provided a route to advanced studies that his family could afford. The institute provided full scholarships in exchange for 8 years' service as a military surgeon.

Helmholtz carried out his doctoral studies under the direction of the great physiologist Johannes Müller. Despite his exhaustive knowledge of physiology, Müller was a vitalist – a person who believes that life ultimately is directed by intangible forces that have no physical properties. Some of Helmholtz's earliest work provided evidence that these hypothetical vital forces were, at best, irrelevant to understanding living organisms. Helmholtz was one of a group of gifted physiology students who formalized their support of mechanism and opposition to vitalism by swearing allegiance with an oath that began, 'No other forces than the common physical-chemical ones are active within the organism'.

Helmholtz earned his medical degree in 1842 with research showing that nerve fibers are extended parts of nerve cells. In 1843 he was appointed assistant surgeon to the Royal Hussars at Potsdam and began discharging his military obligation. In his spare time he conducted studies in an improvised laboratory. This work culminated, in 1847, in a convincing argument for one of the fundamental principles of modern physics: the principle of conservation of energy.

Helmholtz clearly possessed greater promise as a scientist than as a military surgeon. In 1848, he was released from his remaining 3 years of military service to fill a teaching position in anatomy in Berlin. A year later he was invited to become extraordinary (associate) professor of physiology in Königsberg, now the Russian city of Kaliningrad, on the Baltic sea. His financial security permitted him to marry his fiancée of more than 2 years, Olga von Velten. Her fragile health declined in Königsberg, and the family was advised to move to a warmer climate. By the time he left in 1855 to take up the chair of physiology at Bonn, Helmholtz had invented the ophthalmoscope (1850), completed historic work on the speed of nervous

conduction (1850), and studied the focusing motion of the lens of the eye (1855). He had begun his work on color vision and his theory of unconscious inference in human perception.

In Helmholtz's 3 years at Bonn he completed the first volume of his comprehensive *Treatise on Physiological Optics* (1856) and began to study the physical and psychological nature of sound. An attractive offer to become a professor of physiology drew him to Heidelberg University. Olga Helmholtz's health continued to deteriorate, and she and Helmholtz's father both died in 1859. Helmholtz found solace in his research, and then married Anna von Mohl in 1861. His research led to the second (1860) and third (1867) volumes of the *Treatise on Physiological Optics* and, in 1863, his landmark volume on sound and hearing, *On the Sensations of Tone as a Physiological Basis of the Theory of Music*. He devoted increasing energy to important work in physics and mathematics and in 1871 was appointed to the chair of physics at Berlin, the nation's most prestigious physics position.

The last 23 years of Helmholtz's life were ones of fame and undiminished scientific productivity, primarily in physics. In 1882 Helmholtz was made a member of the nobility and the traditional 'von' was appended to his name. The psychophysics of Gustav Fechner attracted Helmholtz's interest, and he published four articles on the topic. Helmholtz suffered a severe fall returning from America in 1893, recovered only slowly, and in June 1894 suffered a stroke. His health rapidly declined, and he died on 8 September 1894, leaving a remarkable body of research and interpretation to modern science. (*See* **Fechner, Gustav Theodor**)

HELMHOLTZ ON VISION

Helmholtz's three-volume *Treatise on Physiological Optics* integrated previous work with his own studies of the physiological, sensory, and perceptual aspects of vision. For example, he measured many of the optical characteristics of the eye, demonstrated how the eye focuses on different distances, and developed a theory of visual space. He invented the ophthalmoscope, a device still used for visual examination of the retina. Most important, however, was his theory of color vision. (*See* **Color Vision, Neural Basis of**; **Color Perception, Psychology of**)

In 1802 Thomas Young had suggested that the retina contains three kinds of color-sensitive receptors and that the three associated 'primary' colors combine in some fashion to produce the complete range of colors that humans experience. Helmholtz's 1858 elaboration of Young's theory proposed that three types of color-sensitive light receptors in the retina give rise to experiences of red, green, or blue–violet light when stimulated. Each type of receptor contains a chemical that reacts with differing sensitivity to different wavelengths of light, exciting neurons and sending impulses to different parts of the brain. Helmholtz used his theory to explain a variety of visual experiences, including the results of mixing colors, color blindness, and negative afterimages. While the Young–Helmholtz theory has been modified, elaborated and corrected, it provided the foundation for the current understanding of vision.

HELMHOLTZ ON HEARING

Helmholtz made many contributions to understanding sound and hearing, including his explanation of the phenomenon of timbre, or tonal quality. A violin playing middle C has a timbre different from that of a trombone playing the same note. Helmholtz explained that the difference is created by different patterns of overtones, or harmonics, added to the base frequency. In typical fashion, Helmholtz did not simply advance a theory; he also provided inventive demonstrations. For example, he built a series of tuning forks to vary the intensity of different overtones and produce synthetically the timbres of various musical instruments. His work provided early theoretical and empirical bases for modern music and speech synthesizers.

In addition to advances in the physics of sound, Helmholtz made major discoveries about the anatomy and physiology of the ear. A portion of the inner ear, the basilar membrane, contains thousands of tiny hair cells that must be stimulated for sound to be heard. Helmholtz proposed that the basilar membrane vibrates, or 'resonates', when placed near a sound source. The membrane is narrow at one end and wider at the other, and Helmholtz theorized that high-pitched sounds cause the most resonance where the basilar membrane is narrowest, while low-pitched sounds cause the most resonance at the wide end of the membrane. A good model of Helmholtz's theory is a harp, with short strings at one end and long strings at the other. High-pitched sounds will cause short strings to resonate, while lower-pitched sounds will cause longer strings to resonate. As different parts of the basilar membrane resonate, hair cells are stimulated; impulses are sent to the brain, and the listener hears corresponding

frequencies of sound. The sound heard is related to the intensity of resonance at different places on the basilar membrane.

The greatest competition to Helmholtz's 'place theory' has come from 'frequency theory', which contends that the basilar membrane vibrates as a whole and that analysis of sounds into pitches occurs in the brain, rather than in the ear. Both theories only partially explain the phenomenon of hearing. Helmholtz's theory has been shown to be incorrect in some details, but it set an important foundation for later studies of hearing, such as those by Nobel laureate Georg von Békésy.

HELMHOLTZ'S EPISTEMOLOGY

Helmholtz's scientific achievements carried implications for epistemology, the branch of philosophy concerned with the nature and origins of human knowledge. Helmholtz's interest in philosophy was primed by his father's devotion to Kant and Fichte, although Helmholtz took issue with portions of their writings. (*See* **Epistemology**)

Helmholtz rejected nativism, the view that thought springs from innate sources, in favor of empiricism, the view that thought arises from sensory stimulation. He distinguished between sensation (the response of the sense organs to stimulation) and perception (the meaningful interpretation of sensations). Like Kant, Helmholtz thought that sensations are the raw material of meaningful perception, but Kant believed that fundamental perceptual interpretations, such as the location of events in space and time, and their quantity, existence and causality, were innate. Helmholtz contended that meanings were learned, not innate, with the exception of causality. He showed, for example, how space perception – one of Kant's innate categories – could be learned from the focusing motions of the eyes on near and distant objects. (*See* **Kant, Immanuel**; **Space Perception, Development of**; **Perception: Overview**)

Helmholtz was intrigued by differences between human perception and physical reality. He studied visual illusions, in which simple line drawings create predictable perceptual errors. Helmholtz was convinced that the senses do not transmit anything like a miniature replica of physical reality to the brain. Instead, the senses send 'tokens' or 'signs' of the physical world to the brain. Based on experience, the brain unconsciously constructs a meaningful perception from these signs. He called this process 'unconscious inference'. In his *Treatise on Physiological Optics* Helmholtz wrote, 'The sensations of the senses are tokens for our consciousness, it being left to our intelligence to learn how to comprehend their meaning.' Helmholtz's description of how sensory information unconsciously creates meaningful perceptions is sometimes regarded as the first information processing approach to cognition. (*See* **Unconscious Processes**; **Illusions**; **Information Processing**)

Helmholtz thought that the introspective psychology of his day was of no help in understanding perception because perception was an unconscious process and introspection produces reports of conscious experiences. As Helmholtz wrote, 'Here we have to do with mental activities, of which self observation cannot give us any information at all, whose existence can only be inferred from the physiological investigation of the sensory organs.' (*See* **Introspection**)

Helmholtz had an unwavering disregard for vitalism and the findings of many studies were brought to bear upon it. Helmholtz's support for the principle of conservation of energy (1847) is an early example. This principle, also proposed by Julius Robert Meyer and James Prescott Joule, is that energy may be changed from one form to another, but it is never created or destroyed. For example, electrical energy flowing to a light bulb is transformed into light and heat, but the amount of energy is unchanged. Helmholtz said that this principle also applied to living organisms. He argued that animals convert the chemical energy in nutrients into an equal amount of heat and work. Careful experiments with frog muscles showed that heat was produced when they contracted. If the principle of conservation of energy is true of living organisms, then there is no role for hypothetical energies that have no physical source, such as vital forces.

Shortly after his work on the conservation of energy, Helmholtz provided further evidence against vitalism by measuring the velocity of a nerve impulse (1850). Vitalists thought that the vital forces in nerves acted immeasurably rapidly, perhaps instantaneously. Helmholtz constructed an apparatus that held a frog's leg muscle and its motor nerve. When the nerve was electrically stimulated, the muscle contracted. The stimulus current also started a timing device and the muscle's contraction stopped it. Helmholtz stimulated the nerve at different distances from the muscle and estimated the speed of nervous conduction from the differences in reaction time. His average estimate was 27 meters per second. Modern studies have altered this estimate, but the most important outcome was to show that nerve impulses are not instantaneous: they are

measurable by ordinary instruments, and act on a scale consistent with physical and chemical processes. He carried out similar experiments with human reaction times, concluding again that nerve impulses are ordinary physical events, not the product of ethereal vital forces.

Helmholtz's commitment to the empirical study of a remarkable array of phenomena and his capacity to integrate and synthesize science and philosophy mark him as one of the most important scientists of the nineteenth century and as a seminal figure in the history of modern psychology.

Hull, Clark L.

Introductory article

Laurence D Smith, University of Maine, Orono, Maine, USA

CONTENTS

Clark L. Hull (1884–1952) was a prominent American behaviorist and learning theorist, known for his influential book Principles of Behavior*. He designed machine simulations of intelligence and proposed a mechanistic psychology that bridged behaviorism and cognitive psychology.*

INTRODUCTION

A leading experimental psychologist during the second quarter of the twentieth century, Clark C. Hull is best known for his 1943 book *Principles of Behavior*, an influential exposition of learning theory. As a behaviorist with longstanding interests in the higher mental processes, he also developed an early research program for machine simulations of intelligent behavior, producing a mechanistic psychology that bridged behaviorism and cognitive psychology. A portrait of Hull during his years at Yale is reproduced in Figure 1. (*See* **Animal Learning**)

BACKGROUND

Hull was born in rural New York in 1884 but grew up near Sickels, Michigan, where he attended a one-room school and worked on the family farm. In his youth he developed a passion for geometry, admiring its systematic arrangement in a hierarchy of postulates and theorems. While preparing for a career in engineering at nearby Alma College, he contracted poliomyelitis which left him able to walk only with the aid of a steel leg brace of his own design. Partly for reasons of health, and partly in response to a reading of William James's *Principles of Psychology*, Hull soon decided on a career in psychology. Significantly, he was attracted to the field by the opportunities it provided for systematic theorizing as well as for the design of mechanical apparatus.

While completing his undergraduate degree at the University of Michigan, Hull studied philosophy under Roy Wood Sellars and psychology under Walter Pillsbury and J. F. Shepard. To further his interest in the psychology of reasoning, he enrolled in Sellars's course in logic, for which he constructed a logic machine made of rotating metal plates that would generate the implications of various syllogisms. This device would prove to be the first in a series of Hull's mechanical simulations of cognitive and behavioral phenomena.

Pursuing graduate work at the University of Wisconsin, Hull studied under Joseph Jastrow and completed his doctorate in 1918 with a dissertation on concept formation. This research produced Hull's first quantitative learning curves and evinced the methodological rigor that would characterize his later work. Remaining at Wisconsin for the next decade, he taught courses and performed research in the areas of hypnosis and aptitude testing, eventually publishing well-received books on each of these topics. (*See* **Concept Learning**)

Hull came to regard his work on hypnosis and testing as a digression from his aim of discovering general laws of thought and behavior, but one aspect of his research on testing did contribute to the development of his behaviorism. To expedite the calculation of correlations between various tests, he designed and built a machine that computed correlation coefficients from data coded on punched paper tapes. Completed in 1925 with support from the National Research Council, the machine convinced Hull that a purely physical device with the proper arrangement of parts was capable of carrying out operations characteristic of higher-level mental processes. Armed with this insight, Hull underwent a conversion to behaviorism in the next few years, teaching seminars on it and devoting careful study to Ivan Pavlov's newly translated *Conditioned Reflexes*. As an admirer of the British empiricists, Hull revered Thomas Hobbes and David Hume as the philosophical forerunners of behaviorism, and regarded Pavlovian conditioned reflexes as the material analogues of the empiricists'

Figure 1. Clark L. Hull during his years at Yale University (Archives of the History of American Psychology, the University of Akron).

association of ideas. (*See* **Behaviorism, Philosophical**; **Hume, David**; **Pavlov, Ivan Petrovich**)

HULL'S CONTRIBUTION TO BEHAVIORISM

During the 1920s and 1930s, Hull blended behaviorist concepts with proposals for the machine simulation of intelligent behavior to form an ambitious program for a mechanistic psychology. The study of conditioning, he felt, would provide the basis for an experimental science of thought processes, conceived materialistically as mental habits. Accordingly, he enlisted the aid of several associates in designing and constructing machines that simulated various learning processes. The first of these was described in *Science* in 1929 in collaboration with the chemist H. D. Baernstein. Encouraged by the ensuing publicity (the journalist George Gray described the Hull–Baernstein machine as the forerunner of an entire generation of 'thinking machines'), Hull and his colleagues produced a series of such devices during the 1930s. Although the machines varied in internal structure (ranging from electrochemical to purely mechanical), they exhibited an impressive array of learning phenomena, including conditioned associations, extinction, spontaneous recovery, higher-order conditioning, trial-and-error learning, and maze learning. Significantly, Hull saw the need to incorporate a source of behavioral variability in the machines, as well as a system of hierarchical control to coordinate the parts and a means by which the machines could store representations of the environment. Such features, Hull stressed, would imbue the machines with a degree of 'ultra-automaticity' that would supersede the capacities of 'ordinary, rigid-type machines'. (*See* **Machine Learning**; **Simulation Theory**; **Artificial Intelligence, Philosophy of**; **Conditioning**; **Knowledge Representation, Psychology of**)

Although Hull was not the first to design and build machine simulations of intelligent behavior, he gave unusually cogent and explicit statements of the rationale for what he later came to call the 'robot' approach. As early as 1926, Hull's intellectual diaries – his 'idea books' – contained a clear explanation of the simulation method:

> It has struck me many times of late that the human is one of the most extraordinary machines – and yet a machine. And it has struck me more than once that so far as the thinking processes go, a machine could be built which would do every essential thing that the body does… [To] think through the essentials of such a mechanism would probably be the best way of analyzing out the essential requirements of thinking… [An] automaton might be constructed on the analogy of the nervous system which could learn and through experience acquire a considerable degree of intelligence.

Hull regarded the design of machines that could exhibit intelligent behavior as equivalent to the formulation of a theory of that behavior, an insight that would underlie later research on computer simulations in the field of artificial intelligence. Viewing intelligent machines as a vindication of materialist philosophy, he often cited them in his rhetorical attacks on 'subjectivists' such as the vitalist Hans Driesch and the Gestalt psychologist Kurt Koffka, both of whom taught at Wisconsin during Hull's years there. Significantly, Hull's interest in machine simulations led him into interactions with Nicolas Rashevsky and Warren McCulloch, two leading architects of subsequent developments in artificial intelligence, and his 'robot' approach influenced Kenneth Craik, one of the founders of British cybernetics in the 1940s. (*See* **McCulloch, Warren**)

Concurrent with his work on machine design, Hull began a series of articles on behavior theory that appeared in the journal *Psychological Review* and, along with his move to Yale University in 1929, served to raise his visibility as a leading behaviorist. Cast in the form of deductive systems containing postulates and empirically testable theorems, the 'miniature systems' presented in the papers covered various forms of adaptive behavior and introduced the concepts that became standard explanatory devices for Hullians in the decades to come. Among the concepts were fractional anticipatory goal responses, habit-family hierarchies, and pure stimulus acts. The pure stimulus acts were hypothetical implicit responses that ran in parallel to event sequences in the environment and could thus function as internal 'replicas' of the world, providing an organic basis of symbolic knowledge. Hull used such concepts in his attempts to account for the emergent phenomena of knowledge, purpose, and insight. They became key constructs for a later generation of mediational behaviorists, whose theorizing proved to be a bridge between the behaviorist era and the eventual cognitive revolution of the 1960s. (*See* **Epistemology**; **Animal Cognition**)

As Hull repeatedly reminded his readers, the miniature systems really amounted to exercises in machine design. His 1936 presidential address to the American Psychological Association presented a theory of trial-and-error learning and concluded with a demonstration of one of his conditioning machines. However, this would be his last public demonstration of such a machine, and Hull's mechanistic emphasis quickly receded from public view. The reasons for this shift are several. One important factor was that the logical positivist philosophy which swept through psychology in the 1930s eschewed analogical explanations in favor of logical explanations. As a result, the apparent rigor of Hull's deductive theoretical systems appealed to his psychological contemporaries, who, in contrast, failed to grasp the significance of simulational methods and remained largely unimpressed by his machine simulations.

Hull's theoretical papers of the 1930s laid the foundation for his *Principles of Behavior*, which appeared in 1943 and became the most-cited work in experimental psychology during the following years. Increasingly aware of the rhetorical power of logical methods, Hull cast the book in the form of an elaborate hypothetico-deductive system containing 16 postulates and more than a hundred corollaries and theorems. Reaction potential, the basic measure of learned behavior, was defined in terms of such now-familiar concepts as habit strength, drives, and incentive; reinforcement of stimulus–response connections was said to take place through drive reduction. The system served as a focal point of extended debates among learning theorists, pitting Hull against such adversaries as Edward C. Tolman and Kurt Lewin. Although the book contained a brief discussion of the robot approach, the debates over learning were by this time being framed in terms of such logical positivist concepts as postulate systems, correspondence principles and intervening variables. (*See* **Learning, Psychology of**; **Tolman, Edward C.**; **Lewin, Kurt**)

During the 1930s and 1940s, Hull's preeminent standing in American psychology was enhanced by his position of leadership in Yale's Institute of Human Relations, which was well funded by the Rockefeller Foundation during the Depression years. Through the Institute, Hull attracted a large number of young social scientists to pursue the application of behavioral principles to a range of topics in social learning, aggression, psychopathology, and personality theory. Various books produced by this group – notably the 1939 classic *Frustration and Aggression* – inspired much research among later generations of Hullians. The talented cast of collaborators who came under Hull's influence at Yale included Daniel Berlyne, John Dollard, Eleanor Gibson, Carl Hovland, Neal Miller, O. H. Mowrer, Charles Osgood, Robert Sears, and Kenneth Spence. Among these, Spence remained particularly close to Hull, refining the Hullian system and transmitting it to scores of doctoral students during his productive career at the University of Iowa.

Hull had long planned to supplement the *Principles* with sequel volumes on individual cognition and social behavior, but plans for the trilogy were never realized. When the learning theory debates of the 1940s revealed the complexity of even the simplest forms of adaptive behavior, he became immersed in the details of his system, repeatedly revising the 1943 postulates in light of anomalous findings. His final two books, completed in the years just before his death in 1952 of heart disease, never achieved the scope or influence of the *Principles*.

During its heyday, the prominence of Hull's system made it a target for widespread criticism. Some critics, notably Sigmund Koch, attacked the system on methodological grounds for its problematic handling of intervening variables and its failure to provide genuine deductions of testable implications. Others, including B. F. Skinner, criticized it for its empirical shortcomings and for its

premature attempt at logical rigor and quantitative precision. As the Hullian system fell from favor during the 1960s, its leading status among behaviorists was usurped by Skinner's relatively atheoretical tradition of operant psychology. Behaviorists of a Hullian stripe turned to circumscribed studies of topics in conditioning research or drifted towards a more cognitively oriented mediational behaviorism. At the same time, Hull's earlier program for machine simulations of intelligence was superseded by the postwar emergence of cybernetics, computer-based studies of artificial intelligence, and the information-processing perspective of cognitive psychology. (*See* **Skinner, Burrhus Frederic**)

CONCLUSION

As a transitional figure bridging behaviorism and cognitive psychology, Hull has received mixed treatment from historians. Considered as an example of behaviorist theorizing, his mechanistic psychology has been portrayed as the grand failure of behaviorism that allowed cognitive approaches to gain ascendancy during the cognitive revolution of the 1960s. Considered as a program for machine simulations of cognitive processes, his mechanistic psychology has also been viewed as a significant precursor to the work on artificial intelligence which had a central role in furthering that revolution. Taken as a whole, however, Hull's work stands as a notable, if sometimes flawed, effort to bring the study of mental life under the canopy of natural science and materialist philosophy. (*See* **Materialism**)

Hume, David

Introductory article

John Biro, University of Florida, Gainesville, Florida, USA

CONTENTS

In his 'science of man', Hume set out to construct a complete account of the workings of the human mind, in many ways anticipating the aims, questions, and even some of the answers, of modern cognitive science.

INTRODUCTION

David Hume (1711–1776) was the last of the three great British empiricist philosophers of the late seventeenth and early eighteenth centuries, a Scot following an Englishman (John Locke, 1637–1704) and an Irishman (George Berkeley, 1685–1753). He developed and pushed to its limit the thesis advanced by his two predecessors that sense experience is the only source of the contents of the mind and that all our beliefs and whatever knowledge we may possess must thus be traceable to it. In doing so, he deployed arguments that seem to lead to skepticism concerning many things we normally take ourselves to know, though it can be also argued that he intended merely to show that our commonsense knowledge cannot, and need not, be based on the metaphysical claims of philosophers, especially not of rationalist ones.

In his best-known philosophical work, *A Treatise of Human Nature*, he announces himself as engaged in developing a 'science of man' on the model of Newton's science of matter, in which we would, through careful observation of our own and others' cognitive behavior, discover the fundamental properties and activities of the human mind: a prerequisite of understanding anything else. In its aims, in the questions it addresses, and even in some of its results, Hume's science looks forward to modern cognitive science.

HUME'S LIFE

David Hume was born in Edinburgh in 1711. His family had a small estate in the Borders, and Hume spent most of his early life there. He received little formal education, following his passion for reading and learning on his own, clear in his ambition to be a 'scholar and philosopher'. After some half-hearted attempts at a more practical career in the law and in commerce, Hume spent three years living modestly in France while writing the *Treatise*, a work he had been planning since his late teens. It was published when he was 28 years old, and met with little success. A more cautious and more accessible recasting of its doctrines in the two *Enquiries* (*An Enquiry Concerning Human Understanding* and *An Enquiry Concerning the Principles of Morals*) fared better; but it was only later, with the appearance of his *Essays, Moral and Political*, that Hume began to achieve that literary fame which he described in his brief and remarkably candid *My Own Life* as 'my ruling passion'. These essays earned him European fame and the correspondence of some of the leading intellects on the Continent. They also earned him financial independence. This was buttressed by his service from time to time in various military and diplomatic missions, both before and after the publication of his *History of Great Britain*, which, while controversial, cemented his reputation as a writer. He was able to retire to Edinburgh in comfort for the last half dozen years of his life, dying peacefully in 1776.

CENTRAL PHILOSOPHICAL VIEWS

In his own time and until recently, Hume's philosophy was seen as essentially, sometimes exclusively, skeptical. It was thought to consist in a string of arguments designed to show the impossibility of knowledge – indeed, even of reasonable belief – about many of the things that our commonsense view of the world takes for granted. According to commonsense, there is a world of bodies outside, and independent of, our minds – bodies that stand

in causal relations to one another, which we can discover through reason or experience. Thus we can predict their behavior, at least to some extent, giving us reason to act in one way rather than another. How we act matters, both practically and morally. We are cognizers, enduring subjects to whom knowledge or belief can be attributed, and agents who can be judged for their actions. Hume's famous discussions of external existence, of necessary connection, of personal identity, of the passions, and of morals, seemed to deny that our ordinary beliefs about any of these things could be supported by either reason or experience. In fact, no belief has any more warrant than any other, and we adopt the ones we do from 'habit' – from unexplainable and irresistible natural inclination.

Many readers of Hume today reject this picture of Hume's philosophy as at least misleading and oversimplified, if not distorting. They are more inclined to take Hume at his word when he declares in the introduction to the *Treatise* that he is pursuing a scientific goal, that of creating a new 'science of man' by 'introducing the experimental method into moral subjects'. As part of this project, he finds it necessary to attack the pretensions of philosophy, including its claim to be able to provide rational justifications of our commonsense beliefs. The skeptical arguments are Hume's way of reducing these pretended philosophical justifications to absurdity, thereby clearing the ground for a descriptive science of the workings of our cognitive and affective capacities. Hume the skeptic thus gives way to Hume the naturalist.

Hume's 'skeptical' arguments may also be seen in a different light in the context of his lifelong campaign against 'enthusiasm', the vehement and dogmatic adherence to religious doctrines, many of them underpinned by metaphysical speculation. In showing the absurdity of the latter, Hume hoped to draw the sting of religious and political extremism, whose dangers he saw both in history and in the politics of his own day. Far from being a threat to common sense, then, these skeptical arguments were deployed by Hume on its behalf.

VIEWS ON MIND, COGNITION, AND LANGUAGE

Mind

The philosophical and religious notion that there is a single and simple entity that is one's mind (soul), which endures unchanged amid the flux of one's thoughts and is the thinker of those thoughts, is, Hume maintains, a fiction, impossible to defend on either rational or empirical grounds. Instead, the mind be seen as the sum of its contents: just as a commonwealth is nothing over and above its constituent parts, so the mind is nothing but 'a bundle of perceptions'. Its identity, like that of a commonwealth, resides in its structure and its functional organization. It is governed by natural propensities that it cannot resist, except in infrequent and brief intervals of philosophical reflection, and then only in theory, not in practice.

Cognition

Hume maintains that all our concepts ('ideas') are derived, directly or indirectly, from sensation ('impressions'), outer or inner. We form our beliefs as a function of the strength of our impressions: as an idea approaches an impression in 'vivacity', 'liveliness', or 'force', it becomes a belief. Thinking consists in a transition from one idea to another. This transition, contrary to philosophical myth, is a matter of natural propensities, not of reflective, rational calculation. It is governed by three 'principles of association': resemblence, contiguity, and cause and effect.

In thinking of something, we naturally think of other things that it resembles (as a picture resembles its subject), adjoins (as my garden adjoins my house), or causes or is caused by (as drinking is caused by thirst or as heat causes ice to melt). Such transitions are the only three kinds of inference that can lead to belief, the last being by far the most important, as it is the only one by which 'the mind can go beyond what is immediately present to the senses … to discover the real existence or the relations of objects'.

However, causal inference is based only on the expectations generated by our experience of the 'constant conjunction' of two events, experience that contains no grounds for positing a necessary connection between the two of the sort that philosophers postulate. Thus no demonstration of a causal relation is possible, and our confidence in our causal beliefs and the predictions we must base on them to survive is not justifiable by rational argument: 'belief is more properly an act of the sensitive, rather than of the cogitative part of our natures'. So is our belief in the existence of bodies, which 'we must take for granted in all our reasonings', even if we cannot justify it by argument.

Language

Hume has little to say about language as a distinct cognitive faculty. He has a theory of meaning, according to which the meaningfulness of a word depends on its standing for an idea with appropriate empiricist credentials. (What counts as appropriate is a matter of considerable controversy.) His chief concern is to press home Berkeley's earlier criticism of Locke's theory of abstract ideas, that the meaningfulness of a general term, such as 'triangle', does not depend on there being a general idea of a triangle, one that is not of a particular triangle, of some specific sort. Given that for Hume, as for most philosophers of the early modern period, thinking and reasoning involve the linking together of ideas, not of words, this relative neglect of language is not surprising.

RESPONSES TO HUME

Hume's influence has been immense. Beginning with Thomas Reid's defense of common sense against the threat of Humean skepticism and Immanuel Kant's heroic attempt to confront Hume's challenge regarding the possibility of genuine causal knowledge, every philosopher since his time has realized that his skeptical arguments have to be faced one way or another: answered, circumvented, or reinterpreted. They have continued to be recognized as among the most penetrating investigations into the fundamental questions about the mind.

There is, however, little agreement about the outcome of those investigations. Hume is the most crystalline of writers, one of the greatest stylists in the English language. Yet the upshot of his discussions is often unclear. (The early twentieth-century philosopher and mathematician, Alfred North Whitehead, aptly remarked on Hume's 'local clarity and global obscurity'.) Is he a skeptic or a naturalist? Can one be both? Is he serious about a Newtonian science of the mind? Or does he really believe that reason 'is, and ought to be, a slave of the passions' and that all beliefs are equally unjustified? Which of his claims and arguments are to be taken at face value? Can they be somehow reinterpreted to make a coherent whole?

RELEVANCE OF HUME'S WORK TO COGNITIVE SCIENCE

Hume's announcement of a new science of the mind seems to be an anticipation of modern cognitive science, in its scope, ambitions, and methods. 'There is no question of importance, whose decision is not compriz'd in the science of man.' Rather than philosophizing about what the mind must be like *a priori*, the new science will be based on 'experience and observation'.

Even more interestingly, Hume's detailed descriptions of the mental operations and processes that generate our concepts and beliefs and explain the transitions among the latter sound remarkably modern. He takes the objects on which these operations and processes work to be representations ('ideas') and has a theory about their semantics. He insists that many of the operations and processes in question are non-reflective, non-conscious, and non-optional – in modern parlance, sub-doxastic and modular ('cognitively impenetrable', and 'informationally encapsulated'). He is acutely aware of the difficulties involved in saying anything sensible about the ownership of the representations and the agent of the cognitive operations and processes in which they figure – the modern 'problem of the homunculus'. In spite of his denial of the possibility of a philosophical justification of causal or of inductive inferences, he gives us both a descriptive and a normative theory of them, an insightful description of how we make them, and a set of rules for making them well. On all these matters, and on many others, he is engaging with the deepest and most difficult questions about the mind, and he gives answers that still command our interest and respect.

Jakobson, Roman

Introductory article

Ilse Lehiste, The Ohio State University, Columbus, Ohio, USA

CONTENTS

Roman Jakobson was one of the most creative and influential linguists of the twentieth century particularly in terms of his contributions to linguistic theory.

BIOGRAPHY

Roman Jakobson was born on 11 October 1896, in Moscow, and died on 18 July 1982, in Boston. He studied at the Lazarev Institute of Oriental Languages and the University of Moscow (1918). During his student years he was active in the Moscow Linguistic Circle (founded in 1915). After teaching briefly at the Higher School of Drama, he moved to Czechoslovakia (1920), where he continued his studies and obtained his doctoral degree (Charles University, 1930). While in Prague, he was a member of the Prague Linguistic Circle (founded in 1926), collaborating for about 10 years with its leading member N. Trubetzkoy (whom he had already met in 1914). In 1933 he was appointed as *docent* at the Masaryk University in Brno, and held the chair in Russian philology and Old Czech literature there from 1937 until he was forced to leave by the German invasion in the spring of 1939. He went first to Scandinavia (1939–1941), and then to the United States. From 1942 to 1946 he taught at the École Libre des Hautes Études in New York; in 1943 he started teaching at Columbia University, and in 1949 he received a professorial chair at Harvard University in Cambridge, Massachusetts (1949–1966). After 1957 he was also Institute Professor at the Massachusetts Institute of Technology (1957–1982).

In an essay published in the first volume of his *Selected Writings*, he describes the intellectual atmosphere at Moscow University during his years there as student. Already during his freshman year, his interests were broader than those of his teachers – representatives of what he characterizes as the orthodox Moscow linguistic school. The first stimulus for the study of modern phonology came from the 1912 monograph on Russian vowels by L.V. Ščerba, which introduced him to the concept of the phoneme. Somewhat later he learned about the work of Ferdinand de Saussure. During these years, students of psychology and linguistics at Moscow University were passionately discussing the philosophical concepts of the *signatum* (that what is signified) and the *denotatum* (that what is referred to), and learned to assign linguistic contents to the terms, first to the *signatum*, and then to its counterpart – the *signans* (the signifier – that which is performing the signifying).

In that autobiographical essay, Jakobson emphasizes the influence of the turbulent artistic movements of the early twentieth century on the changes in thinking about linguistics, singling out in particular the pictorial theory and practice of cubism, in which everything was based on relationships. In a later presentation he put it more categorically: 'There is an inventory of simple relations common to all tongues of the world.'

Jakobson was also inspired by the Russian poet Velimir Xlebnikov, who played with minimal pairs in his poetry in verses such as '/v,idil vid,il v'os,in vos,in,/' (*videl vydel vesen v osen*), where the initial consonants differ only by presence and absence of palatalization. Xlebnikov's search for the 'infinitesimals of the poetic word' prompted an intuitive grasp of what were to be called some decades later the ultimate phonemic units – *distinctive features*.

JAKOBSON'S LINGUISTIC CAREER: CONTRIBUTIONS TO PHONOLOGICAL THEORY

Jakobson started his linguistic career as a philologist, studying language history, including the historical study of literary texts. His doctoral dissertation dealt with the metrics of the South Slavic epic. While his literary interests continued into his later years, he gravitated more and more to the study of language, first of all Russian. But the study of specific languages was always illuminated

by insights derived from his developing linguistic theories, and he continued to search for linguistic universals in the structure of specific languages with which he was working.

The two concepts with which Jakobson will always be associated are distinctive features and binarism. Distinctive features – contrastive characteristics of sounds – are a concept that was under lively discussion in the Prague Linguistic Circle, of which Jakobson was an active member during his stay in Czechoslovakia. Phonemes – speech sounds that are associated with differences in meaning – were redefined as bundles of distinctive features. The first public presentation of the theory took place at the First International Congress of Linguists at The Hague in 1928. The paper was written by Jakobson in October 1927 in response to a question presented by the organizing committee of the congress; it was later approved and countersigned by S. Karcevski and N. Trubetzkoy, distributed to members of the congress in 1928, and published (in 1930) in the *Actes du 1er Congrès International de Linguistes du 10–15 avril, 1928*. The theory was elaborated and defended in a series of publications by Jakobson and Trubetzkoy, and it has been expanded, refined – and criticized – by many linguists ever since.

Jakobson's system differs from that of Trubetzkoy in several respects, of which the most significant for future linguistic theorization was his introduction of the principle of binarism. This means that every opposition consisted of two possible states or poles: presence or absence of a sound characteristic, or choice between two (and only two) possible characteristics. Jakobson presented the first arguments in this respect in 1938, in a communication to the Third International Congress of Phonetic Sciences in Ghent.

In the distinctive features theory, the universal set of speech sounds is organized according to a set of characteristics specifying place of articulation and/or manner of articulation. These characteristics – labeled features – were first described in articulatory terms, such as dental–labial, or voiced–voiceless. In a significant collaboration with the physicist Gunnar Fant, the features were assigned acoustic characteristics. In later studies, distinctive features have been related to human speech production and perception mechanisms. Distinctive features have become the basis of much of generative phonology (e.g. Chomsky and Halle 1968, and many later publications). Likewise, the notion that linguistic oppositions are binary has become almost an axiom in much of linguistic theory.

CONTRIBUTIONS TO OTHER SUBFIELDS OF LINGUISTICS

Jakobson's significance in the development of linguistic theory is by no means limited to his contributions to phonological theory. He was one of the first to look at language acquisition and loss from the point of view of what these two processes can reveal about the structure of language. In studying linguistic universals, he came to suggest that what he called the inventory of simple relations common to all tongues of the world pertained both to the early acquisition of children's language and to the most stable verbal properties in those types of aphasic regress which display a mirror picture of infants' development.

His continuing interest in the structure of Russian included the phonetics and phonology of Russian, historical morphology of Russian, dialectology of Russian, and even the Russian spelling system; of particular significance for grammatical theory are his studies of Russian morphology.

His interests in language typology led to observations of areal convergences – the development of *Sprachbünde* – areas where language contact has led to the emergence of typological similarities between unrelated languages. All through his life he maintained an interest in metrics and continued to make major contributions in this area.

As a Slavic philologist, he continued his investigations of Slavic epic poetry. He also published extensively in folklore and comparative mythology, especially the mythology of Slavic peoples. To quote Robert Austerlitz:

> Jakobson's contributions to linguistics should be viewed in the context of his interest and work in folkloristic, ritual, and literary texts: here he pursues both overt and subliminal messages with all the tools in his arsenal. This is where his most striking and innovative contributions to the study of the human instrument for communication lie. The inscription on his tombstone – *russkij filolog* – is therefore justified.

Jakobson was also a charismatic teacher. An entire generation of American Slavists was inspired and trained by him, as well as numerous general linguists. A Supplement to Volume XXVII of the *International Journal of Slavic Linguistics and Poetics* (1983), edited by Morris Halle, contains articles by nine scholars, offering appraisals on Jakobson's contributions to the various branches of linguistic science, and constitutes a fitting memorial to the scholar and teacher. But his influence reached across disciplines to such scholars as the anthropologist Claude Levi-Strauss, who was introduced to structural linguistics through Jakobson's work.

Jakobson discovered new and illuminating aspects in whatever linguistic problem he approached, and his creativity was matched by his productivity: the complete bibliography of his writings comprises 98 pages. Jakobson was one of the true intellectual giants of the twentieth century.

Kant, Immanuel

Introductory article

Andrew Brook, Carleton University, Ottawa, Canada

CONTENTS

Immanuel Kant (1724–1804) has had an enormous influence on cognitive research: the dominant model of the mind in contemporary cognitive science is thoroughly Kantian. Nonetheless, some of his most distinctive ideas have played little role in it.

INTRODUCTION

Immanuel Kant may be the single most influential figure in the history of cognitive research before the twentieth century, indeed the intellectual grandfather of cognitive science. Kant held that cognition requires application of concepts as well as sensory input, and that synthesis and mental unity are central to cognition. He advanced a functionalist model of the mind almost 200 years before functionalism was articulated, and he had some highly original things to say about self-consciousness. However, while much of contemporary cognitive science is Kantian, there remain many ideas from Kant's model of the mind which cognitive science has not assimilated.

KANT'S LIFE

Kant was the last great thinker of the German Enlightenment. He focused on the human individual (rather than, say, society). Though said to be one-quarter Scottish (some think that 'Kant' is a Germanization of 'Candt'), Kant lived his whole life in Königsberg (now Kaliningrad) just south of Lithuania. His father was a saddle maker. He was devoutly religious but hostile to many conventional religious observances. By the time of his death, he had served some terms as Rector of the University of Königsberg and effectively the official philosopher of the German-speaking world.

Kant's most famous work is the *Critique of Pure Reason* of 1781 and 1787 (two editions). He was already 57 when he wrote the first edition, yet he went on to write the *Critique of Practical Reason* (1788) on moral reasoning, the *Critique of Judgement* (1790) – a work devoted to a number of topics including reasoning about ends, the nature of judgment, and aesthetics – and books on natural science, cosmology, history, geography, logic and anthropology. From the point of view of cognitive science, his two most important works are the *Critique of Pure Reason* and a small book composed from lecture notes late in his life, *Anthropology From a Pragmatic Point of View* (1798).

MAIN PHILOSOPHICAL VIEWS

Kant started out as a conventional rationalist. Then, memories of reading David Hume 'interrupted my dogmatic slumbers', as he put it. He called the new approach 'critical philosophy'. Critical philosophy asks the question: what must we be like to experience as we do? Kant's answer provided the framework for most subsequent cognitive research.

Philosophy of mind and knowledge were by no means the only areas in which Kant made seminal contributions. He founded physical geometry. His work on social ethics is the basis for modern liberal democratic theory. His deontological approach to the justification of ethical beliefs put ethics on a new footing, and remains influential. He taught metaphysics, ethics, physical geometry, logic, mechanics, theoretical physics, algebra, calculus, trigonometry, and history.

Kant aimed to do two principal things in the *Critique of Pure Reason*: to justify our conviction that physics, like mathematics, is a body of necessary and universal truth; and to insulate religion, including belief in immortality, and free will from the corrosive effects of this same science. Kant had not the slightest doubt that 'God, freedom and immortality' exist, but feared that if science is relevant to their existence it will show them not to exist.

Fortunately, as he saw it, science is quite irrelevant to the question of their existence.

MODEL OF THE MIND

It was the pursuit of the aim of putting physics on a secure footing that led Kant to his views about how the mind works. He approached the foundations of physics by asking: what are the necessary conditions of experience? Put simply, he held that for our experience, and therefore our minds, to be as they are, our experience must be tied together in the way physics says it is. But this also tells us a lot about what our minds must be like. As we will see, his attempt to insulate religion from science led him to some very original views about our awareness of ourselves.

Interestingly, Kant held that psychology (by which he meant the introspective study of the mind) could never be a science. Once, after saying that chemistry would never be a science, he went on, 'the empirical doctrine of the soul … must remain even further removed than chemistry from the rank of what may be called a natural science proper'. Kant thought we should study the mind by thinking through what the mind must be like and what capacities it must have to represent things as it does. This is his famous 'transcendental method'; as we will see, despite its nonempirical roots, it has become an essential method of cognitive science.

Kant made a number of substantive claims about the mind. The most famous is his claim that representation requires concepts as well as percepts; that is, rule-guided acts of cognition as well as signals of the senses. As he put it, 'concepts without intuitions are empty, intuitions without concepts are blind'. In more contemporary terms, the claim is that to discriminate anything from anything else, we need information; but for information to be of any use to us, we must also be able to organize information.

Kant held that to organize information requires two kinds of synthesis. The first ties the raw material of sensible experience together into objects. In terms of contemporary binding theory, colors, lines, shapes, textures, etc., are represented in widely dispersed areas of the brain. These dispersed representations have to be brought into relation to one another and integrated into a representation of a single object.

The second kind of synthesis ties these individual representations together into what might be called 'global representations', in such a way that to be aware of any of the representations thus tied together is to be aware of some of the others, too, and of the group of them as a single group. Kant thought that the capacity to form global representations is essential to both the kind of cognition that we have and the kind of consciousness that we have.

Though by no means all global representations are conscious (Kant is widely misunderstood on this point), the unity found in them is also a feature of consciousness, one that greatly interested Kant. In his view, unified global representations are the result of unifying acts of synthesis, and it takes a unified consciousness to perform such acts.

In addition to what he said about consciousness in general, Kant made some original claims about consciousness of self. These claims arose in the course of his attempt to insulate immortality (and God and free will) from the attacks of science. His rationalist predecessors thought that they could prove that the mind is substantial, and simple (without parts), and that it persists in a special way. This opened the door to a proof of immortality. Descartes, Leibniz, and Reid all took this approach. However, if arguments and evidence are relevant to determining the existence of immortality at all, then argument and evidence could also show it not to exist. For Kant, the best hope was to insulate such matters from argument and evidence entirely. That way, conclusions could be accepted on the basis of faith (and Kant did so accept them) without being at risk from science. Kant thought that introspection provides strong prima facie counterevidence to his anti-intellectual conclusions about what we can know about the nature of the mind. In introspection, one does appear to be substantial, simple and persisting, just as rational psychology says ('rational psychology' was Kant's name for these views). It was incumbent upon Kant to show that introspection gives us nothing of the sort.

In the course of his attack on introspection, Kant made a number of claims. He distinguished two quite different kinds of self-awareness, awareness of one's states and awareness of oneself as the subject of these states. He claimed that the cognitive and semantic machinery used to obtain awareness of self as subject is unusual. In it, we 'denote' but do not 'represent' ourselves. In other words, we designate ourselves without noting 'any quality whatsoever' in ourselves. He argued that the representational basis of awareness of self as subject is not a special experience of self but any experience of anything whatsoever. When one is aware of oneself as subject, he claimed, one is aware of oneself in a way that is not awareness of features of

oneself, a way in which 'nothing manifold is given'. Finally, he asserted that when we are aware of ourselves as subject, we are aware of ourselves as the 'single common subject' of a number of representations.

Kant's conception of the mind is an early example of functionalism. To model the mind, we must model what it does and can do, that is to say, its functions.

KANT'S INFLUENCE

The influence of Kant was enormous even in his own time. When he died, he was the dominant philosopher throughout the German-speaking world. His ideas had a major influence on empirical students of the mind in the nineteenth century. His influence waned during the heyday of behaviorism, but increased again with the revolution in cognitive science of the 1960s and 1970s, though this time the influence was indirect and not widely acknowledged.

KANT AND COGNITIVE SCIENCE

Kant influenced cognitive science via nineteenth-century cognitive researchers, Herbart and Helmholtz in particular. These figures are rightly regarded as the precursors of contemporary cognitive research, but it is seldom realized that they both regarded themselves as Kantians. Some of Kant's doctrines are built into the very foundations of cognitive science.

The first of these is the transcendental method. Transcendental arguments attempt to infer the conditions necessary for some phenomenon to occur. Translated into contemporary terms, this has become the method of postulating unobservable mental mechanisms in order to arrive at the best explanation of observed behavior. This approach completely supplanted introspection and rational inference from concepts, the two dominant methods of studying the mind before Kant, and is now the most important method of cognitive science.

Secondly, the doctrine that most representation requires concepts as well as percepts has become as orthodox in cognitive science as it was central to Kant.

Thirdly, the functionalist conception of the mind, and the claim that we can model cognitive function without knowing very much about the underlying structure, derive from Kant. Kant even shared functionalism's lack of enthusiasm for introspection. Indeed, he went further than contemporary functionalists in one respect: he thought that we could know nothing about the underlying structure, an application of his general doctrine that we can know nothing about anything as it is in itself.

Interestingly, other ideas equally central to Kant have been largely ignored in cognitive science. Recall Kant's claim that cognition requires two kinds of synthesis. The first kind of synthesis is widely studied in the form of binding. Indeed, one model, Anne Treisman's three-stage model, is very similar to Kant's. According to Treisman, object recognition proceeds in three stages: feature detection, location of features on a map of locations, and integration and identification of objects under concepts. This is similar to Kant's three-stage model of apprehension of features, association of features in something like clusters (Kant called this stage 'reproduction'), and recognition of these 'clusters' as objects falling under concepts. However, Kant's second kind of synthesis, the activity of tying multiple representations together into a global representation, has received little attention.

The same was true until recently of Kant's doctrine of the unity of consciousness. In Kant's view, unity in representation requires unity in the thing doing the representing. Indeed, the whole topic of mental unity has been neglected in cognitive science until recently.

Finally, Kant's views on consciousness of self have played little role in cognitive science. Kant did not consider consciousness of self to be essential to all forms of unified cognition, but he made a number of penetrating discoveries about it. Some closely related ideas have now reappeared in the philosophy of language.

Thus, while, the dominant model of the mind in contemporary cognitive science is Kantian, some of his most distinctive ideas have not yet been taken up. This article has discussed only a few of Kant's ideas about cognition. He also had a complex model of representation in space and time, and strong views on what we can and cannot know. Many philosophers now have serious doubts about these, and they have not played a significant role in cognitive science.

Köhler, Wolfgang

Introductory article

Alfred D Kornfeld, Eastern Connecticut State University, Connecticut, USA

CONTENTS

Wolfgang Köhler (1887–1967) was a German–American Gestalt psychologist. He conducted seminal research into insight, and believed that psychology should model itself after field physics.

INTRODUCTION

Wolfgang Köhler was born in Reval, Estonia, in 1887. He attended the universities of Tübigen, Bonn, and Berlin, and was awarded a PhD in 1909 by Berlin for a dissertation on psychoacoustics under the direction of Carl Stumpf. At Berlin Köhler also studied with the Nobel laureate physicist Max Planck, whose quantum field physics would profoundly influence Köhler's ideas about the relationship between conscious experience and brain processes.

While working as an assistant at the Psychological Institute in Frankfurt am Main, Köhler collaborated with Max Wertheimer and Kurt Koffka on investigations of apparent movement: the phi phenomenon. Wertheimer's publication of their findings in 1912 marks the beginning of the Gestalt psychology movement. Köhler, along with Wertheimer and Koffka, would later be recognized as a leader of this movement.

INSIGHT RESEARCH

In 1913, Köhler was appointed as director of the Prussian Academy of Sciences Anthropoid Station at Tenerife in the Canary Islands. After the onset of the First World War, he was stranded at Tenerife, and was unable to return to Germany until 1920. This enforced isolation proved to be fortuitous, because it enabled him to conduct ingenious investigations of animal problem-solving which would earn him international recognition.

Prior to Köhler, researchers in the field of animal learning had stressed the gradual and mechanical formation of connections between stimuli and responses following reinforcement of 'correct' responses. Their investigations were based on the view that animals reproduce learned responses according to their previous experiences and rewards. Köhler's research, which was reported in his 1917 book *The Mentality of Apes*, led him to reject this interpretation. He found that chimpanzees could utilize simple objects to solve problems, and this suggested to him that animals could learn by perceiving relationships.

Köhler observed that chimpanzees were able to learn to manipulate boxes and bamboo poles and sticks in order to reach fruit that had been placed beyond their grasp. For example, some of Köhler's chimpanzees were able to obtain fruit placed at the top of their cages by building three-box towers. Sultan, Köhler's favorite chimpanzee, would achieve fame in the psychological literature for his ability to insert a small hollow rod into a larger hollow rod in order to create a stick long enough to reach fruit that had been placed outside his cage. Such intelligent solutions, which Köhler termed 'insight', were characterized by the sudden emergence of the correct response following a period during which the animal would often quietly stare at the objects and apparently 'think' about the problem.

Köhler's analysis of the nature and significance of insight was criticized for ignoring the role of previous learning. In fact, Köhler did not deny the importance of experience, but contended that what is vital is how experience is integrated with the features of the current situation. Köhler's analysis was also criticized because it seemed to imply the existence of a 'mysterious' inner agent responsible for solving problems. Köhler, however, emphatically denied that his analysis required the assumption of an inner problem-solving agent. He would later claim that his introduction of the term 'insight' was meant to be a description, rather than an explanation, of intelligent problem-solving behavior.

While at Tenerife, Köhler also investigated discrimination learning. He found that chimpanzees and chickens could learn consistently to choose the darker of two stimuli. Köhler concluded that both insight and discrimination tasks involve relational learning. (*See* **Animal Learning**)

PSYCHOPHYSICAL ISOMORPHISM

The concept of psychophysical isomorphism reflects Köhler's belief that psychology should be based on models derived from physics. Wertheimer had already used this concept in discussions of the phi phenomenon, but it assumed a more prominent role for Köhler. He pointed out that field physics described natural systems as organized functional wholes dependent on the relations among local conditions but not derived from the separate actions of parts. Such systems tend towards a dynamic equilibrium characterized by both regularity and simplicity and governed by laws of self-distribution, such as those governing the forces maintaining the shape of a soap bubble.

Köhler hypothesized that self-distribution principles should also regulate consciousness and brain activity. The theory of psychophysical isomorphism posits a one-to-one correspondence between the spatial and temporal organizations of conscious experience and cerebral electrical patterns. However, it does not predict a literal structural or quantitative identity between the psychological and neurological realms. For example, the perception of a square enclosing a circle should be correlated with a pattern of brain currents that follows the general organization of this relationship, without, however, reproducing it geometrically. In this respect, the relationship that Köhler proposed between the electrical activity of the brain and conscious experience has been compared to the relationship between a map and the actual city that it represents.

Much later, Köhler was to explore psychophysical isomorphism by examining the relationships between cortical patterns of excitation and figural aftereffects in vision. The results of these investigations appeared to support the theory of psychophysical isomorphism. However, when the physiological psychologist Karl Lashley subjected psychophysical isomorphism to further investigation by laying strips of metal foil on the surface of the visual cortex of monkeys, he found no visual disturbances in the monkeys even though the visual cortical fields were disrupted. These results were widely interpreted as a refutation of psychophysical isomorphism. Gestalt psychologists would later attempt to demonstrate how psychophysical isomorphism could be applied to thinking and perception, but their efforts were largely ignored because of these negative findings. (*See* **Object Perception, Neural Basis of**; **Vision: Form Perception**; **Reasoning and Thinking, Neural Basis of**)

KÖHLER AND AMERICAN PSYCHOLOGY

In 1922, Köhler was appointed Professor of Psychology and Director of the Psychological Institute at the University of Berlin. He was a visiting professor at Clark University in the United States from 1925 to 1926. While at Clark, he delivered a series of lectures that presented his chimpanzee research as well as general Gestalt organizational principles. These lectures were subsequently published, along with those of his contemporary and rival John B. Watson, in a volume entitled *Psychologies of 1925*.

Köhler's increased familiarity with American psychology, especially Watsonian behaviorism, was reflected in his 1929 book *Gestalt Psychology*. This book is widely considered to be the standard exposition of such Gestalt concepts as insight, part–whole relationships, psychophysical isomorphism, and the nature of phenomenological experience. Employing a model strongly influenced by quantum field physics, Köhler proposed parallel structural organizations in consciousness, the nervous system, and the physical environment. In this framework, everyday conscious experience illuminates the nature of the myriad relationships between the psychological and physical realms. Köhler was very critical of behaviorism's reductionistic methods and rejection of consciousness. He insisted that the phenomenal, everyday world of consciousness must be the starting point for all scientific investigation.

Although *Gestalt Psychology* was very influential, its partisan tone, and especially its severe critique of behaviorism, offended some American psychologists and created the unfortunate impression that Köhler's program was largely negative in nature.

In spite of these reservations Köhler attained wide recognition in American psychological circles for the originality and significance of his achievements. Harvard University invited him to deliver the 1934–1935 William James Lectures. These lectures provided the basis for the volume *The Place of Values in a World of Facts*, which presented a view of knowledge that integrated psychology, physical

science, and the philosophy of values. Köhler proposed that the experience of 'rightness' and 'wrongness' was determined by a phenomenally objective gestalt quality. This quality, which he termed 'requiredness', did not just operate in the realm of perception and thinking, but also furnished a basis for understanding the nature and meaning of values. Köhler's lectures were generally well received, especially by the philosophers in the audience, and Harvard's joint philosophy–psychology department considered offering him a position. However, the distinguished psychologist E. G. Boring, who was the director of Harvard's psychological laboratory, was disappointed by the non-experimental and philosophical content of the lectures and seems to have played a major role in dissuading Harvard from doing so. (Boring would later recognize Köhler's importance for American psychology.)

With the Nazi rise to power, Köhler found himself in an untenable position. Frustrated by Nazi interference in his work and angry about the dismissal of Jewish and politically suspect non-Jewish colleagues, he resigned from the Berlin Psychological Institute in 1935. A man of considerable personal courage and integrity, Köhler is credited with making the last anti-Nazi statement published in Germany before the Second World War, in which he defended Jews for their contributions to the science and culture of Germany. Köhler and his family emigrated to the United States. He was appointed a professor of psychology at Swarthmore College in 1935, and would remain there until 1958. After his retirement from Swarthmore, Köhler lectured at Dartmouth College and Princeton University. He was elected president of the American Psychological Association in 1958, and was a recipient of the Distinguished Scientific Contribution Award of that association.

Köhler died at Enfield, New Hampshire, in 1967.

EVALUATION OF KÖHLER

For more than fifty years, Wolfgang Köhler was a forceful advocate for Gestalt psychology. As a Gestalt psychologist, Köhler believed in the primacy of organizational principles in thinking and perception. The distinguishing characteristics of his approach to Gestalt psychology were his seminal research into insight and his conviction that psychology should model itself after physics. Köhler's concept of insight has become standard textbook material and is still a point of departure for discussions of problem-solving. His concept of psychophysical isomorphism has not fared as well, and is regarded by many as a historical curiosity derived from a discredited model of central nervous system functioning. Kohler's speculations about the brain processes associated with psychophysical isomorphism are now generally thought to be irrelevant to understanding perceptual and cognitive processes. (It has, however, recently been suggested that a more sophisticated model of the brain, based on connectionist networks, might resurrect the isomorphism hypothesis.)

Köhler seems to have relished his confrontational role as an advocate of the Gestalt movement. He vehemently criticized the extreme positivistic views and Procrustean methodology that dominated the psychology of his time. As an alternative, he proposed more flexible and creative research methods that would enable psychologists to investigate complex and meaningful psychological processes. Underlying his research and theorizing was the belief that Gestalt psychology would provide the basis for a revolution in the methods and subject matter of psychology.

This call for sweeping reforms in the field seems to have had little effect on the practice of mainstream psychology. Perhaps the explanation is that Gestalt psychology itself was viewed by many as too philosophical and unscientific. Köhler's ideas about the role of relational learning in solving problems were much more influential. The second generation of behavioristic psychologists, the 'neobehaviorists', well understood the challenge that Köhler's findings posed for their stimulus–response models of learning. They developed imaginative experimental paradigms and a more advanced stimulus–response framework in an attempt to meet this challenge. Thus, Köhler can be credited with encouraging neobehavioristic psychologists both to study phenomena they might otherwise have ignored and to develop more sophisticated models of learning.

Köhler's influence on contemporary psychology is evident in the areas of thinking and problem-solving. His idea of the role played by configural factors in recall resembles contemporary views of memory organization. Köhler's investigations of problem-solving emphasized nonassociated factors and relational elements, and may thereby have influenced information processing models of thinking. Although Köhler's focus on the active organizational principles underlying perception and thinking anticipated a major theme of current cognitive psychology, it would be inaccurate to call him a cognitive psychologist. Köhler was rooted in an earlier period that did not possess the

information processing and structural models of the mind that define modern cognitive science. Nonetheless, Köhler occupies a position of honor in the history of psychology for his role in directing attention to the primacy of organized mental processes in intelligent human and animal behavior. (*See* **Reasoning**; **Theory of Mind**)

Lashley, Karl S.

Introductory article

Jack Orbach, Queens College, Flushing, New York, USA

CONTENTS

Karl S. Lashley was a major figure of twentieth-century neuropsychology, whose work on the relation between brain function and behavior, especially learning and memory, has proved seminal.

INTRODUCTION

Karl Spencer Lashley, one of the titans of the twentieth century in neuropsychology, was born in 1890 in Davis, West Virginia and died in 1958 in Poitier, France. A small-town Appalachian boy with the heart of a naturalist, he grew up to become a world-class animal psychologist. His research and theorizing concerning the relation between brain and behavior has had a lasting influence on psychology and neurology. That influence was further enhanced by the contributions of some of his students, particularly Frank A. Beach, Donald O. Hebb, and Roger W. Sperry, who was awarded the Nobel Prize in medicine in 1981.

The major question Lashley set for himself was: how does the brain work in the process of remembering things? His research convinced him that contemporary theories of learning and memory were erroneous – that learning could never be explained in terms of the formation of simple connections at synapses of particular neurons. His contributions to neuropsychology are collected in a volume of his selected papers, and his research and theories are reviewed in two volumes by Jack Orbach (see the Further Reading section).

EARLY YEARS

From childhood, Lashley's mother encouraged him in intellectual pursuits. He learned to read at the age of four and made avid use of the household library. But reading was not the only source of his attraction to science. He had the instincts of an observer and displayed a deep interest in animal and plant life. A favorite boyhood pastime was to wander in the woods, observing and collecting various species, including butterflies, snakes, frogs, snails, mice, and raccoons. As this interest in animals persisted throughout his life, he was never without a pet. At one time he owned a cat and a parrot, but the combination created unexpected problems when the voluble bird displayed a tendency to adopt the cat's kittens. Other pets included cockateels, monkeys, and dogs. One dog, '*Till Eulenspiegel*', developed a fondness for daiquiris and 'pink ladies'.

Lashley had a mechanical aptitude that appeared early. He was fascinated by his mother's sewing machine and learned to use it efficiently, later, as an adult, making sails for his boats and drapes for his home. Meanwhile, as a substitute for sewing, his father bought him a jigsaw to use in woodworking. This started Lashley on a hobby that became a lifelong pleasure. He produced a steady flow of elegantly designed and finely executed articles, even living room furniture. After retirement, he continued his cabinet-making and repair work, including the remodeling of his house. As a laboratory researcher, Lashley found that this aptitude served him well, and he demanded similar skills from his students, requiring them to construct their own devices for experiments.

When Lashley was seven, his father fell prey to gold fever and decided to take his family northwest to prospect. Years later he recalled the excitement of the gold rush and meeting with such swashbucklers as Swiftwater Bill and Klondike Pete, who sported nugget jewelry and recounted tall tales about fabulous strikes and the dangers of encountering bird-sized Alaskan mosquitoes!

At college, Lashley's plan was to major in Latin. In order to fill a vacant hour in his schedule, he enrolled in a course in zoology. The teacher of this class had a profound influence upon the 16-year-old boy: 'Within a few weeks in his class I knew that I had found my life's work.' After

earning his degree at the University of West Virginia, Lashley was awarded a teaching fellowship in biology at the University of Pittsburgh and enrolled as a Master's candidate. His thesis was on the permeability of the eggshell. But his most important contact that year was with another teaching fellow, Karl Dallenbach, who later said of Lashley: 'Though he had never taken a course in psychology, he was permitted to take my laboratory course. In this small class, we worked intimately together on various experiments. Lashley was intensely interested and was an outstanding student. In this course, he showed the promise that he later fulfilled.' After receiving his Master's degree, Lashley accepted a fellowship at Johns Hopkins University to work with the eminent biologist H. S. Jennings on the invertebrate *paramecium*. His doctoral research was on asexual reproduction of *hydra*. He received his PhD in genetics in 1914. Though interested in learning as a topic, he remained a nativist all his life.

PASSION FOR MUSIC

At age 11, Lashley had a few piano lessons but he found practicing scales impossibly boring. Then, at 18, he picked up the violin and learned to play without formal instruction. He claimed that he first heard classical music at 20 and was immediately fascinated by it. His first wife, a pianist, introduced him to the literature of chamber music. It didn't take long before he taught himself to play the cello (Figure 1). He collected an extensive library of instrumental music, joined the Jacksonville Orchestra and organized a small group of Florida musicians to meet regularly at his home (called 'Fiddler's Cove') for the playing of chamber music. He was a trustee and benefactor of the Jacksonville College of Music. Always on the alert for behavior that might shed light on how the nervous system worked, he once calculated the speed of finger movements involved in playing a fast cadenza on the piano, and compared this with the known speed of neural transmission. The comparison revealed that the intervals between successive finger movements were too short to support the theory that each movement is aroused by motor impulses set off by sensory impulses from the preceding finger movement. There is just not enough time for a sensory message from the finger to go to the brain and pass to the motor area and then for a motor impulse to trigger the next finger movement. Lashley cited this example to support the notion of 'central patterning' of complex motor sequences in the brain (something that today we call 'motor programs').

DEVELOPING INTEREST IN PSYCHOLOGY

Lashley's interest in psychology, first aroused in Pittsburgh, continued at Hopkins. While majoring in zoology, he took two minors: one with Adolph Meyer, professor of psychiatry; the other with John B. Watson, who became the father of behaviorism. Watson's impact on him was so great that, 44 years later, Lashley asserted: 'Anyone who knows American psychology today knows that its value derives from biology and from Watson.' In 1914, he joined Watson to carry out field experiments on homing, nesting, and reproductive behavior of sooty and noddy terns on the Dry Tortugas (west of Key West, Florida).

During the First World War, Lashley was assigned to educate the public and the military on the dangers of venereal diseases. Working together, he and Watson showed and discussed movies designed to further the campaign against these afflictions. The movies illustrated what damage could be wrought on the genitals. In later years, Lashley enjoyed telling of the time when they went to a small town and distributed advertisements announcing a free movie. The advertisements included no mention of the subject matter and, according to Lashley's account, he and Watson were fortunate to escape in one piece from the sheriff and enraged citizenry.

While holding a postdoctoral scholarship, Lashley continued to work with Watson, studying the effects of strychnine and other drugs on maze learning in rats. At the same time he journeyed frequently to Washington, DC to study the brain-lesioned monkeys of the psychologist Shepherd Ivory Franz. Eventually, he acquired the surgical and histological skills to embark on an ablation program of his own on the neural basis of learning and memory. This program brought him worldwide recognition, and his research career was solidly launched.

After stints in academic posts at Minnesota and Chicago, Lashley was chosen in 1935 for a chair at Harvard. The invitation came from a search committee charged by the President of the University to find 'the best psychologist in the world'. Not bad for someone who never took a didactic course in psychology! Finally, in 1942, he was appointed Director of the Yerkes Laboratories of Primate Biology in Orange Park, Florida, where he wrote some of his most memorable papers, including *In Search of the Engram* (1950), in which he concluded that he could not find the memory trace in any one place in the brain.

RESEARCH AND THEORY

In his 1929 monograph (see Further Reading), Lashley enunciated his controversial concepts of *mass action* and *equipotentiality.* Empirically, the term *mass action* summarizes the results of many brain ablation experiments – that the loss of the maze habit in rats is determined by the size of the lesion and not by its locus in the brain. Theoretically, *mass action* refers to a theory of how the cerebral cortex works, that it is the *pattern* of activity, independent of its *locus,* that is relevant, and that the memory trace is reduplicated and distributed in the brain. The concept *equipotentiality* refers to the fact that intact neurons can take over the function of destroyed cells. In his later years, Lashley discarded this concept and preferred to cite the facts of sensory and motor equivalence. Examples include the recognition of unfamiliar visual stimuli by the eye not used during monocular learning to recognize those stimuli (*interocular transfer*), and the performance of skilled movements by the hand not practiced during learning (*intermanual transfer*). Lashley loved to point out impishly that right-handers can write with their left hands, with their feet (on the beach), and even with their noses. In short, neurons that are not used during the course of learning can still show the effects of learning – that is, they can mediate memories (referred to as *Lashley's lesson* by Orbach, 1998). The recovery of function in patients after suffering from brain lesions also points to the same fact, that neurons inactive during learning can still show the effects of learning.

By the early 1920s, Lashley's research results on Pavlovian conditioning led him to break away from Watson's theorizing on learning. He found Watson's Stimulus–Response formula troubling because it failed to include the brain in the causal sequence. Does a stimulus cause a response? No, answered Lashley, a stimulus excites the brain, and it is the resultant activity in the brain that is responsible for the response. Thus, he revised Watson's formula to read Stimulus–Brain–Response. In this way, he provided for psychological functions that need to be sustained in the brain, such as selective attention and the memory trace. Unfortunately, the model of the day assumed that brain processes were linear – that is, the neural activity was thought to flow directly from input to output, as in a telephone line. It wasn't until 1938 that Lashley came up with a mechanism to explain how neural activity is sustained after the stimulus has ceased. This mechanism, called the reverberatory circuit, was borrowed from the neuroanatomical descriptions of Lorente de Nó. But it was Lashley's student Hebb who illustrated the wide application of reverberatory circuits for neuropsychological theory in a landmark book published in 1949. Hebb's theory of *cell assemblies* in the brain took the neuropsychological community by storm.

In 1952, Lashley wrote: 'I have never been able by any operation on the brain to destroy a specific memory. From such experiments, I have been forced to conclude that the memory trace is diffuse, that all memories are somehow represented in all or almost all parts of the cerebral cortex. Whatever the nature of the trace, it must be reduplicated throughout wide areas.'

Finally, in 1957, he wrote: 'The neuron is a living organism, subject to continual variation in its

functional capacity according to its metabolic state. It shows an all-or-none response in that it does or does not fire. But its 'all' may vary greatly from time to time. Comparison of the nervous system with a digital computer (and with soldered wire circuits) implies a uniformity in the action of neurons which is contrary to fact.' Thus, Lashley dismissed the rigid circuitry of early theories of artificial intelligence.

Lewin, Kurt

Introductory article

Lenelis Kruse, University of Hagen, Hagen, Germany
Carl F Graumann, University of Heidelberg, Heidelberg, Germany

CONTENTS

Kurt Lewin (1890–1947) was one of the prominent figures in twentieth century psychology. His impact on psychology was fundamental to the development of experimental social psychology, cognitive psychology, and action research.

INTRODUCTION

Kurt Lewin is one of the most frequently quoted psychologists of the twentieth century. His work is usually associated with words such as field theory, life space, barrier, valence, success and failure, leadership style, group dynamics, and action research. Lewin is claimed to be the father of various developments in psychology, such as experimental social psychology, cognitive psychology, and action research.

Lewin became a prominent figure in both German and American psychology as a result of his engagement in many different areas of research as well as of application, and through his role as a highly influential teacher who gathered around him groups of talented students. The antithesis of an armchair psychologist, Lewin from his earliest student years was politically active in various areas of public life.

BIOGRAPHY

Born in 1890 in a small town in Prussia (now belonging to Poland), Kurt Lewin grew up as one of four children in a Jewish family. Later on the family moved to Berlin where Lewin graduated from a humanistic gymnasium. As a student he first concentrated on medicine and biology, but soon became interested in philosophy, theory of science, and psychology. His dissertation on mental activities in the inhibition processes of volition was published almost at the same time as another, quite different, paper on the 'war landscape' that reflected Lewin's experiences while he served in the army during the First World War. These papers anticipate the wide scope of Lewin's later research interests, which ranged from experimental research on volition to conceptualizations of ecological problems.

Lewin's interest in social problems became apparent when he joined a socialist student group and took an active part in social and educational activities for workers in agriculture and industry. From this interest in practical problems resulted two 'applied' publications, one on rationalization in agriculture, one on the socialization of the Taylor system.

On his return from the war he was appointed to the Psychological Institute of Berlin University, Lewin worked with Wolfgang Köhler, the leader of the Berlin Gestalt psychology group. Later on he became an assistant in the new section of applied psychology, where he remained until his emigration in 1933. Although he received the title of professor in 1927 it was impossible for a Jewish citizen to be appointed to a tenured position. During these years Lewin concentrated on experimental studies of will, affect, and action, which became the basis for the development of his field theory. He always worked with talented students, some of whom not only shared his later fate as refugees but also won international reputations by their association with Lewin (they included Dembo, Zeigarnik, and Rickers-Ovsiankina). The year 1929 became an important date in Lewin's life. Through an American student who had worked with Lewin and had made the work of the Lewin group known to American psychologists, Lewin received an invitation to attend an international congress at Yale University. His lecture on environmental forces (presented in German!) and a short film on the effect of these forces demonstrated by a small girl trying to sit on a stone apparently impressed his audience so much that he was invited as visiting professor to Stanford University in 1932. Lewin was forced to leave Germany when the Nazis seized power in 1933, and was fortunate to receive

a timely invitation to join the faculty at Cornell University. After 2 years he was offered a position at the Iowa University Child Welfare Research Station, where he worked for 8 years as a professor of child psychology. During these years Lewin won excellent students as disciples and later as colleagues, such as Barker, Cartwright, Festinger, French, Lippitt, White, and Zander. His research interests shifted to social psychology. In 1937 he became one of the founders of the Society for the Psychological Study of Social Issues.

Another institution which still exists at the University of Michigan in Ann Arbor is the Research Center for Group Dynamics. Originally founded at the Massachusetts Institute of Technology in 1945, it reflected the social engagement of Lewin and his increasing concern with the interaction between research and practice which culminated in his conception of 'action research'. Students and colleagues at the center developed methods of studying and changing human relations. This institution became the frame of Lewin's last period of life, ended abruptly by a heart attack at the age of 56 in 1947.

RESEARCH TOPICS

Since the Lewin heritage is mostly associated with field theory it is appropriate to take a closer look at its central themes and concepts. The key term of field theory is the 'life space' (or total situation); i.e. the sum of all facts that determine a person's behavior at a given time. From this conception the popular and much debated formula was derived that $B = f(LS)$: behaviour B is a function of the life space $f(LS)$ and the latter is the product of the interaction between a person P and the person's environment E. Theoretically and methodologically essential is the interdependence between P and E. As a nonmetric mathematical discipline, topology is of interest for field theory since it focuses on spatial relations of which the most important is the whole–part relation – a favorite topic of Gestalt theorists. Topological psychology describes 'regions' and 'boundaries' and the relations between them as well as 'locomotion' within and between such regions.

A few words are in order about the dynamics of the field, for which the central term is the 'tension system'. It exists whenever in P a psychological need or intention exists with respect to a quality of the psychological environment; i.e. the environment as it is experienced by a person. Such qualities are called 'valences' and are either positive (attractive) or negative (qualities to be avoided by P). Tension systems and their interdependence have been shown to be at work in a series of experiments dealing with a variety of dynamic or motivational phenomena, such as rigidity, substitution, satiation, frustration, forgetting and – of special interest to social psychologists – the studies of various forms of conflict resulting from the interaction between the 'driving' and 'restraining' forces of a psychological field, limited by a 'boundary' and 'barriers'. Since the conception of a field of forces, governed by the methodological principle of interdependence, is not restricted to individual persons, Lewin successfully transferred it to field experiments in which he and his group studied the phenomena and dynamics of group life, an innovation in the history of experimentation. Of these group experiments the ones dealing with leadership style and group 'atmosphere', such as 'autocratic', 'democratic' and '*laisser-faire*', have gained lasting notoriety and popularity.

In some of Lewin's social psychological studies his own fate is mirrored as a member of a minority group, as a Jewish emigrant, and as a person who had to adapt to another culture. Mainly these studies underline his interest in a synthesis of social research and social change.

ASSESSMENT

For several decades, mainly in the social psychological literature of the 1970s and 1980s, Kurt Lewin was almost unanimously hailed as one of the great men in this field. In this period the 'Lewin tradition' (Patnoe) or the 'Lewin legacy' (Stivers and Wheelan) seemed to be part and parcel of contemporary social psychology. The postwar history of this field, centered as it has been in the USA, seemed to be dominated by Lewin and his followers. Leon Festinger, himself a prominent associate of Lewin's, documented in 1980 how three generations of Lewin's students and their students had built and shaped modern social psychology over a period of more than thirty years. Festinger also tried to make it clear that Lewin's final creation, the Research Center for Group Dynamics, was an effective and lasting monument to him. It is remarkable, therefore, that when Festinger went on to assess Lewin's impact on social psychology he felt obliged to state that 'for at least two decades the social psychology literature has been virtually devoid of mention of … Lewinian concepts and terms'.

What is Lewin's stature at the beginning of the twenty-first century? Terms characteristic of Lewinian theorizing that were already being omitted

from the literature of thirty years ago are still rare; at any rate, they have lost the specificity that Lewin meant to give them. While 'field theory' is still a frequently used term it is no longer connected with the Lewinian components of 'topology', 'hodological space' and 'vectors', while many terms that were originally or temporarily defined by Lewin's theorems have now acquired (or regained) a much broader, almost loose meaning – e.g. 'force', 'valence', 'life space', and 'group dynamics'.

Irritating to an outside observer is also the presence of two traditions with little overlap. On the one hand there is the Lewin–Festinger–Schachter tradition as represented in Festinger's and Patnoe's books. It is the tradition of experimental social psychology from which the present mainstream interest in social cognition may be derived. On the other hand, under the (also Lewinian) title of 'group dynamics', there is the broad movement of sensitivity training techniques, interpersonal workshops, and encounter groups.

A common origin of both forms of group dynamics, the experimental and the therapeutic variety, is seen by some historians in Lewin's late interest in 'action research', in which 'combination of social research, action, and research evaluation action' (as described by Back) Lewin had tried to systematize experimentation with small groups for purposes of social change, an effort that he could not bring to a conclusion owing to his untimely death. Hence, a certain ambiguity has remained; in books and journals entitled 'group dynamics' we occasionally find both small group research and group therapy. However, most experimental social (and cognitive) psychologists have come to avoid the term for clarity's sake. Although, strictly speaking, field theory, topology, and action research no longer rank among the major methodologies of psychology, and Kurt Lewin is cited in a historical context rather than in the research chapters of modern textbooks, Lewin's overall impact on contemporary psychology must not be underrated. While his theory and methodology in the 1960s could still be offered as a 'contemporary systematic framework', it has meanwhile almost disappeared from the agenda of theories. Social psychology has increasingly become individualistic (again).

Historically, it is interesting to see that Lewin and his generation suffered the same fate that the 'Gestalt and field' generation inflicted upon their predecessors and their theories. Theories are not necessarily replaced by refuting them but very often by providing new perspectives that are comprehensive enough to allow for some kind of continuity. Lewin's (and the Gestalt psychologists') emphasis on the perceptual (cognitive) primacy of the self-organizing whole or field over its component 'elements' as well as on the interdependence between features of the person and the person's environment have become elements of the common stock of psychological knowledge.

Luria, Alexander R.

Introductory article

David E Tupper, Hennepin County Medical Center, Minneapolis, Minnesota, USA

CONTENTS

Alexander Romanovich Luria (1902–1977) was a Russian neurologist and psychologist recognized as one of the preeminent neuropsychologists of the twentieth century. His primary interest was the study of the cerebral localization of psychological functions, but he also was involved in developmental psychology, cross-cultural cognitive research, the study of frontal lobe impairments, aphasiology, educational and rehabilitative interventions, and personal biographies of individuals with unusual cognitive characteristics.

INTRODUCTION

Alexander Romanovich Luria (Figure 1) was born in Russia on 16 July 1902, in Kazan, a city east of Moscow. After a cultured upbringing in his early years, during which he learned German, French, and English and demonstrated quick acquisition of philosophy, history, and literature, Luria entered the University of Kazan in 1917. He remained a student in the newly formed department of social sciences until 1921, when he graduated with a degree in the humanities. Luria was an active student, and his study of sociology also prompted an interest in psychology. After graduation, Luria took a job as a laboratory assistant at the Institute of the Scientific Organization of Labor, and also continued to study in Kazan at the Pedagogical Institute and the medical school. Early in his career, Luria recognized that a valid approach to psychology needed to incorporate dynamic aspects of behavior and include both biological and cultural influences. He moved to Moscow at the end of 1921 and, soon thereafter, developed such a deep interest in psychoanalysis that he set up and chaired a psychoanalytic circle, and arranged the publication of important psychoanalytic works. Correspondence with Sigmund Freud confirmed permission for the circle to provide authorized translations into Russian of his important psychoanalytic writings, which was overseen by Luria. (*See* **Freud, Sigmund**)

Figure 1. Alexander R. Luria during the Eighteenth International Congress of Psychology, held in Moscow in 1966. Reproduced from E. D. Homskaya, *Alexander Romanovich Luria: A Scientific Biography*, with the permission of Kluwer Academic/Plenum Publishers, © 2001.

In 1922 Luria was offered a position at the Moscow Institute of Psychology, where he focused his research on more objective methods to study affective processes, rather than the more subjective methods used in psychoanalysis. This work led to his development of the 'combined motor method' by which Luria measured motor responses to affective stimuli in various clinical, criminal and student groups with a chronoscopic apparatus similar to a lie detector. The ideas developed in this research probably represent the early evolution of Luria's interest in self-regulatory mechanisms, which became prominent in his later research on

the frontal lobe. In 1923, Luria worked briefly in education at the Krupskaya Academy of Communist Education. He initiated new research in that setting, analyzing verbal associative reactions in children to study the development of speech and cognition.

Luria's life was changed in January 1924 when he met Lev Vygotsky, a technical school teacher from Gomel, at the Second All-Russian Congress on Psychoneurology in Leningrad. Luria was so impressed with Vygotsky's approach to psychology that he helped arrange an invitation for Vygotsky to work in Moscow. From the time that they first met to the time of Vygotsky's death in 1934, Luria and Vygotsky, along with Alexei Leontiev, a like-minded colleague, worked together to create a practical and Marxist-oriented Soviet psychology described as a 'cultural-historical' approach. The main principle that united Luria and Vygotsky in this new theory was the idea that psychology could view higher psychological functions (namely, conscious activity) only in the context of their development in historical and cultural processes and demonstrated via objective principles of brain function. This 'troika' of researchers, sharing a common theoretical base, collaborated on a vigorous research program in Moscow, and studied the mediated nature of psychological functions in children and adults, as well as the organization of psychological functions in patients with aphasia, Parkinsonism, and learning difficulties. The central aspect of the theory for the research was the role of cultural mediation in the constitution of human psychological processes, and the role of the social environment in structuring those processes. The researchers believed that higher mental processes are formed initially between people, in social interaction, and only later become internalized in individuals as inner speech and other cognitive structures. All higher mental functions are therefore initially culturally determined and mediated. Although Vygotsky's further elaboration of this theory was cut short by his premature death, Luria remained true to a dynamic, cultural-historical theory for the rest of his life, even in his neuropsychological practice. (*See* **Vygotsky, Lev**; **Learning and Instruction, Cognitive and Situative Theories of**)

CROSS-CULTURAL EXPEDITIONS

During the summers of 1931 and 1932, Luria organized two psychological expeditions to central Asia in an attempt to further support the cultural-historical theory. The research was planned with a number of prominent investigators, including Vygotsky, who was too ill to actually join the trips. The purpose of the investigations was to study the influence of the cultural and social environment on the development of psychological processes, as rapid sociological change was taking place in the villages of Uzbekistan and Kirghizia at that time. More specifically, the researchers were interested in changes in perception, problem-solving and memory associated with historical changes in economic activity and schooling, and a number of naturalistic experiments with both literate and illiterate people were designed and implemented during the expeditions. The investigators used observational and clinical methods to test their hypothesis that the structure of human cognitive processes differs according to the ways in which various social groups live out their lives. They found that people whose lives are dominated by concrete, practical activities have a different method of thinking from people whose lives require abstract, verbal, and theoretical approaches to reality. Despite a number of problems interpreting the data, the investigators concluded that cultural factors affect mental processes and that these differences vanish as soon as people are exposed to more industrialized situations. Unfortunately, results from the cross-cultural investigations were not fully analyzed or published immediately, as the Stalinist government considered such research racist; Luria's complete account of the research was not published in book form until 40 years later. (*See* **Culture and Cognitive Development**)

After Vygotsky's death in 1934, Luria returned to Moscow where he joined the Medico-Genetic Institute and studied the psychological development of twins, focusing on the relative contributions of biological and social determinants to cognition. Luria continued his twin research at the Medico-Genetic Institute until 1936 when such research was proclaimed illegal by the government. He then defended his reorganized manuscript on the combined motor method as a doctoral thesis in Tbilisi and reentered full-time medical school, subsequently graduating as a medical doctor in 1937. Luria thereby became one of the youngest psychologists and medical doctors in the country.

NEUROPSYCHOLOGICAL CONTRIBUTIONS

In the years before the Second World War, Luria worked mainly in the field of neuropsychology in the neurological clinic of the State Institute of Experimental Medicine. Working with many different

kinds of neurological and neurosurgical cases, Luria first developed his personal, creative, detective-like approach to neurological diagnosis, which involves searching for damaged psychological capabilities within functional psychological systems. Luria's approach to neuropsychological diagnosis was qualitative in nature, and used a variety of 'simple' tasks presented to the patient until a common defective cognitive link (factor) could be identified, which indicated the impaired cerebral region. Because of his earlier cultural-historical theorizing, Luria also became particularly interested in the cerebral organization of speech mechanisms, and the effects of aphasia on voluntary actions.

With the advent of war Luria was called away to organize a rehabilitation hospital in Kisegatch in the southern Urals. This renovated sanatorium was converted into a specialized rehabilitation facility for soldiers recovering from dysfunctions caused by brain wounds. Along with the medical and rehabilitation treatment provided there, Luria was particularly interested in the rehabilitation of mental activity in patients with localized brain damage, and he applied his theory of the dynamic systemic localization of higher psychological functions at this time. In contrast to narrow localizationist or nonspecific equipotentialist theories of cerebral organization, Luria's systemic theory maintained that one should conceptualize the higher mental functions as functional systems of various brain regions working in concert to complete socially determined activities. Luria was one of the first psychologists in the world to attempt an integration of major neuropsychological views, and he is considered by many to be the founder of neuropsychology in the Soviet Union. At the end of the war, Luria returned to the Burdenko Neurosurgical Institute and started teaching at Moscow State University, with which he kept in close academic contact for the rest of his life. (*See* **Brain Damage, Treatment and Recovery from**)

A joint session of the Academy of Medical Sciences and the Academy of Sciences took place in Moscow in 1950, and resulted in the interruption of Luria's neuropsychological work and the closing of his laboratory in the Neurosurgical Institute. The meeting was an ideological defeat of Soviet biological and medical sciences unless based on Pavlovian principles, and caused Luria to take refuge in a more sanctioned position in the Institute of Defectology of the Russian Federation's Academy of Pedagogical Sciences. In this challenging political climate, it was necessary for Luria to modify the nature of his research. He returned to his past use of the combined motor method and applied this method to the study of the development of verbal regulation in normal children and children with mental retardation. Based on earlier work initiated with Vygotsky, he continued to study the ontogenesis of the regulating function of oral and written speech. Luria also modified his clinical methods and created diagnostic tests and methods of educational instruction for these children. He more generally pursued his scientific interests within the context of a series of studies of the development of language and thought in children with mental retardation, and wrote several important monographs on these topics. (*See* **Pavlov, Ivan Petrovich**; **Neuropsychological Development**)

In 1959 Luria's laboratory at the Burdenko Neurosurgical Institute was reestablished, and he was permitted to return to the study of neuropsychology. In the remaining 18 years of his life, Luria's laboratory became a leading neuropsychological institution in the Soviet Union. In addition to his clinical activities and increased teaching responsibilities at Moscow State University, Luria continued to develop and expand his ideas concerning the cerebral organization of psychological processes. He became particularly interested in the analysis of speech and language disturbances, and executed further investigations into aphasia and neurolinguistics, the regulative role of speech and language in frontal lobe activities, and the diagnosis of local brain damage, all themes that had interested him in earlier years. (*See* **Language Disorders**; **Aphasia**; **Executive Function, Models of**)

Among the most important of Luria's contributions to neuropsychology is his conceptualization of the three functional units of the brain. Initially developed as a didactic tool, Luria's concept postulated three main functional cerebral blocks organized according to the dynamic localization of higher mental functions. Luria stated that the whole brain participates in each mental activity, with each of the three units or blocks of the brain contributing specific components. Thus, the first unit, housed in the brainstem, is responsible for general cerebral activation and arousal, and participates in wakefulness and attention; the second functional unit, located in posterior cerebral regions, serves to process sensory information, and provides for analysis, coding, and storage of the information; while the anterior and especially the frontal regions of the brain are responsible for the development and execution of intentions, plans and movements. Depending upon the area of the brain or unit affected by brain damage, any of a variety of functional psychological disorders could result. Luria's books *Higher Cortical Functions in*

Man and *The Working Brain* contain detailed descriptions of his neuropsychological diagnostic methods, his theoretical conceptualizations of functional units and dynamic localization, and historical and background information on the evolution of neuropsychological concepts. (*See* **Frontal Cortex**)

CASE STUDIES IN ROMANTIC SCIENCE

In the later years of his life Luria was a prolific writer on diverse psychological topics. Returning to his early ideal of creating a unified psychology, Luria contributed two detailed and personal-scientific summaries of unique individuals designed to provide a more synthetic, romantic scientific perspective for psychology, to contrast with classical, analytic approaches.

The first case study described S., an exceptional mnemonist who was endowed with a virtually limitless memory. Luria's account is documented in *The Mind of a Mnemonist*, where he considers not only the unique character of S.'s memory but also reveals important aspects of S.'s mind, behavior, and personality. Luria worked with S. for over 30 years and came to understand not only the exceptional gifts that S. possessed but also the unique handicaps that S. experienced in his personality and daily life. The second case study, *The Man With a Shattered World*, describes a young soldier, Zasetsky, who suffers a traumatic gunshot wound to the left hemisphere which impaired a number of higher cognitive abilities, and required Zasetsky to relearn many of these abilities in order to compensate for his lost faculties and try to live a normal life again. Over the course of 25 years, with the use of writing as his only means of expression, Luria assisted Zasetsky to rebuild his memories and his grasp on reality. These two cases illustrate Luria's interests in developing a person-centered psychology that would synthesize classical and romantic science.

During the latter part of his career, Luria received numerous awards and honors in the Soviet Union and internationally. He remained professor of psychology and chair of neuropsychology at Moscow State University for many years, and had a long association with the Burdenko Neurosurgical Institute, where he was director of the neuropsychology laboratory. Luria died from heart failure on 14 August 1977.

CONTEMPORARY IMPLICATIONS

Contemporary neuropsychology has benefited from Luria's work in a number of ways. Luria maintained a strong conceptual emphasis and internally consistent theory throughout his work, based on cultural-historical theorizing and culminating in his theory of the dynamic systemic localization of cerebral functions. This theory is widely accepted and used worldwide, and counters the more quantitative and atheoretical approaches to neuropsychology developed in North America. Luria's three-block model of cerebral organization has also provided the impetus for the creation of newer and more complex models of intellectual or cognitive functioning, as exemplified by J. P. Das's planning–attention–simultaneous–successive (PASS) model of cognition. A number of clinical neuropsychological batteries have evolved from Luria's diagnostic methods, including Luria's Neuropsychological Investigation developed by Christensen, and the Luria–Nebraska Neuropsychological Battery by Golden and colleagues. Finally, Luria's rich clinical and theoretical case descriptions of individuals with self-regulatory impairments from frontal lobe damage are unparalleled in contemporary neuropsychological literature, and have instigated significant research endeavors into these mysterious executive functions.

During his 75 years, Alexander Romanovich Luria became a respected, prolific and important neuropsychologist. His work has had a significant global influence on psychological theory and practice, particularly in the area of neuropsychology. As a contemporary of Lev Vygotsky, Luria was significantly influenced by Vygotsky's approach to understanding the mind as inseparable from the surrounding society and culture. Although his later work contributed greatly to the developing field of neuropsychology, the cultural-historical theme provided the basis for Luria's work all his life, and places him in a prominent position in the history of Soviet psychology.

Marr, David

Introductory article

Lucia M Vaina, Boston University and Harvard Medical School, Boston, Massachusetts, USA

CONTENTS

David C. Marr (1945–1980) was a theoretical neurophysiologist and cognitive scientist whose work symbiotically integrated data from experimental neuroscience and psychophysics with novel computational models, thus providing an explicit foundation for the field of computational neuroscience.

INTRODUCTION

David Courtnay Marr (Figure 1) was born on 19 January 1945 in Essex, England. He went to the English public school Rugby, on a scholarship, and between 1963 and 1966 he studied at Trinity College, Cambridge, where he obtained his BA degree in mathematics with first-class honors. For his doctoral research he continued in theoretical neuroscience, under the supervision of Giles Brindley. His education involved training in neuroanatomy, neurophysiology, biochemistry and molecular biology. At Trinity College in 1971 he received an MA (with distinction) in mathematics and a PhD in theoretical neurophysiology. After obtaining his PhD, he accepted a research appointment at the Medical Research Council (MRC) Laboratory of Molecular Biology under Sydney Brenner and Francis Crick, and he retained an affiliation with the MRC until 1976.

CONTRIBUTIONS TO THEORETICAL NEUROSCIENCE: WHAT IS IT THAT THE BRAIN DOES?

In three successive papers that combine high-level theoretical speculation with meticulous synthesis of the available neuroanatomical data, Marr proposed a definite answer to this question for the cerebellum, archicortex and neocortex. Common to these three studies is the idea that the central function of the brain is statistical pattern recognition and association in a very high-dimensional space of 'elemental' features. The basic building block of all three theories is the codon, or a subset of features, with which a cell that is wired in such a way as to fire in the presence of that particular codon is associated.

A paper entitled 'A theory of cerebellar cortex', published in 1969 (see Further Reading), represents the essence of Marr's doctoral research. The paper is a theoretical model that made critical predictions elucidating how the cerebellum learns the motor skills involved in performing actions and maintaining posture and balance. The fundamental elements of the model are the known cell types in the cerebellum, their connectivities and the synaptic

Figure 1. David Marr (1945–1980).

actions of the cerebellar cortex. The process involves context recognition and learning. The former was described at the level of the mossy fiber–granule cell–Golgi cell circuitry, and the latter was described at the level of the parallel fiber–Purkinje cell synapse, heterosynaptically strengthened by the inferior olive climbing fiber. Linked through learning to the context of the previous movement in the sequence, the Purkinje cell, presumably implementing the codon representation, associates (through synaptic modification) a particular movement with the context in which it is performed. Subsequently, the context alone causes the Purkinje cell to fire, which in turn precipitates the next elemental movement. Basically the cerebellum model is a one-layer network (of granule cells) with fixed synapses, and an associative memory store and a set of conditioning inputs (the climbing fibers).

The second paper, entitled 'A theory for cerebral neocortex', published by Marr in 1970 (see Further Reading), extended the codon theory to encompass a more general type of statistical concept learning, which he assessed as being 'capable of serving many of the aspects of the brain's functions', in particular the formation and organization of networks capable of classifying and representing 'the world'. This hypothesis is an early attempt at a theory of unsupervised learning relating to methods of cluster analysis. The paper discusses the structure of the relationships which appear in the afferent information, and the usefulness to the organism of discovering them. These two ideas are combined by the 'fundamental hypothesis' which is based on the existence and prevalence in the world of a particular type of 'statistical redundancy'. The fundamental hypothesis, as set out in Marr's 1970 paper, states that:

> Where instances of a particular collection of intrinsic properties (i.e. properties already diagnosed from sensory information) tend to be grouped such that if some are present, most are, then other useful properties are likely to exist which generalize over such instances. Further, properties often are grouped in this way.

The neocortex model keeps track of probabilities of events, and to do this it needs an extensive memory of a special kind, allowing retrieval that is based on the content rather than the location of the items. In his third theoretical paper, entitled 'Simple memory: a theory for archicortex', published in 1971 (see Further Reading), Marr considers the hippocampus as a candidate for fulfilling this function. In analyzing the memory capacity and recall characteristics of the hippocampus, Marr integrated combinatorial–mathematical constraints on the representational capabilities of codons with concrete data derived from neuroanatomical and neurophysiological studies. In modern terms, the hippocampal model consists of a recurrent network with two layers of trainable 'hidden' units that encode and classify input patterns connected to an associative memory store. The paper postulated the involvement in learning of synaptic connections modifiable by experience – a notion that originated from the research of Donald Hebb in the late 1940s. The paper is a mathematical proof of efficient partial content-based recall by the model, and it offered a functional interpretation of many anatomical structures in the hippocampus, together with concrete testable predictions.

'Truth, I believed, was basically neuronal, and the central aim of research was a thorough analysis of the structure of the nervous system'. This view expressed by Marr in 1982 in his book, *Vision: a Computational Investigation into the Human Representation and Processing of Visual Information* (see Further Reading), combined with his initial training in mathematics, shaped the quantitative, analytical methodology that he applied in these three studies. In a letter to Francis Crick in 1977 he summarizes his fundamental views as follows:

> For a mathematician, understanding (or explanation) is all, yet in science proof is, of course, what counts. In the case of information-processing devices, understanding is very important; one can know a fact about a device for years without really understanding it, and part of the theoretician's job is to place into a comprehensible framework the facts that one already knows. I still think that the cerebellum is a good example. For sure, the idea that the parallel fiber–Purkinje cell synapse might be modifiable may not have been very difficult to arrive at, and other theories have since incorporated it, but that surely is only part of the story. I found the real impact of the story to lie in the combinatorial trick. That is, the granule cell arrangement, with associated inhibitory interneurons, had been right in front of people's eyes ever since Cajal (modulo inhibition and excitation), but its significance had not been appreciated. Of course my theory might be wrong, but if it is right, then I would regard a major part of its contribution as being explanatory. And also, that is almost inevitable.

Many of the ideas developed in these three papers were subsequently extended and adapted to be consistent with later neurobiological discoveries. This topic was addressed in *From the Retina to the Neocortex* by L. M. Vaina (see Further Reading).

A PIONEER OF COMPUTATIONAL NEUROSCIENCE

After the publication of these three fundamental papers, Marr moved to the Massachusetts Institute of Technology (MIT) Artificial Intelligence Laboratory where he was a visiting scientist in the group of Marvin Minsky and Seymour Papert. 'Since the facilities and the people were really impressive' (as he wrote to Sydney Brenner in 1973), Marr relocated from Cambridge, England to Cambridge, Massachusetts for a faculty appointment in the Department of Psychology at MIT, and in 1980 he was promoted to full professor with tenure.

While at MIT, his decision to break with the previous research was stated clearly in a letter to Giles Brindley (written in October 1973):

> I do not expect to write any more papers in theoretical neurophysiology – at least not for a long time. I do not regard the achievements of your 1969 or my papers negligible. At the very least, they contain techniques that anyone concerned with biological computer architecture should be aware of.

This decision was motivated by his realization that, without an understanding of specific tasks and mechanisms – the issues from which his earlier theories were 'once removed' – any general theory would always be incomplete.

He proposed a new methodology for understanding the brain by essentially inventing a field and a mode of study now referred to as *computational neuroscience*. In his opening remarks at a workshop organized in 1972 by Benjamin Kaminer at Boston University, Marr suggested an 'inverse square law' for theoretical research, according to which the value of a study varies inversely with the square of its generality – an assessment that favors top-down reasoning firmly supported by functional (computational) understanding, together with bottom-up work grounded in an understanding of the mechanism.

Proposing that the primary unresolved issue in brain science was what function must be implemented and why, Marr argued fiercely against the usefulness of the theoretical approaches to brain science adopted in the early 1970s, such as the catastrophe theory pioneered by Rene Thom, and neural nets (of that time). Instead, he proposed a fundamentally novel approach to biological information processing which required that any problem must be addressed at several different levels of abstraction. What exactly was the task executed by the system? On what properties of the world could a system performing this task be expected to rely? What methods could be shown to be effective in the performance of the task? Given a particular method, what are the appropriate algorithms for implementing it? Given a particular algorithm, what neural circuitry would be sufficient to perform it? These questions formed the core of Marr's research philosophy, and they were explicitly formulated as three levels of explanation of information processing. At the highest level is a computational theory – that is, a theory of how a task could be performed. The computational theory must specify what is being computed and why it is a useful thing to compute. At the next level is a representation and an algorithm (or a set of algorithms) to achieve that representation. At the third level lies the question of how the algorithm is actually implemented in the hardware of the system. A key point in Marr's approach is that the three levels should be considered relatively independently.

Marr's originality and depth of thinking stem from his emphasis on the computational theory level – not because it was the most important level, but because it had been generally neglected by most researchers. The computational theory of a task not only constrains the nature of the algorithm(s) for performing it, but also constrains the nature of the representation of the information at any given stage of processing. In addition, it specifies how the image is related to the outside world, by explicitly spelling out the limits on how the image can be interpreted. Knowledge of the constraints allows recovery from the image of the properties of the scene. For example, stereopsis depends on the constraint that only one point on the retina receives light from the same source as another (unique) point on the other retina, and that the changes in disparity will be small. Although there are some possible exceptions, in general this constraint holds because the world is largely composed of smooth surfaces.

A COMPUTATIONAL THEORY OF VISION: HOW DOES THE BRAIN SEE?

This theoretical framework was the 'signature' of the research conducted in the MIT Vision Group that was formed and inspired by David Marr. The group included many talented and creative students and colleagues, such as Tomaso Poggio, Shimon Ullman, Ellen Hildreth, Eric Grimson and Keith Nishihara. Together they were seeking computational insights into the working of the visual system, and they put them to the test of implementation as computer models. Within only a few years many ground-breaking papers on computational vision had been published, including a theory of

binocular stereopsis, a theory of low-level image representation, representation of direction selectivity in the cortex and a theory of the way in which shapes and actions are categorized.

Marr's book entitled *Vision: A Computational Investigation into the Human Representation and Processing of Visual Information* (see Further Reading) is a lucid presentation of this work which proposes a general theory of the visual processing stages up to (but not including) object recognition. The framework of this theory is based on three main symbolic representations of the visual world which are created, maintained and interpreted by the process of vision. First, the *primal sketch* is mainly concerned with the description of changes in intensity of the image and their local geometry, on the grounds that intensity variations are likely to correspond to object boundaries or other physical realities. The primal sketch representation is constructed from symbolic primitives such as zero crossings, edges, contours and blobs. Secondly, the *two-and-a-half-dimensional sketch* ($2\frac{1}{2}$*-D sketch*) is a viewer-centered description of the relative distances, contours and orientations of surfaces. Thirdly, the *three-dimensional model* (*sketch*) is an object-centered representation of objects with the goal of later allowing manipulation and recognition. This representation must be initially related to and derived from the two-and-a-half-dimensional sketch, which means that there must be a relationship between the schema of an object and the way in which the organization of its surfaces appears to the perceiver.

Each of these representations is associated with algorithms used to produce them and computational theories describing specific modules in the visual system that are used to construct the sketches at each level. The idea of the vision process as a set of relatively independent modules is a powerful one from both computational and evolutionary perspectives, and some of the modules have been isolated experimentally.

DAVID MARR'S VISION

In the winter of 1978 David Marr was diagnosed with leukemia. He died on 17 November 1980 in Cambridge, Massachusetts. His entire work provided solid proof that in behavior and brain sciences a good theory does not have to sacrifice mathematical rigor for faithfulness to specific findings. More importantly, it emphasized the role of explanation over and above mere curve fitting, making it legitimate to ask why a particular brain process is taking place, and not merely what differential equation can describe it.

Through his published work, intellectual leadership, and the harmonious blend of insight, mathematical rigor and deep knowledge of neurobiology that characterizes his research, David Marr has given us a new intellectual landscape. More than two decades after his quest was cut short, research in neurobiology and cognitive sciences increasingly emphasizes the importance of elucidating the computations performed by the brain, and the most exciting developments are those prompted (or at least accompanied) by computational theories.

McCulloch, Warren

Introductory article

Jerome Y Lettvin, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA
Taffy Holland, Old Lyme, Connecticut, USA

Warren Sturgis McCulloch (1898–1969) was an important figure in the development of current views on the relation of brain, as mechanism, to spirit, as process. He was particularly interested in the physiology of the nervous system.

The concert of body and mind remains the major philosophical problem it has been since antiquity. But systems that act purposively, and modify their action to optimize performance, have proliferated since the mid-twentieth century. In some ways they have changed how we view the mind–body problem; and the paper 'A logical calculus of the ideas immanent in nervous activity', written by McCulloch and Pitts and published in 1943, helped make this change possible.

McCulloch was born and grew up in Orange, New Jersey. He showed early abilities in carpentry, building design, construction, blacksmithing, surveying, and sailing. He wrote poetry, and continued to do so throughout his life.

After high school he attended Haverford College for a year, where he concentrated on the philosophical problems of epistemology. He went on to Yale, where he took his BA in 1921 while in the Naval Reserve. After two years in the navy, he went on to Columbia University in New York, taking an MA in 1923 and an MD in 1927.

His internship and residency at Bellevue Hospital (1927–1928) launched his career in neurology. From 1928 to 1930 he worked on experimental epilepsy research in the Neurosurgical Laboratory and Department of Neurology at Columbia University. Then, from 1930 to 1931, he studied head injury under Foster Kennedy at Bellevue Hospital, while teaching physiological psychology at Seth Low Junior College.

From 1931 to 1932 McCulloch did graduate work in mathematical physics at New York University. What he learned during this break in his clinical work was to serve him well in his later studies in physiology.

From 1932 to 1934 he was Resident in Neurology at Rockland State Hospital (Orangeburg, New York State). In 1934 he committed himself to the study of neurophysiology at Dusser de Barenne's laboratory in Yale, where he was able to begin the main thread of his scientific life: the attempt to understand the brain.

In Holland, Dusser de Barenne had developed the technique of strychnine neuronography. By this technique it was possible to map out corticocortical connections in live mammalian brain, a prohibitively complex task by ordinary anatomical methods.

The cortex can be mapped, by cytoarchitectonic methods (such as used by Brodmann), into many distinct areas, surprisingly clearly bounded. These areas are functionally distinct, and their numbering has become the mode of reference by which clinicians and physiologists identify the locus of cortical representation of specific motor, sensory, and cognitive functions.

As his wife, Rook, said of McCulloch, his goal was set early in his life: namely, to understand man and man's understanding. His mission was not to unravel the sources of misery and madness in man but to explain man himself. To him, neurology was a necessary introduction to the philosophical questions, a tool rather than a profession.

For the next 15 years, McCulloch devoted himself to the localization of function in the brains of cats, macaques, and chimpanzees. Unfortunately, that work has largely been neglected with the development of more precise modern methods. Some of McCulloch's subtler observations about cortical function have almost been forgotten.

McCulloch and Dusser de Barenne wrote on the phenomenon of 'suppression', which they distinguished from 'inhibition' and 'extinction'. Between the motor and premotor areas of the cortex lies a strip which they called '4s'. When stimulation of this area preceded by several minutes a testing stimulus of the motor area, over a period of a few minutes, no response to the stimulation of the motor area was obtained. The area 4s coincided with that strip from which Marion Hines had obtained, by electrical stimulation, a cessation of movement and a relaxation of contracted muscles.

Suppressor strips (of which there are several in the cortex) are largely ignored, and left unexplained, in current accounts of cortical physiology. McCulloch, Snider, and Magoun associated them with activity of the reticular formation in the brain stem.

After the death of Dusser de Barenne, McCulloch stayed at Yale to finish and publish the papers describing their joint work. Then, in 1941, at the instigation of Percival Bailey and Gerhardt von Bonin (both of whom had worked with de Berenne at Yale), McCulloch became Director of the Laboratory of Basic Research at the Neuropsychiatric Institute in the University of Illinois College of Medicine. In 1945 he became Full Professor of Psychiatry and Clinical Professor of Physiology.

He and his family (Rook, his two daughters Taffy and Jean, his son David, and his adopted son George Duncan) took a house in a western suburb of Chicago. The family had a farm in Old Lyme, Connecticut, and every summer there would be scholars, artists, and scientists visiting from all over the world. There would also be the neighbors, to whom Warren and Rook were unstintingly generous. Rook was the farmer, Warren engaged in building, and guests joined in all the activities. The dam that Warren designed for the large pond was one of the few dams in the region untouched by the hurricane in 1938.

McCulloch's 12 years at the Neuropsychiatric Institute were productive. He, Garol, Bailey, Von Bonin, Roseman, Ward, Davis, and others worked on the strychnine neuronography of the cortex, finishing the effort begun at Yale.

Other research was also going on in McCulloch's laboratory. Fred and Erna Gibbs came from Boston City Hospital and set up their laboratory of encephalography. Craig Goodwin designed and maintained most of the electrical and electronic apparatus. Elwood Henneman began his studies on the spinal cord, which would occupy him for the rest of his life at Harvard Medical School.

At about the same time, Snider and Magoun at Northwestern University Medical School in Chicago were discovering the bulboreticular facilitatory and inhibitory nuclei. These large-celled groups in the brain stem act on all spinal reflexes, one greatly enhancing them, the other diminishing them to complete suppression. The whole reticular formation in the brain stem is very mysterious; it has global effects on the state of the organism, and feeds upward to the forebrain as well as downward to the spinal cord. This work opened a new view on the cortical suppressor strips, which has since fallen out of favor but is still debated.

In 1942, Walter Pitts came to the laboratory. When he visited McCulloch he was not yet 18; but he had already joined Rashevsky's group in mathematical biophysics at the University of Chicago. McCulloch instantly recognized Pitts's talents. Pitts was as well read in poetry, philosophy, and history as in mathematics and logic. The affinity between the two men was strong and obvious. Walter became part of the family, and lived with them in 1943.

McCulloch explained to Pitts the problems of studying the brain, the nature of reflexes, the physiology of synaptic connections, and the problem of making sense of it all. Turing's famous 1939 paper on the 'universal logical engine' was well known to both men. McCulloch pointed out that there was an analogy between the synaptic actions of excitation and inhibition and logical operations, and that the nervous system may be an engine performing logic. With great enthusiasm, they produced 'A logical calculus of the ideas immanent in nervous activity', which was highly influential.

Pitts met Norbert Wiener towards the end of 1945, and was invited to become Wiener's student at the Massachusetts Institute of Technology. He moved to Boston, but revisited Chicago to write a second paper with McCulloch – 'How we know universals: the perception of auditory and visual forms' – in 1947. This ambitious venture is as remarkable as the first, but less widely recognized.

By 1946, and until 1953, McCulloch was chairing the Josiah Macy Jr Foundation Meetings on Cybernetics, multidisciplinary meetings to deal with problems involved in the nature of information and its processing.

While he continued to oversee and guide the laboratory, his interests had changed. So when Jerome Wiesner, at Wiener's request, invited McCulloch to MIT in 1951, McCulloch gladly accepted. Here he could devote himself fully to a new venture with no administrative responsibilities. With him came Pat Wall and Jerry Lettvin.

At that time, the Research Laboratory of Electronics at MIT was a playground of new thought. Engineers, mathematicians, and scientists mingled with linguists and poets, artists and musicians, philosophers and critics, in a common creative effort, in a climate where ideas could be explored without the promise of results.

Two problems remained from McCulloch's years at the Neuropsychiatric Institute. First was the question of whether the brain could be regarded as (or imitated by) a logical engine – a project already started by John von Neuman and being actively pursued at MIT. The second question

concerned the nature of inhibition. Is it a specific synaptically mediated signal, or is it also mediated in other ways?

McCulloch devoted himself to the problem of developing a mode of logic for modeling neurons. He left the laboratory experimentation on nervous action to his group. However, he remained very involved in the design and prosecution of the experiments.

The laboratory studies on vision and on smell, on synaptic interactions, and on self-repair of the nervous system, all done using frogs and salamanders, are now well known. But one study, which occupied the first three years, has been almost ignored. The 1955 paper 'Reflex inhibition by dorsal root interaction' shows that electrical currents produced by the impulses in one set of nervous fibers affect the threshold for invasion of an impulse into the branchings of adjacent fibers. Every branching is a two-bit switch; the oncoming impulse in the fiber can invade one or other branch, or both, or neither. What happens at this switch depends on the electrical field produced by what is happening everywhere around it. This makes nervous processing very much more complex than had previously been thought. The implications of this work are potentially explosive.

Warren McCulloch made vital contributions to the study of the brain at a time when the field was undergoing revolutionary change. His work raises serious problems about the nature of process in living things as compared to logical engines. His pleasure in paradox spices all his writings, and his insistence on underlying metaphysics is the ghost in the living machines he studied. McCulloch was a 17th century figure in 20th century clothes.

Newell, Allen

Introductory article

Roheena Anand, Nature Publishing Group, London, UK

CONTENTS

Allen Newell (1927–1992) was a pioneer in the field of artificial intelligence. Much of the work he initiated continues to be of fundamental importance today.

INTRODUCTION

Allen Newell was one of the greatest thinkers in the field of artificial intelligence (AI). In recognition of the enormity of his achievements, he was made the first president of the American Association for Artificial Intelligence, and received one of the first awards for research excellence from the International Joint Conference on AI. In his lifetime Newell wrote and contributed to 250 publications, including ten books. His final book was entitled *Unified Theories of Cognition*, and the title represented his lifelong goal: to understand the workings of the human mind.

BEGINNINGS

Allen Newell was born in San Francisco in 1927. His father was Dr Robert R. Newell, a renowned professor of radiology at Stanford Medical School, and his mother was Jeanette Le Valley. Newell looked up to his father a great deal, seeing him as '… in many respects a complete man … He'd built a log cabin up in the mountains … He could fish, pan for gold, the whole bit. At the same time, he was the complete intellectual … Within the environment where I was raised, he was a great man. He was extremely idealistic. He used to write poetry.'

At 17, Newell, perhaps influenced by his father's outdoor pursuits, dreamt of being a forest ranger but a career in science became his main preoccupation after witnessing the atomic-bomb tests on the Bikini Atoll. Newell was 19 and had just been drafted into the US Navy. He had observed the tests on board a ship full of scientists; and his job afterwards involved making maps of the distribution of radiation over the atolls.

He completed his first degree in physics at Stanford in 1949, having already published his first paper (on the subject of X-ray optics). At Stanford, Newell took a course on mathematical methods in physical science given by the mathematician George Polya. This proved to be a significant influence on the course of his future studies – implicitly if not explicitly – by introducing him to the idea of solving problems using a method grounded in heuristic reasoning.

After a year studying pure mathematics at Princeton, Newell left to join the RAND Corporation, a think-tank based in Santa Monica. He worked for RAND for the next 11 years, though not always on site. It was here that he met Herbert A. Simon, then Professor of Industrial Administration at the Carnegie Institute of Technology (CIT), who was to play a large part in Newell's life and studies. (*See* **Simon, Herbert A.**)

At first he studied logistics systems and organizational science, specifically with reference to the military. The Systems Research Laboratory at RAND grew from Newell's first efforts (along with those of Bob Chapman, Bill Biel and John Kennedy) to study information handling and decision-making processes by military pilots for which it was necessary to construct a full-scale mock-up of an early warning station. Newell then worked with Cliff Shaw, a systems programmer, to produce a computer program to simulate a radar display of air traffic. This project brought about the realization for them that computers could be used for symbolic as well as for numerical processing.

There came a new epiphany for Newell in 1954 during a seminar by Oliver Selfridge on pattern recognition, when he realized that it would be possible to build more complex intelligent adaptive systems than had ever been built before, and importantly that they could be programmed on digital computers. From then on, his main preoccupation was the architecture of the human mind. (*See*

Pattern Recognition, Statistical; **Pattern Vision, Neural Basis of**)

BUILDING SYSTEMS

The way to learn about systems is to try to build one.

Newell's first steps towards this goal took the form of programming a computer to learn to play chess. Chess had always interested researchers in this area because of its perceived difficulty as a form of thought and its innate logic. Newell's chess program was reliant on heuristic search, and led to his first publication on this topic. However, while the design was promising, the restricted memory of computers of the time proved to be an obstacle. (*See* **Search**)

Newell's working relationship with Simon continued from there on. Instead of moving to Stanford's Behavioural Sciences unit, he joined CIT to complete a doctoral degree and work on simulations. Newell, Simon and Clifford Shaw joined forces in 1955 to build a computer program that would demonstrate complex information processing. They started to construct a system with the aim of working in geometry, but changed direction to work on propositional logic (this decision was due in part to Simon's owning a copy of *Principia Mathematica*). From this collaboration came 'logic theorist' (LT), one of the first working AI programs. It incorporated many of the ideas that have since become foundations of this topic, one of the most fundamental being that of heuristic search.

While building LT and their chess-playing programs, the team were faced with the problem that none of the current computer languages supported the symbolic processing that was so central to their programs; therefore they had to spend time building their own tools. In 1957, there emerged from these efforts the first implemented list-processing language, called simply 'information-processing language' (IPL). Over the next seven years, six different versions of this language were developed. The language introduced many of the ideas that became fundamental first to list processing and later to computer science in general: lists, associations, schemata, dynamic memory allocation, data types, recursion, associative retrieval, functions as arguments, and generators.

Newell received his Ph.D. from CIT in 1957. His thesis described his work on LT and chess. In it were ideas that would appear 25 years later in Soar (originally standing for 'state, operator and result'): dynamic subgoal creation, multiple evaluation, methods for controlling search, resource-limited reasoning, learning based on applying existing knowledge, and the close integration of learning and problem solving. (*See* **Soar**; **Problem Solving**).

Four years later, in 1961, Newell would join the faculty as a professor. He was instrumental in the creation of CIT's computer science department and its subsequent development into one of the best departments of its kind in the world.

After their work on LT, the team returned briefly to the realm of chess, and, using a version of IPL, wrote a chess-playing program called NSS (after the initials of the authors). This differed from others around at the time in that it aimed to simulate human players rather than just go for the win.

LT as a system exhibited intelligent behavior, but in a limited domain: all its methods and knowledge were specific to propositional logic. The next major step, rather than building more task-specific systems, was the generalization of these basic techniques to construct a single system that would model human behavior across many different domains. The 'general problem solver' (GPS) was thus conceived. This was a system that, in Newell's words, 'separated out the program structure for problem solving from the program structure to describe a particular task'.

GPS was constructed by studying human protocols for logic tasks. It was apparent from this that they required a more goal-directed strategy: means–ends analysis, where actions are selected based on their ability to achieve a goal. Thinking-aloud protocol analysis was used (and indeed resurrected, since it was then generally out of favor), and problem-behavior graphs tracked the performance of subjects, coding decisions that were being made and comparing them to those made by the computer.

However, there were problems with GPS. In Simon's words, it would 'burrow into a deep pit of successive subgoals with no way for the top program levels to regain control'. A potential solution lay in the use of production-system languages, where each instruction was a condition followed by an action. This and other aspects of GPS would eventually be generalized in Soar, the problem-solving architecture based on problem spaces and production systems that was developed by Newell, John Laird and Paul Rosenbloom.

In 1972 Newell and Simon published *Human Problem Solving*, the culmination of their investigations into complex problem solving. It covered protocol analysis, GPS, and production systems, presenting a computational theory of human problem solving based on heuristic search in problem spaces.

Simon and Newell's research paths diverged slightly after the writing of this book, with Simon in his own words, then concentrating on 'GPS, EPAM the sequence extrapolator and BACON, while Newell's emphasis was on computational architecture and attempts to model the control structure underlying intelligence'.

THEORIES OF MIND

> Diversions occur, make them count: salvage what is possible for the main goal.

In 1968, Newell, with Gordon Bell, wrote a book on computer systems, in the process of which they created languages for two different levels of computer design: the system level (PMS) and the instruction level (ISP). This work was a diversion from Newell's main preoccupation with intelligence, but it served to crystallize ideas of architectures and hierarchies of levels for analyzing computational systems.

Other work on computer and software systems design followed, along with a number of publications, up to 1982. The L* language was developed by Newell, George Robertson, Peter Freeman and Don McCracken with the system programmer in mind in that it was meant to facilitate the construction of a customized operating system and user interface.

Newell was also willing to observe rather than participate, and played an advisory role in the ARPA program of research on speech recognition in the 1970s. He wrote the final report for this, which proved to be very influential at the time.

In 1973 Newell became a consultant to Xerox PARC (dedicated to exploring digital electronic technologies in the context of office information systems). A year later he was joined by two of his former students (Stuart Card and Thomas Moran), thereby forming the Applied Information-Processing Psychology Project, part of his long-term project to apply psychological theory to human–computer interaction (or user-interface design). Existing psychological data were examined for regularities, and from this analysis an engineering-level model of routine cognitive skills, and a methodology for analyzing new tasks in terms of the basic processes required to perform them, were constructed. This work resulted in the publication of *The Psychology of Human–Computer Interaction*, and led Newell back to human mental architecture.

> An architecture is a fixed set of mechanisms that enable the acquisition and use of content in a memory to guide behavior in pursuit of goals. In effect, this is the hardware–software distinction: the architecture is the hardware that is supporting the software and the software is the collection of data structures that encode the content. This is the essence of the computational theory of mind.

SOAR

> Choose a final project to outlast you.

A unified theory of cognition is usually based around one central cognitive activity – with Soar (and previously GPS), this was problem solving. Soar allowed multiple problem spaces to be used in solving a single problem, thereby overcoming some of the constraints of the GPS system. Soar was a production system to which learning by chunking and a universal weak method were added. The concept of chunking had existed in previous AI programs where memory organization was studied in terms of chunks, and in learning by adaptive production systems.

Soar represents all long-term knowledge as productions and all short-term knowledge as attribute values. Problem solving is formulated as processing within problem spaces; all goals are generated from architectural 'impasses'; and all learning occurs via chunking.

Soar was to become the central focus of Newell's research for the rest of his life, and it quickly became clear that it had many of the properties required to model human cognition, for the above reasons. This realization prompted Newell to propose Soar as the basis for a unified theory of cognition. He did not mean it to be the fundamental 'theory of theories', but rather a vehicle for him to demonstrate and explore what a unified theory would look like.

Newell's lectures on Soar at Harvard in the late 1980s prompted worldwide research on the topic as a theory of cognition, and Newell took an active role in research on cognitive development, natural language, instruction taking, visual attention, human–computer interaction, and syllogistic reasoning. (*See* **Natural Language Processing**; **Cognitive Development, Computational Models of**; **Visual Attention**; **Human–Computer Interaction**)

NEWELL'S VISION

> What lives is what your scientific descendants must use to solve their problems.

Work still continues today on Soar, but Newell's contribution to the field of AI is broader – indeed, without him, it would not be what it is today. Herb

Simon, himself a giant in the field, had the following to say about Newell:

> He was a person who not only dreamt but gave body to his dream, brought it to life. He had a vision of what human thinking is. He spent his life enlarging that vision, shaping it, materializing it in a sequence of computer programs that exhibited the very intelligence they explained.

Olds, James

Introductory article

Phillip J Best, Miami University, Oxford, Ohio, USA

The discovery by James Olds (1922–1976) of reward systems in the brain was an important advance in our understanding of brain–behavior relationships. Olds later developed new techniques for recording the activity of individual brain cells in freely behaving animals, and used these techniques to study brain activity during learning.

After graduating from Amherst College in 1947, Olds went to Harvard University to study for a Ph. D. in Social Psychology under Talcott Parsons. At Harvard he became interested in animal learning and motivation, and brain mechanisms of behavior. The prevailing view at that time was that of the behavioral theorists like Clarke Hull and B. F. Skinner, who believed that learning occurs because the immediate consequences of a response reinforce a connection between that response and the preceding stimulus. According to Hull's 'drive reduction theory', physiological deficiencies, or needs, produce drives. The responses the animal makes that result in reduction of these drives are reinforced. Responses that do not reduce drives are not reinforced, and would therefore occur less frequently in the future. Responses that result in increased internal drives should result in negative reinforcement, or 'punishment'; and their frequency should decrease rapidly and significantly.

According to this point of view, behavioral theory had no need to hypothesize any internal, 'mental or emotional' processes like thinking or feeling. In fact, such terms were eschewed. Indeed, the behaviorist saw no need to investigate the brain to understand behavioral processes.

An alternative view to strict behaviorism was held by Edwin Tolman, who placed more emphasis on the information processing that should result from experiencing an important event. He also emphasized the significance of 'internal' processes in explaining behavior. Tolman was a visiting professor at Harvard during Olds's graduate career and profoundly influenced his thinking. Olds also liked to think about the brain in his attempts to explain the results of his behavioral experiments.

Olds was also strongly influenced by the writings of Donald O. Hebb, who was the most prominent biological psychologist in North America. One of his professors at Harvard, Richard Solomon, suggested that if Olds wanted so much to study the brain, he should go to Hebb's laboratory at McGill University.

When Olds arrived at Hebb's laboratory, he was assigned to work with a graduate student named Peter Milner on a project to investigate the behavioral effects of electrical stimulation of an animal's brain. Until that time, the most common method for studying brain–behavior relationships had been to examine the behavioral effects of brain damage. Most knowledge of brain function had been learned by inducing lesions in selected brain structures and carefully examining the consequences of the damage on specific behavioral processes: for example, sensory and motor deficits, or changes in arousal, motivation, learning, or memory.

A small number of studies had used electrical stimulation of the brain to study brain–behavior relationships. William Randolph Hess had just won a Nobel Prize for studies showing that electrical stimulation of a certain part of the brain, the hypothalamus, induces aggressive attack behavior. Another group of scientists had discovered that stimulation of another part of the brain, the midbrain reticular formation, induced arousal in sleeping animals. And a group at Yale had reported that stimulation of certain parts of the brain produced fear-like behavior.

Recognizing the value of these new electrical stimulation techniques, researchers at Hebb's laboratory began to study the effects of brain stimulation on behavior. When Olds arrived at McGill, Peter Milner and another student, Seth Sharpless, were studying the arousing effects of electrical stimulation of the midbrain reticular formation. Milner taught Olds how to implant the electrodes in rats.

While testing his first animal, with an electrode aimed at its midbrain reticular formation, Olds noticed that the animal did not avoid the places on the testing table where it had just received stimulation. In fact, the stimulus seemed to reinforce the responses that brought the animal back to those places where it had just been stimulated. Olds was able to use the stimulation to reinforce the animal for moving to any location on the testing

table. He realized that the brain stimulation possessed all of the positive reinforcing properties of natural rewards such as food or water to a hungry or thirsty rat: the animal behaved as if it 'enjoyed' the electrical brain stimulation, rather than finding it aversive.

Later, Olds discovered that the electrode was not after all in the midbrain reticular formation. It was a few millimeters away, in an area of the forebrain known as the septal area. In order to investigate this phenomenon objectively, Olds and Milner implanted other animals, and showed that electrical brain stimulation to the septal area acted as a positive reinforcer for lever-pressing behavior. Their study aroused such interest that it became the most cited paper in the field of psychology for the next two decades.

Soon thereafter, Olds and others demonstrated that electrical stimulation in various areas of the forebrain, notably areas related to the hypothalamus, induced a variety of consummatory behaviors, such as eating, drinking, sex, nest building, and parental behavior. Further, whenever a stimulus was found to elicit consummatory behavior, that stimulus was found to be rewarding. So, when a brain stimulus increased the drive for a consummatory behavior, it was also positively reinforcing. This result contradicted the fundamental premise of drive reduction theory, that reinforcement occurs only when drives are reduced. The results of brain stimulation experiments were so dramatic, and so counter to the prevailing behaviorist tradition, that they led to a flurry of research that produced a paradigm shift in the study of the biological mechanisms of behavior. Thereafter, brain stimulation became a standard method for investigating brain–behavior relationships.

After leaving Hebb's laboratory at McGill in 1955, Olds became a research associate in the laboratory of H. W. Magoun and D. B. Lindsley at UCLA. In 1958 he moved to the University of Michigan, where he and his wife Marianna (Nicky) and their students addressed a number of important questions about the nature of rewarding brain stimulation and its implications for motivation and reinforcement. They mapped the locations of the brain where electrical brain stimulation produced different degrees of reward, and showed that the reward produced by electrical stimulation could far exceed the reward produced by natural biological motivation. The rats would even cross an electrified grid floor to receive the stimulation, or starve themselves in the presence of abundant food when presented with a lever whose depression would result in rewarding brain stimulation.

Olds's group studied the relationship between rewarding brain stimulation, various hormonal conditions, and natural biological motivational behaviors, such as feeding, drinking, and sex. They found significant interactions between the motivational state of the animal and the rewarding effects of electrical stimulation. Stimulation produced the greatest reward in the lateral hypothalamus, a region traversed by the medial forebrain bundle. Lesions in this region had previously been shown to interfere with consummatory behaviors, such as feeding, drinking, sex, and nest building. Stimulation of the sites that produced consummatory behaviors was also generally rewarding.

This research program radically changed the way psychologists thought about motivation, reward, and reinforcement. It has also had a major influence on the study of drug addiction. Many of the areas of the brain where stimulation was found to be especially intense are now known to be the areas where addictive substances produce their highly motivating effects.

In the early 1960s Olds began to consider the limitations of the use of electrical and chemical brain stimulation in the study of brain–behavior relationships. He sought new techniques for recording the activity of individual brain cells in awake, freely behaving animals. Techniques had been developed to record the activity of individual neurons in invertebrate preparations, and some progress had been made in recording from individual brain cells in anesthetized or immobilized vertebrate animals. However, neither of these techniques was suited for recording for very long periods of time, or from individual brain cells in awake freely behaving animals. The only brain recording techniques being used at that time in freely behaving animals were the electroencephalography and multiple-unit techniques which recorded the activity of small clumps of cells but could not distinguish individual cells. Neither of these techniques provided enough resolution for Olds's purpose.

Olds eventually learned that large, blunt, soft, wire electrodes, could record from individual neurons in awake, freely behaving animals for reasonable periods of time. The task was formidable, because the cellular signals were of very low amplitude, the background noise level was generally very high, it was often difficult to distinguish the activity of one brain cell from another, and behavioral movements would often produce electrical signals in the recording wires that were difficult to distinguish from neuronal activity. Olds patiently solved each of these problems by

designing special electronic circuits to analyze the signals and to discriminate between true nerve signals and artifacts. He was one of the first to introduce general-purpose computers into the laboratory to perform real-time, online signal analysis.

His original intention was to use single-cell recording techniques to study brain mechanisms of reinforcement. Since graduate school, he had been interested in the idea that some change in the brain is responsible for changing the likelihood of a response or for increasing the strength of connections between a stimulus and a response or between two stimuli. While searching for the site, or sites, where reinforcement occurred, his early recording studies included the study of motivation and states of arousal. While his laboratory produced an impressive set of studies of cellular changes in different brain areas during changes in motivation and arousal, he was not able to identify the sites where reinforcement occurred. Since his behavioral paradigms typically included a learning component, he decided to investigate regional differences in cellular activity during learning per se. He was the first to show changes in single brain-cell activity during learning in freely behaving animals.

In 1969 Olds moved to the California Institute of Technology, where his research focused on isolating those parts of the brain that were critical for learning. There was particular interest in the hippocampus, because lesions there in humans produced severe memory deficits. Olds's laboratory was the first to report reliable changes in activity in hippocampal neurons during Pavlovian conditioning. He embarked on a large program to study the activity of many areas of the brain simultaneously during Pavlovian conditioning to determine which areas changed the most, which changed the earliest during learning, and which showed the shortest latency response to the stimuli. This program was very successful, making a number of important discoveries, including the discovery that the earliest conditioned changes in brain activity often occurred in sensory pathways.

Before his program had come to complete fruition, James Olds died, apparently of a heart attack, while swimming off Newport Beach, California, in 1976 at the age of 54.

Olds received many awards and honors during his career, including the Newcombe Cleveland Prize of the American Association for the Advancement of Science in 1956, the Hofheimer award from the American Psychiatric Association in 1958, the Warren Medal from the Society of Experimental Psychologists in 1962, the Distinguished Scientist Award from the American Psychological Association in 1967, and the Kittay Prize from the Kittay Scientific Foundation in 1976. He was elected to the National Academy of Science. If his career had not been cut so short he might well have received a Nobel Prize.

Pavlov, Ivan Petrovich

Introductory article

Richard Bowen, Colorado State University, Fort Collins, Colorado, USA

CONTENTS

Ivan Petrovich Pavlov (1849–1936) was a Russian physiologist most famous for his research on the conditioned response. His work provided a firm experimental grounding for many of the concepts currently accepted in psychology.

INTRODUCTION

Ivan Petrovich Pavlov (1849–1936) was a Russian physiologist best known for his groundbreaking studies on 'conditioned responses'. Less well known are his contributions to other aspects of physiology, particularly those dealing with digestive functions. Indeed, it was while studying digestive secretions that Pavlov became interested in the integration of brain and body, which ultimately occupied the bulk of his career. In 1897 Pavlov published his experimental results and generalizations in a book called *Work of the Digestive Glands*, which included defining the role of the brain in control of digestive function. For this work, he became the first Russian and the first physiologist to receive the Nobel prize, which was awarded in 1904.

Pavlov was born in the Russian town of Ryazan. His father was a priest and, as was customary in such situations, when Pavlov came of age, he began studying for the priesthood. While at the seminary he was exposed to texts on physiology and to Darwin's work on evolution, which led him in 1870 to abandon his religious training and enroll in the University of St Petersburg. His first research project as a student involved investigation of pancreatic nerves. Pavlov continued his studies at the Military Medical Academy between the years of 1875 and 1879. He finished his dissertation and earned the degree of doctor of medicine in 1883. Pavlov gained the attention of such prominent researchers as Ludwig, Heidenhain, and Bofkin during the next several years, and was appointed a professor at the St Petersburg Institute of Experimental Medicine in 1895.

PAVLOV AS A PHYSIOLOGIST

Early Career

Pavlov's first independent work focused on the physiology of blood circulation, which began with studies on the influence of variations in blood volume on blood pressure. He also investigated the nervous control of the heart, and argued that four types of nerves controlled the rhythm and strength of cardiac contractions. He came to believe that in order to understand the true physiological mechanisms of an organ, that organ had to be observed as it functioned as a part of the whole body. Towards that end, Pavlov began to use unanesthetized, neurologically intact dogs for his studies, an experimental paradigm that would become the mainstay of his most important accomplishments. Pavlov's methodology involved training dogs to lie calmly on the operating table while he incised the skin and surface tissues, exposed the artery, and connected it to instruments for measuring blood pressure.

Pavlov's second independent work concerned digestive physiology. He started studying digestive processes as early as 1879, and it was his major focus from 1890 to 1897. The bulk of this work also was based on experimentation with dogs, and involved developing fistulas through which secretions from the salivary glands, stomach, pancreas and small intestine could be collected over time. His technique was truly unique in that he did not cut the nerve supply nor contaminate the secretions with food. Among other things, these experiments led to a description of the neural control of pancreatic secretion, the demonstration that chewing and swallowing alone stimulated gastric secretion, and the finding that the types and amounts of secretions from the stomach varied in response to different foods. Finally, and importantly, Pavlov observed that the mere sight of food stimulated secretion from both salivary glands and stomach.

The Salivary Reflex as a Window to the Brain

Pavlov's initial work on digestive secretions confirmed what others had noted: that introduction of food or mild irritants into the mouth led rapidly to the secretion of saliva. He and his students (the 'Pavlovians') subsequently observed that their dogs would also secrete saliva when food was near enough for them to see or smell it. Moreover, the same pattern of salivation was seen when the dogs were shown their empty food bowl, when the person who fed them entered the room, or even when they heard footsteps approaching their pens. Clearly, the cortical regions of the brain were directing such responses, and Pavlov recognized that such 'psychic secretion' provided a unique opportunity to study neural processing in the brain. He felt strongly that understanding higher brain function required a purely physiologic approach, and exhibited substantial disdain for studies by the animal psychologists of his day. In promoting his use of the salivary reflex, Pavlov stated:

> In this manner the investigation of the cerebral hemispheres is brought into line with the investigations conducted in other branches of natural science, and their activities are studied as purely physiological facts, without any need to resort to fantastic speculations as to the existence of any possible subjective state in the animal which may be conjectured on analogy with ourselves.

Investigations on Conditioned Reflexes

Between 1897 and 1936 Pavlov and his associates published more than five hundred papers dealing with conditioning of the salivary reflex. This massive body of work was an extension of his early experience in collecting saliva from conscious dogs in which a salivary duct was surgically diverted to the exterior surface of the skin and the saliva was collected into tubing. The chief advantage of this method over other approaches of the day was that it provided an objective and easily quantifiable end point – Pavlov could measure the time between stimulus and response, and (as volume) the magnitude of the response. Additionally, the stimuli applied to elicit the salivary reflex were of the type encountered every day and thus more likely to reveal normal function than stimuli such as electrical shocks, employed by some other investigators.

Recognizing the necessity of isolating his dogs from all but the stimulus under study, Pavlov arranged for the construction of a building dedicated to his investigations. The animal rooms within this building were soundproofed and allowed investigators to remain hidden behind a wall while collecting saliva, without the dogs being aware of their presence.

Introduction of bread, sand or an acidic solution into the mouth induces secretion of saliva. This is an example of an unconditioned reflex. The sight of food also will induce secretion of saliva; this is called a conditioned reflex or conditioned response because it requires experience. The Pavlovians demonstrated that conventionally raised dogs salivated in response to the sight of bread, but that dogs raised exclusively on milk did not salivate when they saw bread, until they learned to associate bread with something to eat. Development of a conditioned reflex is thus an example of associative learning.

Pavlov and his students performed hundreds of experiments to delineate the prerequisites and characteristics of the conditioned salivary reflex. Most famously, they conditioned dogs so that when a neutral stimulus such as the sound of a beating metronome was allowed to reach the animal, secretion of saliva would commence within a few seconds. In addition to salivating, the dog would also turn its head in the direction from which food was usually presented and begin to lick its lips vigorously, but these responses were difficult to quantify. Eliciting such a conditioned reflex was found to depend on several factors. First, the dog had to be hungry; even after conditioning, a satiated dog failed to secrete saliva in response to the stimulus. Second, the neutral stimulus had to be applied in the correct temporal sequence with respect to the true stimulus. That is, if the metronome (or bell, light or nonfood odor) was presented simultaneously with feeding or after feeding, it subsequently failed to elicit the conditioned reflex. This was demonstrated in numerous experiments. As one example, a loud buzzer was sounded 5–10 s after presentation of food on 374 successive occasions, but in none of these trials did the dog develop a conditioned salivary reflex to the buzzer. In contrast, applying the buzzer shortly before the meal on a single occasion was reported to successfully establish a conditioned reflex. Finally, a conditioned reflex can be lost if the neutral stimulus is applied a number of times without being followed by stimulating the unconditioned reflex (i.e. if the buzzer is sounded several times without presentation of food, the buzzer will ultimately fail to stimulate flow of saliva). Such loss of a conditioned response is called *extinction*.

One of Pavlov's most intriguing demonstrations of conditioned reflexes involved the use of a noxious instead of neutral stimulus. Unconditioned dogs respond to the prick of a needle by withdrawal, as one would expect. Pavlov demonstrated that dogs conditioned to a needle prick followed by food not only developed a normal conditioned salivary response, but did so without aversion to the needle prick.

CONTRIBUTIONS TO PSYCHOLOGY AND NEURAL SCIENCE

Pavlov began his work on conditioned reflexes at a time when much attention was focused on understanding brain function, with little progress to show for it. This period also coincided with the beginnings of psychology as a separate discipline, and psychologists frequently constructed elaborate theories of mental function without constraint by or support from experimental observations.

Signalization: Establishing a Conditioned Reflex

The concept of a reflex was recognized well before Pavlov began his work, but he was the first to apply rigorous experimental analysis to its understanding. He considered that unconditioned reflexes were the result of inborn connections in the nervous system, which enabled an innate coupling between stimulus and response. Complex unconditioned reflexes were equated to instincts. Conditioned reflexes, in contrast, required establishment of new connections within the brain; another name Pavlov used for these was 'acquired reflexes'.

Pavlov's greatest contribution was in developing the concept of *signalization*, and proposing its role in behavior and survival. Conditioned reflexes are established within cortical regions of the brain as alternative pathways to invoke preexisting unconditioned reflexes. An example of signalization in Pavlov's dogs was when the sound of a buzzer was sensed, propagated through the auditory nerve to the cortex, then relayed to nerves innervating the salivary glands, leading to secretion of saliva. A connection was thereby established between the environment and the unconditioned salivary reflex. Pavlov referred to signals from the environment as 'first signals', to distinguish them from language ('second signals'), which he considered a special case of great importance to humans. He explained signalization using a telephonic analogy:

> My residence may be connected directly with the laboratory by a private line; and I may call up the laboratory whenever it pleases me to do so; or on the other hand, a connection may have to be made through the central exchange. But the result in both cases is the same. The only point of distinction between the methods is that the private line provides a permanent and readily available cable, while the other line necessitates a preliminary central connection being established. In one case the communicating wire is always complete, in the other case a small addition must be made to the wire at the central exchange.

Unconditioned reflexes, particularly in chains, lead to behaviors. Signalization and conditioned reflexes allow sophisticated behaviors, including habits, to develop. By careful scientific study of the simple salivary reflex, Pavlov thus contributed a crucial insight to psychology.

A Darwinian View of Signalization and Conditioned Reflexes

Pavlov was influenced deeply by Darwinism and recognized that innate, unconditioned reflexes were critical for survival in any environment. The unconditioned reflex of withdrawing from fire rather than being attracted to it clearly contributes to fitness. However, because the environment is constantly changing, fitness can be greatly enhanced if organisms are endowed with the ability to form temporary connections in the brain that allow alternative pathways to invoke innate reflexes. Such temporary connections are, of course, the embodiment of Pavlov's signalization theory. Smelling smoke or seeing the glow of an approaching fire act essentially as neutral stimuli to condition animals to avoid fire. All in all, conditioned reflexes are of great adaptive significance, allowing animals to avoid predators, seek out mates, and find food.

CONCLUSION

Ivan Petrovich Pavlov was a self-proclaimed physiologist whose work ultimately had the most profound effects on psychology. Through intense study of salivary reflex conditioning, he and his students provided a firm experimental grounding for many of the concepts familiar to psychologists and neural scientists today and led the way toward scientific study of the brain.

Penfield, Wilder

Introductory article

Louise Fabiani, Montreal, Quebec, Canada

CONTENTS

Wilder G. Penfield (1891–1976), the founder of the Montreal Neurological Institute, possessed a rare talent for combining science and medicine in the study of the human brain. This approach made many advances possible, including the mapping of the human cerebral cortex, improvements in neurosurgical technique, and developments in the treatment of epilepsy and other neurological diseases.

BEGINNINGS

Wilder Graves Penfield was born in January 1891 in Spokane, Washington, USA. His father, Charles Penfield, was a physician at the time of Wilder's birth. However, a few years later he gave up his practice to answer 'the call of the wild'. The result was a separation from Wilder, his brother Herbert, his sister Ruth and their mother Jennie (née Jean Jefferson). In 1899, Charles Penfield moved to California to live in the woods, by hunting and fishing, while the rest of the family moved to Wisconsin, where Jennie's family lived.

Before long, both older siblings moved away to marry, leaving Wilder and his mother. The two were very close, and both attached a high value to religion, family, hard work and the greater good.

When Wilder was still a boy, Jennie encouraged him to aim for a Rhodes Scholarship. After graduating with a philosophy degree from Princeton University in 1913 with excellent grades and a fine record as a football player, Wilder did win the coveted prize on the second attempt. However, the First World War disrupted his plans and he did not commence his studies in Oxford, England, until 1915, after a brief stint at Harvard University and some volunteer work in the medical corps in France. Following many bouts of indecision, he eventually settled on medicine, the profession that had been practised by his grandfather and abandoned by his father.

The ship on which Wilder sailed back to England in 1915 was torpedoed by the Germans. His leg was shattered, and during the long period that it took to heal, he convalesced in the home of the famous Canadian physician, Sir William Osler, who was living in Oxford. Osler was considered to be the first Canadian neurologist, and he became one of Wilder's first mentors.

In 1917, Wilder Penfield married Helen K. Kermott, who was herself the daughter of a physician. They had four children: Wilder Jr, born in 1918, Ruthmary, born in 1919, Priscilla, born in 1926 and Amos Jefferson ('Jeff'), born in 1927.

After finishing his medical training in 1918 at Johns Hopkins University in Baltimore, Maryland, Wilder decided on a career in surgery. As an intern at the Peter Bent Brigham Hospital in Boston, Massachusetts, he focused on neurosurgery. His first job was in New York City.

Although he was to spend decades in medicine, Penfield devoted those early years to basic science – neurocytology and neuropathology. Curious about the most fundamental causes of epilepsy, he traveled to Spain and Germany, where he studied tissue-staining techniques with renowned neuroscientists. From those early experiences he retained an appreciation of the discipline of scientific research, as well as the spirit of collaboration. He was to become that rare kind of generalist – a physician who carefully observed and gathered data, a scientist who studied disease but who never forgot about human suffering.

A STRONG WILL AND A GENEROUS SPIRIT

In 1924, while working in New York, Wilder Penfield met William Cone, a fellow surgeon. The two were to become close friends and collaborators for 36 years, often performing the same operation. When Penfield and his family moved to Montreal in 1928 at the invitation of Edward Archibald, the director of the Royal Victoria Hospital (RVH), Cone went with him.

At the RVH, Penfield hoped to realize his dream of an institute where medical practice and research could go hand in hand. He discussed the concept with Archibald, and began to contact various philanthropists for building and maintenance funds. The combination of surgical practice, spending time with his growing family, and all that fundraising meant that he was a very busy man.

In 1934, the Montreal Neurological Institute and Hospital (MNI) officially opened. Penfield was its first director. At the MNI, those who worked with patient care communicated with those in research, who were in turn interdependent. Not only did this make sense from a strictly practical viewpoint (as the study of the brain is one of the most complex fields of research in the world, those who are working on a specific aspect of the subject depend heavily on each other), but also cooperation was good for morale. Penfield's strength of will, generous spirit and collaborative idealism energized the institute from the very beginning. Very soon, news of the MNI's successes spread around the world. Patients – and hopeful neurologists – flocked to Montreal.

Penfield would be neither slowed down nor dissuaded in the pursuit of his vision. In the building itself, which grew from a sketch he had made on scrap paper, his mark was everywhere. Careful floor specifications accounted for research facilities, wards and even the placement of the research-animal rooms (on the upper floors, with access to light and fresh air). An art lover, he also chose the Art Nouveau look of the lobby. The ceiling, which was decorated with pictures of ganglia, featured a ram's head (the sign of Aries is associated with the brain) encircled with Egyptian hieroglyphs. The cast-iron lampstands resembled spinal columns. The names of famous neuroscientists were inscribed along the top edge of the walls, and the centerpiece was an impressive white marble statue. (Years later, when a new wing opened in 1951, Penfield commissioned one of his operating nurses, Mary Filer, to paint a mural called 'The Advance of Neurology', which depicted Penfield, Osler, Hippocrates and other luminaries.)

One of Penfield's earliest and most difficult operations at the MNI was on his own sister. Ruth Inglis had suffered from headaches and 'spells' (epileptic events) since her teens. Decades later, the pain became unbearable. It was found that she had a brain tumor. Unless it was immediately removed, it would cause blindness and then death. Penfield was forced to break the medical taboo against treating close relatives, and in fact there was no better team for performing the dangerous operation. Penfield and Cone had to cut out part of Ruth's frontal lobe before they reached the tumor. To their amazement, Ruth lived – and with little impairment. (However, her brother did notice the signs of frontal lobe damage. For example, she no longer seemed able to plan and coordinate household duties.) Although the tumor eventually killed her, Penfield's risky procedure gave her an extra two years of life. (*See* **Frontal Cortex**; **Epilepsy**)

THE 'LITTLE MAN'

Researchers working on animals in the nineteenth and early twentieth centuries discovered that if they stimulated the open brain with a mild electrical current, a limb moved, for example, on the opposite side of the body. That is, a right-brain stimulation led to a left-body movement, and vice versa. Later, neurosurgeons applied the same technique in conscious patients (the brain itself cannot feel pain). In his search for epileptic foci (i.e. specific points in the brain that would cause seizures), Penfield began to detect patterns in patients' reactions to particular types of stimulation.

Penfield's 'Montreal procedure' came to associate function with location (functional neuroanatomy), depending on which side of the central sulcus was being tested. When the pre-central gyrus was stimulated with a light electrical current, Penfield detected a muscle twitch in a particular site on the opposite side of the body – for example, the big toe moved. On the post-central gyrus, a similar current provoked sensation, such as tingling, again in a specific site. Many patients and many painstaking trials later, Penfield and his associate, Theodore Rasmussen, were able to draw the body part most commonly associated with each stimulated point in the cortex. More sensitive areas, such as the thumb and lips, were disproportionately large (i.e. compared with the representations from less sensitive areas.) Linked together, the drawings formed two representations of the human body (motor and sensory). Each roughly drawn 'little man' was a homunculus – the brain's map of the body surface. (*See* **Cortical Map Formation**)

Penfield was forever indebted to the brave patients who responded to his tests. The resulting map was indispensable for neurosurgeons, as it enabled them to operate with minimal risk of damaging the primary motor cortex.

MORALS AND MIND

In the early 1950s, with his first career winding down, Penfield became yet another of a long line

of physicians to try his hand at fiction. He eventually published two novels. In 1960, he handed over the directorship of the MNI to Theodore Rasmussen and embarked on a second career of writing and travel. With family friends, Georges Vanier, the Governor-General of Canada, and his wife Pauline, Penfield co-founded the Vanier Institute of the Family, which was set up as a research and funding agency for the study and promotion of the solid values with which he was raised – values that seemed to be in jeopardy during the permissive 1960s. Penfield also accepted invitations to be a Canadian goodwill ambassador to many countries around the world.

Just before his death in April 1976, he completed two last books of non-fiction. One of them, *The Mystery of the Mind*, examines possible explanations for the relationship between mind and brain. Penfield had observed the numerous ways in which the mind – personality and behavior – could be radically altered by brain injury, surgery or disease (e.g. his sister's postoperative changes). Philosophically, he was a dualist – he regarded the mind and the brain as separate, although related. Decades of neurological study jostled with even older beliefs. At the contemplative end of his life, the spiritual won over the material. He concluded that the greatness of the human mind and the mystery of the soul could not be reduced to the activity of neuronal tissue – a thought-provoking opinion from one of the most famous neurosurgeons ever to have lived. (*See* **Cognitive Science: Philosophical Issues**; **Consciousness, Cognitive Theories of**; **Consciousness, Philosophical Issues about**; **Mind–Body Problem**; **Neural Correlates of Consciousness as States and Trait**; **Philosophy of Neuroscience**; **Philosophy of Mind**; **Dualism**)

SUMMARY

Wilder Penfield was one of the twentieth century's most outstanding neurologists, neurosurgeons and scientists. Under his leadership, the Montreal Neurological Institute, which he founded in 1934, became a place where science and medicine combined harmoniously. Penfield's search for an effective treatment for epilepsy motivated him to study the brain at many levels – from cellular to anatomical – and led to the development of the Montreal procedure. Through various specific electrical stimulations of the exposed brain, a sensory–motor map of the body surface could be drawn.

Piaget, Jean

Introductory article

Kurt Fischer, Harvard Graduate School of Education, Cambridge, Massachusetts, USA
Ulas Kaplan, Harvard Graduate School of Education, Cambridge, Massachusetts, USA

CONTENTS

Jean Piaget, one of the founders of cognitive science, established that children build their intelligence through acting in the world and that they develop through a sequence of qualitatively different organizations of thought and action. He related the diverse fields of human knowledge to the developing minds of children.

INTRODUCTION

Jean Piaget helped lay the groundwork for cognitive science in the twentieth century and became one of the best-known and most influential cognitive scientists. The enormous body of research and theory that he created continues to drive many of the central questions about the mind today, especially how it develops and takes different forms. He studied how infants and children construct knowledge of objects and events in the physical world, investigating with his many collaborators a wide array of tasks and concepts. His own label for his approach was *genetic epistemology*, the study of the development (genesis) of knowledge in its diverse forms (epistemology). His most famous research involved two phenomena: (1) conservation – understanding what conserves, or remains constant, when an object is changed, such as when a clay ball is reshaped into a sausage, and (2) object permanence – understanding that an object continues to exist even when it is not perceived. However, he studied scores of other developmental phenomena, covering most topics in epistemology of the physical world.

KNOWLEDGE: ACTIVITY, DEVELOPMENT, AND LOGIC

Piaget showed in all these domains how infants and children build their own skills and knowledge: 'Comprendre, c'est inventer' ('To understand is to invent'). The most important organizing concepts in his work were: (1) knowledge is based in activity: people actively transform objects and events in order to know them; (2) these activities develop systematically through a series of qualitatively different patterns, which can be characterized as stages; (3) logic is the basic organizing force behind the mind, and the most clearcut stages involve distinct forms of logic in action. Piaget's theoretical work focused primarily on characterizing (a) the forms of logic that organize the mind as children develop, and (b) the processes of change that regulate children's developing activities, which he called *equilibration*. He also worked with scholars from many disciplines with the goal of capturing the whole array of human knowledge. (*See* **Piagetian Theory, Development of Conceptual Structure**)

PIAGET'S DEVELOPMENT

Jean Piaget was born in Neuchâtel, Switzerland, on 9 August 1896, as the oldest child of Rebecca Jackson and Arthur Piaget. He was a precocious child, showing an early interest in biology and publishing at the age of 11 his first article, on an albino sparrow. He studied mollusks during his adolescence, assisting the director of a natural history museum in Neuchâtel. As a result of his publications about mollusks, he became a well-known zoologist by the end of high school.

He went on to study natural sciences at the University of Neuchâtel and received his PhD at the age of 21 based on a study of mollusks in Swiss lakes. Meanwhile, his interdisciplinary interests developed from an early age, fostered by his father (a professor of medieval literature) and godfather Samuel Cornat, who stimulated his interest in philosophy, religion, and logic. He became intensely involved from an early age with not only biology but also psychology, logic, epistemology, philosophy of science, and religion, and published two

papers in philosophy. One of his early goals was to find a source of absolute truth, ranging from religion to logic. After his graduation in 1918, he studied psychoanalysis and experimental methodology at the University of Zurich, and then went to Paris to study at the Sorbonne. He came into contact with the new intelligence-testing movement founded by Alfred Binet and Théodore Simon, and under Simon's supervision he devised and administered tests to schoolchildren.

Errors and Qualitative Changes in Development of Intelligence

In this period, he became interested in the errors that children make in performing cognitive tests. Much of his future work built on using these errors to infer children's strategies of acting and reasoning. He found that at specific ages children share certain distinctive strategies as evidenced by their systematic errors, and that those strategies change regularly with age. What matters in intelligence is less the number of correct responses than the type of reasoning. As evidenced by children's errors as well as by their correct responses, older children do not merely know more, but they act and think differently from younger children, showing qualitative changes in intelligence. One of Piaget's major focuses for the rest of his career was characterizing the nature of these qualitative changes in intelligence, along with the mechanisms of change.

Piaget was a brilliant observer and had a great eye for insightful collaborators. He and his colleagues discovered hundreds of strategies and errors in children's activities that initially surprised people and eventually captivated the interest of cognitive scientists and educators. These observations convinced many people that children's knowledge is based in their own activity and undergoes powerful reorganizations with age. Piaget viewed children as having a logic of their own by which they actively construct their world, deriving all knowledge from their actions. Children's minds are not merely immature versions of the adult mind, but they operate with distinct principles based in earlier, less sophisticated logic. Children have fundamentally different ways of making sense of the world, and at different periods of life they create qualitatively distinct mental structures to make sense of their activities and experiences. Infants begin by building a logic of direct action on the world, what Piaget called *sensorimotor* intelligence. Eventually they build such complex action systems that they create concrete representations of objects at about age two (*preoperational* intelligence). By six to eight years children construct a logic of *concrete operations* on objects, events, and people. Operations are mental actions that can be done both in the mind and on the real world. Building on this concrete logic, children of 10 to 12 years invent a formal, hypothetical logic that Piaget called *formal operations*, which has much in common with the rational logic of scientists and mathematicians.

Building the Foundation for Genetic Epistemology

In 1921, Piaget became the director of the Jean-Jacques Rousseau Institute in Geneva, which had been founded by his mentor Édouard Claparède. In 1923 he published his first book, *Le langage et la pensée chez l'enfant* (*Language and Thought in the Child*), based on his talent at interviewing schoolchildren about their understanding of phenomena in the world.

In the same year he married Valentine Châtenay, who herself was a talented psychologist and observer of children. The couple had three children: Jacqueline, born in 1925, Lucienne in 1927, and Laurent in 1931. Jean and Valentine observed their children's development intensively in the natural context of their home. Building on earlier work by James Mark Baldwin, Paul Guillaume, and others, they kept detailed diaries of their observations and created many seminal tasks that formed the foundation for major paradigms in cognitive science, such as object permanence (search of hidden objects), the logic of movement in space, and verbal imitation. In this way, consistent with Piaget's general approach, he built his own knowledge of human development through his and his wife's activities with their children – an interaction between theory and nature.

Piaget considered his early publications, including his first five books, to be working papers, not finished scientific documents. His and Valentine's observations with their infants produced the beginnings of his theory as it is known today. He first presented the new conception of infant development in a paper to the British Psychological Society in 1927, which was elaborated in three seminal books, *La Naissance de l'intelligence chez l'enfant* (*The Origins of Intelligence in Children*) (published in 1936), *La Construction du réel chez l'enfant* (*The Construction of Reality in the Child*) (1937), and *La Formation du symbole chez l'enfant* (*Play, Dreams, and Imitation in Childhood*) (1945). These works not only described a series of stages of cognitive

development in infancy and early childhood, but more importantly, according to Piaget in his 1936 book *The Origins of Intelligence in Children*, they taught him 'in the most direct way how intellectual operations are prepared for by sensorimotor action, even before the appearance of language'. Among his many important collaborators in later work were Bärbel Inhelder and Alina Szeminska, who helped to formulate explanations of the later stages of intelligence – concrete and formal operations.

PIAGET'S FRAMEWORK AND THE BREADTH OF HUMAN KNOWLEDGE

Piaget saw himself not primarily as a psychologist but as a genetic epistemologist, a scientist who studies the origins and development of human knowledge by combining biology and logic. He sought to uncover the nature of the growth of human knowledge, not only in children but in history. At the center of his framework, he saw an individual actively and continuously making sense of the world: 'I am a constructivist. I think that knowledge is a matter of constant, new construction, by its interaction with reality, and that it is not pre-formed. There is a continuous creativity.' By acting on the world, whether on material objects or on other social beings, people are constantly adapting to the world they live in and simultaneously creating their own reality. Piaget emphasized that simultaneously (a) individuals actively construct their own worlds, and (b) they interact constantly with the world in this construction, adapting their knowledge to their experience.

In his effort to integrate philosophical questions about human knowledge with empirical questions about human development, Piaget emphasized the unified structure and functioning of the human mind in an era of emphasis on the fragmented nature of human knowledge, led especially by behaviorism. He created an empirically based, epistemological breakthrough connecting philosophy to cognitive science and the development of intelligence. In particular, he explicated the development of knowledge in terms of key philosophical and scientific categories, starting with object, space, causality, and time in the three books based on his own children's development and moving on to incorporate quantity (number), classes, relations, scientific experimentation, and of course logic. He also examined in depth the structure and growth of human knowledge in human history and across knowledge disciplines, although his work with children is more famous. According to Piaget, individual development connects closely with species development, with intriguing parallels in which individual development sometimes follows historical development and sometimes reverses it. The development of a human being is a reflection of the development of humankind. At the heart of this parallelism is people's active construction of knowledge and reality, which creates qualitative transformations of activity and knowledge in order to adapt to the richly varying world.

In 1955 Piaget founded the International Center for Genetic Epistemology in Geneva, Switzerland, to support his search for the origins and growth of knowledge, and he directed the Center until his death in 1980 in Geneva. He led a group of scholars from different disciplines, including psychologists, philosophers, mathematicians, logicians, scientists, and historians of science, to build his vision of the unity of knowledge. Experts would come to the Center to collaborate, often staying for a year and participating in seminars led by Piaget. To master the basic concepts and framework in the discipline chosen for that year, Piaget himself worked intensely to make connections with genetic epistemology. According to Gardner in his 1982 book, *Art, Mind, & Brain*, he was 'pursuing his own religion – the passion for truth, the search for the totality of knowledge'. In 1967, he published *Logique et connaissance scientifique* (*Logic and Scientific Knowledge*), an encyclopedia surveying all the sciences from the viewpoint of genetic epistemology, and for the rest of his life he continued to publish books and articles to fulfill this vision.

With his focus on the breadth of epistemology, Piaget came late in his life to abstain from debates about psychological questions, such as stages and mechanisms of cognitive development, even while his 95 books and hundreds of articles were powerfully shaping the core questions and concepts of psychology, cognitive science, philosophy, and education. At the same time, he defined the limitations of his own explanations of intelligence, suggesting in the posthumously published book *Le possible et le nécessaire* (*Possibility and Necessity*) and elsewhere that, contrary to his earlier hypotheses, intelligence is not founded in logic but instead constructs logic as one of its greatest accomplishments, building on practical activities to eventually create the soaring possibilities of human intelligence.

CONCLUSION

Piaget established one of the central frameworks in cognitive science, including the propositions that

people build knowledge through acting in the world and that children develop through a sequence of powerfully different forms of intelligence before they reach adulthood. He helped bring together the many disciplines relevant to mind and knowledge, moving the field away from narrowly defined disciplines. He created an agenda for understanding mind and knowledge that continues to drive a wide range of research today, especially in cognitive development, learning, psychology, philosophy, cognitive linguistics, and education. Arenas in which great progress remains to be made include analyzing the dynamic processes of cognitive growth, characterizing the fundamental structures of knowledge in general as they extend beyond logic and science, and connecting knowledge and intelligence more effectively to biology, including both brain and body.

Sapir, Edward

Introductory article

Regna Darnell, University of Western Ontario, London, Ontario, Canada

CONTENTS

Edward Sapir (1884–1939) was the foremost linguist among the first generation of North American anthropologists trained by Franz Boas. His work on American Indian languages, linguistic relativity, and culture and personality defined the scope of linguistics within anthropology.

INTRODUCTION

Edward Sapir, a member of the first generation of students of Franz Boas who came to dominate North American anthropology during the first three decades of the twentieth century, was the primary linguistic specialist among these pioneering students of American Indian languages. His humanistic view of language also led him to consider the creative role of the individual in culture and society.

Sapir was born in Lauenberg, Pomerania (now Germany), in 1884, but grew up on the Lower East Side of New York City where his father was a cantor. He obtained a prestigious Pulitzer scholarship which paid his way to Columbia University. After obtaining his first two degrees in Germanic linguistics, Sapir switched to anthropology, purportedly because Boas convinced him of the urgency of recording endangered Native American languages. He obtained a BA degree in 1904, an MA in 1905, and a Ph.D. in 1909 with a dissertation on the Takelma language of Oregon.

First-hand field work was the basis of the Boasian paradigm, in both linguistics and ethnology. Accordingly, Sapir spent the years 1907 and 1908 in California doing fieldwork on Yana, and the years from 1908 to 1910 at the University of Pennsylvania where he worked on Ute and Southern Paiute, before accepting a position as the first Director of the Anthropological Division of the Geological Survey of Canada (part of the Department of Mines). He chose to specialize in the languages of the Northwest Coast, although the program of his division was designed to cover the entire Dominion of Canada.

Despite his growing dissatisfaction with museum work, the impossibility of securing a teaching position in Ottawa, and reductions in funding for research and publication during the First World War, Sapir remained in this position until 1925 when he moved to the University of Chicago. There he became increasingly involved in an interdisciplinary social science synthesis funded by the Rockefeller Foundation and primarily focused on sociology, psychology and psychiatry. Sapir, who insisted that anthropology should study everyday life in North America as well as the exotic and primitive, became the primary translator and synthesizer across these diverse disciplines. In 1931 he moved to Yale University to organize an interdisciplinary seminar for foreign fellows on 'the impact of culture on personality'. At Yale, he developed a school of linguistics which emphasized meaning and process. Although troubled by declining health and by anti-Semitism at Yale, Sapir remained there until his death in 1939 at the age of 55.

AMERICAN INDIAN LANGUAGES

Sapir is remembered within anthropological linguistics primarily for his production of grammars, texts and dictionaries based on his first-hand fieldwork with a series of American Indian languages. Although much of his work was incomplete at the time of his death, the diversity of the languages he studied – Wishram Chinook, Takelma, Chasta Costa, Yana, Kato, Catawba, Ute, Southern Paiute, Hopi, Nootka, Comox, Mohawk, Seneca, Tutelo, Delaware, Abenaki, Malecite, Micmac, Montagnais, Cree, Tlingit, Nass River, Kootenay, Thompson River, Lillooet, Shuswap, Okanagan, Haida, Tsimshian, Sarcee, Ingalik, Kutchin, Navajo, Hupa, Yurok, and Chimariko – provided him

with an extensive database for historical comparative work; this combined with an intuition for language which was called 'genius' by his contemporaries and successors alike.

In 1916, Sapir published a paper called 'Time perspective in Aboriginal American culture: a study in method', which exemplified the Boasian approach to reconstruction of cultural history using examples from some 60 (mostly Amerindian) languages. Sapir demonstrated by the diversity of these miniature analyses that language was more amenable to historical inference than the rest of culture, and that this enabled the student to distinguish between common past history and borrowing. (Boas himself rejected this distinction. His position diverged increasingly from Sapir's as the latter turned to historical inference as a framework for ethnology.)

Based on his own fieldwork, supplemented by that of other Boasians, especially Alfred Kroeber in California, by 1921 Sapir had reduced the 55 linguistic families of North America codified by the Bureau of American Ethnology in 1892 to six superstocks that he thought could be correlated with broad continental migration patterns. Within each of these larger units, Sapir distinguished more conservative subgroups. American anthropologists followed the Sapir classification as a framework for ethnology at least until 1963. Although current classifications tend to be more conservative, many of Sapir's broadest generalizations still preoccupy his successors.

Sapir's only book, *Language: An Introduction to the Study of Speech* (1921) was directed at a popular as well as an academic audience. His dependence on American Indian examples was virtually unique in the Indo-European-based linguistics of the day, and emphasized his anthropological commitment to the equal value and communicative capacity of all human languages.

LINGUISTIC RELATIVITY

Sapir followed his teacher Boas in insisting that the grammatical categories of familiar languages like Greek and Latin could not be applied to unrelated languages. Rather, each language and language family had to be analyzed in terms of its own unique categories. Moreover, Sapir was determined to incorporate the 'psychological reality' of a language for its speakers into his linguistic analysis. He defined the concept of the phoneme, the smallest meaningful unit of sound in a given language, in 1925 and in 1933 he elaborated on the basis of this linguistic distinction in the perceptions of native speakers. The objective character of sounds across languages was less important than their patterning within a single language at a given moment in time. This focus on meaning as construed by native speakers of a language foreshadowed the abstract post-Chomskyan linguistics that has dominated the discipline since the mid-1960s. In contrast, Boas and many of his students within anthropology continued to insist on recording sounds in as much detail as possible using a phonetic grid assumed to apply across languages.

Although the so-called Sapir–Whorf hypothesis of linguistic relativity is best known through the formulations of Sapir's student Benjamin Lee Whorf, many passages in the work of Sapir, and indeed of Boas, share the common-sense assumption that the categories of language influence the way native speakers think about the world around them. Stated in this rather weak form, linguistic relativity seems almost trivial. On the other hand, the strong claim that language determines thought cannot be demonstrated in any fully convincing way.

After Sapir's death in 1939, North American structural linguistics, under the influence of Leonard Bloomfield, moved away from the study of meaning. Even many of Sapir's former students moved towards a more behaviorist and positivist notion of both language and culture. Whorf's accounts of the vast differences between the grammatical cateogies of Hopi, based on his own fieldwork, and what he called 'Standard Average European' were less persuasive in the changed intellectual climate. Efforts to prove or disprove the Sapir–Whorf hypothesis by scientific means produced ambiguous results, leading the linguistic relativity hypothesis itself to fall into disrepute. Neither Sapir nor Whorf, however, understood linguistic relativity as a scientific hypothesis. Rather, it followed from Boasian cultural relativism that each culture, and language, should be understood first in its own terms. Only thereafter could translinguistic insights emerge from what Whorf called 'multilingual awareness.'

Recent returns to questions of linguistic relativity within cognitive linguistics, especially in the work of Stephen Levinson and John Lucy, cite Sapir and Whorf as significant precursors, but have shifted the focus of the argument away from Boasian preoccupations with differences across cultures and languages. Working in a post-Chomskyan linguistic context, they frame linguistic differences within universal grammatical constraints that seem to belie the very diversity that was the original reason

for conceptual relativity in the study of particular languages.

CULTURE AND PERSONALITY

From about 1910, Boasian anthropology began to turn from reconstruction of American Indian cultural histories towards the study of meaning for the individual; what Boas called 'psychology' was later 'called culture and personality'. Sapir preferred to speak about the influence of culture on personality, i.e., how the individual acquired a language already codified within his or her speech community while still retaining a creative ability to modify that language. Sapir was among the first to acknowledge the diversity of individual personalities and social positions within a single society, foreshadowing sociolinguistics and the ethnography of communication.

Few anthropologists or linguists have matched Sapir's extraordinary range of interests, which included American Indian languages, linguistic theory, historical linguistics, the individual in culture, psychology and psychiatry, life history, and folklore. (He also wrote poetry and composed music.) For Sapir, these interests were clearly integrated. For example, working closely with a small number of linguistic consultants on native language texts that expressed their point of view on cultural matters encouraged him to attend to differences between individuals and to consider how all native speakers had somewhat different perceptions of the common culture. Like Boas, Sapir trained consultants to write their own languages and record texts during his absence from the field. This Boasian text tradition encouraged use of the same texts as a database for linguistic, cultural and psychological analysis. Sapir defined culture in terms of symbols in people's heads; his ethnography, compared with that of his contemporaries, relied heavily on linguistic codifications of world views. The 'native point of view' was implicit in the texts.

ANTHROPOLOGICAL LINGUISTICS

Throughout his career, Sapir's professional identity oscillated between anthropology and linguistics. He approached the study of culture as a linguist, focusing on the words and connected texts produced by native speakers of American Indian languages. He approached the study of language by asking questions about the role of culture and socialization in forming the thoughts and actions of individuals: meaning, for him, was culturally constituted rather than universal, at least in its surface forms. Moreover, to the consternation of those linguists who assumed that civilization was a prerogative of literate cultures, Sapir insisted that the insights of Indo-European linguistics could be applied to the study of unwritten languages. Despite the absence of writing, sound changes and other historical processes operated in the same systematic way in American Indian languages. The cultural relativism of Sapir's anthropology, as expressed in Ruth Benedict's *Patterns of Culture* in 1934, applied also to the study of linguistic form.

After his return to academia in 1925, Sapir trained students in both linguistics and cultural anthropology, without apparent disjuncture. The anthropology students were exposed to Sapirian linguistics and the linguistics students worked on American Indian languages, with many of them pursuing careers in anthropology departments.

Sapir was an important figure in the genesis of linguistics as an independent professional discipline, arising from literature and language departments as well from anthropology. He was a founding member of the Linguistic Society of America in 1925 and the paper in which he defined the phoneme appeared in the first issue of its journal *Language* in the same year. Sapir's stature in theoretical as well as descriptive linguistics reinforced the links between the two disciplines. On the one hand, linguists increasingly acknowledged that an adequate science of language could not be based solely on the study of Indo-European languages. On the other hand, language provided anthropologists with their best means of access to unfamiliar cultural worlds. For anthropologists, language has remained the symbol system *par excellence*, although the technical skills of the linguist have become less accessible to most cultural anthropologists. Within both disciplines, Sapir remains the single most significant figure linking linguistics and anthropology in method, theory, and practice.

Saussure, Ferdinand de

Introductory article

W Terrence Gordon, Dalhousie University, Halifax, Nova Scotia, Canada

CONTENTS

Ferdinand de Saussure (1857–1913) is generally acknowledged as the father of modern linguistics. Observations and speculations about human language form a long tradition of philosophical inquiry dating back to antiquity, but it was Saussure who first focused on the systematic nature of language, thus launching twentieth-century linguistics and making it possible to put the discipline on a scientific footing.

INTRODUCTION

Nearly a century after Saussure's first contributions to linguistics, the discipline has passed through various phases of development and expansion which have changed its goals and terminology, although systematicity and the scientific orientation remain at its core. In North America, linguistics in the first half of the twentieth century was dominated by a structuralist approach refined by Leonard Bloomfield (who wrote a positive review of Saussure). Since the 1960s, the North American brand of linguistics has been dominated by transformational generative grammar and its manifold developments and reactions to it. Noam Chomsky's initial comment on Saussure's linguistics was that it focused on systems of elements rather than systems of rules. It is this distinction between the goal of descriptive adequacy (Saussure) and explanatory adequacy (Chomsky) that separates Saussure's linguistics from the dominant note in linguistics today.

Born into a Swiss family that had already produced generations of distinguished scholars, Saussure made his first mark at the age of 21 with a treatise demonstrating that proto-Indo-European (the source of a vast family of languages of Europe, India, and southwest Asia) did not have just three vowels, as had been widely supposed, but five. Saussure began his university teaching career in Paris in 1880, but returned to his homeland in 1891 to accept an invitation to teach at the University of Geneva. It was only late in his career that he agreed to give a course of lectures in general linguistics. This he did between 1906 and 1911, modifying the course from year to year without ever satisfying himself it was complete or worthy of publication. When he died in 1913, those who had followed his lectures thought otherwise, and collated and edited their own notes to produce the *Course in General Linguistics*, which has been in print ever since. The original French text has been translated into more than twenty languages.

The *Course in General Linguistics* has a profound coherence that is achieved by using a set of pairs of basic terms as an organizational principle. The terms of each pair relate to each other, each pair relates to the other pairs, and the entire set relates back to the concept of the linguistic sign. ('Sign', in this sense, refers to anything that tells us about something other than itself; the sign can be a word, a part of a word that carries meaning (the *-ly* in *quickly*, for example), or a group of words making up a complex sign (*do it quickly*).)

LANGUAGE AND SPEECH

Saussure defined the linguistic sign as belonging to language, the system of elements that speakers of a given language know and use. The sounds that actualize a sign belong to speech; i.e. not to system *as* system but in use. Saussure did not invent these terms of course, but he saw the first to insist that linguistics needed to be grounded in the distinction, in order to avoid the errors of scholarship that he thought characterized so much of the work of his predecessors.

SIGNIFIER AND SIGNIFIED

The terms 'signifier' and 'signified' designate the two parts of the linguistic sign for Saussure. The

signifier is a mental image of a recurring unit (usually a short sequence of sounds) that allows a language user to put that element of the language system to use. The signified is the concept connected to the signifier. In the original French, the terms are *signifiant* (literally translated as 'signifying') and *signifié* ('signified'). What may at first appear to be a potentially confusing terminology is, in fact, a reminder both of the necessary distinction between the two parts of the linguistic sign and of the distinction between those parts and the sign as a whole.

SYNCHRONIC AND DIACHRONIC ANALYSIS

The terms 'synchronic' and 'diachronic' describe two fundamentally different ways of analyzing language. Saussure emphasizes that a complete description of language in general or of any particular language must take account both of the community that uses it and of the effects of time on the language system. These two factors are radically different from each other and produce radically different consequences for language. A synchronic analysis takes account of relations that hold among coexisting elements in a language system at any given moment, and is thus independent of any factor attributable to the passage of time. It provides a snapshot of the state of the language under analysis. The idea of systematicity in language implies that, if the linguist's account is valid, it will present that state as a unified whole of interacting elements. By contrast, a diachronic analysis yields a description in which the evolution of only isolated elements of various states of a language at different times constitute the relevant data.

The synchronic and diachronic modes of analyzing linguistic data are autonomous but interdependent. The state of a language is not simply the sum of the changes it has undergone. Diachronic facts do not belong to a state of a language, because any such state is a synchronic phenomenon. But diachronic linguistics deals with forms that replace one another as a system evolves. There is thus a complementarity between synchronic and diachronic linguistics, which Saussure described as the diverging paths that linguistics can take.

FORM AND SUBSTANCE

As in other instances, Saussure imported the terms 'form' and 'substance' from everyday language as a starting point for finer distinctions that were subsequently expressed by more specialized analytical terms. Thus, the distinction between 'form' and 'substance' anticipates the distinctions between 'signification' and 'value' and between 'arbitrariness' and 'motivation'. The *Course in General Linguistics* has little to say about form and substance, but the distinction is crucial to Saussure's design for a sign-based approach to linguistics: the link between sound and thought in the linguistic sign produces form, not substance. Saussure calls the link between signifier and signified, as well as that among signs, 'pure form', indicating by 'pure' that it consists 'solely' of a relation. In this sense, no substance is essential to the formation of the linguistic sign, or to the endlessly complex relations among the signs of a language system, or to the communicative acts for which the system serves.

SIGNIFICATION AND VALUE

The terms 'signification' and 'value' distinguish between two types of meaning: signification is the meaning belonging to a sign taken individually, and value is the meaning that derives from the contrast between or among signs. Again, the terminology is intended as a reminder of both the contrast and the interplay between the terms involved: in this instance, reminding us that the meaning inherent in a sign by itself (signification) is subordinate or preliminary to the meaning emerging from signs in relation to each other (value).

Saussure draws attention to the paradox inherent in any system of values: in order to function, it must contain elements that are unlike whatever they may be exchanged for, and whose value they function to determine, but similar to those elements whose value they function to determine. The principle that distinguishes signification from value distinguishes forms from each other and creates meaning. The signification–value interplay thus harks back to form and substance.

DIFFERENCE AND OPPOSITION

According to Saussure, the meanings created out of distinctions of form are carried by those distinctions alone. That is what he means by 'difference'. No positive elements are required for the formation of a linguistic system; it functions to create perceptually discernible differences, and those differences function to distinguish among ideas for purposes of communication. Such differences in signifiers and signifieds taken separately are what Saussure calls 'pure' differences: purely negative. But, once the linguist's analysis moves to the level of the sign

as a functioning unit of communication, where signifier and signified must be taken together, it is no longer a matter of difference but of 'opposition'. The two components of the sign differ from the components of other signs, but the sign as a whole is merely distinct from others. The features of language structure as Saussure defined them, once he had added the concepts of difference and opposition to his analysis, are all based on the distinctiveness of the linguistic sign. In the language system there are only differences; among signs there are only oppositions.

SYNTAGMATIC AND ASSOCIATIVE RELATIONS

Syntagmatic relations are complex signs consisting of at least two components, such as *im-possible*, *possibl-y*, or *possible suspect*. Saussure does not specify any upper limit for what could be considered a complex sign, but syntagmatic relations of many different types operate in the formation of all signs from the level of compound words to phrases, full sentences, and, by implication, complete texts. The linear structure and the functional combination and integration that characterizes all such data distinguish syntagmatic relations from associative relations. The latter are the connections that language users spontaneously make among signs on the basis of signifiers or signifieds or both.

Saussure conceives of every sign in a linguistic system as the center of a constellation around which distinct groups of other signs may cluster in varying numbers, depending on the complexity of the sign at the center. These word groups are never spoken as such, unlike the groups that form syntagmatic relations are. They are related forms among which speakers choose in forming syntagmatic relations. Thus, at the level of functional units of communication, these two features of language structure again interact intimately with one another.

ARBITRARINESS AND MOTIVATION

In an early chapter of the *Course in General Linguistics*, the arbitrariness of the linguistic sign is mentioned for the first time. 'Arbitrariness' refers to the arbitrary connection between the signifier and the signified of a linguistic sign, in the sense that no language mandates the expression of any of its signifieds by a specific signifier. Conversely, no signifier is constrained by virtue of its inherent properties to signify a specific signified. It is not till all the other complementarities of the *Course in General Linguistics* have been established that the principle of the arbitrariness of the linguistic sign takes its place within the distinction arbitrariness–motivation, or arbitrary–motivated. The logic of this order of presentation emerges from the fact that the difference–opposition, signification–value, and syntagmatic–associative distinctions each operates in its own way to limit arbitrariness, thus creating signs that are at least partially motivated (not completely arbitrary).

CONCLUSION

The foundational complementarities developed in the portion of the *Course in General Linguistics* devoted to synchronic analysis take their place in the section denoted to diachronic analysis. There are additional sections devoted to what Saussure calls 'geographic' and 'retrospective' linguistics, but these are scarcely mentioned in the vast body of literature surrounding his work. Nor has much attention been paid to the obsessive and abstruse scholarship to which Saussure devoted substantial time and effort in an attempt to decode hidden words within visible words of Horace, Virgil, and other Latin authors. But both Saussurean scholarship and serious distortions of his seminal ideas flourish, a century after he first challenged an attentive audience to believe that the course of linguistics needed to be recharted and suggested how it could be done.

Shannon, Claude

Introductory article

Thomas J Carter, California State University, Stanislaus, California, USA

CONTENTS

Claude E. Shannon (1916–2001) is regarded as the founder of information theory. He developed a general model for communication systems, and theoretical tools for their analysis.

INTRODUCTION

Claude Elwood Shannon (1916–2001) is generally considered to be the founder of the contemporary theory of information. Shannon's work in mathematical engineering focused on problems associated with telecommunications and computer systems. His early work developed the application of Boolean algebra to telephone switching circuits. In the 1940s, while working at the Bell Telephone Laboratories, he developed and applied a theoretical model of the communication of information through a transmission channel. This theoretical model allowed him to clearly define a measure of the information content of a message, a measure of the capacity of a communication channel, and relationships between these measures. His theory allows rigorous analysis of the efficiency and reliability of communication through a noisy channel. A noisy channel in this context is one in which the receiver might have some doubt about exactly what message was sent. Shannon's work also forms the basis for the foundational paradigm of cognitive science in which human cognition is analyzed as an information-processing system.

Claude E. Shannon was born on 30 April 1916, in Gaylord, Michigan, to Claude Elwood and Mabel Wolf Shannon. His father was a judge, and his mother was principal of the town's high school. Shannon married Mary Elizabeth Moore on 27 March 1949. They had three children. Shannon died on 24 February 2001 in Medford, Massachusetts, of Alzheimer disease.

Shannon earned double BS degrees in electrical engineering and mathematics in 1936 at Michigan University. He earned his Masters in electrical engineering and his doctorate in mathematics at the Massachusetts Institute of Technology (MIT). Both degrees were awarded in 1940. Shannon's work for his Masters degree, done with Vannevar Bush on Bush's differential analyzer machine, established the relationship between Boolean logic and switching circuits. His Masters thesis, published in 1938 under the title 'A Symbolic Analysis of Relay and Switching Circuits', drew immediate attention, and has since been recognized as fundamental in laying the groundwork for the use of Boolean algebra in the theoretical analysis and design of digital computers. Shannon's work for his doctorate involved the application of mathematical methods to genetics. His doctoral thesis was entitled 'An Algebra for Theoretical Genetics'.

In 1940, Shannon was named a National Research Fellow, and spent a year at the Institute for Advanced Study at Princeton. He was awarded the National Medal of Science (1966), the Jacquard award (1978), the Kyoto Prize in Basic Science (1985), and numerous other awards and honors, including honorary degrees from such institutions as Carnegie-Mellon, Edinburgh, Oxford, Princeton, and Yale.

Bell Telephone Laboratories hired Shannon in 1941 as a research mathematician. He worked at the lab until 1956, and remained affiliated with the lab until 1972. In 1956 and 1957 he was a visiting professor at MIT. In 1958, he was appointed by MIT as Donner Professor of Science, where he remained until his retirement.

During the Second World War, Shannon worked in a team at Bell Labs developing anti-aircraft control and aiming devices. Shannon also continued his work on switching circuits, and developed his general theory of information and communication channels. In 1948, in the *Bell System Technical Journal*, Shannon published his most important work, 'A mathematical theory of communication'. During his career, Shannon applied his theoretical methods to telecommunication systems, computer systems, cryptography and cryptanalysis, the stock market,

and games such as chess-playing machines. A volume of Shannon's collected papers has been published, containing important works selected from 127 published and unpublished papers, including some that had formerly been classified secret, but since declassified.

Shannon had a life-long interest in games, toys, musical instruments, and devices of all sorts. He invented a rocket-powered Frisbee, devices which can juggle, a machine to solve Rubik's cube, and a computer that calculates in Roman numerals.

INFORMATION THEORY

In his classic 1948 paper, 'A mathematical theory of communication', Shannon laid the foundations for contemporary information, coding, and communication theory. He developed a general model for communication systems, and a set of theoretical tools for analyzing such systems. His basic model consists of three parts: a sender (or source), a channel, and a receiver (or sink) (see Figure 1). His general model also includes encoding and decoding elements, and noise within the channel. In his paper, Shannon analyzed both discrete (digital) and continuous systems. Here we will briefly outline the elements of Shannon's analysis of discrete communication channels.

Shannon's first important step was to develop a rigorous, formal, general definition of *information*. He focused on information carried by symbols (such as letters, words, or digits). After abstracting away incidental properties of the symbols (such as their size, color, typeface, etc.), Shannon characterized a symbol by its probability of occurrence. Thus, in general, Shannon's theory analyzes the information carried by a sequence of abstract events, each occurring with a specific probability. It is worth mentioning that Shannon's use of the term *information* is technical, and that successful use of his theory in a particular context depends on the applicability and relevance of his definitions. For example, with Shannon's definition of *information*, a completely random sequence of symbols (each equally likely) has the highest possible information content. This issue of technical applicability has sometimes led to unwarranted expectations of information theory, and an ebb and flow of its reputation over the years since its appearance in 1948.

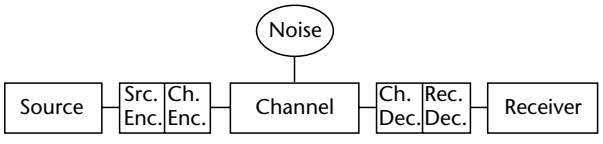

Figure 1. Shannon's general communication model. Fundamental elements are source, channel, and receiver/sink. The general model also includes channel noise, source and channel encoding elements, and channel and receiver decoding elements.

Shannon wanted a quantifiable measure of the information to be derived from the observation of an event occurring with probability p, and he wanted the measure to satisfy certain basic conditions. In particular, he wanted his information measure I(p) to be:

1. Non-negative – that is, $I(p) \geq 0$.
2. Continuous – that is, small changes in p should result in small changes in I(p).
3. Additive for independent events – that is, $I(P_1{}^* P_2) = I(p_1) + I(p_2)$.

The first property assures that the occurrence of an event can never reduce our information about the world (although it may cause us to revise some things we thought we knew). The second property is a standard mathematical requirement. The third property says, for example, that two books of the same size can contain twice as much information as one book, or that if we have two telephone lines, we can transmit twice as much information per unit time as with one line.

From these three properties, we can show that the information measure is given by (the negative of) the logarithm of p: $I(p) = -\log(p)$. Using different bases for the logarithm amounts to using different units of measurement. If we use base 2, then we are measuring information in units of *bits*, the standard unit of measurement in binary computer systems.

A useful way to think about Shannon's definition of *information* is that when we observe an event, our uncertainty about the world is reduced. The amount by which our uncertainty is reduced is the information content (for us) of the event. Thus, for example, before a coin is flipped, we are uncertain whether it will come up heads or tails. When we see that it has come up, say, heads, we have observed an event which has probability one-half. Thus, the information we have received (the reduction in our uncertainty about the world) is $I(1/2) = -\log_2(1/2) = \log_2(2) = 1$ bit. If a coin is flipped twenty times (or, alternatively, if twenty coins are each flipped once), we receive twenty bits of information. More generally, if an event is almost sure to happen (probability very close to 1), the information we receive from that event is very close to 0. If a very unlikely event occurs (probability very close to 0), we gain much more

information. If you learn tomorrow that someone won the lottery, you have learned little, since nearly always somebody wins the lottery. If you learn that you in particular won (a very unlikely event), then you have learned a lot!

ENTROPY

Using this basic definition of the amount of information carried by the occurrence of a single event of probability p, such as the observation of a particular symbol out of a set of possible symbols, Shannon went on to calculate the average amount of information carried per symbol in a stream of symbols. Thus, for example, we might analyze a sequence of words spoken by an individual, or a sequence of characters transmitted by a modem over a telephone line. If we have a finite set of symbols $\{a_i\}$, each of which occurs in the stream with probabilities $\{p_i\}$, then the average information carried per symbol in the stream is given by the weighted average:

$$H = -\Sigma_i \, p_i * \log(p_i)$$

Shannon called this quantity the *entropy* of the stream of symbols. This quantity is sometimes called the *information entropy*, to distinguish it from the *physical entropy* of thermodynamics, as encountered in physics or chemistry. In fact, however, these two notions of entropy are compatible with one another, and it is not a coincidence that they have the same general form. Shannon's methods have been successfully adapted to applications in the physical sciences.

Shannon's seminal paper, 'A mathematical theory of Communication', is a careful and insightful application of these two basic definitions of *information* and *entropy* to a variety of problems of communication.

COMMUNICATION THEORY

Having developed his definitions of information and entropy, and his general model of a communication system (sender–channel–receiver), Shannon addressed two of the most fundamental problems of communication theory.

The first general problem is overall efficiency of transmission, or, said slightly differently, data compression. If I want to send a particular message to someone, what is the shortest stream of symbols I can send to convey that message fully? For example, I once saw a sign which read 'f u cn rd ths, u cn gt a gd jb'. I was able to decode the message as 'If you can read this, you can get a good job'. Instead of sending 45 symbols (letters, spaces, and punctuation), the makers of the sign sent only 31, a reduction of almost one third.

Shannon proved that if we want to be able to encode the symbols of an arbitrary message for transmission, the average number of bits per encoded symbol will have to be at least as large as the entropy of our stream of symbols. That is, $H \leq$ average-code-length. Shannon also pointed out that if we want to come close to the minimum (to the most efficient code), we should encode frequently occurring symbols with short codes. A particular example of this is the Morse code. For example, the two most frequent letters in English text are 'e' and 't'. In Morse code, the code for 'e' is 'dot' and the code for 't' is 'dash', the two shortest possible Morse codes. Thus Morse code is a first step towards efficient coding of English text, although it is far from optimal since it does not take advantage of sequential dependencies among the letters.

The second general problem Shannon addressed is reliability of transmission when the channel is noisy. The simplest way to increase reliability is through repetition (if they might not have heard you right the first time, say it again, and, if necessary, again). Unfortunately, repetition decreases efficiency, since often the repetition will be wasted, if the message got through correctly the first time.

Shannon observed that noise in a channel has the effect of increasing the entropy of the message. He then developed a method for calculating the relative entropy of the channel, and defined the *capacity* of a channel as the difference between the actual entropy of the channel and the entropy of a channel of pure noise (where no message can get through). Shannon's main result was to prove that given a channel with non-zero capacity, there exists a way to encode messages with arbitrarily high reliability (nearly perfect transmission), but wasting an arbitrarily small amount of the channel capacity. This is a remarkable result. At first sight, it seems that if we want to improve the reliability of our transmissions through a noisy channel, we will in effect have to repeat our message, thus wasting some of the channel capacity. Shannon proved otherwise: there exist codes that give high reliability while wasting hardly any of the channel capacity.

Shannon's theoretical model of communication, and his information and entropy tools, have found wide applicability across the broad range of sciences and technology, and he stands as a central figure in the development of the Information Age. Simon, Herbert A.

Introductory article

Edward A Feigenbaum, Stanford University, Stanford, California, USA

CONTENTS

Herbert A. Simon (1916–2001) was an American scientist whose research ranged broadly over the cognitive and social sciences, computer science, economics, and the philosophy of science. For his fundamental, innovative, and penetrating contributions he received the highest research awards in the fields of economics, psychology, computer science and artificial intelligence, including the 1978 Nobel Prize for Economics for his model of bounded rationality in decision-making and problem-solving.

INTRODUCTION

Herbert A. Simon made seminal contributions to several fields of behavioral and social science, to computer science, and to the philosophy of science. His contemporaries often referred to him as the quintessential 'Renaissance man'. For the originality and profundity of his contributions, he received the highest awards of several sciences: the Distinguished Scientific Contribution Award of the American Psychological Association; the A. M. Turing Award of the Association for Computing Machinery; the Nobel Prize in Economics; and the Lifetime Research Achievement Award of the American Association for Artificial Intelligence.

Simon was born in Milwaukee, Wisconsin, in 1916. He did his doctoral dissertation research at the University of Chicago in the mid-1930s, studying organizational and administrative behavior. These studies led to two influential books: the early *Administrative Behavior* (continually revised into the 1990s) and the later (1958 collaboration with J. G. March) *Organizations*. These books laid the foundations of the social science discipline now called organization theory.

In the late 1940s, Simon taught at the Illinois Institute of Technology. He moved to the Carnegie Institute of Technology (now Carnegie Mellon University) in 1949 to help found the Graduate School of Industrial Administration. His most important contributions to economics, psychology, and computer science were made at Carnegie Mellon, and he remained there until his death in 2001. Although he began his career there as a Professor of Industrial Administration, for most of it he was a Professor of Psychology and Computer Science. In 1978, when he was awarded the Nobel Prize in Economics, he received the congratulatory messages from around the world in his office in the psychology department, his academic home.

He wrote 27 books, more than 600 scholarly papers and contributions, and an autobiography entitled *Models of My Life*. In the words of one of the memorial papers written about him, he was the 'model of a scholar'.

THEMES IN SIMON'S WORK

Before discussing the details of Simon's contributions, it is important to mention the themes that run through his contributions to so many fields. One might ask (as Simon himself might have done): what model of Simon could explain how he was able to make foundational contributions to such seemingly disparate fields?

Modeling Decision-making

The most important theme in Simon's work, which tied together his various contributions in different disciplines, was his focus on models of the decision-making behavior of individuals, and of organizations composed of individuals. The 'decision' was, in effect, the unit of behavior that he studied.

For example, in economics, the standard model had been 'economic man' who made choices using unlimited information and unlimited information-processing power. Simon replaced that with a model that had more empirical validity: 'behavioral man', who made decisions that were 'good

enough' using a person's limited perceptual, cognitive, and informational resources. This concept has been called 'satisficing', in contrast with the (unrealistic) 'optimizing' of economic man. In his work in cognitive psychology, Simon viewed problem-solving as a complex emergent of simple decision-making mechanisms; and he viewed the cognitive acts of decision-making as problem-solving. In studying organizational behavior, he believed that one must study the collective decision-making of individuals: the nature of those processes, and the influences on those processes (e.g., informational and motivational).

Empiricism

Secondly, Simon was an empiricist. His theories, and the models formulated to test them, were based on real data from empirical studies or experiments. Although his theories were often elegant, he was much less interested in elegance than in veracity – whether the theory or model represents a reasonable and testable induction from real data.

Information-processing Languages and Artificial Intelligence

The third major theme was Simon's choice of a fundamental framework (and hence, a fundamental language) with which to model all processes of decision-making and cognition in individuals and organizations: the information-processing framework. This view was implicit in his rejection of 'economic man' as a model for decision-making. But in 1955, he specifically chose as his fundamental framework the information processes of the digital computer – hence, computer languages – as the modeling medium for his theories of decision-making. Indeed, his modeling of human cognition using techniques of computer simulation (which he also helped to pioneer) resulted in the launch of a new field of science and engineering, that of artificial intelligence (AI). He is considered one of the four founders of AI along with Allen Newell, Marvin Minsky, and John McCarthy.

PROBLEM-SOLVING

In 1955, and for several decades thereafter, Simon collaborated with Allen Newell on building information-processing models of complex human problem-solving. Their first model, known as 'logic theorist' (LT), proved theorems of logic in much the same way that they were proven by Whitehead and Russell in *Principia Mathematica*. Methodologically, Newell and Simon insisted that a model, to be complete, must 'run' as a computer program. LT first 'ran' in 1956. Immediately thereafter, Newell and Simon began work on their model of human chess-playing behavior, seeking to achieve world-class levels of chess competence on a computer. This goal was achieved only with the advent of the very fast computers of the 1990s.

Together, LT and the models of chess problem-solving explicated a set of concepts and mechanisms of cognition that formed the basis of the fields of cognitive science and artificial intelligence. These concepts and mechanisms in effect defined the 'mainstream' of those fields. They included: the concept of a problem space of possible solutions that must be searched; the concept of heuristics, both general and task-specific; and the use of heuristics to control the search of the problem space, including heuristics for generating plausible moves, pruning search paths, and limiting the search (i.e., 'satisficing').

Simon had anticipated this pioneering work of the mid-1950s with two seminal papers in which he presented (as verbal concepts, not yet computer programs) his theory of rational decision-making and his theory of the influence of the task environment on complex problem-solving. He later synthesized these ideas with his famous metaphor of the 'ant on the beach'. The ant's goal is to reach some distant food. Its path to get there – its behavior – seems intricate and complex. But most of the (apparent) complexity is in the grains of sand to be traversed, not in the ant's simple mechanism for homing in on food. Simon believed that the observed complexity of human problem-solving behavior arises from simple and general underlying search mechanisms that are applied to a complex task environment.

In 1957 and 1958, Newell and Simon began to build (again, in information-processing language as a computer program) their 'general problem solver' (GPS). Their intention was that GPS should be applicable in any task environment. The method they postulated for achieving problem goals was called 'means–ends analysis'. The problem-solver analyzed 'differences' between the current state and the goal state, and chose 'operators' to reduce these differences, until there were no differences remaining. The task environment was represented as a table of associations between operators and the differences they affected.

GPS was tested in a variety of tasks by a series of computer simulation experiments that generated detailed sequences of behaviors. The scientific

goal of Newell and Simon was to show that these sequences matched, step by step, down to a level of great detail, the sequences of behaviors observed in people doing the same tasks in controlled laboratory experiments. Their book on this work, *Human Problem Solving*, is regarded as a landmark of cognitive science and of psychology in the twentieth century.

LEARNING, RECOGNITION, AND RECALL OF VERBAL MATERIAL AND SYMBOLIC OBJECTS

Few aspects of human learning have been studied as rigorously and extensively, in breadth and in depth, as the memorization, recognition, and recall of simple verbal material. To control for effects of word meaning on memorizing, three-letter sequences (usually pronounceable but meaningless) are often used as verbal materials. The major empirically observed phenomena are highly reproducible; yet they depend critically on the verbal materials and experimental conditions. These phenomena are seen by many cognitive psychologists as 'basic' or 'elementary'. The combination of stable reproducibility (implying a simple underlying mechanism) and strong dependence on the 'task environment' of materials and experimental regimes) recalls Simon's 'ant on the beach' metaphor.

In 1956, Simon began a collaboration with Edward Feigenbaum to develop an information-processing model (expressed, of course, as a computer program) that would: offer simple mechanistic explanations of the major phenomena of verbal learning; predict behavior in new experiments; and account for the observed dependence on the task environment using only simple mechanisms. The resulting model was called EPAM (for 'elementary perceiver and memorizer'). It has since been under continuous development, and extension to additional phenomena, primarily by Simon and his collaborator Howard Richman.

The central mechanism of the EPAM model was a network of discriminations (i.e., tests that represent branch points) among the symbols being learned. This network is not given *a priori*. It develops as the learner makes errors, indicating the need for finer discriminations among the symbols to be learned. Only partial information is memorized when that is adequate for performance (once again, 'satisficing'), for example when performing recognition tasks or memorizing symbolic cues to stimulus–response associations.

EPAM used a small 'immediate memory' of about seven symbolic 'chunks'. EPAM is itself a model of what is now called 'working memory', as opposed to long-term semantic memory. In postulating mechanisms for EPAM, Feigenbaum and Simon did not give EPAM any specific mechanisms for forgetting, even though forgetting was omnipresent in the behavior of human subjects. Nevertheless, EPAM did forget in the usual ways observed among human subjects. Forgetting emerged from the combination of the ever-growing network of memorized material and the use of 'satisficing' in storing only partial information as a cue to link stimulus and response. Sometimes (and temporarily, in a predictable way) the cue became inadequate to invoke the correct response.

EPAM was tested by being used as an 'artificial' subject in traditional verbal-learning experiments; it exhibited several of the known stable phenomena. The variety observed in its behavior was a consequence partly of its use of strategies for allocating its time and attention, and partly of its use of many different adaptive mechanisms.

EPAM research of the 1980s and 1990s added mechanisms of auditory short-term memory, phenomena involving articulation in verbal learning, a model of how certain experts at memorization learn extremely long lists of digits, and studies of the effects of context in letter perception. During this period, Simon and Richman extended EPAM to new domains such as chess, visual processing, and categorization.

The EPAM model is the most comprehensive, rigorously developed, and tested model of elementary human verbal learning in cognitive science.

OTHER CONTRIBUTIONS TO COGNITIVE SCIENCE

After his Nobel Prize in 1978, Simon turned part of his attention to economics. Yet he continued to make significant contributions to cognitive science.

Expert Knowledge

What is it that makes an expert different from a novice in performing a task such as playing chess? Several years of work by AI researchers building 'expert systems' pointed to the much larger body of knowledge used by experts, rather than their superior reasoning skills.

Using his own experiments and those of others, Simon studied the question in terms of chess-playing behavior. He reported that in very short visual presentations of complex chess positions, experts were able to encode most of the important

features, whereas novices were able to encode few. Simon inferred that chess experts use learned patterns of important chess features with which they could quickly 'parse' a complex chess position. He estimated the number of those patterns at about 50 000, learned over a period of 10 years.

Scientific Discovery

How are scientific theories formed? By what information processes were the great early discoveries of science made? For example, how did Kepler discover that planets travel around the Sun in elliptical orbits? Simon collaborated with Pat Langley, Gary Bradshaw, and Jan Zytkow to construct models of how several of the significant early discoveries in science may have been made. Simon and his colleagues created computer programs that 'rediscovered' the early scientific principles from data available to the early scientists.

Protocol Analysis

From 1956 until the publication of their book in 1972, Newell and Simon developed methods, called protocol analysis, for analyzing and measuring the details of the behavior that subjects were verbalizing about their problem-solving, moment by moment. The methodology for this intricate and difficult analysis was further developed in a book by Simon and Anders Ericsson in 1984 (revised in 1993).

CONCLUSION

Simon was a great unifier of models of seemingly disparate phenomena. His body of work represents a synthesis of essentially simple abstractions about decision-making. His scientific genius was to cut across the many and varied phenomena, and the (often obscuring) behavioral detail, to the simple but essential model. Simon created works not only of great scientific insight and power but of scientific beauty.

Skinner, Burrhus Frederic

Introductory article

A Charles Catania, University of Maryland, Baltimore County, Maryland, USA

CONTENTS

B. F. Skinner (1904–1990), an American psychologist, provided the experimental foundations of contemporary behavior analysis and its applications. He interpreted verbal behavior in terms of those foundations, and he was outspoken about the differences between the methods of behavior analysis and those of cognitive psychology.

BIOGRAPHY

Born on 20 March 1904, in Susquehanna, Pennsylvania, Burrhus Frederic Skinner (later known mostly as B. F.) grew up when inventions such as those of Thomas Edison were changing life in small-town America. In his school days, Skinner built gadgets to manage his own behavior; one blocked his bedroom door with a sign until he hung up his pajamas (thereby avoiding his mother's intervention). At Hamilton College, in Clinton, New York, he majored in English, also taking courses in science and philosophy. He sent some short stories to Robert Frost after graduation. Encouraged by Frost's reply, Skinner took a year off from academic pursuits to try a career in writing. Giving it up on the grounds that he had nothing to say, Skinner called the time his Dark Year.

Having read John B. Watson, Ivan P. Pavlov, and Bertrand Russell, he turned from English to psychology and entered the doctoral program at Harvard University, where he began a series of experiments on the behavior of rats that led to more than two dozen journal articles and culminated in his 1938 book, *The Behavior of Organisms*. In 1936, he moved to the University of Minnesota, where he continued basic research and also published work on verbal behavior. Then the Second World War occasioned a project on training pigeons to guide missiles. It got only to the demonstration stage, but a fringe benefit was the discovery of shaping, the technique for creating novel forms of behavior through differential reinforcement of successive approximations to a response.

Another product of those days was the Aircrib, which Skinner built for his wife and second daughter. The windowed space with temperature and humidity control improved on the safety and comfort of ordinary cribs while making childcare less burdensome. Despite rumours to the contrary, it was not used for conditioning the infant.

In 1945, Skinner became Chair of the Department of Psychology at Indiana University. After his 1947 William James Lectures at Harvard University on verbal behavior, he returned permanently to Harvard. His 1948 novel, *Walden Two*, described a utopia the experimental character of which was its most important feature: unsatisfactory practices were to be modified until more effective substitutes were found.

The Harvard Pigeon Laboratory provided many of Skinner's students with opportunities to start independent lines of research while he developed reinforcement schedules in collaboration with Charles B. Ferster, revised and expanded his William James Lectures in the 1957 book *Verbal Behavior*, and built his first teaching machines. A Division for the Experimental Analysis of Behavior (Division 25) was established within the American Psychological Association, and the *Journal of the Experimental Analysis of Behavior* began publication in 1958. Within a decade, increased activity in applications led to the companion *Journal of Applied Behavior Analysis*.

Skinner retired from the laboratory in 1962, returning to it only briefly nearly 20 years later, but he continued his writing throughout his life. Among many papers and books were 'Why I am not a cognitive psychologist' in *Behaviorism* (1977), 'The origins of cognitive thought' in *American Psychologist* (1989), and a three-volume autobiography.

Skinner learned of his leukemia in 1989. On 10 August 1990, at his final public appearance, he accepted an award from the American Psychological Association for lifetime achievement in psychology. His remarks criticized cognitive science as the creationism of the twentieth century, in that it sought causes of behavior inside the

organism instead of in the organism's environment. A week later, in hospital, Skinner put the finishing touches to his last paper, 'Can psychology be a science of mind?', for the *American Psychologist*. He died the next day, 18 August 1990. His last word, upon receiving a drink of water, was 'Marvelous'.

THE ANALYSIS OF BEHAVIOR

Skinner followed Pavlov in insisting on the primacy of data and the study of individuals rather than groups, but diverged from Pavlov in many theoretical and empirical ways. For Skinner, behavior was not to be taken as a symptom of something else. As interaction between organism and environment, it should be studied in its own right, not to resolve problems of physiology or to open the way to cognitive or other levels of analysis. Skinner did not disapprove of physiology, but argued that without a science of behavior neuroscientists would not know what to look for in the nervous system.

In Pavlovian conditioning, the conditional stimulus reliably precedes the unconditional stimulus and comes to produce behavior related to the responses elicited by the unconditional stimulus. The prototypical example is the elicitation of salivation by some stimulus that consistently precedes food. In Skinner's operant behavior, the contingencies are different: a discriminative stimulus sets the occasion on which responses have some consequence; in the absence of the stimulus, responses do not produce that consequence. The prototypical example is the rat whose lever presses produce food in the presence but not the absence of a light. The rat comes to press the lever only when the light is present. Discriminative stimuli, colloquially called signals or cues, do not elicit responses; instead, they set the occasions on which responses have consequences. Such behavior, called *operant* because it operates on the environment, does not entail associations or stimulus–response connections. The three-term contingency, in which discriminative stimuli set the occasion upon which responding has consequences, is not reducible to pairwise stimulus and response relationships.

Skinner complained that he was sometimes misunderstood to be a stimulus–response theorist, but though some behavior sequences can be analyzed as chains in which each response produces stimulus conditions that occasion the next, he recognized that others must be integrated so that responses appear in proper order without depending on stimuli produced by earlier responses.

Admitting the possibility of behavior without eliciting stimuli was crucial. Behavior has causes other than eliciting stimuli. It was a profoundly simple concept: behavior now depends on its past consequences. Saying it another way: the consequences of current responses reinforce or select the responses that will occur later. Selectionism had replaced associationism.

Operants are classes of responses defined by their environmental effects rather than by topography (what they look like). Consider a rat, a lever, and a device for delivering food. If lever pressing does nothing, the rat presses only occasionally. If pressing produces food, the rat presses more often. The food is a *reinforcer*. The effectiveness of reinforcers changes over time (as in deprivation or satiation) and a given reinforcer might reinforce some responses but not others. Furthermore, the effects of reinforcement are not permanent: responding decreases to its earlier levels, or extinguishes, when reinforcement is discontinued.

The discovery that behavior could be maintained easily even when only occasional responses were reinforced led to schedules of reinforcement, which arrange reinforcers based on number of responses, the times when they occur, or various combinations of these and other variables. Different schedules produce different temporal patterns of responding.

Reinforcement operates on populations of responses within individual lifetimes much as evolutionary selection operates on populations over successive generations in Darwinian natural selection. (Skinner also considered implications of a third variety of selection, sometimes called cultural or memetic selection, that occurs when behavior is passed on from one organism to another, as in imitation.)

Reinforcement as selection is illustrated by the procedure called shaping, which creates novel behavior through reinforcement of responses that successively approximate it. For example, if the strongest of a rat's initially weak lever presses are reinforced, the force of pressing will increase and the criterion for reinforcement can be moved up to the strongest of the new population. With continuing increases in force and changes in criterion, the rat soon presses with forces that would never have been observed without shaping.

Shaping opened up education, developmental disabilities, and behavioral medicine to applications of behavior analysis. When research produced variable results, solutions were sought not by averaging over more subjects but by refining procedural details to identify sources of variability. The applied analysis of behavior is recognized for both

effectiveness and accountability; treatment of early autism is among its several notable successes.

Consequences operate in the context of other sources of behavior. Behavior arising from an organism's evolutionary history or phylogeny often interacts with behavior arising from its experience or ontogeny. Imprinting, which occurs when a duckling sees some moving object shortly after hatching, provides an example. The stimulus acquires special significance for the duckling, which then follows wherever it goes. Imprinted stimuli had been said to elicit or release following. But ducklings that must stand still to keep an imprinted stimulus visible learn to do so. In natural environments, following usually keeps ducklings close to mother ducks, but in other environments ducklings can learn to do different things. Genetic histories made ducklings capable both of learning and of becoming imprinted, but environmental contingencies determined what they learned to do.

VERBAL BEHAVIOR

The analysis of verbal behavior examines the functions of words. It differs from linguistics, the study of language, in that linguists describe practices of verbal communities in terms of the grammars, vocabularies, and phonetic units characterizing different languages. These descriptions of language structure tell little about their functions.

This behavioral distinction is analogous to that between physiology and anatomy in biology. For example, walking could be studied structurally by examining coordinations among the legs and other body parts. Analyses of particular muscle interactions and their extensions to running and other gaits might provide a grammar of movements that distinguished possible from impossible gaits. However, that grammar would not predict when someone might switch from standing to walking to running. Structure and function are different topics. Behavior analysis, following from Skinner's work, deals mainly with function, whereas cognitive science deals more often with structure (e.g. organization in what is perceived or learned).

The relevance is that Skinner's 1957 book, *Verbal Behavior*, was mainly about language function. A critical 1959 review by the linguist Noam Chomsky was more concerned with language structure than with the functional content of Skinner's account. *Verbal Behavior* provided a taxonomy of function rather than structure (for example, identifying verbal classes by their effects rather than by their topographies), applying it to a broad range of verbal phenomena. Later expansions extended the taxonomy to the origins of novelty in verbal behavior. Skinner consistently treated words as behavior rather than as vehicles for something else (a pervasive metaphor in everyday language is of words as carriers of ideas or meanings, making it hard to talk about sentences without referring to them as containing other entities).

One function of verbal behavior is instruction; people often do things because they are instructed to do them. Following instructions has social consequences and is crucial to many social institutions – families, schools, industry, the military – so it is important to understand not only how instructions work but also how they can go wrong (e.g. as in following unethical orders without question). Skinner called behavior that depended on words 'rule-governed behavior', though it is now more often called 'verbally governed behavior'. In verbal governance, what we say about what we do often determines what we do. In particular, one way to get people to do something is to shape not their doing but what they say about doing it. Contemporary analyses of verbal behavior include experimental studies of how these relations come about and the conditions under which they occur.

BEHAVING AND KNOWING (BEHAVIOR AND COGNITION)

Skinner's analyses were also about how we come to know ourselves. We think we have privileged access to private events such as feelings and thoughts, but how do we learn to talk about them? Parents who see the colors that a child sees can respond appropriately to the child's color-naming and so can teach the names, but how can a verbal community without access to relevant stimuli create and maintain verbal responses? In referred pain, a bad tooth in the lower jaw may be reported as a toothache in the upper jaw; here the dentist is a better judge than the patient of where the bad tooth really is. If we can be mistaken even about the location of a toothache, how can other reports of private events be reliable?

Skinner did not deny the private, but started from the fact that common vocabularies can be based only on what is mutually accessible to and therefore shared by speakers and listeners. If private feelings do not have public correlates, how can one tell when anyone else has them? If one cannot tell, how can one ever teach appropriate words? This is a problem because much of the language of cognitive thought originates in the vocabulary of private events.

According to Skinner, many processes called cognitive (e.g. thinking, visualizing) are kinds of behavior, but difficulties arise when they are invoked as explanations instead of as kinds of behavior in themselves. Skinner explicitly eschewed dualism, the distinction between mental and physical worlds. He did not deny events taking place inside the skin, but maintained that they should be called private rather than mental.

Skinner regarded internal causes as surrogates for external ones. Circularity is obvious if one characterizes individuals based on behavior (e.g. that person is greedy) and then uses the characterization as an explanation (e.g. he did it because of greed). Skinner argued that many cognitive explanations that invoke images or other internal representations, though more complex, are essentially of this sort and discourage further inquiry.

When Skinner criticized representations in cognitive psychology, the issue was not whether lasting effects are produced by stimuli (an organism that has responded to a stimulus is a changed organism). Rather, it was about the form the change takes. Skinner opposed copy theories of behavior or perception. A representation is not necessarily a copy (a spoken letter may represent a seen one but has no visual properties in common with it), so it is of interest that the most successful cognitive accounts, such as those in terms of parallel distributed processing, do not involve representations that function as copies. In this regard, behavior analysis shares its views with cognitive scientists who are advocates of neural nets and connectionist systems.

Sperry, Roger

Introductory article

Colwyn Trevarthen, University of Edinburgh, Edinburgh, UK

Roger Wolcott Sperry received the Nobel Prize for Physiology and Medicine in 1981. Famous for experiments on the embryology and regeneration of functional nerve connections, on perception and learning in split-brain cats and monkeys, and on hemispheric modes of consciousness in human beings following commissurotomy, his belief that awareness and memory depend on the generation of motor images in the brain is now central in brain theory, important in understanding both self-awareness and communication.

Roger Wolcott Sperry (1913–1994) (Figure 1), who received a Nobel Prize for Physiology and Medicine in 1981 for his research on brain science, devoted his scientific work to a search for the neural circuits of action and consciousness. From an undergraduate psychology project at Oberlin College with R. H. Stetson (an expert on timing in speech and music), to appointment as Hixon Professor of Psychobiology at the California Institute of Technology and fame as a neuropsychologist who discovered new ways to reveal the mental functions of the cerebral hemispheres, Sperry was a meticulous experimenter on the growth and functions of neural systems. A quiet-spoken, taciturn man, he seemed to have the skill of a magician in making basic laws of brain activity apparent in a new form. He was also a plain-speaking thinker about the power of consciousness in guiding what we do, and he wrote passionately about the nature of human values. As a young man he had accepted the doctrine of the philosopher John Dewey that thought is a form of conduct, with corresponding responsibilities, and this belief remained with him throughout his life.

Sperry's first experiment, the results of which were published when he was 26 years old, used electromyography (recording the electrical signals of contracting muscles) to demonstrate the infinitely varied yet coherent neural instructions for a simple human movement, namely making a circle in the air in different planes with an extended arm. The results led to a concept of the 'motor image', which anticipated the classical work on the 'Coordination and Regulation of Movement' of the Russian physiologist Nicholas Bernstein, and to the following statement of Sperry's concept of the role of movement in generation of awareness:

> An objective psychologist, hoping to get at the physiological side of behaviour, is apt to plunge immediately into neurology, trying to correlate brain activity with modes of experience. The result in many cases only accentuates the gap between the total experience as studied by the psychologist and neural activity as analysed by the neurologist. But the experience of the organism is integrated, organised, and has its meaning in terms of coordinated movement. (Sperry, 1939, p. 295)

A contemporary behavioral scientist may feel that this text ought to be displayed as a caution in all experimental psychology laboratories and functional magnetic resonance imaging (fMRI) units, where immobile subjects ponder prefabricated thoughts or are excited by stimuli intended to arouse named categories of perception or emotion.

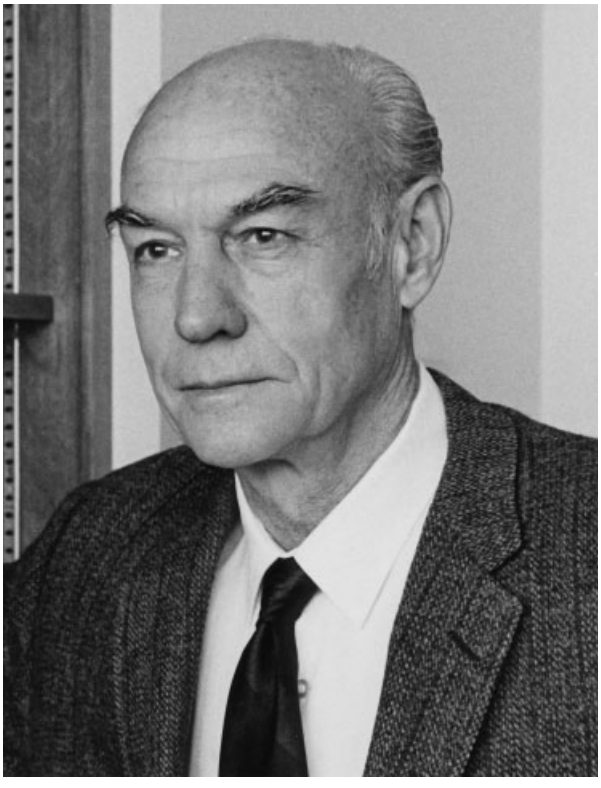

Figure 1. Portrait of Roger W. Sperry.

Sperry's graduate research, undertaken with Paul Weiss at the University of Chicago, initiated a series of experiments on plasticity of nerve–muscle systems and regrowth of motor nerves in rats and monkeys. Subsequently, his studies of the patterning of connections from eye to brain and from brain to muscles in fish and amphibia proved that chemical markers of some kind were guiding nerve axons to form the right connections. Experiments on the growth of eye-to-brain connections in fish and newts after surgical rotation of the eyes made Sperry world famous before he was 40 years of age (Figure 2(a)). They confirmed that the chemical markers would rebuild visual connections by inherent mapping principles, even when rearranged eye-to-body relationships produced totally nonfunctional reactions to stimuli. Visual areas map out the space for action in terms of body form automatically, without teaching from stimulation. This cast doubt on prevailing theories of the construction of functional brain circuits by learning. Sperry's 'chemoaffinity' principle is now accepted as being a primary factor in the early growth of nerve-cell connections. This is despite revolutionary advances in molecular biology and new models to explain order emerging in complex nonlinear dynamic systems of nerve cells, axonal and dendritic branches, and synapses, and selective retention of elements under the validation of environmental input. Emergent order and selection do create new functions and transform sensory and motor maps, but these maps retain a basic functional design of 'behavior space' – a product of a cell-to-cell communication that is set up in the embryo before the sensory nerves are connected to the brain.

Throughout his career, Sperry constantly tried to explain the creativity of 'experience', in the true sense of that word – that is, how conscious minds in active bodies 'try' to know. Cognitive psychology now favors analysis of human consciousness in terms of the data-transforming powers of intelligence – the processing and storage of information for mind work. Sperry had a deep conviction about and respect for the vitality and complexity of whole living organisms, and he emphasized the services of motor action to cognition. He attempted to determine how brains seek and generate information – not just logically processing what comes in, but how they create a useful sense of stimuli and how sensory information is taken in to monitor and guide intended movements. This interest led him to examine pathways within the visual cortex, and from visual areas to motor output. For every question Sperry found revolutionary answers. Step by step, he presented clear data on the living structure of cerebral pathways.

Mapping of skin or retina to the brain in a fish, a frog or a newt makes it possible for the animal to anticipate what will happen when it moves.

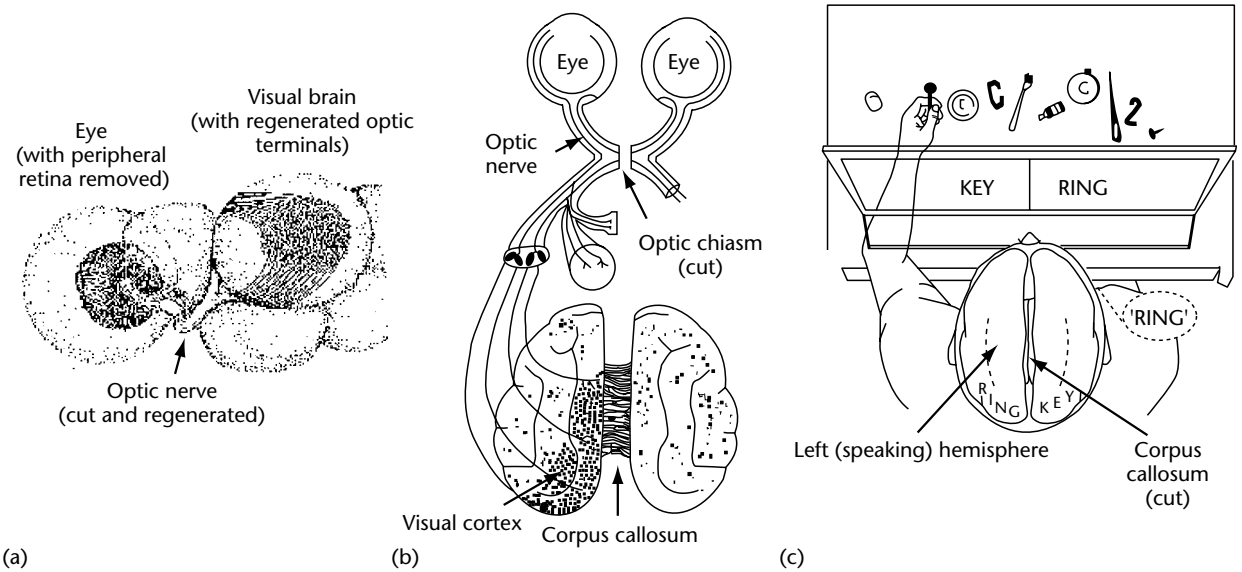

Figure 2. Drawings by Sperry showing three important experiments in the study of brain growth and function. (a) Selective regrowth of eye-to-brain connections in fish after removal of the peripheral parts of the retina and surgical section of the optic nerve. (b) Division of visual input to the cortices of the two cerebral hemispheres in cat brain. (c) Division of the corpus callosum in a human patient; the left hand (right hemisphere) feels a key, but the patient says (with left hemisphere) that he sees the word 'ring'.

Sperry's nerve regrowth experiments that were designed to determine how the maps are made are simple and elegant. The surgical skill necessary to operate under a binocular microscope on the nerves of animals only a few centimeters in length gave Sperry the means to conduct a brilliant study of the cortical mechanisms of vision in a mammal. He sliced through loop connections just beneath the gray matter of the visual cortex, making the incisions with tiny specially shaped knives through holes in the blood-vessel-rich membrane that covers the cerebral cortex. By showing that operated cats could perform difficult visual discriminations with little loss after this surgery, he disproved a theory of 'psychoneural isomorphism', that integration of perceptions was by local linking of features to make a neural analogue of a photographic image. He found that visual pattern recognition was mediated by deep cortico-cortical loops which the surface surgery left intact. This was one demonstration in a series that he designed to highlight the involvement of longer connections and separate brain parts in the unity of sight. A visual 'image' in the brain is not like a photograph or movie – it is more like a rumour spread by telephone calls between distant points.

Sperry's research on coordination of movements and awareness led him to investigate how intentions relate to consciousness in cats, monkeys, and humans. The 'split-brain' studies which eventually earned him his Nobel Prize were started in the University of Chicago, and continued at the California Institute of Technology after Sperry moved there in 1954. They germinated from an idea that was implanted in Sperry's mind in the 1940s while he was working with Karl Lashley at Yerkes Laboratory of Primate Biology in Florida. The aim was to find out how consciousness could be related to brain pathways. As Lashley interpreted his own extensive experiments, there was no clear location of learning and no function for the millions of fibers that bridge the gap between the two halves of the cortex in the corpus callosum, the largest single fiber tract in the brain. In Sperry's attack on this question, visual input to the cortices of the two cerebral hemispheres was divided by cutting the half of optic fibers that cross the midline under the brain in the optic chiasm (Figure 2(b)). Ronald Myers and Sperry showed that visual learning in a cat could be doubled by transecting both the optic chiasm and the corpus callosum, thereby producing the 'split brain'. A major advance in understanding how brain connections serve in awareness, and how the cerebral cortex works with brainstem structures that were not divided by the surgery, was made possible. Eventually it led Sperry to direct inventive testing of the effects of the operation, by dividing the corpus callosum in human patients, tests that demonstrated the different consciousness of the two human hemispheres (Figure 2(c)).

In 1960, the neurosurgeon Joseph Bogen suggested to Sperry that an improved understanding of the human mind could be obtained by methods based on those that had been perfected at the California Institute of Technology in the late 1950s for elucidating visual and touch learning in split-brain monkeys. The equivalent human operation, known as commissurotomy, had been used by neurosurgeons to prevent the interhemispheric spread of intractable epilepsy, but no effects on consciousness were reported. Most probably the tests had been inappropriate, or the surgery was incomplete. A new series of operations was medically justified for individuals with severe seizures, and better-controlled testing, like that developed for the studies on animals, could aid the post-surgical care of these patients. The first paper on surgically divided awareness in humans was published by Bogen and Sperry with Michael Gazzaniga in 1962, nine years after Myers and Sperry's first report on split-brain learning in cats. There followed a rich series of tests of the differences and interactions between images and memories, feelings and intentions in the left and right cerebral cortices of a small and devoted group of patients who were grateful for the improvement in their lives, and for the attention that they received in collaboration with Sperry's team.

Apart from firmly linking aspects of consciousness to identified parts of the brain, the results of experiments by researchers who joined Sperry at the California Institute of Technology clarified the functions of the brain areas involved in language and thinking. They proved that intentional 'mind sets' (anticipating the type of strategy that would be needed for the subject to carry a conscious act of any kind to a successful conclusion) were allocating particular territories of the cerebral cortex, directing attention and the information-processing of perception, and preparing the body to move in precisely directed ways, using intention, memory, and emotions to generate a receptive consciousness.

The California Institute of Technology commissurotomy studies stimulated a new era in neuropsychology of the hemispheres, and accelerated the testing of left-brain and right-brain mental functions in normal individuals. In Sperry's mind the findings generated a new line of philosophical inquiry and a new teaching venture that kept him hard at work until his death in April 1994. He

believed that the 'cognitive revolution' of the 1970s was inspired by the research on consciousness in commissurotomy patients, and he continued to spare no effort in explaining his thinking, despite increasing disability due to a serious central motor disorder that weakened him and progressively restricted his freedom of action and participation in academic meetings. This infirmity in no way diminished the acuteness of his thought or the fluency of its expression.

Roger Sperry's thoughts on the causal potency of consciousness were developed after 1965 in a series of philosophical papers on 'Mind, Brain and Humanist Values'. His scientific colleagues, many of whom were still persuaded that consciousness must be a notion beyond the reach of rigorous science, were puzzled. Was he becoming mystical? Surely he was being philosophically naive. However, anyone who had crossed logical swords with Roger Sperry knew the danger of assuming that he could be naive. He was too thorough and tenacious to miss a weakness in his own or another's argument. On the other hand, he was stubborn, and the notion of consciousness and its innate values as a causal force in nature, as a director of human experience and knowledge, was consistent with his original phenomenological beliefs, and it did become an abiding conviction. Now, of course, his message seems far less deluded, and more a prophetic realization of how universal 'autopoetic' or self-creative emergent principles must apply (and with great force) in the consciously monitored activities of the human brain and mind, directing not only the elementary physiology of the neurons in patterned arrays, but also the culturally contrived mechanisms of society in harmony with ancient requirements for human life on earth. And it is not so odd, in the twenty-first century, to say that if we do not find lasting values to guide our collective actions, things may go badly for our societies and for the world that coexists with our dangerously increasing numbers. In that context, Sperry's thinking on global causality and the place of the human mind and human conscience in the making of a liveable future has increased validity.

New notions of causality propounded by physicists with regard to the origins of the cosmos and the evolution of matter give scientific authority to the nonreductive psychology that Sperry had developed as a biologist who was aware of the special creativity of neural systems. However, physics can provide only the most general, abstract enlightenment about psychological processes. What Sperry set out to do was to challenge the powerful orthodoxy of psychometrics, experimental psychology, and reductive brain science that seeks linear explanations for the construction of behavior and consciousness, all deriving from the input of information from sources that have no intrinsic values and no moral force. As he challenged behavioristic notions of learning with his demonstrations of innate forces in the growth of nerve connections to form functional networks, and as he insisted that surgical operations could locate motives for learning in animals and show the real anatomy of human consciousness and its creative subdivisions, so he concluded that human values are not just convenient fictions with short-term validity. Rather, he believed that they are rooted in inherited psychobiological principles for acting in harmony with the physical and social world in which humans have evolved.

Sperry's writings are lucid, not least when his ideas challenge accepted theory. His later writings are motivated by strongly formed personal beliefs, but they remain a clearly articulated call for new scientific thinking. He always advocated keeping 'the big picture' in mind.

George Adelman, Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Boston, Massachusetts USA

CONTENTS

Hans-Lukas Teuber (1916–1977) was a neuropsychologist known for his research on the effects of brain injuries on human sensation, perception, language, and memory. He founded the MIT Department of Psychology (now Brain and Cognitive Sciences) in 1964, an early instance of brain and behavioral scientists working together in a single graduate department in the US.

INTRODUCTION

Best known for his work on perception and his behavioral research on brain-injured World War II veterans, Hans-Lukas Teuber arrived at MIT in 1960 to establish its first department of Psychology. He organized the department around his vision of a science of brain and behavior that would emphasize the biological and physiological aspects of the field rather than the more traditional aspects of learning, psychophysics, personality, and social psychology. Through his organizational skills, and working with a faculty he selected that shared his view of a unified field of brain and behavior research, he was able to define and study problems and questions that still lie at the heart of the cognitive and brain sciences. The department he created was a prototype of many of the new 'neuroscience' departments that would be established at universities and medical schools throughout the United States.

LIFE AND WORK

Hans-Lukas Teuber was born in Berlin in 1916, and educated at the College Français, a Huguenot school where all subjects were taught in French. He studied Greek, Latin, ancient history and the natural sciences, receiving his baccalaureat in 1934. At home his parents Rose (Knopf) and Eugen Teuber stimulated his interests in music, literature, animal behavior, and mathematics. His father had studied under Wilhelm Wundt, and in 1913 had set up the primate research center at Tenerife (Canary Islands) where Wolfgang Köhler, one of the founders of Gestalt psychology and the next director of the primate center, carried out his famous experiments on intelligence in anthropoid apes. It was in the early 1930s in Berlin that Hans-Lukas Teuber first met another of his parents' friends, Kurt Goldstein, and became aware of Goldstein's studies of brain-injured German veterans of World War I.

Teuber entered the University of Basle in Switzerland in 1935. Continuing his search for integrative principles, which he later said was shaped by his father's example and disparate interests, Teuber studied philosophy of science, chemistry, biology and zoology, comparative anatomy, and embryology. Lectures by the embryologist Hans Spemann were particularly influential, awakening his interest in the possibility of using concepts and methods of experimental embryology to study central nervous system functions. At Basle Teuber participated in small interdisciplinary group discussions of the methodology of various sciences and how to bridge the gap between biological and social science. Here he met a fellow student (of art history), Marianne Liepe, and they soon made plans to marry.

At Kurt Goldstein's suggestion Teuber applied for the Holtzer Fellowship to study psychology at Harvard University. Liepe moved to the United States in 1939 to continue her study of art history at Vassar College. Teuber's entry to the United States was delayed until 1941 by the outbreak of World War II. Immediately on arrival, he married Liepe, and began his studies in psychology at Harvard. He and Liepe became naturalized US citizens in 1944.

While a graduate student Teuber supported himself and his family (Andreas Wolfgang was born in 1942, Christopher Lawrence in 1946) by working as a research assistant on a project on the effectiveness of psychological interventions – counseling of various kinds – in preventing juvenile delinquency. His Ph.D. dissertation grew out of this research (*Dyadic Groups: A Study in Counseling Relationships*) and was written under the direction of the social psychologist Gordon Allport. Teuber later said that his work on this project had been valuable in convincing him of the importance of control groups and of quantitative measures of behavior. His enthusiasm for social psychology as a science, however, was never great.

According to Teuber's later recollections, the most important influences on his thinking during his years at Harvard were Karl Lashley and Kurt Goldstein (Goldstein was a visiting professor at Harvard when Teuber entered). Through them he became acquainted with the work of W. B. Cannon, L. J. Henderson, and J. W. Gibbs. Teuber thought that Gibbs's work in physical chemistry might be applicable to both biological and social systems. Frequent personal contacts with Goldstein convinced Teuber, as he later wrote, of the strategic role of experimental neurology within the framework of general biological science, and suggested a reconsideration of the earlier German work (Bethe, von Uexküll, Weiss) in comparative physiology of nervous systems and problems of sensorimotor integration.

In 1944 Teuber interrupted his graduate studies to enter the US Navy, which classified him as a 'pharmacist's mate' and assigned him to the San Diego Naval Hospital. There Teuber met Morris Bender, who headed the neurology wards and was interested in sensory disturbances and causalgia following cerebral injuries. Teuber's background in experimental psychology and his knowledge of Goldstein's work led Bender, a gifted clinical neurologist, to propose a collaboration. The two were soon developing experiments on behavioral consequences of brain injuries sustained by servicemen in battles in the Pacific. Several papers on alterations in visual perception resulted. Teuber regarded their research as continuing in the tradition of Goldstein and Gelb and also of Poppelreuter, Head, and Holmes, who had studied brain-injured soldiers from World War I; he was interested not simply in the presence or absence of particular 'symptoms' associated with different sites of injury but in their scientific significance for a general understanding of normal behavior and brain function.

Teuber returned to Harvard in 1946 and completed his dissertation. He then moved to the Psychophysiological Laboratory, which he and Bender established at the Bellevue Psychiatric Hospital in New York City; Teuber became its director when Bender left to head the Neurology Department at the Mount Sinai College of Medicine. From 1948 to 1960 Teuber held faculty appointments at New York University's College of Medicine and at the Graduate School of Arts and Science, where he taught courses in neuroanatomy, physiological psychology, and social psychology of small groups. He was appointed Area Consultant to the US Veterans Administration in 1948 and received funding to study World War II veterans with injuries of the brain from penetrating missiles. In the same year he was invited to participate in the Macy Foundation's conferences on cybernetics, where a small interdisciplinary group (including Norbert Wiener, Warren McCulloch, John von Neumann, and Margaret Mead) met annually to see whether concepts from cybernetics, information theory, and computer theory could be developed into a common, transdisciplinary framework for integrating the social and natural sciences.

At the American Psychological Association meeting in Boston in 1948 Teuber gave a paper laying out his vision of a new field forming 'in the border region of psychology and neurology'. Using examples from his research with Bender, Teuber called this border region 'neuropsychology', a field in which the fundamental question is how does neural structure 'mediate' psychological functions, and in which the behavior of brain-injured patients plays a strategic role ('experiments of nature') as a source of clues to normal brain–behavior functions. This vision guided Teuber's empirical research in the Psychophysiology Laboratory at New York University, and would later be realized in the psychology department he founded at MIT.

As head of the Psychophysiological Laboratory, Teuber, and the research group he gathered around him (Sidney Weinstein, Lila Ghent Brain, Josephine Semmes, Mortimer Mishkin, William Battersby, Rita Rudel, and others), continued to recruit and test World War II veterans with brain injuries and a control group with peripheral nerve injuries. They devised quantitative testing procedures to assess somatosensory, visual, visuospatial, and cognitive impairments associated with injuries in different brain sites. In addition to setting high standards for methodological rigor in behavioral testing, research from the Psychophysiology Laboratory demonstrated the importance of testing large

populations of patients and of using research designs that permitted clear interpretations of relationships between behavioral deficits and site of injury. ('Double dissociation of symptoms' – demonstration of contrasting sets of behavioral symptoms with contrasting cerebral lesions – was one of Teuber's off-repeated methodological maxims.)

Research from the laboratory appeared in a steady stream of papers during the 1950s on: brain injuries and alterations in visual and visuospatial phenomena (extinction, completion, pattern perception, critical flicker frequency, eye movements, and visual searching); alterations in performance on complex visual tasks and in body schemata; judgments of visual and postural vertical; recognition of objects by touch; somatosensory thresholds; and performance on intelligence tests. Some of this work was summarized in two monographs published in 1960, *Visual Defects after Penetrating Missile Wounds of the Brain* (Teuber, Battersby, and Bender) and *Somatosensory Changes after Penetrating Brain Wounds in Man* (Semmes, Weinstein, Ghent, and Teuber). The latter has been credited with changing traditional concepts of hemispheric asymmetry in the mediation of somatosensory performance. Other work brought then-widely-accepted distinctions between specific and general behavioral effects of lesions into question and challenged widely held beliefs about effects of brain injuries on IQ test performance.

Teuber's theoretical views evolved with his empirical work, and he published two particularly influential synthetic reviews of the literature while at the NYU Psychophysiological Laboratory. One, 'Physiological psychology' (in the 1955 *Annual Review of Psychology*) was an overview which one leading neuroscientist and historian of neuroscience (Charles Gross) later said set the program of the field for the next decade. The other was the chapter on 'Perception' in the 1960 *Handbook of Physiology: Neurophysiology*, *vol 3* in which Teuber comprehensively reviewed research on classic problems of perception and located them in the broader context of sensory-isolation studies, ethological research, studies of behavior following brain injuries, and experimental embryology.

Drawing on work by von Holst and Sperry, Teuber developed throughout the 'Perception' chapter a critique of the assumption, on which both field theories and scanning theories of perception rely, that brain correlates of perception can be understood by viewing the nervous system as a passive receiver of sensory information. By contrast he wrote: 'Throughout this chapter we have stressed the potential role of a central corollary discharge which is postulated as coordinating efferent and afferent processes. This corollary discharge presumably travels from motor into sensory systems at the onset of every [self-initiated] bodily movement and thus permits anticipatory adjustment of the perceptual process … It can be seen that these concepts are closely related to the earlier neurologic postulates of "schemata" as the neural basis for awareness of posture and spatial orientation … .' Within such a theoretical framework, the distinction between voluntary and involuntary motor activity becomes important, while differences among perceptual, sensorimotor, and visuospatial processes become less so.

In 1960 Teuber was invited to MIT to head the Psychology Section of the Department of Economics and Social Science and to plan an independent doctorate-granting Department of Psychology at the Institute. Teuber seized the opportunity to organize his department according to his vision of a science of behavior and the brain and to bring together on the faculty people who shared his vision.

The first two senior appointments, together with Teuber himself, indicated the scope and direction of the department Teuber envisioned. Richard Held, an experimental psychologist from Brandeis University, had recently demonstrated through a series of ingenious experiments the importance of voluntary movement in developing and maintaining perceptual–motor coordination. Walle Nauta, a neuroanatomist then at the National Institutes of Health, had discovered a silver-staining technique that identified axonal degeneration following experimental brain lesions and permitted tracing of pathways in the brain. (The presence of a neuroanatomist, especially one as distinguished as Nauta, in a psychology department at a time when behaviorist learning theory dominated most psychology departments, was unprecedented.) Teuber's own work on perception in brain-injured adults continued at MIT, and his interest in ethology (again unusual for the time) encouraged his students (beginning with Robert Yin) to investigate the perception of human faces.

The junior faculty Teuber assembled used a variety of behavioral, physiological, and anatomical techniques to investigate a variety of psychological topics: memory, eye–hand coordination, space perception, visual backward masking, perceptual–motor development in animals reared in sensory isolation, learning, language, and others. What unified research in the MIT department and

distinguished it from other psychology departments at the time was its focus on behavior in relation to brain function. Investigations often involved both behavioral neurophysiological or neuroanatomical techniques; even when only behavioral data were gathered, they were usually interpreted in terms of hypotheses concerning underlying neural processes.

Early faculty in the department included Joseph Altman, Stephen Chorover, Peter Schiller, Alan Hein, Wayne Wickelgren, Merrill Garrett, Jerry Fodor, and Whitman Richards (the first student to receive a Ph.D. from the department). They were later joined by Gerald Schneider and Ann Graybiel (both of whom also received their degrees from the department), Molly Potter, Sue Carey-Block, and Emilio Bizzi. Before Teuber's untimely death in 1977 he had made plans to add David Marr to the faculty. Visiting scientists, research associates, postdoctoral fellows, and graduate students also contributed to the MIT Psychology Department's distinctive brain–behavior focus, including Charles Gross, Helen Mahut, David Ingle, Harvey Karten, Donald Stein, Thomas Bever, Suzanne Corkin, Donald Pfaff, and Larry Squire. Several generations of undergraduate students at MIT were exposed to Teuber's very popular introductory psychology course, in which he propounded his vision of a new kind of psychology in elegant, witty lectures.

Although the pace of his empirical work slackened at MIT, Teuber was much sought-after as a speaker and discussant at conferences because of his wide-ranging knowledge and ability to identify key unanswered questions. Throughout his career, Teuber was an active participant in international societies (e.g., International Neuropsychological Symposium, International Brain Research Organization, European Brain and Behavior Society, French Psychological Society) as well as North American organizations (e.g., American Psychological Society, Psychonomic Society, Society for Neuroscience). He played an important role in introducing the work of Alexander R. Luria and other Russian neuropsychologists to their counterparts in North America and Europe (Teuber and Luria visited each other's laboratories in the 1950s); his preface to the English translation of Luria's *Higher Cortical Functions in Man* (1966) thoughtfully analyzed Luria's contributions in the context of other national traditions of neuropsychological research. In 1970 Teuber was elected to associate membership in the Neurosciences Research Program, an interdisciplinary program founded by the MIT biophysicist Francis O. Schmitt to bring together world experts in the many disparate sciences and clinical disciplines involved in understanding how the nervous system mediates behavior. Teuber's broad knowledge of neurobehavioral research and his vigorous interaction with his fellow Associates helped strengthen the organization and its impact on the emerging new field of neuroscience.

While at MIT, Teuber wrote numerous syntheses of research on brain and behavior, many drawing on research in the department to exemplify and promote the new field he was working to institutionalize at MIT. In 1969 the Alfred P. Sloan Foundation launched its program in the neurosciences (the first programmatic funding for the new field) and made its first award (and largest overall) to the MIT Psychology Department, designating it a 'center of excellence' not only because of the strength of the department's faculty and staff but because of its unusually integrated approach. Teuber's creativity and effectiveness as an institution-builder were reflected in the many honors and awards he received before he died in a drowning accident in 1977 at the age of 61. He was a member of the Society of Experimental Psychologists (1960), the American Academy of Sciences (1962), the National Academy of Sciences (1972), the French Neurological Society (1968), and the National Institute of Neurology Faculty, Mexico (1967). He received the Karl Spencer Lashley Award for Research in Neurobiology (1966), the Apollo Achievement Award, NASA (1969), the Kenneth Craik Award in Experimental Psychology (1971), MIT's James R. Killian Faculty Achievement Award, Oxford University's Eastman Professorship, and honorary degrees from the Université Claude Bernard (Lyon, France) and the Université de Genève (Switzerland).

Teuber told an interviewer in 1966 that he attributed to his father's influence his own tendency not to feel at home in any single field, and his career demonstrates his powerful drive to synthesize research results and to bring disparate methods to bear on fundamental questions about behavior in relation to brain function. The name he gave to the new field he envisioned changed (largely for rhetorical reasons) several times during his lifetime: psychology, neuropsychology, psychophysiology, brain and behavior, behavioral biology, psychology and brain sciences. The unvarying thread was the inclusion of some term referring to an organism's behavior. It would probably have pleased him that the MIT Psychology Department is now called the Department of Brain and Cognitive Sciences.

Tolman, Edward C.

Introductory article

Nancy K Innis, University of Western Ontario, London, Ontario, Canada

CONTENTS

American psychologist Edward C. Tolman (1886–1959) was author of the learning theory known as purposive behaviorism. Tolman is also noted for introducing important psychological concepts, such as the intervening variable and the cognitive map, which are widely used today.

INTRODUCTION

Edward Chace Tolman was an American psychologist who is perhaps best known today for introducing the idea of a cognitive map. He did so on 17 March 1947, when he delivered the 34th Annual Faculty Research Lecture at the University of California. The occasion celebrated his long and distinguished career in the Psychology Department at Berkeley. The title of his talk was 'Cognitive Maps in Rats and Men', and the concept caught on.

EARLY BACKGROUND

Edward Tolman, the son of Mary Chace and James Pike Tolman, was born in West Newton, Massachusetts, an affluent suburb of Boston, on 14 April 1886. He attended the excellent Newton public schools and then, following family tradition, enrolled at the Massachusetts Institute of Technology (MIT). James Tolman had been in the first graduating class at MIT and was a member of the Board of Trustees, and Edward's elder brother, Richard, was a graduate student there at the time Edward enrolled. Although their father wanted his sons to take over his prosperous cordage business, they both opted for academic careers. Richard would become an eminent physical chemist, spending most of his career at the California Institute of Technology.

After obtaining his undergraduate degree in electrochemistry from MIT in 1911, Edward entered the doctoral program at Harvard. His humanitarian interests, and a disinclination to compete directly with Richard, led him to the new science of psychology, a discipline that was beginning to apply experimental findings to human problems. He received his PhD in 1915 for studies of human memory, under the supervision of Hugo Munsterberg, Director of the Harvard Psychology Laboratory. Although Edward became an experimental, rather than an applied, psychologist, he always retained a strong interest in the human condition. Towards the end of his career he began applying his theoretical principles to personality and social psychology.

In 1915, Tolman accepted his first academic position, as an Instructor at Northwestern University in Evanston, Illinois. Here he continued his research on human memory. In 1918, his contract was not renewed, apparently because of wartime cutbacks; but Tolman always believed that his association with a pacifist student periodical led to his dismissal. However, that summer he was offered an appointment at the University of California, Berkeley, where he would remain for the rest of his career. It was a good move for Edward, both personally and academically. In California, he lost his New England reserve, revealing the warm, fun-loving nature that colleagues would always associate with him. His research interests changed too, and he began to study animal behavior. His first major project with rats was on the inheritance of the ability to learn. This marked the beginning of a long-term research program in behavior genetics at Berkeley. Initiated by Tolman, this work was continued under the direction of his graduate student, and later colleague, Robert Tryon. Tolman turned to more theoretical pursuits.

A NEW FORMULA FOR BEHAVIORISM

Just as Tolman was starting out in psychology, a new theoretical system – behaviorism – was

beginning to take root in America. Led by a young researcher, John Watson, behaviorists rejected the subjective approach of psychologists who used the method of introspection to study unobservables such as consciousness. Instead, they took the more objective position that psychology was the study of behavior. Their research examined the overt responses of subjects, often animals, to environmental stimuli, using classical conditioning methods. This led to their being labeled stimulus–response (S–R) psychologists. Tolman's interest in behaviorism was stimulated initially in a course at Harvard taught by comparative psychologist Robert Yerkes. Tolman liked the fact that this system was scientific and objective. However, he was never able to accept whole-heartedly the brand of behaviorism promoted by Watson.

Tolman believed that behavior was more than simple reflex reactions to stimuli. In 1922, he introduced his own 'new formula for behaviorism' with the aim of providing a scientific treatment of concepts, such as motive and purpose, that had been rejected as subjective and mentalistic by other behaviorists. His approach reveals the influence of two other Harvard professors, Edwin Holt and Ralph Barton Perry, both of whom had written about such concepts as purpose and cognition as objective terms. Over the next ten years, Tolman published articles providing objective definitions for emotions, ideas, and consciousness, as well as for purpose and cognition. He also supervised a number of students whose research with rats in mazes provided support for his theoretical position. He brought theory and data together in a book, *Purposive Behavior in Animals and Men*, published in 1932. Tolman's system of psychology, with its emphasis on the goal-directed nature of behavior, became known as *purposive behaviorism*.

PURPOSIVE BEHAVIORISM

In *Purposive Behavior* Tolman identified four factors that played a role in producing behavior – stimuli, heredity, training, and physiological state – now referred to as independent variables. Intervening between these causal factors and the observed behavior (the dependent variable) were motivational and cognitive behavior-determinants – purposes and cognitions. Tolman suggested that purposiveness was revealed in the behavior itself, by the fact that responding persisted until the goal was achieved. Cognitions were expectations about the relationship between environmental stimuli, referred to as 'signs', and the goals that they indicated. Two types of expectations were identified. Long-term expectations that depended on genetics or past experience (training), he called *means–end-readinesses*. Others, that were specific to the ongoing situation providing information about how to achieve current goals, were labeled *sign-gestalt-expectations*. Tolman used a lot of hyphenated terms like these to refer to his constructs, often making his theory difficult to understand. Soon the simpler term *expectation* began to be used by learning theorists to refer to both types of cognitions. However, Tolman believed that it was important to distinguish between them. A similar kind of distinction has been made more recently by comparative cognition researchers who talk about reference and working memory.

Tolman also attempted to provide an objective definition of conscious awareness or attention with the idea of *behavior-adjustments*. These were responses by means of which the animal sampled its environment before making a response. For example, if these were overt, a rat might wiggle its nose from side to side before choosing to run down an arm of the maze. Later these responses were labeled *vicarious-trial-and-error* (VTE) behavior and became an important feature of Tolman's only attempt to quantify his theory with his schematic sowbug model. The whimsical term merely indicated the tropistic nature of an organism's movement toward or away from a goal.

INTERVENING VARIABLES

Not long after his book was published, Tolman introduced the term *intervening variable* to refer to the motivational and cognitive determinants of behavior that he had identified. For Tolman, a theory was no more than a set of intervening variables, and the task of the psychologist was to operationally define them. This could be accomplished by means of standard experiments in which an independent variable correlated with the construct being studied is systematically varied while all others are held constant. Tolman referred to his revised position as 'operational behaviorism' because it used operational definitions and because the behavior being observed by the researcher involved an organism acting on – operating on – its environment.

Tolman's book and subsequent theoretical articles were well received by his colleagues, and in 1937 he was elected President of the American Psychological Association (APA). In his presidential address, after comparing his brand of behaviorism with that of the currently more popular

S–R theorists, such as Clark Hull, Tolman outlined his system for his colleagues. He concluded with the surprising statement that 'everything important in psychology … can be investigated in essence through the continued experimental and theoretical analysis of the determiners of rat behavior at the choice point in a maze'. In his talk he had shown in detail how operational behaviorism could account for such choice-point behavior. But, of course, he saw that his system had broader implications. Soon he turned his attention to its application to humans.

COGNITIVE MAPS IN RATS AND MEN

Tolman brought his ideas about the behavior of rats and humans together in his Faculty Research Lecture at Berkeley. Again he compared his theory of learning with that of the S–R psychologists, this time using compelling metaphors. In contrast to the 'telephone-switchboard' type of connections proposed by his S–R rivals, for Tolman learning involved 'something like a field map of the environment [being] established in the rat's brain'. The suggestion of a mental map in the brain was the first time that Tolman gave a direct physiological referent to one of his intervening variables. The map metaphor was very appropriate since much of the data supporting Tolman's position had come from studies of rats in mazes.

Two types of cognitive maps – 'broad and comprehensive' and 'narrow and striplike' – were identified. On mazes, rats with broad maps responded to the general location of the goal rather than learning a specific route to it; those with narrow maps became fixated on a particular route. Narrow maps, which were less adaptive, were established as a result of brain damage or when conditions were highly motivating or frustrating.

At the end of his Berkeley lecture, Tolman suggested that human social maladjustments could be interpreted as narrowings of cognitive maps as a result of strong motivation or frustration. He hoped that psychologists could help establish a society in which frustrations and motivations were modulated, one that would produce broad cognitive maps, and thereby appropriate psychological adjustment. Over the next few years, many of his articles were devoted to extending his theory to human social learning.

Tolman's own cognitive map was a broad map. He was eclectic in his approach, and open-minded and tolerant in his treatment of the ideas of others.

PERSONALITY AND SOCIAL PSYCHOLOGY

Tolman had a real affinity for personality and social psychology, and his later writings reflect this interest. He had first applied his ideas to human behavior during World War II. As a pacifist, he despised war and violence. In 1933–4, during a sabbatical year in Vienna, he witnessed with considerable dismay Hitler's rise to power. On returning to the USA he worked to help émigré psychologists fleeing from Europe to find positions in America. He was also involved with the Society for the Psychological Study of Social Issues (SPSSI), a group of psychologists committed to applying their expertise to problems arising from the economic depression and the looming possibility of war. In his address as Chairman of SPSSI in 1940, Tolman introduced ideas that were presented at greater length in a book, *Drives Toward War*, published in 1942. Although it started out as a motivation textbook, the major aim of the book was to identify mechanisms for harnessing human aggression to prevent future wars between nations. It illustrated Tolman's strong belief that basic psychological research could provide solutions to social problems. He would always remain optimistic about the role of psychology in meliorating the human condition.

THE FIGHT FOR ACADEMIC FREEDOM

Edward Tolman was a staunch defender of academic freedom. As the Communist scare swept America in the late 1940s, the Regents of the University of California demanded an anti-Communist oath of loyalty from the faculty. Tolman was one of the first to speak out against this violation of academic freedom and became leader of the Group for Academic Freedom, formed to oppose the oath. In 1950, he and about 20 others, who had been fired from the university for refusing to sign the oath, took the Regents to court. After a long struggle they eventually won their case and were reinstated. The oath controversy was widely reported in the media, and Tolman's principled stand gained him the respect of professors throughout the USA. The fight over the oath, however, took a personal toll on Tolman, and his health began to deteriorate. He died at his home in Berkeley on 19 November 1959.

Turing, Alan

Introductory article

B Jack Copeland, University of Canterbury, Christchurch, New Zealand

CONTENTS

Alan Turing was a British mathematical logician who pioneered computer science, cognitive science, artificial intelligence, and artificial life.

OVERVIEW OF TURING'S WORK

The mathematical logician Alan Mathison Turing OBE (1912–1954) contributed to logic, mathematics, cryptanalysis, philosophy, mathematical biology, and formatively to computer science, cognitive science, artificial intelligence (AI), and artificial life. He was elected a Fellow of King's College, Cambridge in 1935 and in 1936 published his most important work, 'On computable numbers, with an application to the Entscheidungsproblem'. From 1936 to 1938 he studied for a PhD at Princeton University, returning to King's in 1938. At the outbreak of war with Germany (September 1939) he moved to Bletchley Park, the wartime headquarters of the Government Code and Cypher School (GC&CS). At Bletchley, Turing single-handedly broke Naval Enigma and was the principal designer of the Bombe, a large-scale electromechanical machine for revealing Enigma message keys by a process of high-speed search. From 1945 Turing worked at the National Physical Laboratory (NPL) in London, pioneering computer science and AI, and from 1948 at the University of Manchester as Deputy Director of the Computing Machine Laboratory (there was no Director), taking up a specially created Readership in the Theory of Computing in 1953.

RELEVANCE AND ROLE OF TURING'S WORK IN COGNITIVE SCIENCE

The Universal Turing Machine

As everyone who uses a personal computer knows, the way to make the machine perform some desired task is to open the appropriate program stored in the computer's memory. But the earliest large-scale electronic digital computers, the British Colossus (1943) and the American ENIAC (1945), did not store programs in memory. To set up these computers for a fresh task, it was necessary to modify some of the machine's wiring, rerouting cables by hand and setting switches. The basic principle of the modern computer – controlling the machine's operations by means of a program of coded instructions stored in the computer's memory – was thought of by Turing in 1935. His abstract 'universal computing machine', as he called it – it would soon become known as the universal Turing machine (UTM) – consists of a limitless memory in which both data and instructions are stored, in symbolically encoded form, and a scanner that moves back and forth through the memory, symbol by symbol, reading what it finds and writing further symbols. By inserting different programs into the memory, the machine is made to carry out different computations. The UTM (described in 'On computable numbers') was the first formal model of computation. Turing's idea of a universal stored-program computing machine was promulgated in the US by John von Neumann and in the UK by Maxwell Herman Newman. By 1945 groups in both countries were attempting to build an electronic stored-program universal digital computer: a Turing machine in hardware. (*See* **Computation, Formal Models of**)

The Church–Turing thesis

Before the advent of computing machines, a computer was a human being: a mathematical assistant whose task was to calculate by rote, in accordance with a systematic method supplied by an overseer. Like a filing clerk, the computer might have little detailed knowledge of the end to which the calculations were directed. The Church–Turing thesis (advanced independently by Turing and the American Alonzo Church in 1936) says in effect that the UTM can perform any calculation that can be done

by an idealized human computer (who lives forever and never runs out of paper and pencils).

The Turing machine and the brain

According to a prominent theory in cognitive science, the brain is a Turing machine, in the sense that any information processing of which the brain is capable can be done by the UTM. A stronger version of the theory holds that the brain is fundamentally similar to the UTM, in that both are 'symbol systems': machines that process formal symbols by means of a fixed repertoire of basic computational operations. (*See* **Symbol Systems**)

Uncomputability

In 'On computable numbers' Turing proved that some well-defined mathematical problems are uncomputable, in the sense that they cannot be solved by the UTM – and so, according to the Church–Turing thesis, cannot be solved by a human being working by rote. An example is the following. Some Turing machines print '1' at some stage in their computations. All the remaining Turing machines never print '1'. Consider the problem of deciding, given an arbitrary Turing machine, which of these two categories it falls into. Turing showed that this problem cannot be solved by the UTM.

Turing developed these ideas further while at Princeton, laying the foundations of the branch of mathematical logic that investigates and codifies problems 'too hard' to be solvable by the UTM, and introducing the concept of an oracle machine (or *o*-machine) – a 'new kind of machine' able to solve problems that the UTM cannot. In modern cognitive science, *o*-machines form the basis for a controversial new class of models of cognition termed 'hypercomputational'.

Computer Pioneer

Turing's technical report 'Proposed electronic calculator', dating from the end of 1945 and containing his design for the 'Automatic Computing Engine' (ACE), was the first relatively complete specification of an electronic stored-program digital computer. The earlier 'First draft of a report on the EDVAC' (May 1945), written in the US by von Neumann (familiar with the UTM since before the war), discussed at length the design of an electronic stored-program digital computer, but in fairly abstract terms, saying little about programming, hardware details, or even electronics. Turing's report, on the other hand, contained specimen programs in machine code, full specifications of hardware units, detailed circuit designs, and even an estimate of the cost of building the machine (£11,200). Had Turing's ACE been built as he planned, it would have been in a different league from the other early computers, but his colleagues at the NPL thought the engineering work too difficult to attempt and a considerably smaller machine was built. Known as the 'Pilot Model ACE', this machine ran its first program on 10 May 1950. With a clock speed of 1 MHz, it was for some time the fastest computer in the world. Computers derived from Turing's ACE design remained in use until about 1970, including the Bendix G-15, arguably the first personal computer. (Delays beyond Turing's control resulted in the NPL's losing the race to build the world's first stored-program electronic digital computer. That honour went to Newman's Computing Machine Laboratory at Manchester, where the 'Manchester Baby' ran its first program on 21 June 1948.)

Artificial Intelligence

Turing was the first to carry out substantial research in the field of AI. He was thinking about AI at least as early as 1941, and during the war circulated a typewritten paper on machine intelligence among his colleagues at GC&CS. Now lost, this was undoubtedly the earliest paper in the field of AI. It probably concerned machine learning, heuristic problem-solving, and machine chess, topics that Turing discussed extensively at GC&CS. His thinking on AI was probably influenced by his work on the Bombe, which involved him in the design of, for example, a 'majority vote gadget', mechanizing the process of evaluating a hypothesis on the basis of unreliable data, and a 'Ringstellung cut-out', an early example of the use of heuristics (rules of thumb) to constrain search.

In February 1947 Turing gave the earliest known public lecture to mention computer intelligence, providing an exciting glimpse of a new field. He discussed the prospect of machines acting intelligently, learning from experience, and beating humans at chess.

Intelligent machinery

In 1948 Turing wrote a report for the NPL entitled 'Intelligent machinery'. Described by an NPL bureaucrat as 'not suitable for publication', this farsighted paper was the first manifesto of AI. In it Turing gave a wide-ranging and imaginative survey of the prospects of AI and brilliantly introduced many of the concepts that were later to

become central in the field, in some cases after reinvention by others. These included the logic-based approach to problem-solving, now widely used in expert systems, and the idea, subsequently made popular by Allen Newell and Herbert Simon, that (as Turing put it) 'intellectual activity consists mainly of various kinds of search'. (The idea of solving a problem by means of a guided search through the space of possible solutions was central to the Bombe.) Turing anticipated the concept of a genetic algorithm in a brief passage concerning what he called 'genetical or evolutionary search'. Genetic algorithms employ methods analogous to the processes of natural evolution in order to produce successive generations of software entities that are increasingly fit for their intended purpose. 'Intelligent machinery' also contains the earliest description of (a restricted form of) what Turing was in 1950 to call the 'imitation game' and is now known simply as the Turing test. In 1952 he said of the imitation game that 'you might call it a test to see whether the machine thinks, but it would be better to avoid begging the question, and say that the machines that pass are (let's say) "Grade A" machines', and predicted that it would be at least 100 years before computers would stand a chance at the imitation game (with no questions barred). (*See* **Turing Test**)

Can machines think?

In 1950 Turing famously remarked that this question is 'too meaningless to deserve discussion'; however, his later accounts of the imitation game (in 1951 and 1952) reveal a milder attitude and contain liberal use of such phrases as 'programming a machine to think' and 'making a thinking machine'.

Gödelian arguments against AI

Turing was among the first to write about the Gödelian arguments against AI (which originated with Emil Post in 1921). Turing discerned a simple fallacy in such arguments. In 'Intelligent machinery' he wrote: (*See* **Artificial Intelligence, Gödelian Arguments against**)

> The argument from Gödel's and other theorems … rests essentially on the condition that the machine must not make mistakes. But this is not a requirement for intelligence.

In 'Proposed electronic calculator' (the earliest surviving written statement of Turing's views concerning machine intelligence), Turing wrote:

> There are indications however that it is possible to make the machine display intelligence at the risk of its making occasional serious mistakes. By following up this aspect the machine could probably be made to play very good chess.

The risk that the machine will produce incorrect results is the price of heuristic search.

Neural Simulation

Probably Turing's earliest surviving mention of his interest in neural simulation is in a letter to the cyberneticist W. Ross Ashby: 'In working on the ACE I am more interested in the possibility of producing models of the action of the brain than in the practical applications to computing.' The major part of 'Intelligent machinery' consists of an exquisite discussion of neural simulation and machine learning, in which Turing anticipated the modern approach known as connectionism. Donald Hebb and Frank Rosenblatt are widely regarded as the founders of connectionism and it is not widely realized that Turing had outlined much of the connectionist project as early as 1948. He introduced what he called 'unorganized machines', giving as examples networks of neuron-like elements connected together in a largely random manner; he described one type of network as 'the simplest model of a nervous system', and hypothesized that 'the cortex of the infant is an unorganized machine, which can be organized by suitable interfering training'. From a historical point of view, his idea that an initially unorganized neural network can be organized by means of 'interfering training' is of considerable significance: this idea did not appear in the earlier work of McCulloch and Pitts. In Turing's model, the training process renders certain neural pathways effective and others ineffective. He anticipated the modern procedure of using an ordinary digital computer to simulate neural networks and the process of training them. He claimed a proof (now lost) of the proposition that an initially unorganized network with a sufficient number of neurons can be organized to become a universal Turing machine with a given storage capacity. This proof raised the possibility, noted by Turing, that the human cognitive system may be a universal symbol processor implemented in a neural network. (*See* **Learning through Case Analysis**; **Neurons, Computation in**; **McCulloch–Pitts Neurons**; **Perceptron**)

Artificial Life

During his final years Turing pioneered artificial life. He used the Manchester Ferranti Mark I (the first commercially sold electronic stored-program

computer) to model biological growth, and he appears to have been the first person to engage in the computer-assisted exploration of nonlinear dynamical systems. He programmed the computer to simulate a chemical mechanism by which the genes of a zygote may determine the anatomical structure of the resulting animal or plant. (*See* **Artificial Life**)

Tversky, Amos

Introductory article

Maya Bar-Hillel, The Hebrew University, Jerusalem, Israel

CONTENTS

Amos Tversky is best known for his pathbreaking work, along with Daniel Kahneman, on heuristics and biases in judgment under uncertainty, and for prospect theory, *a theory of decision under uncertainty. His research showed that people are 'irrational', namely, their judgments and decisions deviate in systematic ways from normative dictates.*

BIOGRAPHY

Amos Tversky was born on 16 March 1937, in Haifa, Israel, his parents' second child; his mother was a social worker (later to become a Member in Israel's first Parliament), and his father was one of the newly emerging State of Israel's first veterinarians. Tversky served as an officer in the paratroops regiment of the Israeli army, winning Israel's highest honor for bravery. As a student at The Hebrew University of Jerusalem he majored in psychology and philosophy, and after graduation in 1961 enrolled in Michigan University's mathematical psychology program. In 1965 he wrote an award-winning dissertation under the supervision of Clyde H. Coombs.

At Michigan he met future collaborators, such as Robyn Dawes, Ward Edwards, Dave Krantz, and Paul Slovic. There he also met his wife-to-be, Barbara (née Gans, later a Professor of Psychology at Stanford University). He spent a year as Fellow at Harvard University's Center for Cognitive Studies, after which he returned to The Hebrew University, serving on its faculty as Professor of Psychology until 1978. It was there that Tversky began his extraordinary collaboration with Daniel Kahneman, which was to last over a quarter of a century and yield some of the most influential and innovative ideas in the area of judgment and decision-making (JDM).

Soon after his return to Israel, the 1967 Six Day War broke out, and Tversky fought in it. Subsequently he also fought in the 1973 October War. During 1970–2 he spent a year as Fellow at Stanford's Center for Advanced Studies and a year at the Oregon Research Institute. In 1978 he moved to Stanford University, where he was the inaugural Davis-Brack Professor of Behavioral Science and Principal Investigator at the Stanford Center on Conflict and Negotiation until his untimely death on 2 June 1996. Throughout his years at Stanford, he maintained very close ties with Israel, visiting regularly a couple of times each year. In 1984/5 he spent a year at The Hebrew University, and from 1992 was Senior Visiting Professor of Economics and Psychology and Permanent Fellow of the Sackler Institute of Advanced Studies at Tel Aviv University. Many of his students themselves became Professors of Psychology in universities across the world.

Tversky won many awards during his short life: Distinguished Scientific Contribution Award of the American Psychological Association (1982); McArthur Prize (1984); Warren Medal of the Society of Experimental Psychologists (1995). He received Honorary Doctorates from the University of Goteborg (1985), State University of New York at Buffalo (1987), University of Chicago (1988), and Yale University (1994). He was a member of the Society of Experimental Psychologists (1979), the American Academy of Arts and Sciences (1980), the National Academy of Science (1985), and the Econometric Society (1993).

CONTRIBUTIONS

Probability Judgments

Until the early 1970s, the prevalent view of how people judge uncertainty was that they followed normative dictates to a good first approximation, although they were limited, fallible, and imperfect in doing so. Comparing notes from their experience in teaching college statistics, Tversky and Kahneman noted some common statistical errors among their students (e.g. insufficient appreciation for the role of sample size), as well as among their more sophisticated colleagues (e.g. insufficient attention

to sample error) which led them to discard this view of 'Man as an intuitive statistician'. They proposed an alternative picture whereby people intuitively and spontaneously replace judgments of probability or of frequency by quite different judgments, which are more cognitively natural and easy for the human mind to perform. Such a cognitive strategy is called a *heuristic*, and two were put forth.

First, when relying on representativeness, 'an event is judged probable to the extent that it represents the essential features of its parent population or generating process'. A famous example is Linda, who is '31 years old, single, outspoken and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.' Most people think Linda is more likely to be a feminist bank-teller than a bank-teller – even though, of course, all feminist bank-tellers are bank-tellers. This normative violation is known as the *conjunction fallacy*. It follows from, and indicates that, people fail to consider the normative logical constraints their judgments should obey, instead following the heuristic judgment that Linda sounds more like a feminist – even a feminist bank-teller – than like a prototypical bank-teller.

Second, when relying on availability, people judge the likelihood of an event by the ease with which it can be brought to mind, whether by mental construction or by retrieval from memory. Consider people's inclination to think that there are fewer English words whose penultimate letter is N than words whose final letters are ING.

In 1974, the heuristics and biases work was published in *Science*, and became Tversky and Kahneman's single most cited paper. It also gave its name to a leading school within the area of JDM, and helped turn JDM from a marginal area in cognition into one of its fastest growing areas. Shortly thereafter, Tversky and Kahneman expanded into the study of decision-making, described in the following section.

In his later years, Tversky developed his *support theory*, positing that probabilities are attached not to actual events in the world, but to descriptions or mental representations thereof, called 'hypotheses'. A hypothesis' probability depends on the relative strength of its supporting evidence versus evidence supporting its alternative. For example, unpacking an event such as 'dying an unnatural death' into its constituents (e.g. road accident, homicide, suicide, drowning, other) greatly increases its perceived support, hence its perceived likelihood, by bringing to mind overlooked constituents and highlighting others. Hence, the notion of unpacking a hypothesis, which changes an event's description without changing the event, accounts for how the sum of the estimated probabilities of an event's components can exceed that of the event itself.

Decision and Choice

Tversky had begun to make his mark in both empirical and formal aspects of decision and choice already in his Michigan days. He had developed an elegant mathematical model to capture the notion that when faced with a multitude of options, we often reduce the possibilities by successively eliminating those options which are inferior on some aspect important to the choice. But it was within his remarkable collaboration with Kahneman that the full impact of his thinking came to fruition. In 1979, they published their seminal paper on prospect theory. The paper appeared in *Econometrica*, and at the time of Tversky's death this paper by two cognitive psychologists was the most cited paper of all time (1703 citations) to appear in this most prestigious of economics journals. One reason for this remarkable fact is the paper's popularity outside of economics – not only among cognitive and social psychologists, but also among jurists, political scientists, physicians, and more. Indeed, Kahneman and Tversky's work is arguably the most influential contribution of cognitive psychology to neighboring disciplines in the second half of the twentieth century.

Prospect theory (PT) offered a descriptively adequate alternative to subjective expected utility theory (SEU), the normative cornerstone in economic theory of individual decision-making under uncertainty. In SEU, utilities are derived from 'rational' (namely, consistent) choice, and the utility of a 'gamble' (namely, an uncertain choice) is the sum of the products of the utility of each of its possible final outcomes by the (subjective) probability of this outcome's occurrence. PT kept the form of the utility function, but substituted each of its components by a more psychologically realistic counterpart.

Final outcomes (also known as 'states of wealth') were replaced by gains or losses, namely by changes in final states. More accurately, the carriers of utility were posited to be descriptions, or 'frames', of changes in wealth as gains or as losses (recall the similar, though chronologically later, idea in support theory). Thus, they range from $-$ to $+$, not just from 0 to $+$ as in SEU. The 0 point is either the actual status quo or some frame-induced reference point. People's attitudes to risk are 'reflected' around this point, so that

where they are risk-averse in one domain, they are risk-seeking in the other, and vice versa. Probabilities, on the other hand, are subjected to a function which imposes on them decision weights.

This was a radical conceptual change, as there exists no mental operation that automatically converts changes of states into final states, whereas probabilities, even when objectively given, are distorted by the decision weights. That our decision intuitions are not based on the decision's impact on final wealth is immediately apparent: we usually have a poor idea, if any, of just what our state of wealth is at any given moment. Moreover, the intuitions of people whose wealth differs by orders of magnitude are often highly similar (e.g. almost everybody, rich or poor, would reject a gamble which offers even odds of gaining or losing $1000). That our reponse to probabilities is not linear can be demonstrated by the following classical example. Imagine you are playing a game of Russian roulette, in which you must fire a gun loaded with k live bullets and 6 − k empty chambers. You can deduct one live bullet by paying some large amount of money. When would you be more inclined to pay: if the gun has a single live bullet, or if it has four live bullets? The drop in the probability of death is the same – 1/6 – in both cases, but the greater willingness to pay in the former case than in the latter follows from the shape of the decision weights function. Altogether, at objective probabilities of 0 and 1 interesting discontinuities arise, which have no parallel elsewhere in the probability range. These are known as the *certainty effect*.

The dramatic effect which framing can have on decision is demonstrated in the following notorious problem. A virulent strain of flu is expected to hit next winter, and could claim 600 lives. Two alternative programs, A and B, have been proposed to combat it. If A is adopted, 200 of those lives can be saved (400 of those lives will be lost). If B is adopted, there is a 1/3 chance of saving all 600 lives, but a 2/3 chance of saving none (there is a 1/3 chance of nobody dying, but a 2/3 chance all 600 will die). Typically, most people prefer A under the description outside the brackets, but prefer B under the description within the brackets. This example clearly shows that people do not have a canonical representation of final outcomes, as the final outcomes described outside of and within the brackets are identical. They do not even have a canonical representation of gains and losses, as those, too, are identical within and outside the brackets. Rather, when given a pseudo 'gain-frame' (the outcomes are described in terms of lives saved), they passively accept it, exhibiting risk-aversion (preferring the sure-thing), and when given a pseudo 'loss-frame' (outcomes described in terms of lives lost), they become risk-seeking (reject the sure-thing). It is violations of invariance such as this that most clearly prove that a normative utility theory can never be descriptively adequate, because no normative theory can afford to give invariance up.

Another powerful notion to have come out of PT is that of 'loss aversion' (or: 'losses loom larger than gains'). To wit, for most people, offsetting a possible loss of $X requires a possible gain, at equal odds, considerably larger than $X, and often as large as $2X. Loss aversion has become a popular and useful tool in analyzing real-life situations outside the psychological laboratory. Consider, for example, the difficulty of resolving international conflicts by give and take. Suppose a seemingly symmetrical negotiation around arms reduction. An 'honest broker' believes that one of my ABCD missiles has roughly equal impact, in terms of arms reduction, to one of my enemy's MNOP missiles. But 'losing' one of mine can only be offset, for me, by 'gaining' about two of the enemy's – whereas for my enemy it is the other way around.

Additional Work

Tversky made substantial contributions in two additional areas, loosely related to his pathbreaking work in JDM – the axiomatic foundations of measurement, and the study of similarity judgments.

His feature-based theory of similarity challenged many common assumptions about similarity. Thus, Tversky posited that similarity need not be symmetrical: the son resembles the father more than the father resembles the son. Similarity also need not be the complement of dissimilarity: the USA and Britain may be simultaneously more similar to each other and more dissimilar from each other than North Korea and South Korea. His theory predicts that weights are given to features in a manner that is sensitive both to the task (similarity versus dissimilarity) and to which of A and B is the subject and which the object of the judgment.

His experiments and examples in this area are characterized by the same clarity, perceptiveness, and wit which characterize the examples shown before, and which helped popularize his work by their sheer appeal and catchiness. At the same time, his mathematical modeling is characterized by a unique style of using formal thinking to clarify psychological ideas. Even people with little mathematical sophistication can follow his reasoning

and benefit from the formal treatment, which invariably highlights essential conceptual distinctions and somehow cuts nature at the correct joints.

Tversky had a passion about 'getting things right'. Accordingly, his publications are notable not so much for their number as for their impact (at the time of his death, he had published more papers in *Psychological Review* than any previous author). His work will no doubt have a lasting, if not dominating, influence on JDM.

von Neumann, John

Introductory article

Arthur W Burks, University of Michigan, Ann Arbor, MI, USA

CONTENTS

John von Neumann (1903–1957) was an interdisciplinary thinker who not only brought fresh approaches to seemingly disparate fields, but discovered and developed their interrelationships. His greatest achievement in cognitive science was his contribution to the concept of the stored-program computer, where he applied the logical correspondence between nervous systems and computing systems to the logical design of electronic computers.

INTRODUCTION

John von Neumann was a Hungarian-born prodigy who became a world-famous mathematician, physicist, logician, economist, engineer, and computer scientist. From 1921 to 1926, he lived and studied variously in Budapest, Berlin, and Zurich. In Berlin, he studied chemistry under the Nobel laureate Fritz Haber. At the Swiss Federal Institute of Technology in Zurich, he earned a bachelor's degree in chemical engineering; while there, he often had talks with the distinguished mathematician Hermann Weyl. He received his doctoral degree in mathematics from the University of Budapest in 1926, and from 1927 to 1930 he taught at the University of Berlin as a *privatdocent*.

In 1927, von Neumann published his paper, 'Zur Hilbertschen Beweistheorie', having worked on set theory and mathematical logic for several years. This work contributed to David Hilbert's program to reduce mathematics to a rigidly formal system of logic and arithmetic. Von Neumann was invited to visit Princeton University in 1930; three years later he became a Full Professor at the nearby Institute for Advanced Study, as a colleague of Weyl, Albert Einstein, and other notable scholars.

Von Neumann was highly interdisciplinary. In mathematics, he contributed to the theory of rings of operators in Hilbert's multidimensional spaces. In quantum mechanics, he showed that Schrödinger's wave mechanics and Heisenberg's matrix mechanics are mathematically equivalent, even though they are intuitively very different.

Von Neumann published his seminal paper, 'Theory of games of strategy' in 1928. In 1944, he wrote *Theory of Games and Economic Behavior* jointly with the economist Oscar Morgenstern. This theory addresses a sophisticated component of human cognition and action, as it applies mathematics to a fundamental aspect of human activity: conscious intentional goal-seeking. The phenomenologist Franz Bretano attempted to distinguish the mental from the physical, asserting that only the mental could possess intentionality. However, several computer programs based on goal-directed strategies have been developed – for example, in checkers and chess – that take the first tiny step towards designing a computer with a general power of rational thought.

ELECTRONIC COMPUTERS

Von Neumann's interest in electronic computers was kindled by developments in the early years of the Second World War, during which a causally connected sequence of four electronic computers launched the modern computer revolution. These were: the special-purpose Atanasoff–Berry Computer (ABC) of Iowa State University; the manually programmed general-purpose Electronic Numerical Integrator and Computer (ENIAC) of the University of Pennsylvania's Moore School of Electrical Engineering; the stored-program Electronic Discrete Variable Computer (EDVAC), also of the Moore School; and the stored-program Institute for Advanced Study (IAS) Computer. Von Neumann entered the picture in August 1944, having been invited to consult for the Moore School team as the ENIAC was nearing completion and the EDVAC was being envisioned.

J. Presper Eckert and John W. Mauchly, who were planning for the EDVAC, had decided that the computer would have a memory separate from

and interacting with an arithmetic unit. The memory would be large enough to hold not only numerical data but also instructions in coded binary form, both to be entered automatically prior to a problem run. The memory, which would be regenerated periodically, would consist of mercury-delay-line tanks adapted by Eckert and T. Kite Sharpless from those used for radar detection of enemy aircraft. The arithmetic unit would perform addition, subtraction, multiplication, division, and perhaps square-rooting, all serially and in the binary number system.

When von Neumann arrived, he was occupied primarily (and secretly) with consultations on the two atomic bomb projects. Nevertheless, his contribution to the design of the EDVAC constitutes his most important contribution to cognitive science. His idea was to proceed in two stages: first, develop a logical design in terms of a new logical language of his own invention; then, have computer engineers work out the electronic circuitry according to that design. The idea, which was to become standard, was that the logical structure could be developed before the much more complex electronic circuitry was devised.

Figure 1(a) is a simple example of what von Neumann had in mind for the logical stage. It shows the structure of a binary serial adder, the core of the arithmetic unit, as it adds two binary streams $A(t)$ and $B(t)$ for $t = 0, 1, 2, \ldots$. At each moment of time t, the sum $S(t)$ is 1 just in case an odd number of the two input bits $A(t)$ and $B(t)$ and the carry-back bit $M(t)$ are 1. The carry bit $N(t)$ is 1 just in case at least two of its inputs $A(t)$, $B(t)$, and the delayed carry bit $M(t)$ are 1. These are the defining rules of binary addition. Figure 1(b) is the state transition table describing the behavior of 1(a).

Von Neumann's new computer logic is an 'iconic logic of switching and memory nets': 'iconic' because it gives a two-dimensional diagram of a computer circuit of any complexity, and 'switching and memory' because any clocked computer circuit can be constructed from complexes of switches and unit delays. The unit delay provides the memory, when put in a cycle with switches, that can remove a word and replace it with a new one. More generally, von Neumann realized from his background in logic that the structure of any clocked digital computer could be represented in his iconic logic of switching and memory nets. He realized also that this language could be used to settle many questions concerning the structure and the machine language of an electronic computer at this logical stage.

The iconic logic of switching and memory nets has other switching symbols not shown in figure 1, in particular, switches for 'not' and 'and'. When these are added, the logic becomes universal in the sense that the logical and computing structure of any clocked electronic digital computer can be represented in it.

COMPUTERS AND NEURAL NETS

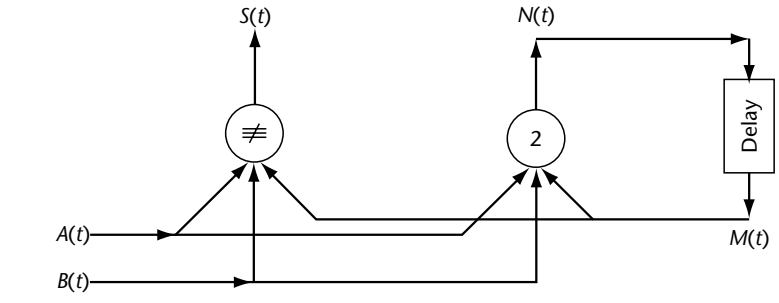
Von Neumann's first paper on the EDVAC, 'First draft of a report on the EDVAC', was distributed to selected people in the US and England in June 1945. In this paper, von Neumann states the source of his iconic logic of switching and memory nets. In a section entitled 'Neurons, synapses, excitatory and inhibiting types', where the threshold-2 switch of figure 1(a) is excitatory and a negation is inhibitory, he wrote:

> Following W. Pitts and W. S. McCulloch ('A logical calculus of the ideas immanent in nervous activity', *Bull. Math. Biophysics*, vol. 5 [1943], pp. 115–133) we ignore the more complicated aspects of neuron functioning: Thresholds, temporal summation, relative inhibition, changes of the threshold by after effects of stimulation beyond the synaptic delay, etc.

McCulloch and Pitts had seen a deep analogy between how the neural nets of nervous systems operate and a new mathematical logic symbolism in which each simple logical switch is followed by a unit delay. Von Neumann then saw that this logical structure, in which every switching action of 'not', 'or' and 'and' is followed by a unit delay, was an entirely new mathematical logic that could be applied to the electronic action of the planned EDVAC. This newly discovered correspondence between the logic of the EDVAC and the logic of neural nets shows the vital importance of physiology and neurology in shaping cognitive science.

Using his new logic of nets, von Neumann worked out the logical design of the memory and of the arithmetic unit of the EDVAC, together with the communication channel between them. This much of the EDVAC's architecture was a sufficient semantic basis for him to specify the machine language of the EDVAC, which he did in the last section of his paper, entitled 'The code'.

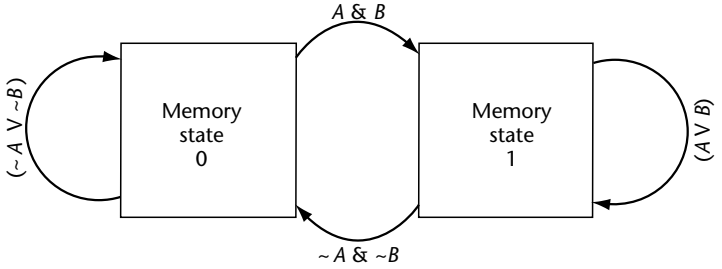
After the Second World War, von Neumann turned to the design of the IAS Computer, alternatively called the Von Neumann Computer. He had, in his paper on the EDVAC, suggested a new, better kind of computer memory. This entailed combining the functions of a standard cathode ray tube (as used in television sets) with those of an iconoscope (as used in television cameras) to make



(a)

Input state		Present memory state *M*	Next memory state *N*	Output state *S*
0	0	0	0	0
0	1	0	0	1
1	0	0	0	1
1	1	0	1	0
0	0	1	0	1
0	1	1	1	0
1	0	1	1	0
1	1	1	1	1

(b)



(c)

Figure 1. Local and global ways of representing a von Neumann logical net binary serial adder. Figure 1(a) shows a three-part logical net specifying an electronic circuit for serial addition. There is a logical inequivalence switch on the left. It signifies that the output sum, $S(t)$, is 1 whenever either just one or all three of the input bits $A(t)$, $B(t)$, and $M(t)$ are 1; but that otherwise $S(t)$ is 0. There is a threshold-2 switch in the middle, since a carry occurs when at least two of its three inputs are 1. Finally, there is a delay for carry-back on the right, which obeys the recursion: $M(0) = 0,\ M(t+1) = N(t)$. Figure 1(b) shows the state transition table (truth table) specifying the behavior of this logical net; and figure 1(c) shows the corresponding state transition diagram.

a computer storage tube. An iconoscope converts a pattern of varying light and dark into corresponding variations in electric charges; a cathode ray viewing tube converts those variations back into a (black-and-white) picture. Von Neumann reasoned by analogy that a single tube could be designed to carry out both functions and thus be a memory tube in which the bits 0 and 1 were distinguished at each of 1,024 spots on the inside of the front of the cathode ray tube by two different levels of electric charge. Frederick C. Williams of Manchester University invented such a tube in late 1946.

This form of computer memory allowed random access to the bits it held, so that a better way to treat binary words than the serial processing of the EDVAC was possible: one could now store, transfer, and process all the bits of a word in parallel. The June 1946 report by Burks, Goldstine and von Neumann, called 'Preliminary discussion of the logical design of an electronic computing instrument', laid out the complete general plan for the first computer with a random-access memory. There were to be 40 memory cathode ray tubes, each storing one bit of a 40–bit word, which could be either a 40–bit binary number or a pair of single-address instructions. Each tube would store 1,024 bits, but each word or instruction would be transferred in bit-parallel between the memory and the

arithmetic unit or the control, or from the arithmetic unit to the memory.

Moreover, this report contained the first simple formulation of a modern programming language, the descriptive design of the first modern program control, and the paradigm of the first modern computer architecture. In particular, the address-substitution instruction is stated much more clearly than in the EDVAC paper, and the control apparatus to execute it is described completely.

COMPUTER SELF-PROGRAMMING

The Moore School team had realized the great advantage the EDVAC would offer for setting up problems, compared with the ENIAC's manual plugboard system. It would now be possible to enter a program automatically, by transferring it from punched paper tape or magnetic wire into the memory of the computer. But von Neumann saw further that when instructions are stored in read–write memory, they also can be operated on by the program as the problem run progresses. His address-substitution instruction, invented for this very purpose, changes the address reference of an instruction without changing the operation it directs. This new instruction would be used to select a particular entry from a function table of entries. The fact that the EDVAC, the IAS Computer, and all their descendants can be instructed to write their own programs shows that modern electronic computers are potentially cognitive systems of considerable intellectual power.

Von Neumann's address-substitution instruction, which he had also proposed in his 1945 paper, was one of his most important inventions, for it led him to his 'Library of subroutines', the first automatic programming system. He and Goldstine developed this in their reports of 1947 and 1948 entitled 'Planning and coding of problems for an electronic computing instrument'. Von Neumann's idea was to have a library of the most commonly used subroutines, so that the programmer need only write a 'combining routine' to instruct this library as to what subroutines to use in what order, and the boundary conditions for compounding them into a single program.

SELF-REPRODUCING CELLULAR AUTOMATON

Soon after the war, von Neumann became engaged in advising the US government on computers and military policy. He was appointed to the Atomic Energy Commission, and for his contribution to this, and for his other achievements, President Eisenhower personally awarded him the Medal of Freedom in 1956. He continued to make scientific contributions, with the central goal now of creating a theory of automata. His first project was the design of a self-reproducing cellular automaton, which he partially worked out before his death from cancer in 1957. Burks completed and edited this design in a 1966 book, *Theory of Self-Reproducing Automata*.

Von Neumann's construction of a logical net diagram for a self-reproducing automaton was the first contribution to a subject now called 'artificial life'. This automaton operates in a potentially infinite two-dimensional space of squares – an infinite checkerboard array. Each square contains a 29-state automaton that is directly connected to its four contiguous neighbors, so that its state at time $t+1$ is determined by the states of these neighbors at time t.

These 29 states and their interaction are complicated, but the architecture of the self-reproducing automaton is straightforward. It has two main parts, a tape unit and a constructing unit, each of which is a finite automaton. The tape unit can construct an indefinitely extendable storage tape that it can write on, read from, or erase at the request of the constructing unit. The constructing unit uses the tape unit as its source of instructions for constructing an automaton in a blank area of the cellular space. It has an attached 'constructing arm', which it can extend out through any empty area of space, use to construct any automaton that is completely described on the tape, and then withdraw.

Suppose, finally, that the complete cell-by-cell description of the self-reproducing automaton is put on its own tape, and the automaton is started. It will then carry out the following operations in succession: first, send its construction arm out into an empty area and direct its construction tip to construct a copy of itself, including its tape; then, read its own tape and copy all the information on it onto the new tape it has just constructed.

The result will be a complete copy of the self-reproducing automaton in a new region of cellular space. This is automaton self-reproduction. Using a computer with a very large screen, one could program this process as a dynamic display with different colors representing the different states of each cell.

Von Neumann's final work was *The Computer and the Brain*, published in 1958. It was argued earlier that a modern electronic computer is a cognitive system, on the basis of von Neumann's derivation

of his iconic logic of switching and memory nets from the McCulloch and Pitts logic of neurons. *The Computer and the Brain* strengthens this thesis.

Vygotsky, Lev

Introductory article

Laura E Berk, Illinois State University, Normal, Illinois, USA
Sara Harris, Illinois State University, Normal, Illinois, USA

CONTENTS

Russian psychologist Lev Semenovich Vygotsky (1896–1934) originated sociocultural theory, which regards social interaction between children and more expert members of their culture as the wellspring of cognitive development. Vygotsky's theory and especially his most influential concept – the zone of proximal development – inspired research into many aspects of teaching and learning.

INTRODUCTION

Lev Semenovich Vygotsky laid the groundwork for the sociocultural perspective on cognitive development that rose to the forefront of the fields of child development and education during the last two decades of the twentieth century. Sociocultural theory emphasizes the vital connection between the individual's social and psychological worlds. Specifically, it regards communication between children and more expert members of their culture as the source of consciousness, of distinctly human, higher cognitive processes, and of the capacity to regulate thought and behavior.

Born in 1896 into a well-to-do Russian-Jewish family, Vygotsky experienced an intensely intellectual home life. His elementary education took place at home, through a private tutor who used a variation of the Socratic method – an experience that may have contributed to Vygotsky's later view of adult–child dialogue as central to cognitive development.

As an adolescent, Vygotsky attended public high school and then a selective private Jewish school, where he developed strong interests in literature and theater. After winning a lottery that determined which of a small number of Jewish students were to be admitted, Vygotsky enrolled at Moscow University and majored in law, one of the few fields that permitted Jews to live outside restricted areas. He also attended Shiniavsky People's University, an unofficial institution staffed by leading scholars who had been expelled from faculty posts for their political views. In 1917, the year of the Russian revolution, 21-year-old Vygotsky graduated with a firm grounding in history, philosophy, psychology and literature, the last of which remained his primary interest. He then returned to his hometown of Gomel to teach Russian language and literature at vocational schools for tradesmen and teachers. During those years he read widely in psychology, and set up a small laboratory at Gomel Teachers College for students to run simple psychological experiments – events that laid the groundwork for his transition to psychological research.

In 1919 Vygotsky contracted tuberculosis. Judging from the extraordinary productivity of his brief career, he may have understood that his days were numbered. Captivated by psychology, in 1924 he gave an influential address before the Russian psychological community and as a result was invited to join prominent Soviet psychologists at the Psychological Institute in Moscow. Thus, Vygotsky entered the field without formal training.

Collaborating with other talented researchers, Vygotsky set two lofty goals. The first was theoretical: creating a unifying perspective in psychology that would resolve the theoretical contradictions of his time. The second was practical: addressing serious problems of Soviet society, including reducing the high rate of illiteracy and improving the circumstances of children with physical disabilities and psychological problems. Vygotsky helped found the Institute of Defectology (the Russian term for the field of abnormal psychology) and in 1925 was appointed scientific leader of research and education for children with disabilities. That same year he finished his doctoral dissertation, on the psychology of art. He held various professorships and either directed or was affiliated with many psychological research and pedagogical organizations. Despite repeated bouts of illness, he

wrote prolifically, producing in 1929–1930 alone almost fifty works.

In 1934 Vygotsky suffered his last tuberculosis attack. Nevertheless, he continued to work at a frantic pace, finishing one of his most important works, *Thought and Language*, from his deathbed. He died in 1934 at the age of 37 years. For the next two decades his publications were banned in the Soviet Union because of Stalinist repression. In the 1950s they began to be reissued. They were first translated into English in the 1960s, and new facets of his 180 works continue to be disseminated around the world today.

VYGOTSKY'S THEORY

Massive social changes following the Russian revolution energized Vygotsky as he forged a new sociocultural perspective on child development and education consistent with Marxist principles. Just as human history evolves through revolutionary social movements and authentic social activities of labor and production, so the child develops through social interaction and participation in culturally meaningful endeavors.

According to Vygotsky, infants are endowed with basic perceptual, attentional, and memory capacities that they share with other animals. These follow a natural course of development as the infant makes direct contact with the environment. Once children become capable of mental representation, especially through language, their capacity to communicate with more knowledgeable members of their culture greatly expands. As experts guide, prompt, and explain during joint adult–child activities, they transfer to children the values, beliefs, customs, and skills of their cultural group. Through these experiences, basic mental capacities are transformed into uniquely human, higher cognitive processes. These include, among others, controlled attention, deliberate memorization and recall, categorization, planning, problem-solving, abstract reasoning, and self-regulation of thought and behavior.

In sum, Vygotsky claimed that any higher cognitive capacity first appears between people, in social interaction. Only later can children take over responsibility for that capacity, applying it on their own. Symbolic 'tools of the mind' – especially language, the most flexible and widely used representational system – enable this transfer of cognition from the social to the psychological plane. At first, the adult assists the child in regulating his or her activities, as illustrated by the following excerpt of communication between a 4-year-old child and his mother, who helps him master a difficult puzzle:

> Sammy: 'I can't get this one in.' [Tries to insert a piece in the wrong place]
>
> Mother: 'Which piece might go here?' [Points to the bottom of the puzzle]
>
> Sammy: 'His shoes.' [Looks for a piece resembling the clown's shoes, but tries the wrong one]
>
> Mother: 'Well, what piece looks like this shape?' [Pointing again to the bottom of the puzzle]
>
> Sammy: 'The brown one.' [Tries it, and it fits; then attempts another piece and looks at his mother]
>
> Mother: 'That's it. Try turning that one just a little.'
>
> Sammy: 'There!' [Puts in several more pieces while commenting to himself, 'Now a green piece to match,' 'Turn it' (the puzzle piece), as his mother watches]

Soon children take the language of these dialogues and direct it toward the self, at first engaging in audible self-talk called 'private speech.' Gradually, children internalize private speech, integrating socially derived ways of thinking into their inner speech – the silent verbal dialogues we carry on with ourselves while thinking and acting in everyday situations. As private speech becomes less audible, its structure modifies; it becomes more abbreviated and efficient. Simultaneously, the function of speech changes, from influencing others to clarifying thoughts and regulating (or gaining voluntary control over) behavior. During the preschool years, Vygotsky observed, children frequently speak aloud to themselves for the purpose of self-regulation. With cognitive maturity and mastery of many challenging activities, private speech is largely transformed into inner speech by middle to late childhood.

Vygotsky's most influential theoretical concept – the zone of proximal development (ZPD) – specifies the region in which this transfer of abilities from social interaction to individual functioning occurs. Vygotsky originally introduced the ZPD to argue against traditional intelligence tests, which assess static abilities rather than the ever-changing quality of human cognition. He suggested that tests should measure not what children already know and can do by themselves but what they can do with the assistance of a more knowledgeable partner. Hence, the ZPD refers to a range of tasks that the child cannot yet handle alone but can accomplish with the help of adults and more skilled peers.

The ZPD is closely related to a core assumption of Vygotsky's theory: that education leads, or elicits, cognitive development. Through collaboration with

teachers, parents, and more expert peers on tasks within the ZPD, the child actively constructs new competencies. Vygotsky argued that educative environments must utilize the ZPD, providing tasks carefully selected to awaken those capacities the child is ready to master with social support. As education leads to new knowledge and skills, it permits children to attain a new level of understanding, in which they become aware of their mental activities and regulate thought and behavior more effectively.

According to Vygotsky, the same general principles that govern normal child development also apply to children with disabilities. The most debilitating consequence of a physical or psychological problem, Vygotsky explained, is not the disability itself but its implications for the child's participation in culturally meaningful activities. When a disability interferes with opportunities to experience positive interaction with adults and peers, the child develops a more serious, secondary deficit in higher cognitive processes. Therefore, education must focus on improving social life, to ensure that children with special needs reach their cognitive potential.

CONTEMPORARY RESEARCH AND APPLICATIONS

Vygotsky's theory – especially the concept of the ZPD – has inspired a burgeoning contemporary research literature. Investigators have addressed the features of communication that create the ZPD, coining the term 'intersubjectivity' to describe the fine-tuned adjustments of social partners to one another's perspectives, which establish a common ground for dialogue. Another feature of communication that fosters cognitive progress is 'scaffolding': this refers to a changing quality of social support during a teaching session, in which adults adjust the assistance they provide to fit the child's current level of progress (see Sammy's puzzle-solving with his mother's help, above, for an illustration). Furthermore, numerous investigations have addressed parent–child conversation as the prime source of children's narrative competence. As children internalize their culture's narrative style, they organize personally relevant past experiences into a life story that is central to defining the self.

Energized by Vygotsky's suggestion that peers can create ZPDs for one another, researchers have examined the conditions in which peer collaboration fosters cognitive development. Findings indicate that a crucial factor is cooperative learning – structuring the peer group so that children benefit from one another's expertise and work toward common goals. Furthermore, Vygotsky-based school reform experiments reveal that peer collaboration in classrooms works best when it is supported by a culture of collaboration throughout the educational institution, in which administrators, specialized consultants and teachers cooperate to promote children's learning.

The ZPD has also stimulated a new approach to mental testing called 'dynamic assessment', in which the examiner introduces purposeful teaching into the testing situation to see what the child can attain with social support. Children's responsiveness to individualized teaching and capacity to transfer what they have learned to new tasks predicts future intellectual performance.

Vygotsky's claims about the role of self-directed communication in regulating thought and action have prompted a steady stream of research on private speech. Findings confirm that socially rich contexts and challenging tasks foster this speech-to-self. Consistent with Vygotsky's hypotheses about internalization, audible private speech declines over the late preschool and school years, while signs of inner speech (inaudible muttering and lip and tongue movements) increase. Moreover, children's use of task-relevant private speech is consistently related to focused attention and gains in task performance – outcomes that support the self-regulating function of private speech.

Vygotsky's theory has also sparked a spate of studies on make-believe play as a ZPD in which preschool children acquire a wide variety of culturally adaptive competencies. Findings reveal that pretense originates in joint caregiver–child play, which prepares children for playful cooperation with agemates. Among favorable outcomes of collaborative make-believe are enhanced memory, reasoning, language, early literacy, imagination, perspective taking, and self-regulation skills.

Children with disabilities have also been the focus of Vygotsky-inspired research. For example, because of greater access to supportive parent–child interaction, deaf children of deaf parents (who communicate through sign language) develop more favorably than do deaf children of hearing parents (who either do not use sign language or need time to learn to do so). Deaf children of deaf parents resemble hearing children in quality of parent–child interaction, development of private speech (manual signing to themselves) and self-regulation. In contrast, deaf children of hearing parents display diminished use of private speech and serious self-regulation difficulties. Similar evidence exists for children with attention deficit hyperactivity disorder (ADHD), whose biologically

based cognitive deficits interfere with supportive adult–child interaction and development of private speech.

Finally, Vygotsky's theory has served as the foundation for an expanding literature on cultural variation in cognitive development. A major finding is that each culture selects tasks for children's learning, and social interaction within those tasks leads to knowledge and skills essential for success in that culture. Consequently, children develop unique, culturally relevant cognitive strengths.

CONCLUSION

Vygotsky's theory has not gone unchallenged. Although he acknowledged the role of diverse symbol systems in the development of higher cognitive processes, he elevated language to highest importance. Yet cross-cultural research suggests that a strong emphasis on verbal dialogue and scaffolded teaching may be uniquely Western phenomena. Observations in several village societies reveal that children are expected to learn through keen observation and participation in adult activities, and adults rely more on demonstration and gesture than on verbal communication to transfer culturally adaptive ways of thinking to children. Furthermore, Vygotsky theorized that the natural line and the social line of development join, forming a single developmental pathway. Yet in focusing on the social line, he said little about the natural (biological) line. Investigators in the sociocultural tradition continue to pay less attention to the biological substrate of development than do researchers of other theoretical persuasions.

Sociocultural theory is unique in granting social experience a fundamental role in cognitive development. In its fine-grained examination of social collaboration within the ZPD, Vygotsky-inspired research has deepened our understanding of the everyday processes that spur cognitive development and permit children to become participating members of their communities. In this respect, sociocultural theory complements more traditional approaches to investigating children's cognition, which have focused largely on solitary experimentation and discovery.

Walter, Grey

Introductory article

Walter J Freeman, University of California, Berkeley, California, USA

CONTENTS

An autonomous robot embodies the principles of goal-seeking and scanning that characterize animal behavior. Grey Walter (1910–1977), a physiologist adept in electronics engineering with major accomplishments in early electroencephalography, used his wartime exposure to radio detection and ranging (RADAR) to build a simple 'brain' that endowed his artificial 'turtle' with complex adaptive behaviors.

INTRODUCTION

Nobel prize-winning Sir Winston Churchill in his history of the Second World War wrote a chapter on the 'wizards' who had helped Britain win the war in the air by the development and use of radar. William Grey Walter (1910–1977) was one of those young wizards. He used his experience to design and construct a lifelike robot with a nonlinear dynamic brain, which offered an existence proof that brains are simpler than many of us have supposed.

BIOMEDICAL ENGINEERING

In the decade before the war Grey Walter had already done important work in a field we now call biomedical engineering by his discoveries in electroencephalography (EEG), a medical procedure in which the oscillating fields of electric potential on the scalp and in the brain are measured and interpreted. His first achievement was to identify correctly the source of the alpha rhythm (8–12 Hz). A German psychiatrist, Hans Berger, in 1929 had discovered brain waves by attaching one electrode to the forehead and another to the back of the head. He used a primitive Fleming electronic 'valve' ('vacuum tube' for Americans, the predecessor of the transistor) to amplify the potential difference. He erroneously inferred that alpha came from the frontal lobes. Walter used his knowledge of the theory of potential, volume conduction, and electronics to triangulate the waves and locate their source in the occipital lobe. He also invented the use of low-frequency delta waves (1–2 Hz) to locate brain tumors and abscesses, as well as foci of brain damage that triggered bouts of epileptic activity, then widely known as 'paroxysmal cerebral dysrhythmias'.

After the war he gathered a group of young engineers, along with surplus radar, radio, and other electronic equipment, to work in a laboratory at Bristol University, which rapidly became one of the world's leading centers for EEG research. One of their achievements was automated spectral analysis of EEG traces. A standard method for EEG analysis, since its discovery, had been to measure the power in various frequency bands, including alpha and delta, also beta (15–30 Hz) which Berger identified as the carrier of brain information, and theta (3–7 Hz) as well as alpha, which he concluded were gating frequencies of packets of brain information. Walter used his skills in analog electronics to conceive a device built by engineers that displayed the frequency content in an EEG trace, even as the trace was displayed with an ink-writing oscillograph, a pen whose fluctuations left a trace on moving paper that became the mainstay of electroencephalographers.

Another notable discovery was a very slow change in electrical potential at and around the vertex of the head, measured with respect to indifferent reference points such as the ear lobes. Walter named this event the contingent negative variation (CNV), because it was seen only after a warning signal had been given to a human subject, who would then plan a possible movement in anticipation of a second signal. German researchers discovered a comparable slow potential in a similar behavioral context, calling it the *Bereitsschaftpotential* ('readiness potential'). The intriguing aspect of these electrical potentials is that they permit the observer to predict that a subject will make a response within the next half to one second, before the subject is aware of an intention to act. Some psychologists regard this cerebral phenomenon as evidence that intentional actions are initiated

before awareness of such actions emerges, and that consciousness is involved in judging the values of actions rather than in the execution of them. Simply put, we learn what sort of person we are by observing not our good intentions but our own actions, which often surprise us.

Walter extended his temporal spectral analysis of time series to spatial analysis by conceiving a bank of amplifiers connected to an array of 22 oscilloscopes. This advance enabled him to show not only the amplitude but the phase difference of each trace of the alpha waves with respect to the others, by using cinemas of the oscilloscopes. With his 'toposcope' he visualized the spread of alpha waves across the surface of the brain in ways resembling the ebb and flow of tidal waves around the earth. Alpha activity has the peculiarity that it is most apparent when a human subject is at rest with eyes closed, and it disappears when the eyes are opened or if mental arithmetic is undertaken. Walter proposed that the alpha represented 'scanning' by the brain in search of local centers of activity when none was present, and that it stopped when a 'target' was found in the cortex. This 50-year-old hypothesis was and still is controversial, but it is still not disproven.

AUTONOMOUS, ADAPTIVE ROBOTS

Walter's greatest achievement stemmed from his wartime experience with electronics. Guided missiles with proximity fuzes were then one of two very active foci of interest, the other being devices for scanning the horizon for targets to be identified and intercepted. The scanning mechanism he helped develop was known as the 'plan position indicator', consisting of the point of light created by an electron beam that moved from the center to the edge of the oscilloscope screen and created a bar like the spoke of a wheel. The spoke rotated counterclockwise at the refresh rate of the screen. A likely radar target appeared as a bright spot, giving its direction and distance. This device is in widespread use today, for example, in ships, submarines, and air traffic control centers. It was the basis for Walter's toposcope when applied to alpha waves.

Walter had a very rich, speculative imagination. The concept of a machine that would define a goal and seek it by scanning resonated with his interest in brains as biological systems that evolved through learning from the consequences of their own goal-oriented actions. He undertook to incorporate these two cognitive operations, goal-seeking and scanning, into an electronic 'toy' that would simulate these most basic characteristics of animal (and human) behavior.

The outcome was fully spectacular, though at the time its significance was not recognized, and his device has been all but forgotten. It was a roving machine so lifelike, as he described it in his book *The Living Brain*, that an old lady who felt pursued by it ran upstairs and locked her door.

He named his device *Machina speculatrix* in order to distinguish it from passive devices, such as his earlier conception of *M. sopora* that incorporated Norbert Wiener's principle of stabilization of machine performance by negative feedback ('*Cybernetics*'), and from W. Ross Ashby's '*Homeostat*' that extended the principle of the stability of biological organisms by introducing adaptation through learning. These stable models used what the Harvard physiologist Walter Cannon called 'homeostasis', but unlike plants and sessile automata, *M. speculatrix* was continually on the prowl in search of its designer-endowed goal: moderate illumination. His three-wheeled vehicle, which came to be known as 'Grey Walter's turtle', had two motors, one for progression by the front wheel dragging the hind wheels like a child's tricycle and one for turning the front wheel. Its drive system, batteries and 'brain' were mounted on a chassis. Above it he hung a carapace from a center pole, so that it could swing inwardly from any direction and contact the chassis. This contact operated a switch, so that if the tortoise hit an obstacle or encountered an incline, it would stop, back up, turn, and eventually move around it or avoid it altogether. This 'receptor' gave the device the sense of touch, information about the direction of gravity, and the means to explore objects in its environment by touch.

He also gave *M. speculatrix* a photocell for sensing light, and designed its circuits to use homeostatic feedback to seek and maintain a moderate level of illumination, which varied with its location and orientation but also with the charge in its two batteries. Its hutch was brightly lit, and when its batteries were fully charged, that level was aversive, so it moved out into its contracted world, continually swinging in cycloid loops first away from the light, then, as its batteries ran down back toward the light in its hutch (see 'Illustrations' webpage). In a single charge cycle it could explore nearly 100 m^2, dealing with obstacles by pushing them aside or going around them, though sometimes straying too far and being found 'starved to death' behind a couch. When it regained its hutch, it turned itself off and took nourishment from electrical contacts on the floor.

As a means for detecting the internal state, Walter fixed a marker light on the carapace that stayed on when the turning motor was on but went out when turning stopped. When the turtle encountered its own light in a mirror, it stopped and oriented to its own light, but stopping turned out its light. Then it resumed circling, saw its light again, and stopped. This behavior continued until it had passed the mirror. If it encountered another of its own kind, attracted by the other light, a stately dance ensued of bumping and backing. Walter thought that these behaviors expressed self-recognition and recognition of conspecifics.

These complex and not fully predictable behaviors of exploration, negative and positive tropism, discrimination, adaptation to changing internal and external environments, optimization, and stabilization of the internal medium were done with a very simple brain: two miniature valves serving as 'neurons', two mechanical relays, two capacitors, two receptors, and two motors. Walter achieved this by ingenious circuit design. For example, when the turtle was in search mode, the two valves served as serial amplifiers. When it hit an obstacle, the circuit changed to an oscillator, then called a 'multivibrator', which generated the repetitive backing and butting. He went further with new circuitry, which he called the 'conditioned reflex analog' (CORA), to simulate the seven operations he identified in the formation of associative conditioned reflexes. He proposed to embody CORA in a more highly evolved *Machina docilis* ('easily taught') that could learn to go around an obstacle and would then continue to circumvent it after it had been removed. He used *M. docilis* in several prototypic variants to explore different types of memory and the importance of high-frequency oscillations, such as the beta activity he had observed in EEGs, for enriching memory stores. His career was cut short by his tragic motorcycle accident, in which he sustained massive brain damage, leading to his death seven years later.

EVALUATION AND SUMMARY

The significance of Walter's achievements can be understood by recognizing that these complex adaptive behaviors came not from a large number of parts, but from a small number ingeniously interconnected. His devices were autodidacts that could learn by trial and error from their own actions and mistakes. They remembered without internal images and representations. They judged without numbers, and recognized objects without templates. They were the first free-ranging, autonomous robots capable of exploring their limited worlds. They still provide a high standard of accomplishment. The reason is that, despite major advances in locomotion, particularly in simulations of bipedal, quadripedal and hexapedal gaits based on birds, mammals and insects, and despite advances in scanning and navigation that improve robotic comprehension of operating territories, less has been done towards implementation of goal-seeking. The essence of an intelligent machine is that it has within its brain a capacity to conceive desired future states, and it has the degrees of freedom needed to create and adapt its actions in pursuit of those goals in the unpredictable circumstances of the immediate and remote environments. These flexible brain functions that enable simple systems to function in infinitely complex environments are not achieved by rule-driven symbol manipulation, which is at the heart of cognitive science and conventional artificial intelligence. Moreover, Walter emphasized analog electronics to simulate neurodynamics at a time when most of his colleagues, such as John von Neumann, were developing digital computers to implement symbolic logic and deep arithmetic algorithms. His devices were the forerunners of currently emerging machines that are governed by nonlinear dynamics, and that rely on controlled instability, noise, and chaos to achieve continually updated adaptation to ever-changing and unpredictable worlds. He can well be said to have been the Godfather of truly intelligent machines.

Whorf, Benjamin Lee

Introductory article

John B Carroll, University of North Carolina, Chapel Hill, North Carolina, USA

Benjamin Lee Whorf may justly be considered one of the major contributors to cognitive science in the twentieth century.

Benjamin Lee Whorf pioneered in evaluating the idea of what he called *linguistic relativity*, that is, that 'the structure of the language one habitually uses influences the manner in which one understands his environment', to quote the definition offered by Stuart Chase in his foreword to an edition of Whorf's writings. It was an idea proposed much earlier by such thinkers as Roger Bacon (1220–1292) and Wilhelm von Humboldt (1767–1835). It is not clear whether Whorf was even aware of the thoughts and writings of Bacon, von Humboldt, and others; apparently, it was Whorf's own natural genius that impelled him to think along the same lines as Bacon and von Humboldt. Whorf's contribution was to offer several kinds of evidence that the idea of linguistic relativity – the idea that people actually are influenced to think in particular ways by the structure of the language they speak – might indeed be true and valid.

Yet Whorf was not trained as a cognitive scientist. He developed and published his ideas largely independently of others. Only his major teacher Edward Sapir (1884–1939), a professor of linguistics at Yale University, where Whorf studied and taught for several brief periods starting in 1928, exerted a major influence on the development of his ideas.

Whorf was born in 1897 to a bright and talented family, and died of cancer in 1941. His father was a commercial artist who spent much of his time in such pursuits as stage designing, the production of plays, and the development of photolithography. One of Whorf's two younger brothers, John, became well known as an artist – a painter of watercolors – while the other, Richard, became a highly successful actor in motion pictures.

Whorf himself attended Massachusetts Institute of Technology, graduating in 1918 with a BS degree in chemical engineering. He obtained a position with a fire insurance company in Hartford, Connecticut, where he established himself as a specialist in helping chemical manufacturing companies avoid problems with fires. He enjoyed this work and believed that the generous income and free time available to him enabled him to study problems of interest to him to an extent that he could not have done if he had pursued a career as an academician.

For some years after his graduation from MIT he found many interesting things to read and study in the general field of language. For example, in an attempt to resolve what he regarded as conflicts between science and religion, he studied Hebrew, claiming to discover interesting, previously unnoticed relations between the phonetic structure of Hebrew roots and the meanings of those roots – relations that he called oligosynthetic. Interestingly, some current work on the origin of language makes use of an idea about phonetic meanings that is much like Whorf's oligosynthesis. Only around 1928 did Whorf give up his studies of oligosynthesis because Sapir advised him that such studies were at that time not considered proper scientific activities in linguistics. With Sapir's guidance Whorf began to study various Native American languages, mainly Aztec, Maya, and Hopi.

It was in his studies of these languages that Whorf became impressed with the fact that languages differ markedly in their grammatical structures. He envisaged the possibility that these structures influence the cognitive processes of their speakers. Whorf noted that Native American languages such as Aztec and Hopi are very different from what he called 'standard average European' languages like English, French, and Spanish. Often, it seemed, speakers of Native American languages are required to pay attention to aspects of experience that rarely enter the minds of speakers of 'standard average European' languages like English and French. Conversely, Whorf noticed that languages like English and French may require their speakers to attend to aspects of experience that are not featured in the structures of Native American languages, or other non-European languages.

It is useful for understanding this idea to look at an example of a structural difference between English and certain other languages, such as Chinese. Actually, some aspects of this example will be familiar to many speakers of English because like many other 'standard average European

languages', English has not one but two singular personal pronouns, *he* (generally meaning a male) and *she* (normally meaning a female). It has no singular pronoun, except possibly *they* (when it denotes a single person) that can apply either to a male or a female. Chinese does possess such a pronoun ('ta'); thus it would seem that speakers of Chinese are not continually required to indicate the sex or gender of people they speak about, as speakers of English often are.

When I was a young student in an American elementary school, in the 1920s, I was told that it was perfectly proper in many circumstances to use the male pronoun *he* (or its grammatical variants *him*, *his*) to apply to females, and I have been doing this for most of my life. (Note the first sentence of the second paragraph above, where I unconsciously accepted Stuart Chase's words 'the manner in which one understands his environment'. But perhaps I should have rewritten it as 'the manner in which one understands his or her environment'.) Anyway, in those days it was thought perfectly proper to write a sentence like 'Each child wrote his name in his book', even though many of the children might be female.

In recent years, however, many speakers of English would regard this sentence as improper, or even ungrammatical. They would prefer it to be rewritten, perhaps as 'Each child wrote his or her name in his or her book', or as 'The children wrote their names in their books'.

Research has shown that when English speakers hear or read the pronoun *he* (or its variants) they tend to assume that the person being talked about is a male, even though, according to prescriptive grammar, it could also refer to a female. Thus, the use of *he* tends to bias their thinking. For example, if somebody is trying to hire an assistant who could be either male or female, and places in a newspaper an advertisement that uses only variants of *he* in talking about the kind of person desired (e.g. 'He has good social skills'), the person who placed this advertisement can be expected to receive mainly nominations of males, with many names of female candidates being excluded because people are inclined to think that only male candidates are desired.

More generally, there are a fair number of instances in which it has been shown or believed that people can be influenced in their thinking by structures in the language they speak. Some of these instances, many in native American Indian languages, were offered by Whorf himself. For example, one can find in the Hopi language a special verb form that refers to actions that are highly repetitive, like shaking, pulsing, or meandering (like a river). Whorf suggested that speakers of Hopi were better prepared by their language to understand the many vibratory phenomena studied in modern physics.

Another instance considered by Whorf was the behavior of English-speaking people with reference to highly flammable substances like gasoline or oil. When drums of oil are described as 'full', people tend to be extremely careful in handling them, whereas when drums of oil are described as 'empty' people tend to be less careful, when in actuality they should be *more* careful because of the possible presence of highly explosive residual fumes.

A case found in the Navaho language is interesting. There are many structures in Navaho that require the speaker to use a special form of the verb that indicates the shape of the object being mentioned or talked about (e.g., whether it is round and flat). As a consequence, in a study done some years ago, it was found that Navaho children whose first language was Navaho tended to show awareness of the form or shape of objects earlier in their lives than Navaho children whose first language was English.

These and other such cases have been examined by scholars who conclude that promising evidence exists for the validity of Whorf's linguistic relativity theory. Psychologists and linguists caution, however, that much more evidence is needed, because there are often alternative explanations, other than linguistic relativity, for the findings. Consequently, the status of Whorf's hypothesis of linguistic relativity continues to be problematical.

Wittgenstein, Ludwig

Introductory article

Justin Leiber, University of Houston, Houston, Texas, USA

CONTENTS

For his views on language, logic, and mind, Ludwig Wittgenstein (1889–1951) is perhaps the most studied, most influential, and most puzzling philosopher of the twentieth century.

CENTRAL PHILOSOPHICAL VIEWS

Bertrand Russell, who turned the young Wittgenstein's attention from aeronautical engineering to logic, tells us that Wittgenstein had all the passionately mad drive, exultantly creative and savagely critical in his thinking, 'of genius as traditionally conceived'. Wittgenstein also displayed the naive arrogance, isolation, unconventionality, and stylistic peculiarities of genius 'as traditionally conceived'. His terse first book, *Tractatus Logico-Philosophicus*, presents seven cardinal numbered sentences, each of which (except the last) is followed by further sub-numbered and sub-sub- numbered commentaries. The seven cardinal sentences are:

1. The world is everything that is the case.
2. What is the case, the fact, is the existence of states of affairs.
3. A logical picture of facts is a thought.
4. A thought is a sentence with sense.
5. A sentence is a truth-function of elementary sentences.
6. The general form of a truth function is $[\bar{p}, \bar{\xi}, N(\bar{\xi})]$.
7. Whereof one cannot speak, thereof one must be silent.

Like Russell, Wittgenstein sharply distinguished logical and mathematical truths from the empirical, and therefore accidental, truths of sensory experience and their summations in natural science as truth functions of the elementary sentences. For Wittgenstein, all meaningful sentences – all that 'can be said' – picture some contingent 'state of affairs', and the totality of such states of affairs constitutes 'the world'. Since, for Wittgenstein, logical and mathematical 'truths' are true no matter what the actual facts are, they are tautologies and cannot be 'said meaningfully' but only shown. Indeed, just before his final sentence, Wittgenstein suggests that his reader understand that the sentences of *Tractatus* itself are, strictly speaking, meaningless, a rungless ladder that one climbs up to 'command a clear view'. Tautologies are the linguistic scaffolding, that must be common to any language in which the facts constituting the world can be stated.

Basic to the *Tractatus* is the view that what can be said – sentences – are 'pictures' of facts, of what, if true, is the case. Complex factual sentences break down completely into elementary sentences which picture facts by a pictorial correspondence between the arrangement of the simple names that constitute the sentences and the arrangement of simple objects of the world (whatever either of them are – for Wittgenstein, as a pure logician, could not give examples of actual names or objects – they just had to be there). Hence 'a sentence is a truth-function of elementary sentences'; and the formula '$[\bar{p}, \bar{\xi}, N(\bar{\xi})]$' is meant to enumerate all possible combinations of these elementary sentences. Although Russell, in his introduction to the *Tractatus*, suggested that Wittgenstein was describing a logically perfect language, Wittgenstein later insisted that he meant that our present languages, when meaningful, display just such logical properties and rest on just such foundations of elementary sentences. His insistence that all natural language sentences must have a consistent, determinate, and semantically complete 'deep structure' is echoed in the similar convictions of the 'generative semanticist' movement in linguistics of the 1970s. In his starkly minimalist program, Wittgenstein, unlike Russell, also wanted to do without the abstract mathematical objects of set theory and wanted to take universal statements, including 'laws' of empirical science, as indefinite conjunctions of elementary sentences.

Given his minimalism about what could be said, and hence what could be in the world, Wittgenstein held that all evaluative or mystical sentences were meaningless, or, as sentence 7 insists,

'unspeakable'; hence, necessarily, one cannot avoid being silent about such matters. But sentence 7, like the other sentences of the *Tractatus*, can exude a pregnant silence: one can show things about such matters, and they are of the highest importance, although such matters are not in the world. After all, the world is just the (entirely accidental) totality of everything that is the case; but that something is good or bad, right or wrong, cannot be a matter of factual accident. Similarly, my mind, as something that can will, also transcends and is powerless to act in the world, and what the solipsist wants to say – '*the world* is *my world*' – is correct but inexpressible.

Wittgenstein then left philosophy to become a village schoolteacher, and afterwards, rather more successfully, an architect. (Although he designed and built only one building, a private mansion, it is a classic of modern architecture. As a schoolteacher, he was a severe disciplinarian and did not get on with his colleagues or with the parents of his 9- and 10-year-old students. He once beat a girl, then denied he had done so, only to return years later to apologize to the villagers.) Wittgenstein returned to philosophy and Cambridge University in 1929 and, teaching small classes attended by luminaries such as G. E. Moore and Alan Turing, he continued gradually to reject the central claims of the *Tractatus*. Indeed, the oracular demands of the *Tractatus* now became the 'bewitchment of the mind by language'. Wittgenstein distilled these lectures and notes into the *Philosophical Investigations*, which he prepared for publication but which, because of delays and continual reworking, only appeared two years after his death.

While the *Tractatus* is a relentlessly systematic, masterful, impersonal monolog, *Investigations* traverses the 'landscape' of language and the mental in tightly woven vignettes, whose voices are both conversational and confessional: the *Tractatus* Wittgenstein, the later Wittgenstein, and the reader or listener who is introduced in lines that begin, 'You will think that…'. Philosophy now presents no theses, not even 'unspeakable' ones. Rather, it is an activity of dissolving characteristic pieces of nonsense from the *Tractatus* and elsewhere. The meaning of a word is rarely what it names. There is no 'general form of the proposition' but rather 'countless' uses of language which emphatically do not form a consistent system. There is no need to assume that whenever we say something our act has to be accompanied by some inner mental event. Philosophical avenues that lead to mind–body dualism and solipsism are energetically undermined: 'It is humiliating to have to appear like an empty tube which is simply inflated by a mind.'

VIEWS ON MIND, COGNITION, AND LANGUAGE

Because Wittgenstein insisted that philosophy was not empirical, not 'natural science', his philosophical views or vignettes constitute his thinking on mind, cognition, and language. But his 'grammatical investigations' reveal aspects of our cognitive life that are subject to empirical investigation.

For example, Wittgenstein points out that 'game' has no one meaning. Some games have rules, some do not; some have boards, pieces, cards, balls, or fields, some do not; some have winners and losers, some do not; some involve running about, some sitting still; and so on. Rather, 'game' picks out exemplars and a 'family of resemblances'. Similarly, Wittgenstein's earlier attempt to find out 'the' meaning of the proposition, and 'the' meaning of a word, was an illusory quest. However, what can mislead a philosopher can prove fertile ground for empirical researchers. In the diverse writings of researchers such as Eleanor Rosch and Amos Tversky, we find striking empirical accounts of the role of stereotypes and exemplars in our thinking. An account of the ways we may feel pulled down an illusory path also serves to illustrate the peculiar contours of our actual folk-psychological cognitive apparatus – or even illusions likely to bedevil cognitive scientists. Seeing how we can misunderstand everyday notions is also, importantly, seeing how they actually operate.

Similarly, Wittgenstein runs through a rich series of examples, drawn in part from Gestalt psychology, of 'seeing as'. Perhaps his best-known example is a line drawing which can be seen as a rabbit or as a duck. Wittgenstein insists that when someone simply sees one aspect, the proper report of him is 'he sees a rabbit' not 'he sees it as a rabbit'. Wittgenstein's point is that the empiricist philosopher's characteristic assumption that sense perception is the passively received foundation of our knowledge is mistaken. But in collecting and narrating our temptations to go wrong in such matters, Wittgenstein (1953) is again suggesting puzzles that can prove fruitful paths for modular cognitive science.

> When it looks as if there were no room for such a form between other ones you have to look for it in another dimension. If there is no room here, there is room in another dimension.

Only that would be a job for natural science, including today's modular sub-personal psychology

which investigates cognitive operations – such as visual and linguistic perception – that are not open to everyday conscious inspection.

In one of his most compelling metaphors, Wittgenstein compares our everyday language, our intentional talk about ourselves and others, to the tangled streets of the 'old city', while our scientific and technical talk he compares to neatly laid-out suburbs. His illusion in the *Tractatus* was to think that, deep down, the old city really had to be the suburbs, that our everyday talk had to translate into, or be revealed as, the 'totality of the true elementary propositions'. His view of language in the *Tractatus* is consonant with views still held by some linguistic philosophers and by some linguists, who assume that natural languages are consistent, interpreted formal systems. His critique of this view and the related claim that consciousness is peculiarly private and peculiarly foundational has inspired cognitive scientists as diverse as the philosopher Daniel Dennett and the linguist Noam Chomsky.

RESPONSES TO WITTGENSTEIN

During the 1920s, Wittgenstein occasionally talked with the physicists, mathematicians and philosophers of the Vienna Circle, many of whom admired the *Tractatus* and shared many of its views. However, the Vienna Circle confidently asserted that sensory experiences or observation sentences were elementary and foundational and constituted a criterion of meaningfulness or verifiability. This emphasis was absent from the austere *Tractatus*, although Wittgenstein's notebooks reveal that he had considered sensory experiences as candidates for elementary facts. The oracular tone of the *Tractatus* – as, later, the conversational narrative vignettes of *Investigations* – fascinated many people who had little professional interest in philosophy, logic, or the philosophy of science (Iris Murdoch's novels vividly present characters to whom reading Wittgenstein was a fundamental rite of passage). And a substantial number of philosophers, especially in the 1950s and 1960s, came to think that *Investigations* conveyed an authoritative, new and final way of doing philosophy. (Some even went as far as imitating Wittgenstein's classroom mannerisms.) Many quite various and contradictory theses have been attributed to *Investigations* by Wittgenstein zealots of one ilk or another. This was perhaps inevitable since Wittgenstein's naturally unsystematic cognitive narratives were meant, as he often announced, to stand in the way of any philosophical theses or antitheses; but that empowered the zealot to read whatever general view he liked into *Investigations*. The philosopher Stanley Cavell has compared the later Wittgenstein to the seventeenth-century epigrammatist La Rochefoucauld. As La Rochefoucauld tersely presents the paradoxical kaleidoscope of the human moral condition, so Wittgenstein sketches the scattered paradoxes, anomalies, and tempting illusions of our everyday cognitive condition. As Daniel Dennett remarks (Dennett, 1999):

> Wittgenstein continues to attract fanatics who devote their life to disagreeing with one another about the ultimate meaning of his words. These disciples cling myopically to their Wittgenstein, not realizing that there are many great Wittgensteins to choose from.

RELEVANCE OF WITTGENSTEIN'S WORK TO COGNITIVE SCIENCE

Alan Turing, who laid many of the foundations for modern computation and cognitive science, appears in the transcripts of Wittgenstein's 1939 lectures on the philosophy of mathematics. Among the dozens of transcripts of Wittgenstein's classes his students made, here alone we hear another forceful voice, Turing daring, and Wittgenstein permitting, even inviting, him, to interrupt and persistently question, and expound alternatives to, Wittgenstein's skeptical views about contradiction in formal systems and human rule following. Turing soon went on to propose the project of simulating the mentality of a human person on a computer, whether through programming, tweaking connectionist nets, equipping a 'child machine' with 'the best eyes and ears money can buy' and sending it to school, or even adding limbs and letting it 'roam the countryside'. Wittgenstein's *Investigations* can be read as a series of vivid narrative reminders of how daunting, complex, and fraught with illusions, such a project might be: how great is the gulf between the 'old city' of personal narrative experience and the formal system embodied in a machine.

Wundt, Wilhelm

Introductory article

Robert W Rieber, John Jay College and the Graduate Center, City University of New York, New York, USA

CONTENTS

Wilhelm Wundt is generally recognized as the founder of experimental psychology. He taught the first formal academic psychology course and helped establish psychology as a separate science.

LIFE HISTORY

Wilhelm Wundt, the first modern psychologist, was born in 1832 near Heidelberg in Baden, the only child of a Lutheran pastor. He began to study under a Lutheran vicar, who was most likely his father's assistant, and in fact left home early to continue studying with him. At the age of 13, he started at a gymnasium – roughly equivalent to an American academic prep school – and at 19, he entered university. He studied medicine, but it is unlikely that he ever seriously considered practicing it. It is believed that he only did so to remain away from home and a couple of years later he switched to studying physiology. In 1855 Wundt earned his doctorate from Heidelberg in physiology. In 1857 he was appointed Dozent at Heidelberg. He served as an assistant to Hermann Helmholtz, who was a professor of physiology, between 1858 and 1864. During this time, a conception of psychology as a distinct science was beginning to emerge.

With Wundt's first publication in 1853 began the most extraordinary record of publications in the history of psychologists, with some books and almost 500 articles appearing in the next 60 or so years. Between 1858 and 1862 he published sections of his *Contributions to the Theory of Sensory Perception*, which formalized his ideas about psychology. Titchener, who was one of his greatest students, asserted that this volume outlined the program of Wundt's entire life. It dealt with a program similar to physics and chemistry for an experimental psychology. In this work, he emphasized the importance of method for scientific advancement. To him, the use of the experimental method, whenever possible, was mandatory. He also stressed in *Contributions* that psychology should begin with simple questions and then progress to the difficult metaphysical ones. He used physiological methodology in dealing with psychological problems. Wundt replaced the old method of meditation with a more exact and exacting method of introspection.

In 1864 Wundt was appointed assistant professor. In 1866 he was chosen to represent Heidelberg in the Baden Chamber – a distinguished scholarly group of the period – but he soon resigned because of time restraints. Wundt created and developed the first school of psychological thought, structuralism, whose basic building block was sensation. He advanced his status rapidly at Heidelberg and, starting in 1867, he taught a course at Heidelberg entitled 'Physiological Psychology', which was the first formal offering of an academic course of this nature. He believed that physiology follows one method to achieve knowledge and that psychology follows another; they are two bodies of knowledge. The manner of connection between elements in the subject's immediate experience is entirely different from those occurrences studied by physiology. One of his most important books, *Principles of Physiological Psychology*, was framed from his lecture notes and published in parts between 1873 and 1874. When the last edition was published in 1911, it had gone through six editions and comprised three large volumes. It is regarded as one of the most important books in the history of psychology.

Wundt was not seeking to study the relation between the body and the mind but the relation between sensation and the process of psychological judgement. The result was a purely psychological interpretation with no appeal to the relation of stimulus and sensation. Physiological psychology was concerned with the process of excitations from stimulation of the sense organs, through sensory neurons to the lower and higher brain centers, and from these centers to the muscles. He established introspection as psychology's distinguishing methodology. He proceeded

in a significantly different fashion from earlier versions of introspection, which actually should be called 'meditation'. Wundt refined the conscious elements of meditation and combined them with experiment. He claimed that in psychology pure self-observation is insufficient. He believed that in the laboratory, unless they can be related to an external or measurable response, observations have no scientific usefulness.

Within a year after the appearance of *Principles of Physiological Psychology*, he was offered a professorship at Zurich and later in 1875 he became professor of philosophy at Leipzig, where he worked for the next 45 years. He began one of the first experimental laboratories of psychology in the world. This laboratory became a focus for those with a serious interest in psychology. This institute of psychology, which he established at Leipzig, eventually became one of the most famous centers for the study of psychology in Europe. Philosophy and psychology students from all over the continent as well as from the United States sought out the opportunity to spend some time with or pursue a degree with Wundt at Leipzig. These students, though not always in agreement with Wundt in their systematic views, were careful to tow the line while at Leipzig, and once away from Wundt they often diverged from the details of his systematic psychology. What they shared with Wundt, however, was an enthusiasm for experimental, laboratory psychology. The laboratory atmosphere fostered specific research studies that appeared as articles in journals. All subsequent psychological laboratories in their early years were closely modeled on the Wundt design.

The availability of co-workers was important. Since a worker can hardly be the experimenter and observer at one and the same time, the experimenter of one study was available as a subject for another. Lest this point be dismissed as trivial, it is pertinent to indicate that introspection as practiced in Wundt's laboratory was not a skill acquired without a period of rigorous apprenticeship. Getting at the elements of experience required arduous training. Moreover, even if nonstudent assistants could be trained as subjects, the nature of the task to which they were assigned would have required payment.

Wundt began to publish a journal, *Philosophical Studies*, in 1881, which was the first journal in the German language committed equally to philosophy and psychology. It often included reports of experimental studies that had been done in his laboratory. About one hundred experimental studies appeared in *Philosophical Studies* during its 20-odd years, most of them having been made in his laboratory, or conducted by Wundt's students soon after they left Leipzig. Consequently, the research bore heavily the impress of Wundt's direction, since typically he assigned the problem on which a particular student was to work. About half of the research studies dealt with problems in sensation and perception, while others were about reaction, attention, feeling, and association.

In his 1893 edition of *Principles of Physiological Psychology*, he published the 'tridimensional theory of feeling': feelings were classified as pleasant or unpleasant, tense or relaxed, excited or depressed. A given feeling might equally be a combination of one of each of the categories.

A survey of the research from his laboratory shows that Wundt did not occupy himself with developing new kinds of experiments. The methods he used were not particularly new. Students of the psychology and physiology of the senses owe much to previous work, particularly to that of Helmholtz. Reaction time studies again owe something, not only to Helmholtz, but also to Donders, whereas the association study can be attributed to Galton. Even the study of feeling, where Wundt was at his most original, in a theoretical sense, depended on the extension of Fechner's method of impression to paired comparisons; studies of expression were linked to the utilization of already existing methods for studying pulse, breathing, and the like. There had been antecedent studies even for attention. Wundt's experimental contribution was to reduce to quantitative terms the research areas already extant.

In 1875, Wundt began sponsoring doctoral dissertations and by 1919 the total had reached 186. He accepted students from all over Europe and even America. These students managed to show extreme breadth of activity after the severely rigorous pure training they had received. Not many of them would follow the detail of Wundt's system. What they took away from Leipzig, however, was a belief in the importance of the laboratory and psychological research.

By 1902, with the fifth edition of the *Principles of Physiological Psychology*, there was no longer any doubt as to the legitimacy of his endeavors. Already, he was concerned with differing trends within the field itself; as well as work that deviated from his own. Wundt was not personally interested in the application of psychology, despite the fact that many of his students devoted much of their careers to it. He dismissed any area of psychology that dared to violate the rules of introspection. Like

many German professors, he had a very low tolerance for opinions that differed from his own. Work other than that of his students received severe criticism. He argued that one should not give the name of experimental psychology to each and every operation that brings about a change in consciousness.

He believed that, when problems more difficult than those of perception and memory are considered, experiment is not feasible. He believed that experimental methodology was not applicable to extremely elaborate processes such as reason, memory, thought, and the like. Cultural or ethnic psychology must be used for those problems. Wundt thought that language, myth, and custom should be used to study the higher mental processes. Language, he believed, was the way to understand thought. He began writing the *Volkerpsychologie*, which means cultural psychology, in 1900. Nine more volumes were published by 1920. Cultural psychology began as the investigation of the various, still-existing stages of mental development in humankind.

To Wundt, psychology is the science that investigates the facts of consciousness and cannot be based on metaphysical assumptions of any sort. He sought to create a systematic structure so that every possible experience was represented. He believed that all our experiences are complex and must be analyzed introspectively. Wundt attempted to measure experience so that others could repeat his procedures. He encouraged empiricism and rejected rationalism.

Wilhelm Wundt published his autobiography, *Erlebtes und Erkanntes*, in 1920, and then died on 31 August 1920, two weeks after his 88th birthday. Although it has been estimated that he published 53 000 pages, Wundt did not have many original ideas or perspectives; he simply refined older ideas so that a better, more complete picture emerged. His method of introspection did not remain as a fundamental tool of psychological experimentation beyond the early 1920s. Wundt's greatest contribution was to show that psychology could be a valid experimental science. Perhaps if he had been more original, psychology's appearance as a separate discipline would have been postponed.

ACT

Intermediate article

Christian Lebiere, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

CONTENTS

The ACT theory of cognition has been used to model a wide range of cognitive tasks. The latest version of the theory, ACT-R, is a hybrid architecture which combines a symbolic production system with a subsymbolic level of neural-like activation processes.

INTRODUCTION

In the twentieth century, cognitive psychology produced enormous amounts of data on all aspects of human behavior. The challenge of cognitive science in the twenty-first century is to provide a coherent, integrated and systematic scientific explanation of these phenomena. Computational modeling has become an increasingly popular tool in a wide range of sciences, from mathematics and physics to economics and the social sciences. By combining precision, lacking in many verbal theories, with the ability to deal with almost limitless complexity, a limitation of mathematical theories, computational modeling provides the most promising approach to a unified theory of cognition.

The 'adaptive control of thought' (ACT) theory of cognition attempts to provide such a unified framework by defining an integrated cognitive architecture that can be applied to a wide range of psychological tasks. The most recent version of the theory, ACT-R, is a hybrid architecture which combines elements of the symbolic and connectionist frameworks. By using a symbolic production system to provide the structure of behavior, it has a direct interpretive link to psychological data, and thus inherits a tractable level of analysis. By associating to each symbolic knowledge structure real-valued activation quantities that control its application, it enables the use of statistical learning mechanisms that provide neural-like adaptivity and generalization. The long-term goal of the ACT theory is to provide constrained computational models of a wide range of cognitive phenomena.

PRODUCTIONS AND CHUNKS AS ATOMIC COMPONENTS OF THOUGHT

How to represent knowledge is the first and most important question concerning the design of a cognitive system. As with data structures in a computer program, the knowledge structures assumed by a cognitive theory will fundamentally determine its characteristics: what knowledge can be represented, how it can be accessed and which learning processes can be used to acquire it. Since many cognitive systems, including ACT, are implemented as computer simulations, it is important to define which representational assumptions constitute theoretical claims and which are merely notational conventions. The ACT theory has from its inception made three theoretical assumptions regarding knowledge representation. The first assumption is known as the procedural–declarative distinction; that is, that there are two long-term repositories of knowledge, a procedural memory and a declarative memory. The second assumption is that 'chunks' are the basic units of knowledge in declarative memory. The third assumption is that production rules are the basic units of knowledge in procedural memory. These assumptions will be examined in detail in the rest of this section.

Unlike other cognitive theories and frameworks such as Soar or connectionism, ACT makes a fundamental distinction between declarative and procedural knowledge. This is not just a notational distinction, but a fundamental psychological claim about the existence of distinct memory systems

with different properties. The best way to state the procedural–declarative distinction is in terms of a production system framework. Declarative memory holds factual knowledge, such as the knowledge that George Washington was the first president of the United States or that $3 + 4 = 7$, while procedural memory holds rules that access and modify declarative memory. This distinction corresponds closely to the common operational definition that declarative knowledge is verbalizable while procedural knowledge is not, with the caveat that some declarative knowledge might exist without being directly reportable because one might lack the necessary procedural knowledge to access and express it. These two memory systems have some common features, such as the build-up and decay of strength, but they also have distinct properties: for example, more flexible access to declarative than to procedural knowledge, and different acquisition and retention characteristics. Some recent results in cognitive neuroscience can be interpreted as supporting the procedural–declarative distinction: for example, results showing that damage to the hippocampus inhibited the creation of new declarative memories but not of new procedural memories (Squire, 1992).

The basic units of declarative memory are called chunks. The purpose of a chunk is to organize a set of elements (either chunks themselves or more basic perceptual components) into a long-term memory unit. Chunks can only contain a limited number of elements: as few as two, often three (which it has been argued is a theoretical optimum), and seldom more than five or six. Elements in a chunk assume specific relational roles: for example, in the chunk encoding '$3 + 4 = 7$', '3' is the first addend, '+' is the operator, '4' is the second addend and '7' is the sum. Finally, chunks can be organized hierarchically, since the elements of a chunk can be chunks themselves. For example, to memorize a long sequence, chunks of finite length can be used to store short pieces of the sequence and can themselves be aggregated into other chunks to encode the full sequence. Chunks have two possible origins: either as direct encodings of objects in the environment or as long-term encodings of particular internal elaborations, called goals. Thus when reading a sentence, every word read, together perhaps with some environmental characteristics such as its position in the sentence, constitutes a chunk. But the understanding of the sentence, which is the goal of the processing, is also available as one or more chunks holding an elaboration of its meaning as a result of the cognitive processing.

Production rules are the basic units of procedural memory. Production rules encode cognitive skills as condition–action pairs. A production rule tests the contents of the current goal and perhaps of declarative memory, then executes one or more actions, which can include modifying the current goal or changing the external environment. Just as for chunks, the size and complexity of productions are limited in that they only perform a limited number of retrievals from declarative memory (usually a single one), and those retrievals are performed sequentially. ACT makes four claims related to production rules. The first is 'modularity', i.e, that procedural knowledge takes the form of production rules that can be acquired and deployed independently. Complex skills can be decomposed into production rules that capture significant regularities in human behavior (Anderson, Conrad and Corbett, 1989). For example, performance in the learning of a programming language, which doesn't show any regularities when organized with respect to the number of problems, exhibits a very regular learning pattern when organized with respect to the production rules used in solving each problem.

The second claim is 'abstraction', i.e., that productions are general, applying across a wide range of problems. The third claim is 'goal factoring', which moderates the claim of abstraction by making each production specific to a particular goal type. Thus, a production that performs addition can apply to any addition problem (abstraction) but only to addition problems (goal factoring).

The fourth claim is 'condition–action asymmetry'. For example, while a chunk holding a multiplication fact can be used to solve either a multiplication or a division problem, productions used to compute the answer to a multiplication problem (e.g. by repeated addition) cannot be used to find the answer to a division problem.

According to the ACT theory, chunks and procedural units thus constitute the atomic components of thought.

FROM THE HAM THEORY OF MEMORY TO A FRAMEWORK FOR MODELING COGNITION

ACT has its roots in the 'human associative memory' (HAM) theory of human memory (Anderson and Bower, 1973), which represented declarative knowledge as a propositional network. HAM was implemented as a computer simulation in an attempt to handle complexity and to specify precisely how the model applied to the task, thus

overcoming the major limitations of the mathematical theories of the 1950s and 1960s. Although it fell short of these goals, the theory was afterwards developed in significant ways.

The next step was the introduction of the first instance of ACT, ACTE (Anderson, 1976). It combined HAM's theory of declarative memory with a production system implementation of procedural memory, thus precisely specifying the process by which declarative knowledge was created and applied, and added basic activation processes to link procedural and declarative memory. While the distinction between procedural and declarative knowledge had little support at the time, it has found increasing popularity and support from recent neuroscientific evidence for a dissociation between declarative and procedural memories. The next major step in the evolution of the ACT theory was the ACT* system (Anderson, 1983), which added a more neural-like calculus of activation and a more plausible theory of production rule learning. ACT* was successfully applied to a wide range of psychological phenomena and had a profound influence on cognitive science, but, although some computer simulations were available, it existed primarily as a verbally specified mathematical theory.

The first computational implementation of the theory to be widely adopted was ACT-R (Anderson, 1993). ACT-R was introduced to capitalize on advances in skill acquisition (Anderson and Thompson, 1989) to improve production rule learning, and to tune the subsymbolic level to the structure of the environment to reflect the rational analysis of cognition (Anderson, 1990). Due to these theoretical advances as well as computational factors such as the standardization of the implementation language, Common LISP, and the exponentially increasing power of desktop computers, ACT-R has been adopted as a cognitive architecture by a growing group of researchers. The needs of that user community to apply ACT-R to an increasingly diverse set of tasks, and a growing need for neural plausibility, led to further advances which were embodied in a new version of the theory, ACT-R 4.0 (Anderson and Lebiere, 1998). As suggested by the use of version numbers, the changes in the theory were relatively minor and largely consisted of a reduction in the grain size of chunks and productions.

Through its widening range of applications and the increasing constraints on model development, ACT-R can be regarded as being well on the way to achieving HAM's long-term goal of providing a rigorous computational framework for modeling cognition. The technique of using computational simulation rather than mathematical analysis to provide tractability in complex domains has been widely adopted not only in cognitive modeling but in many other sciences as well. Because it tightly integrates a symbolic production system with a neural-like activation calculus, ACT can be termed a hybrid activation-based production system cognitive architecture. As such, it constitutes a general framework for modeling cognition (another example of such a framework being connectionism). While frameworks can often make general qualitative predictions, in order to obtain precise quantitative predictions for specific experiments they need to be instantiated into detailed theories, such as the various members of the ACT family, that exactly specify the system's mechanisms and equations. A serious potential problem resulting from the generality of frameworks is the possibility of instantiating them into competing theories and incorrectly citing those theories' accomplishments as support for the framework itself. To avoid that danger and to ensure cumulative progress in the development of the ACT theory, Anderson and Lebiere made available on the web every simulation described in Anderson and Lebiere (1998), and promised that the account provided by those models would remain valid in future instantiations of the theory (*The ACT Web*: see Further Reading list).

THE MECHANISMS OF ACT

While the specific mechanisms of the ACT theory have changed significantly over more than 20 years of evolution, the assumptions that underlie the theory have remained fairly constant. ACT operates in continuous time, predicting specific latencies for each step of cognition, such as production firing or declarative retrieval. At the symbolic level, the procedural–declarative distinction states that there are two memory systems, with a production rule component operating on a declarative component. Declarative knowledge is composed of chunks, each having a limited number of components, which can be described alternatively in terms of a propositional network. Procedural knowledge is composed of production rules, or condition–action pairs, which are the basic units of skills. Conditions apply to the state of declarative memory, while actions result in changes in declarative memory. Cognition is goal-directed and maintains at all times a current goal which a production must match in order to apply. At the subsymbolic level, real-valued quantities such as chunk activation and production utility control the application of that

symbolic knowledge. Those subsymbolic parameters are learned, and reflect the past use of their respective symbolic structures. Activation computation is a dynamic process that involves the spreading of activation from a set of sources, usually the contents of the current goal, to related nodes, as well as time-related decay.

ACQUIRING PRODUCTIONS: ACT* AND PUPS

The learning of skills in the form of production rules is one of the more complex mechanisms of the ACT architecture, and has seen the most fundamental changes over the course of the development of the theory. In ACT*, the first version of the theory to provide a comprehensive account of the learning of production rules, procedural learning is accomplished by a set of mechanisms that compile into production rules the process of interpreting declarative knowledge. In other words, procedural skills are learned by doing. For example, if one dials a telephone number or enters one's password by explicitly remembering the number and then iteratively identifying and keying each digit (or letter), the knowledge compilation process would create a production that directly encodes and keys each character without retrieving it from declarative memory. Knowledge compilation is accomplished by two separate processes: composition, which takes a sequence of production firings and compiles them into a single equivalent production; and proceduralization, which takes an existing production and encodes the result of declarative retrievals (in our example, the phone number or password) directly into a new production. Unlike the learning of a declarative fact, which can take place in a single episode, the learning of a procedural skill in the form of production rules requires many iterations for the new knowledge to be refined into its final form and ready to be applied. ACT* has three mechanisms that take new production rules and tune them for optimal performance. The generalization process broadens the applicability of new production rules by making their conditions more general. The discrimination process performs the opposite task, narrowing the applicability of new rules by making their conditions more specific (in our example, the production would be specific to the person or account associated with the number or password). Finally, the strengthening process increases the production strength, allowing it to apply faster and more often.

Anderson and Thompson (1989) introduced a different conception of production learning in their 'penultimate production system' (PUPS). Following empirical studies indicating that analogical problem solving played a fundamental role in skill acquisition, they proposed a new mechanism of production creation based on an analogy process. Instead of automatically creating new productions as a function of an interpretive process, PUPS creates productions to encode the solving of a current problem by analogy with a solution to a previous problem encoded in declarative memory. The analogy process discovers a mapping in declarative memory from problem to solution, which is then encoded in a new production that can solve the problem directly without referring to previous examples. Analogy can therefore be regarded as a mechanism for generalizing from examples. Since it operates on explicit memory structures instead of an automatic goal-based trace of operations (as in ACT*), it allows for the addition to the example of chunks of conditions and heuristics to guide the generalization and discrimination processes that produce the final form of the new productions. This results in a more reliable and controlled mechanism.

RATIONAL ANALYSIS AND ITS IMPLICATIONS FOR COGNITIVE ARCHITECTURE

Inspired by Marr's theory of information-processing levels, Anderson (1990) introduced his 'rational analysis' of human cognition, based on the assumption of a rational level used to analyze the computations performed by human cognition. The general 'principle of rationality' states that a cognitive system operates at all times to optimize the adaptation of the behavior of the organism. This does not imply that human cognition is perfectly optimal, but it helps explain why cognition operates the way it does at the algorithmic level given its physical limitations at the biological level and the optimum defined by the rational level that it attempts to implement. Anderson's analysis provides strong guidance on theory development, because given a particular framework (say, an activation-based production system) it strongly constrains the set of possible mechanisms to those that satisfy the rational level.

The rational analysis can be applied to several aspects of human cognition, including memory, categorization, causal inference and problem solving. The task of human memory is analyzed in terms of a Bayesian estimation of the probabilities of needing a particular memory at a particular point in time. The analysis accounts for effects of

recency, frequency and spacing; effects of context and word frequency; and priming and fan effects. It also provides an interpretation of the concept of activation in ACT-R as the logarithm of the odds that the corresponding chunk needs to be retrieved from memory. The rational analysis of categorization can be interpreted as supporting the creation of chunk types in ACT-R. Finally, the analysis of problem solving in terms of expected utilities of procedural operators led to the refinement of the conflict resolution process in ACT-R. In summary, the rational analysis of cognition provided strong guidance for the development of learning mechanisms in ACT-R (the R stands for 'rational') that automatically tune the subsymbolic level to the structure of the environment.

CONNECTIONIST CONSIDERATIONS: ACT-RN

Lebiere and Anderson (1993) describe ACT-RN, which is an attempt to implement ACT-R using standard connectionist constructs such as Hopfield networks and feedforward networks. Symbols are represented using distributed patterns of activation over pools of units. The current goal, or focus of attention, is located in a central memory that holds the components of the goal, which are the sources of activation in ACT-R. Separate declarative memories for each chunk type are implemented using associative memories in the form of simplified Hopfield networks with a separate pool of units for each component of the chunk. ACT-R's goal stack is implemented as a separate declarative memory that associates each goal to its parent goal. Procedural memory consists of pathways between central memory and declarative memories. Each production is represented as a single unit that tests the contents of the current goal in central memory, then, if successful, activates the proper connections to perform a retrieval from a single declarative memory (possibly the goal stack) and update the goal with the retrieval results. There is a rough correspondence between these constructs and neural locations. Goal memory can be associated with the prefrontal cortex, since damage in that area has been associated with loss of executive function. Declarative memory is distributed throughout the posterior cortex, with each type corresponding to hypercolumns or small cortical areas. Procedural memory might be located in the basal ganglia, which have extensive connections to all cortical areas and could therefore implement the functionality of production rules.

As a practical system, ACT-RN was found unsatisfactory in a number of ways. It only provided a partial implementation of ACT-R, with some features and mechanisms being too complex or difficult to map onto a connectionist substrate. While some models adapted well to the connectionist implementation, others, even simple ones, ran into computational hurdles. More fundamentally, it was an imperfect implementation of the ACT-R standard which only approximately reproduced the ACT-R mechanisms and equations. Nevertheless, ACT-RN provided the main impetus for further development of the theory. Some features of ACT-R that were too complex to be implemented in ACT-RN, such as complicated representational constructs in chunks and powerful pattern-matching primitives in productions, were abandoned in the later versions of the theory as being too computationally powerful for any neural implementation. This resulted in a welcome simplification of the theory. Conversely, a feature of ACT-RN which the connectionist implementation provided naturally – generalization based on distributed representations – was added to the theory in the form of similarity-based partial matching of production conditions (Lebiere *et al.*, 1994). Thus, although implementing ACT-R in a neural network did not directly result in a practical system, it did provide a functional theory of neural organization and imposed a strong direction on further developments of the ACT theory.

THE MECHANISMS OF ACT-R: INTEGRATING SYMBOLIC AND SUBSYMBOLIC PROCESSING AND LEARNING

The power of ACT-R as a hybrid architecture of cognition lies in its tight integration of the symbolic and subsymbolic levels. Because of this integration, it is able to combine the most desirable characteristics of symbolic systems, such as structured behavior and ease of analysis, with those of connectionist networks, such as generalization and fault-tolerance, while avoiding their most serious shortcomings, such as the overly deterministic behavior of symbolic systems and the intractability of learning characteristic of connectionist networks. At the symbolic level, ACT-R operates sequentially – only one production can fire in each cycle and only one chunk can be retrieved from memory at a time – corresponding to the basic sequential nature of human cognition. However, each of the basic steps of production selection and of declarative memory retrieval involves the parallel consideration of all

relevant productions and memory chunks, reflecting the massively parallel nature of the human brain.

A typical production cycle in ACT-R works as follows. The conflict resolution process attempts to select the best production that matches the current goal. To that effect, the expected production utilities of all matching productions are computed in parallel and the best production is selected. Typically, that production attempts a retrieval of information from declarative memory. The activations of the relevant memory chunks are computed concurrently, as: the sum of the base-level activations, reflecting the history of use of each chunk; the activation spreads from the components of the goals, reflecting the specificity of that chunk to the current context; a partial matching penalty, allowing generalization to similar patterns; and a noise component providing stochasticity. Once the retrieval is complete, the activation parameters of the chunks involved are automatically adjusted by the subsymbolic learning mechanisms to reflect this experience. The production then executes its action, which typically consists of modifying the goal to incorporate the results of the declarative retrieval and perhaps performing an external action. If a goal is accomplished, the subsymbolic parameters controlling the utility of the productions involved in solving that goal will be automatically learned, and a chunk encoding the results of the goal will enter declarative memory.

Thus, the production system part of ACT-R provides the basic synchronization of a massively parallel system into a meaningful sequence of cognitive steps, while the subsymbolic part is continuously tuned to the statistical nature of the environment to provide the adaptivity characteristic of human cognition.

MATCHING HUMAN PERFORMANCE IN DIVERSE DOMAINS

The idea of using computational precision to eliminate the looseness of the merely verbal mapping between model and task is embodied in what Anderson and Lebiere (1998) call the 'no-magic doctrine', which consists of the following six tenets:

1. Theories must be experimentally grounded. To avoid unprincipled degrees of freedom in the mapping between task stimuli and model representations, ACT-R includes a 'perceptual motor' component called ACT-R/PM which interacts with the task through the same interface as human subjects.
2. Theories must provide a detailed and precise accounting for the data. Because of its experimental grounding, ACT-R makes precise predictions about every aspect of empirical data, including choice percentages, response latencies, etc.
3. Models must be learnable through experience. ACT-R has mechanisms capable of learning symbolic chunks and productions as well as their subsymbolic parameters.
4. Theories must be capable of dealing with complex cognitive phenomena. ACT-R is applicable to tasks ranging from sub-second psychology experiments to complex environments involving substantial knowledge and learning that may take hours.
5. Theories must have principled parameters. The parameters attached to symbolic knowledge structures are learned from experience. The modeler sets the architectural parameters, but variations are increasingly constrained and understood across tasks.
6. Theories must be neurally plausible. ACT-R is situated at a level of abstraction higher than actual brain structures, but the need to provide a plausible mapping between theoretical constructs and actual brain structures imposes useful and powerful constraints on theory development.

ACT-R has been applied to an increasing variety of cognitive tasks in domains as diverse as memory, categorization, problem solving, analogy, scientific discovery, human–computer interaction, decision theory and game theory. In each domain, ACT-R predicts a wide range of measurable aspects of human behavior at a very fine scale, including latency, errors, learning, eye movements and individual differences.

SUMMARY

ACT is a hybrid cognitive architecture that combines a symbolic production system with a subsymbolic level of neural-like activation processes that control the application of the symbolic structures. Learning mechanisms provide for the acquisition of symbolic knowledge and the statistical tuning of the subsymbolic layer to the structure of the environment, as specified by the rational analysis of cognition. The ACT architecture has been successfully applied to a wide variety of cognitive tasks to accurately predict many aspects of human behavior. Adaptive Resonance Theory

Advanced article

Stephen Grossberg, Boston University, Boston, Massachusetts, USA

CONTENTS

Adaptive resonance theory is a cognitive and neural theory about how the brain develops and learns to recognize and recall objects and events throughout life. It shows how processes of learning, categorization, expectation, attention, resonance, synchronization, and memory search interact to enable the brain to learn quickly and to retain its memories stably, while explaining many data about perception, cognition, learning, memory, and consciousness.

INTRODUCTION

The processes whereby our brains continue to learn about, recognize, and recall a changing world in a stable fashion throughout life are among the most important for understanding cognition. These processes include the learning of top-down expectations, the matching of these expectations against bottom-up data, the focusing of attention upon the expected clusters of information, and the development of resonant states between bottom-up and top-down processes as they reach an attentive consensus between what is expected and what is there in the outside world. It has been suggested that all conscious states in the brain are resonant states, and that these resonant states trigger learning of sensory and cognitive representations. The models which summarize these concepts are called 'adaptive resonance theory' (ART) models. ART was introduced by Grossberg in 1976 (see Carpenter and Grossberg, 1991), along with rules for competitive learning and self-organizing maps. Since then, psychophysical and neurobiological data in support of ART have been reported in experiments on vision, visual object recognition, auditory streaming, variable-rate speech perception, somatosensory perception, and cognitive–emotional interactions, among others (e.g. Carpenter and Grossberg, 1991, 1994; Grossberg, 1999a,b; and Grossberg and Merrill, 1996). In particular, ART mechanisms seem to be operative at all levels of the visual system, and these mechanisms may be realized by known laminar circuits of visual cortex. It is predicted that the same circuit realization of ART mechanisms will be found, suitably specialized, in the laminar circuits of all sensory and cognitive neocortex.

THE STABILITY–PLASTICITY DILEMMA

We experience the world as a whole. Although myriad signals relentlessly bombard our senses, we somehow integrate them into unified moments of conscious experience that cohere despite their diversity. Because of the apparent unity and coherence of our awareness, we can develop a sense of self that can gradually mature with our experiences of the world. This capacity lies at the heart of our ability to function as intelligent beings.

The apparent unity and coherence of our experiences is all the more remarkable when we consider several properties of how the brain copes with the environmental events that it processes. First and foremost, these events are highly context-sensitive. When we look at a complex picture or scene as a whole, we can often recognize its objects and its meaning at a glance, as in the picture of a familiar face. However, if we process the face piece by piece, as through a small aperture, then its significance may be greatly degraded. To cope with this context-sensitivity, the brain typically processes pictures and other sense data in parallel, as patterns of activation across a large number of feature-sensitive nerve cells, or neurons. The same is true for senses other than vision, such as audition. If the sound of the word 'go' is altered by clipping

off the vowel 'o', then the consonant 'g' may sound like a chirp, quite unlike its sound as part of the word 'go'.

During vision, all the signals from a scene typically reach the photosensitive retinas of the eyes at virtually the same time, so parallel processing of all the scene's parts begins at the retina itself. During audition, successive sounds reach the ear at different times. Before an entire pattern of sounds, such as the word 'go', can be processed as a whole, it needs to be recoded, at a later processing stage, into a simultaneously available spatial pattern of activation. Such a processing stage is often called a working memory, and the activations that it stores are often called short-term memory (STM) traces. For example, when you hear an unfamiliar telephone number, you can temporarily store it in working memory while you walk over to the telephone and dial the number.

In order to determine which of these patterns represent familiar events and which do not, the brain matches the patterns against stored representations of previous experiences that have been acquired through learning. The learned experiences are stored in long-term memory (LTM) traces. One difference between STM and LTM traces concerns how they react to distractions. For example, if you are distracted by a loud noise before you dial an unfamiliar telephone number, its STM representation can be rapidly reset so that you forget it. On the other hand, you will not normally forget the LTM representation of your own name.

How does new information get stably stored in LTM? For example, after seeing a movie just once, we can tell our friends many details about it later on, even though the scenes flashed by very quickly. More generally, we can quickly learn about new environments, even if no one tells us how the rules of the environments differ. We can rapidly learn new facts, without being forced to just as rapidly forget what we already know. We do not need to avoid going out into the world for fear that, in learning to recognize a new friend's face, we will suddenly forget our parents' faces. This is sometimes called the problem of catastrophic forgetting.

Many learning algorithms can forget catastrophically. But the brain is capable of rapid yet stable autonomous learning of huge amounts of data in an ever-changing world. Discovering the brain's solution to this problem is as important for understanding ourselves as it is for developing new pattern recognition and prediction applications in technology.

The problem of learning quickly and stably without catastrophically forgetting past knowledge may be called the stability–plasticity dilemma. It must be solved by every brain system that needs to rapidly and adaptively respond to the flood of signals that subserves even the most ordinary experiences. If the brain's design is parsimonious, then we should expect to find similar design principles operating in all the brain systems that can stably learn an accumulating knowledge base in response to changing conditions throughout life. The discovery of such principles should also clarify how the brain unifies diverse sources of information into coherent moments of conscious experience.

LEARNING, EXPECTATION, ATTENTION, AND RESONANCE

Humans are intentional beings, who learn expectations about the world and make predictions about what is about to happen. Humans are also attentional beings, who focus their processing resources upon a restricted amount of incoming information at any time. Why are we both intentional and attentional beings, and are these two types of process related? The stability–plasticity dilemma, and its solution using resonant states, provides a unifying framework for understanding these questions.

Suppose you were asked to 'find the yellow ball within half a second, and you will win a $10 000 prize'. Activating an expectation of 'yellow balls' enables more rapid detection of a yellow ball, and with a more energetic neural response, than if you were not looking for one. Sensory and cognitive top-down expectations lead to 'excitatory matching' with confirmatory bottom-up data. On the other hand, mismatch between top-down expectations and bottom-up data can suppress the mismatched part of the bottom-up data, and thereby focus attention upon the matched, or expected, part of the bottom-up data.

This sort of excitatory matching and attentional focusing on bottom-up data using top-down expectations may generate resonant brain states: When there is a good enough match between bottom-up and top-down signal patterns, between two or more levels of processing, their positive feedback signals amplify and prolong their mutual activation, leading to a resonant state. The amplification and prolongation of the system's fast activations are sufficient to trigger learning in the more slowly varying adaptive weights that control the signal flow along pathways from cell to cell. Resonance thus provides a global context-sensitive indicator that the system is processing data worthy of learning.

ART proposes that there is an intimate connection between the mechanisms that enable us to learn quickly and stably about a changing world and the mechanisms that enable us to learn expectations about such a world, test hypotheses about it, and focus attention upon information that we find interesting. ART also proposes that, in order to solve the stability–plasticity dilemma, resonance must be the mechanism that drives rapid new learning.

Learning within the sensory and cognitive domains is often 'match learning'. Match learning occurs only if a good enough match occurs between bottom-up information and a learned top-down expectation that is specified by an active recognition category, or code. When such a match occurs, previously learned knowledge can be refined. If novel information cannot form a good enough match with the expectations that are specified by previously learned recognition categories, then a memory search, or hypothesis testing, is triggered, which leads to selection and learning of a new recognition category, rather than catastrophic forgetting of an old one. (Figure 1 illustrates how this happens in an ART model.) In contrast, learning within spatial and motor processes could be 'mismatch learning' that continuously updates sensory–motor maps or the gains of sensory–motor commands. As a result, we can stably learn what is happening in a changing world, thereby solving the stability–plasticity dilemma, while adaptively updating our representations of where objects are and how to act upon them using bodies whose parameters change continuously through time.

It has been mathematically proven that match learning within an ART model leads to stable memories in response to arbitrary lists of events to be learned (Carpenter and Grossberg, 1991). However, match learning has a serious potential weakness: if you can only learn when there is a good enough match between bottom-up data and learned top-down expectations, then how do you ever learn anything that you do not already know? ART proposes that this problem is solved by the brain by using a complementary interaction between processes of resonance and reset, which are proposed to control properties of attention and memory search, respectively. These complementary processes help our brains to balance the complementary demands of processing the familiar and the unfamiliar, the expected and the unexpected. One of these complementary processes is hypothesized to take place in the What cortical stream, notably in the visual, inferotemporal, and prefrontal cortex. It is here that top-down expectations are matched against bottom-up inputs (Chelazzi *et al*., 1998; Miller *et al*., 1996). When a top-down expectation achieves a good enough match with bottom-up data, this matching process focuses attention upon those feature clusters in the bottom-up input that are expected. If the expectation is close enough to the input pattern, then a state of resonance develops as the attentional focus is established.

Figure 1 illustrates these ideas in a simple two-level example. Here, a bottom-up input pattern, or vector, I activates a pattern X of activity across the feature detectors of the first level F_1. For example, a visual scene may be represented by the features comprising its boundary and surface representations. This feature pattern represents the relative importance of different features in I. In Figure 1(a), the pattern peaks represent more activated feature detector cells, the troughs less activated feature detectors. This feature pattern sends signals S through an adaptive filter to the second level F_2 at which a compressed representation Y (a recognition category, or symbol) is activated in response to the distributed input T. T is computed by multiplying the signal vector S by a matrix of adaptive weights, which can be altered through learning. The representation Y is compressed by competitive interactions across F_2 that allow only a small subset of its most strongly activated cells to remain active in response to T. The pattern Y in the figure indicates that a small number of category cells may be activated to different degrees. These category cells, in turn, send top-down signals U to F_1 (see Figure 1(b)). The vector U is converted into the top-down expectation V by being multiplied by another matrix of adaptive weights. When V is received by F_1, a matching process takes place between I and V, which selects that subset X^* of F_1 features that were 'expected' by the active F_2 category Y. The set of these selected features is the emerging 'attentional focus'.

RECONCILING DISTRIBUTED AND SYMBOLIC REPRESENTATIONS USING RESONANCE

If the top-down expectation is close enough to the bottom-up input pattern, then the pattern X^* of attended features reactivates the category Y which, in turn, reactivates X^*. The network thus enters a resonant state through a positive feedback loop that dynamically links, or binds, the attended features across X^* with their category, or symbol, Y.

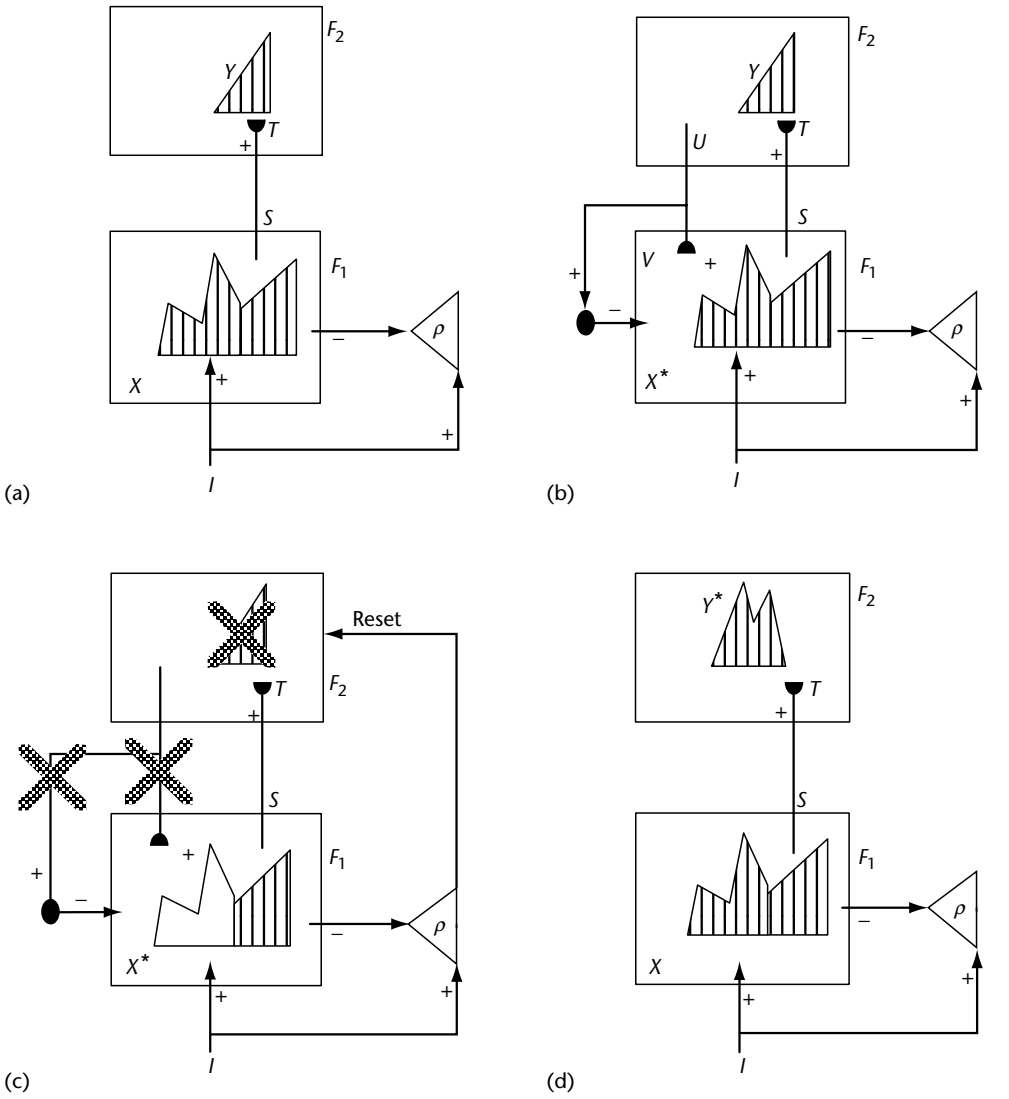

Figure 1. Search for a recognition code within an ART learning circuit. (a) The input pattern I is instated across the feature detectors at level F_1 as a short-term memory (STM) activity pattern X. I also nonspecifically activates the orienting system ρ; that is, all the input pathways converge on ρ and can activate it. X is represented by the hatched pattern across F_1. X both inhibits ρ and generates the output pattern S. S is multiplied by learned adaptive weights, which are long-term memory (LTM) traces. These LTM-gated signals are added at F_2 cells, or nodes, to form the input pattern T, which activates the STM pattern Y across the recognition categories coded at level F_2. (b) Pattern Y generates the top-down output pattern U, which is multiplied by top-down LTM traces and added at F_1 nodes to form a 'prototype' pattern V that encodes the learned expectation of the active F_2 nodes. Such a prototype represents the set of features shared by all the input patterns capable of activating Y. If V mismatches I at F_1, then a new STM activity pattern X^* is selected at F_1. X^* is represented by the hatched pattern. It consists of the features of I that are confirmed by V. Mismatched features are inhibited. The inactivated nodes, corresponding to unconfirmed features of X, are unhatched. The reduction in total STM activity which occurs when X is transformed into X^* causes a decrease in the total inhibition of ρ from F_1. (c) If inhibition decreases sufficiently, ρ releases a nonspecific arousal wave to F_2; that is, a wave of activation that activates all F_2 nodes equally. ('Novel events are arousing'.) This arousal wave resets the STM pattern Y at F_2 by inhibiting Y. (d) After Y is inhibited, its top-down prototype signal is eliminated, and X can be reinstated at F_1. The prior reset event maintains inhibition of Y during the search cycle. As a result, X can activate a different STM pattern Y^* at F_2. If the top-down prototype due to Y^* also mismatches I at F_1, then the search for an appropriate F_2 code continues, until an appropriate F_2 representation is selected. Such a search cycle represents a type of nonstationary hypothesis testing. When the search ends, an attentive resonance develops and learning of the attended data is initiated. (Adapted with permission from Grossberg, 1999b.)

The individual features at F_1 have no meaning on their own, just as the pixels in a picture are meaningless individually. The category, or symbol, in F_2 is sensitive to the global patterning of these features, but it cannot represent the 'contents' of the experience, including their conscious qualia, because a category is a compressed, or 'symbolic', representation. It has often been erroneously claimed that a system must process either distributed features or symbolic representations, but cannot process both. This is not true in ART. The resonance between these two types of information converts the pattern of attended features into a coherent context-sensitive state that is linked to its category through feedback. It is this coherent state, which joins together distributed features and symbolic categories, that can enter consciousness. ART proposes that all conscious states are resonant states. In particular, such a resonance binds spatially distributed features into either a synchronous equilibrium or an oscillation, until it is dynamically reset. Such synchronous states have recently attracted much interest after being reported in neurophysiological experiments. They were predicted in the 1970s in the articles that introduced ART (Grossberg, 1999b).

RESONANCE AS A MEDIATOR BETWEEN INFORMATION PROCESSING AND LEARNING

In ART, the resonant state, rather than bottom-up activation, is claimed to drive the learning process. The resonant state persists for long enough, and at a high enough activity level, to activate the slower learning processes in the adaptive weights that guide the flow of signals between bottom-up and top-down pathways between levels F_1 and F_2. This helps to explain how adaptive weights that were changed through previous learning can regulate the brain's present information processing, without learning about the signals that they are currently processing unless they can initiate a resonant state. Through resonance as a mediating event, one can see from a deeper viewpoint why humans are intentional beings who are continually predicting what may next occur, and why we tend to learn about the events to which we pay attention.

LEARNING AND HYPOTHESIS TESTING

A sufficiently strong mismatch between an active top-down expectation and a bottom-up input – for example, because the input represents an unfamiliar type of experience – can drive a memory search. Such a mismatch within the attentional system may activate a complementary 'orienting system', which is sensitive to unexpected and unfamiliar events. ART suggests that this orienting system includes the hippocampal system, which has long been known to be involved in mismatch processing, including the processing of novel events (e.g., Otto and Eichenbaum, 1992). Output signals from the orienting system rapidly reset the recognition category that has been specifying the poorly matching top-down expectation (Figure 1(b) and 1(c)). The cause of the mismatch is thus removed, thereby freeing the system to activate a different recognition category (Figure 1(d)). The reset event triggers memory search, or hypothesis testing, which automatically leads to the selection of a recognition category that can better match the input. If no such recognition category exists, say because the bottom-up input represents a truly novel experience, then the search process automatically activates an as-yet-uncommitted population of cells, with which to learn about the novel information.

This learning process works well under both unsupervised and supervised conditions (e.g., Carpenter and Grossberg, 1994). Under supervised conditions, a predictive error can force a cycle of hypothesis testing, or memory search, that might not have occurred under unsupervised conditions. For example, a misclassification of a letter F as an E could persist based just on visual similarity, unless culturally determined feedback forced the network to separate them into different categories. Such a search can discover a new or better-matching category with which to represent the novel data. Taken together, the interacting processes of attentive learning and orienting search achieve a type of error correction through hypothesis testing that can build an ever-growing, self-refining internal model of a changing world.

CONTROLLING THE GENERALITY OF KNOWLEDGE

What information is bound into object or event representations? Some scientists believe that exemplars, or individual experiences, can be learned and remembered, like familiar faces. But storing every exemplar requires huge amounts of memory, and leads to unwieldy memory retrieval. Others believe that we learn prototypes (Posner and Keele, 1970) that represent more general properties of the environment, for example, that everyone has a face. But then how do we learn specific episodic memories? ART provides an answer to this question.

ART systems learn prototypes whose generality is determined by a process of 'vigilance' control by environmental feedback or internal volition (Carpenter and Grossberg, 1991; Grossberg, 1999b). Low vigilance permits learning of general categories with abstract prototypes. High vigilance forces memory search to occur when even small mismatches exist between an exemplar and the category that it activates: for example, between letter exemplar F and letter category E. Given high enough vigilance, a category prototype may encode an individual exemplar. Vigilance is computed within the ART orienting system: see Figure 1. Here, bottom-up excitation from an input pattern I is balanced against inhibition from active features across level F_1. If a top-down expectation acts on F_1, then only the 'matched' features are active there. If the ratio of matched features in F_1 to all features in I is less than a vigilance parameter ρ (Figure 1(b)), then a reset, or 'novelty,' wave is activated (Figure 1(c)), which can trigger a search for another category.

The simplest rule for controlling vigilance during supervised learning is called match tracking. Here, a predictive error causes vigilance to increase until it is just higher than the ratio of active features in F_1 to total features in I. The error hereby forces vigilance to 'track' the degree of match between input exemplar and matched prototype. This is the minimal level of vigilance that can trigger a reset wave and thus a memory search for a new category. Match tracking realizes a minimax learning rule that maximizes category generality while minimizing predictive error. That is, it uses the least amount of memory resources that can prevent errors. ART models thus try to learn the most general category that is consistent with the data. This can lead to overgeneralization, like that seen in young children, until further learning causes category refinement. Benchmark studies of classifying complex databases have shown that the number of categories learned scales well with data complexity (e.g. Carpenter and Grossberg, 1994).

MEMORY CONSOLIDATION AND THE EMERGENCE OF RULES

As sequences of inputs are practiced over learning trials, the search process eventually converges upon stable categories. It has been mathematically proven (Carpenter and Grossberg, 1991) that familiar inputs directly access the category whose prototype provides the globally best match, while unfamiliar inputs engage the orienting subsystem to trigger memory searches for better categories, until they become familiar. This process continues until the available memory, which can be arbitrarily large, is fully utilized. The process whereby search is automatically disengaged is a form of memory consolidation that emerges from network interactions. Emergent consolidation does not preclude structural consolidation at individual cells, since the amplified and prolonged activities that subserve a resonance may be a trigger for learning-dependent cellular processes, such as protein synthesis and transmitter production. It has also been shown that the adaptive weights which are learned by some ART models can, at any stage of learning, be translated into if–then rules (e.g. Carpenter and Grossberg, 1994). Thus the ART model is a self-organizing rule-discovering production system as well as a neural network. These examples show that the claims of some cognitive scientists and AI practitioners that neural network models cannot learn rule-based behaviors are incorrect.

CORTICOHIPPOCAMPAL INTERACTIONS AND MEDIAL TEMPORAL AMNESIA

As noted above, the attentional subsystem of ART has been used to model aspects of inferotemporal cortex, while the orienting subsystem models part of the hippocampal system. The interpretation of ART dynamics in terms of inferotemporal cortex led Miller *et al*. (1991) to successfully test the prediction that cells in monkey inferotemporal cortex are reset after each trial in a working memory task. To illustrate the implications of an ART interpretation of inferotemporal-hippocampal interactions, we will review how a lesion of the ART model's orienting subsystem creates a formal memory disorder with symptoms much like the medial temporal amnesia that is caused in animals and human patients after hippocampal system lesions. In particular, such a lesion *in vivo* causes: unlimited anterograde amnesia; limited retrograde amnesia; failure of consolidation; tendency to learn the first event in a series; abnormal reactions to novelty, including perseverative reactions; normal priming; and normal information processing of familiar events. Unlimited anterograde amnesia occurs because the network cannot carry out the memory search to learn a new recognition code. Limited retrograde amnesia occurs because familiar events can directly access correct recognition codes. Before events become familiar, memory consolidation occurs, which utilizes the orienting subsystem (Figure 1(c)). This failure of consolidation would

not necessarily prevent learning. Instead, it would learn coarser categories, because of the failure of vigilance control and memory search. For the same reason, learning may differentially influence the first recognition category activated by bottom-up processing, much as amnesics are particularly strongly bound to the first response they learn. Perseverative reactions can occur because the orienting subsystem cannot reset sensory representations or top-down expectations that may be persistently mismatched by bottom-up cues. The inability to search memory prevents ART from discovering more appropriate stimulus combinations to attend. Normal priming occurs because it is mediated by the attentional subsystem. Data supporting these predictions are summarized by Grossberg and Merrill (1996), who also note that these are not the only problems that can be caused by such a lesion: hippocampal structures can also play a role in learned spatial navigation and adaptive timing functions.

Knowlton and Squire (1993) have reported that amnesics can classify items as members of a large category even if they are impaired on remembering the individual items themselves. To account for these results, the authors propose that item and category memories are formed by distinct brain systems. Grossberg and Merrill (1996) suggest that their data could be explained by a single ART system in which the absence of vigilance control caused only coarse categories to form. Nosofsky and Zaki (2000) have quantitatively simulated the Knowlton and Squire data using a single-system model in which category sensitivity is low.

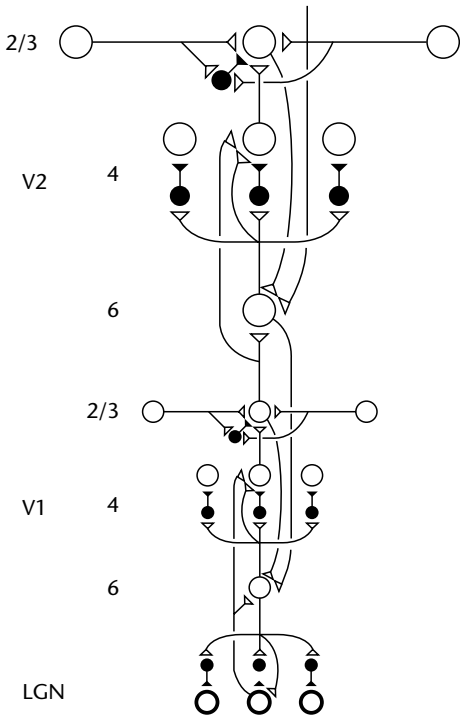

Figure 2. The LAMINART model. The model is a synthesis of feedforward (bottom-up), feedback (top-down), and horizontal interactions within and between the lateral geniculate nucleus (LGN) and visual cortical areas V1 and V2. Cells and connections with open symbols indicate excitatory interactions, and closed symbols indicate inhibitory interactions. The top-down connections from level 6 of V2 to level 6 of V1 indicate attentional feedback. (See Grossberg, 1999a and Grossberg and Raizada, 2000 for further discussion of how these circuits work.) (Adapted with permission from Grossberg and Raizada, 2000.)

CORTICAL SUBSTRATES OF ART MATCHING

How are ART top-down matching rules implemented in the cerebral cortex of the brain? An answer to this question has been proposed as part of a rapidly developing theory of why the cerebral cortex is typically organized into six distinct layers of cells (Grossberg, 1999a). Earlier mathematical work had predicted that such a matching rule would be realized by a 'modulatory top-down on-center off-surround' network (e.g. Carpenter and Grossberg, 1991; Grossberg, 1999b). Figure 2 shows how such a matching circuit may be realized in the cortex. The top-down circuit generates outputs from cortical layer 6 of V2 that activate layer 6 of V1 via the vertical pathway between these layers that ends in an open triangle (which indicates an excitatory connection). Cells in layer 6 of V1, in turn, activate an 'on-center off-surround' circuit to layer 4 of V1. In this circuit, an excitatory cell (open circle) in layer 6 excites the excitatory cell immediately above it in layer 4 via the vertical pathway from layer 6 to layer 4 that ends in an open triangle. This excitatory interaction constitutes the 'on-center'. The same excitatory cell in layer 6 also excites nearby inhibitory cells (closed black circles) which, in turn, inhibit cells in layer 4. This spatially distributed inhibition constitutes the 'off-surround' of the layer 6 cell. The on-center is predicted to have a modulatory, or sensitizing, effect on layer 4, due to the balancing of excitatory and inhibitory inputs to layer 4 within the on-center. The inhibitory signals in the off-surround can strongly suppress unattended visual features. This arrangement shows how top-down attention can sensitize the brain to prepare for expected information that may or may not actually occur, without actively firing the sensitized target cells and thereby inadvertently creating

hallucinations that the information is already there. When this balance breaks down, model 'hallucinations' may indeed occur, and these have many of the properties reported by schizophrenic patients.

CONCLUSION

Adaptive resonance theory is a neural and a cognitive theory of human and animal information processing. ART proposes how the processes whereby the brain can stably develop in the infant and learn throughout life constrain the form of perceptual and cognitive processes such as categorization, expectation, attention, synchronization, memory search, and consciousness in both normal and clinical patients. ART realizes a mechanistic unification of concepts about exemplar, prototype, distributed, symbolic, and rule-based processing. Recent models have shown how predicted ART matching properties may be realized in certain laminar circuits of visual cortex, and by extension in other sensory and cognitive neocortical areas.

Analogy-making, Computational Models of

Boicho Kokinov, New Bulgarian University, Sofia, Bulgaria
Robert M French, University of Liège, Liège, Belgium

CONTENTS

Analogy-making is the process of finding or constructing a common relational structure in the descriptions of two situations or domains and making inferences by transferring knowledge from the familiar domain (the 'base' or 'source') to the unfamiliar domain (the 'target'), thus enriching our knowledge about the latter.

INTRODUCTION

Analogy-making is crucial for human cognition. Many cognitive processes involve analogy-making in one way or another: perceiving a stone as a human face, solving a problem in a way similar to another problem previously solved, arguing in court for a case based on its common structure with another case, understanding metaphors, communicating emotions, learning, or translating poetry from one language to another (Gentner *et al*, 2001). All these applications require an abstract mapping to be established between two cases or domains based on their common structure (common systems of relations). This may require re-representation of one (or both) of the domains in terms of the other one (or in terms of a third domain). The first domain is called the base, or source, and the second is called the target.

Analogy-making is a basic cognitive ability. It appears to be present in humans from a very early age, and develops over time. It starts with the simple ability of babies to imitate adults and to recognize when adults are imitating them, progresses to children's being able to recognize an analogy between a picture and the corresponding real object, and culminates in the adult ability to make complex analogies between various situations. This seems to suggest that analogy-making serves as the basis for numerous other kinds of human thinking; hence the importance of developing computational models of analogy-making.

Analogy-making involves at least the following sub-processes: building a representation, retrieving a 'base' for the analogy, mapping this base to the 'target', transferring unmapped elements from the base to the target, thereby making inferences, evaluating the validity and applicability of these inferences, and learning from the experience – which includes generalizing from specific cases and, possibly, developing general mental schemata. There are, at present, no models that incorporate all of these sub-processes. Individual models focus on one or more of them.

Representation-building

The process of representation-building is absent from most models of analogy-making. Typically, representations are fed into the model. However, there are some models (e.g., ANALOGY, Copycat, Tabletop, Metacat) that do produce their own high-level representations based on essentially unprocessed input. These models (Mitchell, 1993; Hofstadter *et al*, 1995; French, 1995) attempt to build flexible, context-sensitive representations during the course of the mapping phase. Other models, such as AMBR (Kokinov and Petrov, 2001), perform re-representation of old episodes.

Retrieval

The retrieval process has been extensively studied experimentally. Superficial similarity is the most important factor in analogical retrieval: the retrieval of a base for analogy is easier if it shares similar objects, similar properties, and similar general themes with the target. Structural similarity, the familiarity of the domain from which the

analogy is drawn, the richness of its representations, and the presence of generalized schemata, also facilitate retrieval. Most models of retrieval are based on exhaustive search of long-term memory (LTM) and on the assumption that old episodes have context-independent, encapsulated representations. There are, however, exceptions (e.g., AMBR) that rely on context-sensitive reconstruction of old episodes performed in interaction with the mapping process.

Mapping

Mapping is the core of analogy-making. All computational models of analogy-making include mapping mechanisms, i.e., means of discovering which elements of the base correspond to which elements of the target. The difficulty is that one situation can be mapped to a second situation in many different ways. We might, for example, make a mapping based on the color of the objects in both the base and target (the red-shirted person in the base domain would be mapped to the red-shirted person in the target domain). This would, in general, be a very superficial mapping (but might, none the less, be appropriate on occasion). We could also map the objects in the two domains based on their relational structures. For example, we could decide that it was important to map the giver–receiver relationship in the first domain to the same relationship in the target domain, ignoring the fact that in the base domain the giver had a red shirt and in the target domain the giver was wearing a blue shirt.

Experimental work has demonstrated that finding this type of structural isomorphism between base and target domains is crucial for mapping (Gentner, 1983). Object similarity also plays a role in mapping, although generally a secondary one. A third factor is the pragmatic importance of various elements in the target: we want to find mappings that involve the most important elements in the target. Searching for the appropriate correspondences between the base and the target is a computationally complex task that can become infeasibly time-consuming if the search is unconstrained.

Transfer

New knowledge then has to be inserted into the target domain based on the mapping. For example, suppose a new brand of car appears on the market, and that this car maps well onto another brand of car that is small, fast, and handles well on tight curves. But you also know that this latter brand of car is frequently in need of repair. You then wonder whether the new brand of car will also be in frequent need of repair.

Transfer is present in some form in most models of analogy-making, and is typically integrated with mapping. Transfer is considered by some researchers as an extension of the mapping already established, adding new elements to the target.

Evaluation

Evaluation is the process of establishing the likelihood that the transferred knowledge will be applicable to the target domain. In the example above, the evaluation process would have to assign the degree of confidence we would have that the new car would also be in frequent need of repair. Evaluation is often implicit in the mechanisms of mapping and transfer.

Learning

Only a few models of analogy-making have incorporated learning mechanisms. This is somewhat surprising since analogy-making is clearly a driving force behind much learning. However, some models are capable of generalization from the base and target, or from multiple exemplars, to form an abstract schema, as in LISA (Hummel and Holyoak, 1997) and the SEQL model based on SME (Falkenhainer *et al*, 1989).

Below we will review a number of important computational models of analogy-making belonging to different classes and following different approaches. First the 'symbolic' models will be presented. These models employ separate local representations of objects, relations, propositions and episodes (e.g., 'John', 'chair', 'run', 'greater than', 'John ate fish', 'my birthday party last year'). Then, 'connectionist' models will be presented. Here the objects, relations, and episodes are represented as overlapping patterns of activation in a neural network. Finally, a third, hybrid class of models will be presented. These models combine symbolic representations with connectionist activations. They are based on the idea that cognition is an emergent property of the collective behavior of many simple agents.

SYMBOLIC MODELS

ANALOGY

The earliest computational model of analogy-making, ANALOGY, was developed by Thomas

Evans (1964). This program solves multiple-choice geometric analogy problems of the form '*A* is to *B* as *C* is to what?' taken from intelligence tests and college entrance examinations.

An important feature of this program is that the input is not a high-level description of the problem, but a low-level description of each component of the figure – dots, simple closed curves or polygons, and sets of closed curves or polygons. The program builds its own high-level representation describing the figures in *A*, *B*, *C*, and all given alternatives for the answer, with their properties and relationships – for example `((P1 P2 P3) . ((INSIDE P1 P2) (LEFT P1 P3) (LEFT P2 P3)))`. Then the program represents the relationship between *A* and *B* as a set of possible rules describing how figure *A* is transformed into figure *B* – for example, `((MATCH P2 P4) (MATCH P1 P5) (REMOVE P3))` which means that figure P_2 from *A* corresponds to figure P_4 from *B*, P_1 corresponds to P_5, and the figure P_3 does not have a corresponding figure and is therefore deleted. Then each such rule is applied to *C* in order to get one of the alternative answers. In fact, each such rule would be generalized in such a way as to allow *C* to be applied to *D*. Finally, the most specific successful rule would be selected as an outcome. Arguably, one of the most significant features of the program is its ability to represent the target problem on its own – a feature that has been dropped in most recent models.

Structure Mapping Theory

The most influential family of computational models of analogy-making have been those based on Dedre Gentner's (1983) 'structure mapping theory' (SMT). This theory was the first to explicitly emphasize the importance of structural similarity between base and target domains, defined by common systems of relations between objects in the respective domains. Numerous psychological experiments have confirmed the crucial role of relational mappings in producing convincing and sound analogies. There are several important assumptions underlying the computational implementation of SMT called SME (Falkenhainer *et al*, 1989): (1) mapping is largely isolated from other analogy-making sub-processes (such as representation, retrieval and evaluation) and is based on independent mechanisms; (2) relational matches are preferred over property matches; (3) only relations that are identical in the two domains can be put into correspondence; (4) relations that are arguments of higher-order relations that can also be mapped have priority, following the 'systematicity principle' that favors systems of relations over isolated relations; and (5) two or three interpretations are constructed by a 'greedy merge' algorithm that generally finds the 'best' structurally coherent mapping. Early versions of SME mapped only identical relations and relied solely on relational structure. This purely structural approach was intended to ensure the domain independence of the mapping process. Recent versions of SME have made some limited use of pragmatic aspects of the situation, as well as re-representation techniques that allow initially non-matching predicates to match.

The MAC/FAC model of analogical retrieval (Forbus *et al*, 1995) was intended to be coupled with SME. This model assumes that episodes are encapsulated representations of past events; they have a dual encoding in LTM: a detailed predicate-calculus representation of all the properties and relations of the objects in an episode and a shorter summary (a vector representation indicating the relative frequencies of the predicates that are used in the detailed representation). The retrieval process has two stages. The first stage uses the vector representations to perform a superficial search for episodes that share predicates with the target problem. The episode vectors in LTM that are close to the target vector are selected for processing by the second stage. The second stage uses the detailed predicate-calculus representations of the episodes to select the one that best matches the target. These two stages reflect the dominance of superficial similarity as well as the influence of structural similarity.

Gentner's ideas – in particular, their emphasis on the structural aspects of analogical mappings – have been very influential in the area of computational analogy-making and have been applied in contexts ranging from child development to folk physics. Various improvements and variants of SME have been developed, and it has been included as a module in various practical applications.

Other Symbolic Models

A number of other symbolic models have helped to advance our understanding of analogy-making. Jaime Carbonell proposed the concept of derivational analogy, where the analogy is drawn not with the final solution of the old problem, but with its derivation, i.e., with the way of reaching the solution, an approach developed further by Manuela Veloso. Smadar Kedar-Cabelli developed a model of purpose-directed analogy-making in

concept learning. Mark Burstein developed a model called CARL which learned from multiple analogies combining several bases. Mark Keane and his colleagues developed an incremental model of mapping, IAM, which helps explain the effects of order of presentation of the material observed in humans.

CONNECTIONIST MODELS

Research in the field of analogy-making has, until recently, been largely dominated by the symbolic approach, for an obvious reason: symbolic models are well equipped to process and compare the complex structures required for analogy-making. In the early years of the new connectionist paradigm, these structures were very difficult to represent in a connectionist network. However, advances in connectionist representation techniques have allowed distributed connectionist models of analogy to be developed. Most importantly, distributed representations provide a natural internal measure of similarity, thereby allowing the system to handle the problem of similar but not identical relations in a relatively straightforward manner. This ability is essential to analogy-making and has proved hard for symbolic models to implement.

Multiple Constraints Theory

The earliest attempt to design an architecture in which analogy-making was an emergent process of activation states of neuron-like objects was proposed by Keith Holyoak and Paul Thagard (1989) and implemented in a model called ACME. In this model, structural similarity, semantic similarity, and pragmatic importance determine a set of constraints to be simultaneously satisfied. The model is supplied with representations of the target and of the base, and proceeds to build a localist constraint-satisfaction connectionist network where each node corresponds to a possible pairing hypothesis for an element of the base and an element of the target. For example, if the base is 'train' and the target is 'car' then all elements of trains will be mapped to all elements of cars; there will therefore be hypothesis nodes created not only for 'locomotive → motor' but also for 'locomotive → license plate', 'locomotive → seat-belt buckle', etc. The excitatory and inhibitory links between these nodes implement the structural constraints. In this way, contradictory hypothesis nodes compete and do not become simultaneously active, while consistent ones mutually support each other. The network gradually moves towards an equilibrium state, and the best set of consistent mapping hypotheses (e.g., 'locomotive → motor', 'rails → road', etc.) wins. The relaxation of the network provides a parallel evaluation of all possible mappings and finds the best one, which is represented by the set of most active hypothesis nodes.

ARCS is another related model of retrieval. It is coupled with ACME and operates in a similar fashion. However, while mapping is dominated by structural similarity, retrieval is dominated by semantic similarity.

STAR

STAR-1 was the first distributed connectionist model of analogy-making (Halford *et al*., 1994). It is based on the tensor product connectionist models developed by Smolensky. A proposition like MOTHER-OF (CAT, KITTEN) is represented by the tensor product of the three vectors corresponding to MOTHER-OF, CAT, and KITTEN: MOTHER-OF $\otimes$ CAT $\otimes$ KITTEN. The tensor product in this case is a three-dimensional array of numbers where the number in each cell is the product of the three corresponding coordinates. This representation allows any of the arguments, or the relational symbol, to be extracted by a generalized dot product operation: (MOTHER-OF $\otimes$ CAT) $\bullet$ (MOTHER-OF $\otimes$ CAT $\otimes$ KITTEN) = KITTEN. The LTM of the system is represented by a tensor that is the sum of all tensor products representing the individual statements (the main restriction being that the propositions are simple and have the same number of arguments). Using this type of representation, STAR-1 solves proportional analogy problems like 'cat is to kitten as mare is to what?'

STAR-2 (Wilson *et al*, 2001) maps complex analogies by sequentially focusing on various parts of the domains – simple propositions with no more than four dimensions – and finding the best map for the arguments of these propositions by parallel processing in the constraint satisfaction network (similarly to ACME). The fact that the number of units required for a tensor product representation increases exponentially with the number of arguments of a predicate implies processing constraints in the model. Wilson *et al* claim that humans are subject to similar processing constraints: specifically, they can, in general, handle a maximum of four dimensions of a situation concurrently. The primary interest of the modelers is in exploring and explaining capacity limitations of human beings and achieving a better understanding of the development of analogy-making capabilities in children.

LISA

John Hummel and Keith Holyoak (1997) proposed an alternative computational model of analogy-making using distributed representations of structure relying on dynamic binding. The idea is to introduce an explicit time axis so that patterns of activation can oscillate over time (thus the timing of activation becomes an additional parameter independent of the level of activation). Patterns of activation oscillating in synchrony are considered to be bound together, while those oscillating out of synchrony are not. For example, 'John hired Mary' requires synchronous oscillation of the patterns for 'John' and 'Employer' alternating with synchronous oscillation of the patterns for 'Mary' and 'Employee'. Periodic alternation of the activation of the two pairs represents the whole statement. However, if the statement is too complex there will be too many pairs that need to fire in synchrony. Based on research on single-cell recordings, Hummel and Holyoak believe that the number of such pairs of synchronously firing concepts cannot exceed six. Representations in LISA's working memory are distributed over the network of semantic primitives, but representations in long-term memory are localist – there are separate units representing the episode, the propositions, their components, and the predicates, arguments, and bindings. Retrieval is performed by spreading activation, while mapping is performed by learning new connections between the most active nodes. LISA successfully integrates retrieval of a base with the mapping of the base and target, even though retrieval and mapping are still performed sequentially (mapping starts only after one episode is retrieved).

HYBRID MODELS

Two groups of researchers have independently produced similar models of analogy-making based on the idea that high-level cognition emerges as a result of the continual interaction of relatively simple, low-level processing units, capable of doing only local computations. These models are a combination of the symbolic and connectionist approaches. Semantic knowledge is incorporated in order to compute the similarity between elements of the two domains in a context-sensitive way.

Copycat and Related Architectures

The family of Copycat and Tabletop architectures (Mitchell, 1993; Hofstadter *et al*, 1995; French, 1995) was explicitly designed to integrate top-down semantic information with bottom-up emergent processing. Copycat solves letter-string analogies of the form '*ABC* is to *ABD* as *KLM* is to what?' and gives plausible answers such as *KLN* or *KLD*. The architecture of Copycat involves a working memory, a semantic network (simulating long-term memory) defining the concepts used in the system and their relationships, and the 'coderack' – the procedural memory of the system – a store for small, nondeterministic computational agents ('codelets') working on the structures in the working memory and continually interacting with the semantic network. Codelets can build new structures or destroy old structures in working memory. The system gradually settles towards a consistent set of structures that will determine the mapping between the base and the target.

The most important feature of these models of analogy-making is their ability to build up their own representations of the problem, in contrast with most other models which receive the representations of the base and target as input. Thus these models abandon traditional sequential processing and allow representation-building and mapping to run in parallel and continually influence each other. The partial mapping can influence further representation-building, thus allowing the gradual construction by the program of context-sensitive representations. In this way, the mapping may force us to see a situation from an unusual perspective in terms of another situation, and this is an essential aspect of creative analogy-making.

AMBR

AMBR (Kokinov, 1994) solves problems by analogy. For example, 'how can you heat some water in a wooden vessel, being in the forest?' The solution, heating a knife in a fire and immersing it in the water, is found by analogy with boiling water in a glass using an immersion heater.

The AMBR model is based on DUAL, a general cognitive architecture. The LTM of DUAL consist of many micro-agents, each of which represents a small piece of knowledge. Thus concepts, instances and episodes are represented by (possibly overlapping) coalitions of micro-agents. Each micro-agent is hybrid: its symbolic part encodes the declarative or procedural knowledge it is representing, while its connectionist part computes the agent's activation level, which represents the relevance of this knowledge to the current context. The symbolic processors run at a speed proportional to their computed relevance, so the behavior of the system

is highly context-sensitive. The AMBR model implements the interactive parallel work of recollection, mapping and transfer that emerge from the collective behavior of the agents and which produces the analogy. Recollection in AMBR-2 (Kokinov and Petrov, 2001) is reconstruction of the base episode in working memory by activating relevant aspects of event information, of general knowledge, and of other episodes, and forming a coherent representation which will correspond to the target problem. The model exhibits illusory memories, including insertions from general knowledge and blending with other episodes, and context and priming effects. Some of these phenomena have been experimentally confirmed in humans.

CONCLUSIONS

The field of computational modeling of analogy-making has moved from the early models, which were intended mainly to demonstrate that computers could, in fact, be programmed to do analogy-making, to complex models that make nontrivial predictions of human behavior. Researchers have come to appreciate the need for structural mapping of the base and target domains, for integration of and interaction between representation-building, retrieval, mapping and learning, and for systems that can potentially scale up to the real world. Computational models of analogy-making have now been applied to a large number of cognitive domains (Gentner *et al*, 2001). However, many issues remain to be explored in the endeavor to model the human capacity for analogy-making, one of our most important cognitive abilities.

CONTENTS

Artificial life is the study of life and life-like processes through simulation and synthesis.

INTRODUCTION

Artificial life literally means 'life made by human artifice rather than by nature'. It has come to refer to a broad, interdisciplinary endeavor that uses the simulation and synthesis of life-like processes to achieve any of several possible ends: to model life, to develop applications using intuitions and methods taken from life, or even to create life. The aim of creating life in a purely technological context is sometimes called 'strong artificial life'.

Artificial life is of interest to biologists because artificial life models can shed light on biological phenomena. It is relevant to engineers because it offers methods to generate and control complex behaviors that are difficult to generate or control using traditional approaches. But artificial life also has many other facets involving *inter alia* various aspects of cognitive science, economics, art, and even ethics.

There is not a consensus, even among workers in the field, on exactly what artificial life is, and many of its central concepts and working hypotheses are controversial. As a consequence, the field itself is evolving from year to year. This article provides a snapshot and highlights some controversies.

HISTORY

The roots of artificial life are quite varied, and many of its central concepts arose in earlier intellectual movements.

John von Neumann implemented the first artificial life model (without referring to it as such) with his famous creation of a self-reproducing, computation-universal entity using cellular automata. At the time, the construction was surprising, since many had argued its impossibility, for example on the grounds that such an entity would need to contain a description of itself, and that description would also need to contain a description, *ad infinitum*. Von Neumann was pursuing many of the very issues that drive artificial life today, such as understanding the spontaneous generation and evolution of complex adaptive structures; and he approached these issues with the extremely abstract methodology that typifies contemporary artificial life. Even in the absence of modern computational tools, von Neumann made striking progress.

Cybernetics developed at about the same time as von Neumann's work on cellular automata, and he attended some of its formative meetings. Norbert Wiener is usually considered to be the originator of the field (Wiener, 1948). It brought two separate foci to the study of life processes: the use of information theory and a deep study of the self-regulatory processes (homeostases) considered essential to life. Information theory typifies the abstractness and material-independence of the approach often taken within both cybernetics and artificial life. Both fields are associated with an extremely wide range of studies, from mathematics to art. As a discipline, cybernetics has evolved in divergent directions; in Europe, academic departments of cybernetics study rather specific biological phenomena, whereas in America cybernetics has tended to merge into systems theory, which generally aims toward formal mathematical studies. Scientists from both cybernetics and systems theory contribute substantially to contemporary artificial life.

Biology (i.e. the study of actual life) has provided many of the roots of artificial life. The subfields of biology that have contributed most are microbiology and genetics, evolution theory, ecology, and development. To date there are two main ways that artificial life has drawn on biology: crystalizing

intuitions about life from the study of life, and using and developing models that were originally devised to study a specific biological phenomenon. A notable example of the latter is Kauffman's use of random Boolean networks (Kauffman, 1969, 1993). Biology has also influenced the problems studied in artificial life, since artificial life's models provide definite answers to problems that are intractable by the traditional methods of mathematical biology. Mainstream biologists are increasingly participating in artificial life, and the methods and approaches pioneered in artificial life are increasingly accepted within biology.

The most heavily represented discipline among contemporary researchers in artificial life is computer science. One set of artificial life's roots in computer science is embedded in artificial intelligence (AI), because living systems exhibit simple but striking forms of intelligence. Like AI, artificial life aims to understand a natural phenomenon through computational models. But in sharp contrast to AI, at least as it was originally formulated, artificial life tends to use bottom-up models in which desired behavior emerges in a number of computational stages, instead of top-down models that aim to yield the desired behavior directly (as with expert systems). In this respect, artificial life shares much with the connectionist movement that has recently swept through artificial intelligence and cognitive science. Artificial life has a related set of roots in machine learning, inspired by the robust and flexible processes by which living systems generate complex useful structures. In particular, some machine learning algorithms such as the genetic algorithm (Holland, 1975) are now seen as examples of artificial life applications, even though they existed before the field was named. New areas of computer science (e.g., evolutionary programming, autonomous agents) have increasingly strong links to artificial life. (*See* **Artificial Intelligence, Philosophy of**)

Physics and mathematics have also had a strong influence on artificial life. Statistical mechanics and thermodynamics have always claimed relevance to life, since life's formation of structure is a local reversal of the second law of thermodynamics, made possible by the energy flowing through a living system. Prigogine's thermodynamics of dissipative structures is the most modern description of this view. Statistical mechanics is also used to analyze some of the models used in artificial life that are sufficiently simple and abstract, such as random Boolean networks. Dynamical systems theory has also had various contributions, such as its formulation of the generic behavior in dynamical systems. And physics and dynamical systems have together spawned the development of synergetics and the study of complex systems (Wolfram, 1994), which are closely allied with artificial life. One of artificial life's main influences from physics and mathematics has been an emphasis on studying model systems that are simple enough to have broad generality and to facilitate quantitative analysis.

The first conference on artificial life (Langton, 1989), where the term 'artificial life' was coined, gave recognition to artificial life as a field in its own right, although it had been preceded by a similar conference entitled 'Evolution, Games, and Learning' (Farmer *et al*., 1986). Since then there have been many conferences on artificial life, with strong contributions worldwide (e.g., Bedau *et al*., 2000). In addition to the scientific influences described above, research in artificial life has also come to include elements of chemistry, psychology, linguistics, economics, sociology, anthropology, and philosophy.

CONCEPTS AND METHODOLOGY

Most entities that exhibit lifelike behavior are complex systems – systems made up of many elements simultaneously interacting with each other. One way to understand the global behavior of a complex system is to model that behavior with a simple system of equations that describe how global variables interact. By contrast, the characteristic approach followed in artificial life is to construct lower-level models that themselves are complex systems and then to iterate the models and observe the resulting global behavior. Such lower-level models are sometimes called agent- or individual-based models, because the whole system's behavior is represented only indirectly and arises merely out of the interactions of a collection of directly represented parts ('agents' or 'individuals').

As complex systems change over time, each element changes according to its state and the state of those 'neighbors' with which it interacts. Complex systems typically lack any central control, though they may have boundary conditions. The elements of a complex system are often simple compared to the whole system, and the rules by which the elements interact are also often simple. The behavior of a complex system is simply the aggregate of the changes over time of all of the system's elements. In rare cases the behavior of a complex system may actually be mathematically derived from the rules governing the elements' behavior, but typically a complex system's behavior

cannot be discerned short of empirically observing the emergent behavior of its constituent parts. The elements of a complex system may be connected in a regular way, such as on a Euclidean lattice, or in an irregular way, such as on a random network. Interactions between elements may also be without a fixed pattern, as in molecular dynamics of a chemical soup or interaction of autonomous agents. When adaptation is part of a complex system's dynamics, it is sometimes described as a complex adaptive system. Examples of complex systems include cellular automata, Boolean networks, and neural networks. Examples of complex adaptive systems include neural networks undergoing a learning process and populations of entities evolving by natural selection.

One of the simplest examples of a complex system is the so-called 'game of life' devised by the mathematician John Conway (Berlekamp *et al.*, 1982). The game of life is a two-state two-dimensional cellular automaton with a trivial nearest-neighbor rule. You can think of this 'game' as taking place on a two-dimensional rectangular grid of cells, analogous to a huge checkerboard. Time advances in discrete steps, and a cell's state at a given time is determined by the states of its eight neighboring cells according to the following simple 'birth–death' rule: A 'dead' cell becomes 'alive' if and only if exactly three neighbors were just 'alive', and a 'living' cell 'dies' if and only if fewer than two or more than three neighbors were just 'alive'. From inspection of the birth–death rule, nothing particular can be discerned regarding how the whole system will behave. But when the system is simulated, a rich variety of complicated dynamics can be observed and a complex zoo of structures can be identified and classified (blinkers, gliders, glider guns, logic switching circuits, etc.). It is even possible to construct a universal Turing machine in the game of life and other cellular automata, by cunningly configuring the initial configuration of living cells. In such constructions gliders perform a role of passing signals, and analyzing the computational potential of cellular automata on the basis of glider interactions has become a major research thrust.

Those who model complex adaptive systems encounter a tension resulting from two seemingly conflicting aims. To make a model 'realistic' one is driven to include complicated realistic details about the elements, but to see and understand the emergent global behavior clearly one is driven to simplify the elements as much as possible. Even though complex adaptive systems include systems whose elements and dynamical rules are highly complicated, the spirit of most artificial life work is to look for the complexity in the emergent global behavior of the system, rather than to program the complexity directly into the elements.

Computation is used extensively in the field of artificial life, usually to simulate models to generate data for studying those models. Simulation is essential for the study of complex adaptive systems for it plays the role that observation and experiment play in more conventional science. Having no access to significant computational machinery, Conway and his students first studied the game of life by physically mapping out dynamics with go stones at teatime. Now thousands of evolutionary generations for millions of sites can be computed in short order with a conventional home computer. Computational ability to simulate large-scale complex systems is the single most crucial development that enabled the field of artificial life to flourish and distinguish itself from precursors (such as cybernetics or systems theory).

The dependence of artificial life on simulation has led to debate within the field over the ontological status of the simulations themselves. One version of strong artificial life holds that life may be created completely within a simulation, with its own virtual reality, yet with the same ontological status as the phenomenon of life in the real world. Some hold, however, that simulated, virtual reality cannot possibly have the same ontological status as the reality we experience. These point out that a simulated hurricane can never cause us to become wet. They also believe that if artificial life is to achieve the status of reality, it must include an element of embodiment, an extension into the real, non-simulated world enabling an interaction with that world. Believers in the reality of simulation point out that a simulation has its own embodiment within a computer, that a simulation is not an abstract formula specifying a program but the actual running of a program in a real physical medium using real physical resources. The belief that artificial life has its own bona fide reality is particularly strong among those who generate experimental data with simulations.

Both living systems and artificial life models are commonly said to exhibit emergent behavior – indeed, many consider emergent behavior to be a hallmark of life – but the notion of emergence remains ill-defined. There is general agreement that the term has a precise meaning in some contexts, most notably to refer to the resultant aggregate global behavior of complex systems. The higher-level structures produced in Conway's

game of life provide a classic example of this kind of emergent behavior. In spite of clear examples like the game of life, there is no agreement regarding how one might most usefully define emergence. Some believe that emergence is merely a form of surprise. On this view, emergence exists only in the eye of the beholder and whether a phenomenon is emergent or not depends on the mindset of the observer. Others believe that there is an objective, observer-independent definition of emergence in terms of whether a phenomenon is derivable from the dynamical rules, even if it is often difficult to tell *a priori* what can be derived from the dynamical rules underlying complex systems. These difficulties lead some to argue that the term 'emergence' should simply be dropped from the vocabulary of artificial life. However, this advice is not widely heeded at present.

Complexity is another commonly recognized hallmark of life, and this notion has also so far eluded satisfactory definition. Apparently several different concepts are involved, such as structural complexity, interaction complexity, and temporal complexity. To some, it seems obvious that the biosphere is quite complex at present and that its complexity has increased on an evolutionary timescale. But the difficulties of defining complexity lead others to claim that life's present complexity and its increase over time are either illusory or a contingent artifact of our particular evolutionary history. Understanding complexity and its increase through the course of evolution are at the center of much research in artificial life. In fact, one of the field's main goals at present is to produce and then understand open-ended evolution, an ongoing evolutionary process with continually increasing complexity.

Darwin's view of evolution, with its emphasis on survival of the fittest, implied that the process of adaptation was the key to the creation of intelligent design through life's evolution. However, the role and significance of adaptation is controversial today. Some hold that adaptation is the main force driving the changes observed in evolution. Others maintain that most of evolution consists of non-adaptive changes that simply explore a complex space of morphological forms. Still others claim that much of the apparent intelligence of complex systems is a necessary result of certain complex system architectures. Artificial life may shed light on this debate by providing many diverse examples of evolutionary processes, with an attendant ability to analyze the details of those processes in a way that is impossible with the biosphere, because the analogous assaying of historical data is currently impractical and much of the historical data is simply unavailable.

Analysis of adaptation has led to the idea of a fitness landscape. Organisms (or agents in an artificial life model) are considered to be specified by a genome (or sometimes a set of model parameters). The interaction of the organism with other organisms as well as with its environment yields an overall fitness of the organism, which is often thought of as a real-valued function over the space of possible genomes (or model parameters). In various applications of evolutionary algorithms, such as the genetic algorithm, specifying a fitness function is an essential part of defining the problem. In such cases, adaptation is a form of optimization, 'hill climbing in the fitness landscape'. In artificial life models, however, fitness is often not specified explicitly, but is a property emerging from the interactions of an organism with its world.

The concept of a fitness landscape as an analytical device suffers various limitations. One is that a fitness landscape is generally an approximation; the fitness landscape itself can evolve when organisms in a population interact strongly with each other. Another reason is that on an evolutionary timescale, the space on which a fitness function is defined is changing with the advent of new elements to the genome or new model parameters for artificial organisms. Simulating agent-based artificial life models is a natural and feasible way to study these more general situations.

MODELS AND PHENOMENA

Generally, artificial life models choose a level of biological life to model. The lowest stratum may be thought of as analogous to the chemical level; higher stages include modeling of simple organisms such as bacteria, constituents of more complex organisms such as cells, complex organisms themselves, and varieties of complex organisms that can give rise to ecologies. One might consider a holy grail of artificial life to be the discovery of a single model that can span all these levels; so far the field has had difficulty producing a model that spans even one connected pair of levels.

The most primitive phenomenon explored by some artificial life models is self-organization. Such models study how structure may emerge from unstructured ensembles of initial conditions. Naturally, one aim is to discover the emergence of lifelike structure; some models explicitly aim to model the origin of life – such as chemical soups from which fundamental structures such as self-maintaining autocatalytic networks might be seen

to emerge. Models for the immune system are another example of a lifelike process emerging from chemical interactions. Self-organization has also been studied in models for higher-level living structures, such as metabolisms and cell networks, with Boolean networks whose dynamics converge to different structures depending on model meta-parameters (Kauffman, 1969, 1993).

A host of models target the organismic level, sometimes with significant interactions between organisms. These models typically allow changes in the organisms as part of the system's dynamics (e.g., through a genetic mechanism), and the most common goal of research using these models is to identify and elucidate structure that emerges in the ensuing evolutionary process. Some models fit in between the chemical level and the organismic level, aiming to understand development by modeling interacting cells. Other models are inter-organismic, in the sense that they aim explicitly to model interactions between different types of organisms or agents. These models often contain elements of game theory.

Many of the models studied in artificial life should be viewed as 'purely digital' models. Purely digital models drop any pretense of modeling any pre-existing biological structures; their elements are digital constructs having no direct biological reference. Such models seek to produce novel, purely digital instances of biological phenomena in their emergent behavior. Conway's game of life is a purely digital model at the physical or chemical level, embodying an extremely simple and unique form of 'chemical' interactions (the birth–death rule). The self-organization exhibited in the game of life is not a representation of chemical self-organization in the real world but a wholly novel instance of this phenomenon. Another chemical-level model is AlChemy (Fontana, 1992), which consists of a mixture of 'reacting chemical molecules' that are actually simple programs that produce new programs as output when one program is given as input to another program.

One example of a purely digital model on the 'organismic' level is Tierra (Ray, 1992), which consists of 'organisms' that are actually simple self-replicating computer programs populating an environment consisting of computer memory. Tierra was a mature version of earlier efforts of a model called Core Wars (Dewdney, 1984) and has been followed by more developed versions such as Avida (Adami and Brown, 1994). In Tierra, the world is a one-dimensional ring of computer memory, which may be populated with instructions that are much like idealized microprocessor assembly language instructions (e.g., copy, jump, conditional branch, etc.). The instructions are the microscopic components of the model, and the model's central processing unit (CPU) implements the instructions in memory, creating a chemistry from which structure in the model can emerge. The model is generally seeded with a primordial organism consisting of a group of instructions that can copy itself to another place in memory. The copying is accompanied by errors (mutations) that can enhance the functionality of the organisms.

The accomplishments and shortcomings of most artificial life models are exemplified by those of Tierra. On the side of accomplishments, Tierra shows clear evidence of evolution, and the resulting emergence of structure and organization that were not 'programmed' into the model explicitly. Careful analysis of the evolutionary results reveals computational features such as evolution of subroutines and versions of parasitism. On the negative side, the model shows only one level of emergence (e.g., the model must be seeded by a primordial organism; evolution of an unstructured soup has not yet produced an emergent viable organism). Secondly, the evolution of the digital organisms appears to 'level off', reaching a stage where increasingly insignificant innovations are absorbed into the population, instead of displaying the open-ended evolution of natural systems. Reasons for this limitation include (1) simplicity of the model's evolutionary driving force (the evolutionary value of replication with minimal CPU time), (2) structural limitations on the space of innovations possible, which create limitations on organism functionality, and (3) structural limitations on organisms' ability to interact with each other and their environment. Different artificial life models have different detailed reasons for the two limitations we have discussed in Tierra, but the limitations are generally prevalent.

Another important area of artificial life is not so much a modeling activity as much as an implementation activity. This work aims to produce hardware implementations of lifelike processes. Some of these implementations are practical physical devices. But some of this activity is primarily theoretical, motivated by the belief that the only way to confront the hard questions about how life occurs in the physical world is to study real physical systems. Again, there is an analogy with biological levels. The 'chemical' level is represented by work on evolvable hardware, often using programmable logic arrays (e.g., Breyer *et al*., 1998). The 'organismic' level is represented by recent work in evolutionary robotics (e.g., Cliff *et al*., 1993). An

'ecological' level might be represented by the Internet along with its interactions with all its users on computers distributed around the world.

Artificial life, like its antecedent, cybernetics, has a peculiarly broad cultural scope extending beyond cut and dried scientific progress. This breadth is best exemplified by the work of Karl Sims (Sims, 1991), who has coupled rich image-producing computational environments with interactions between those environments and people watching the images at an exhibit. The result is an evolutionary system that is not constrained to live within the confines of a particular model's framework, but rather that is a coupling of two evolutionary subsystems, one of which is natural (the audience). Sims' interactive evolutionary art has produced several visually striking results, and human interaction seems to give the evolutionary system an open-ended quality characteristic of natural evolution.

FUTURE DIRECTIONS

One broad direction artificial life will continue to take in the future is that of synthesis: the synthesis of significant biological phenomena either within the context of model simulation or hardware implementation. A grave difficulty facing progress in this area is the lack of any quantitative basis of comparison for many of the biological phenomena artificial life aims to model. An example of this difficulty is modeling open-ended evolution. How could we know when this is achieved? In general, measurable characterization of phenomena is a prerequisite to quantitative comparison, and much progress is needed in order to achieve this for many target phenomena.

Probably the largest goal of the field is to understand the nature of life itself. This will be furthered to some extent with the quantitative comparisons just mentioned, but there is also a broader goal of discerning what the boundaries of life are, and how the idea of life might be extended to phenomena beyond biological life. Is there a sense in which financial markets or sociotechnical networks are alive, independent of the lives of their biological constituents? Many in the field of artificial life believe that, if the concept of life is properly framed and understood, such questions may well have a precise affirmative answer.

Attractor Networks

Intermediate article

Garrison W Cottrell, University of California, San Diego, California, USA

CONTENTS

Attractor networks are types of neural network that are often used to represent human subjects' content-addressable memory. That is, given part of a memory, such as a name, we can complete the pattern and recall other information about the individual associated with that name.

INTRODUCTION: COGNITION AS ACTIVATION DYNAMICS

How is it we recall information? Many psychologists have suggested that our memory is *reintegrative* – that is, we 're-integrate' the information each time we recall something. The correlate in computer science is called *content-addressable memory* (CAM). Standard retrieval of information from a computer's memory requires an *address*, the location of the information. One can, however, buy an expensive piece of hardware that will retrieve the bits at any address in the memory that match a partial pattern of bits; i.e., based on the *content* of that memory. What is expensive to a computer scientist seems effortless for a human. For example, I can tell you I am thinking of someone who is a former actor, a former President of the United States, a Republican, quite elderly, and a Rhodes scholar. You probably retrieved 'Ronald Reagan', even though part of the description is incorrect. You retrieved this memory through *pattern completion*: given part of the memory, you retrieved the rest of the memory.

In neural networks, systems that provide for the storage and retrieval of such patterns are called *attractor networks*, and have been used to model such diverse phenomena as memory, lexical access, reading, aphasia, dyslexia, associating names and faces, and face recognition. This article very briefly reviews some of the mathematics of such networks and how they are trained.

HOPFIELD NETWORKS

Hopfield networks, named after the physicist John Hopfield who studied them and proved many of their properties, are a particular kind of neural network in which the units are symmetrically connected. (Such networks had been studied earlier; see Cowan and Sharp (1988) for a review. Hopfield (1982) became associated with these networks by proving their stability properties using an energy function and by promoting the idea of them as memory models.) Hopfield networks are important because there is a great deal of elegant theory surrounding them. Unfortunately, the theory shows that as memories, they have a very small capacity. However, the important role they played in the development of the theoretical properties of neural networks makes them worthy of consideration. The following discussion owes much to Hertz *et al*. (1991).

A binary Hopfield network is a collection of N *units*, connected by weighted links. A unit is represented by its activation value, y_i:

$$y_i = g(u_i) \tag{1}$$

$$u_i = \sum_{j=0}^{N} w_{ij} y_j \tag{2}$$

$$g(x) = 1 \text{ if } x \geq 0, \text{ else } -1 \tag{3}$$

where $g(x)$ is called the *activation function* of the units (here, it is also known as the sign function), u_i is often called the *net input* to the unit, and w_{ij} is the weight from unit j to unit i. Also, $y_0 = 1$ by definition. w_{i0} is sometimes called the *bias* of the unit, and is equivalent to the negative of a threshold (which it is explicitly when y_0 is defined as -1 instead of 1). In Hopfield networks, there is a constraint that $w_{ij} = w_{ji}$; that is, the network is symmetrically connected. This is explained later.

This system has a *dynamics*. That is, if we start the system in some state (a pattern of activation on the y_i), it updates its state over time based upon the above equations. For a 'standard' Hopfield network, this is done asynchronously. That is, on each time step of the system, we randomly choose an i between 1 and N, and update the activation of unit i using the above equations.

Given this formulation, the question is: how can we store a set of patterns of activation such that, when presented with a new pattern, the system activations evolve to the closest stored pattern? This idea is illustrated abstractly in Figure 1. The coordinates of the graph are the activations of two continuously-valued units (note this is easier to draw than if we used $-1, 1$ units, as we are here). The 'X's represent stored activation patterns. The arrows represent the idea that, starting from nearby patterns, the system should move towards the nearest one. The boundaries around any pattern are called the *attractor basin* for that pattern.

Following Hertz *et al*. (1991), we start with one pattern, call it $\vec{x} \in \{-1, 1\}^N$, a vector of 1s and -1s of length N. We would at least like this pattern to be *stable*; that is, if we impose this activation pattern on the units by setting all of the y_i, the network should not move from that pattern. The requirement for stability is simply:

$$g\left(\sum_j w_{ij} x_j\right) = x_i \quad \forall_i \tag{4}$$

If the update rule is applied, then, nothing changes. The question, then, is how to set the weights w_{ij} to guarantee this. One common rule is:

$$w_{ij} = \frac{1}{N} x_i x_j \tag{5}$$

Then (assuming no bias):

$$\begin{aligned} u_i &= \sum_j w_{ij} x_j \\ &= \frac{1}{N} \sum_j x_i x_j x_j \\ &= \frac{1}{N} \sum_j x_i = x_i \end{aligned} \tag{6}$$

as required (note: $g(x_i) = x_i$). In fact, if fewer than half of the elements are 'wrong', they will be overruled by the majority that are correct. Thus this system has an attracting state that is the desired pattern. Given a partially correct pattern, it will 'complete' the pattern, just as the reader completed the 'Reagan' pattern. It should be noted that it also possesses another attractor, $-\vec{x}$, called the *reversed state* (Hertz *et al*., 1991). This is the other attracting state of the system.

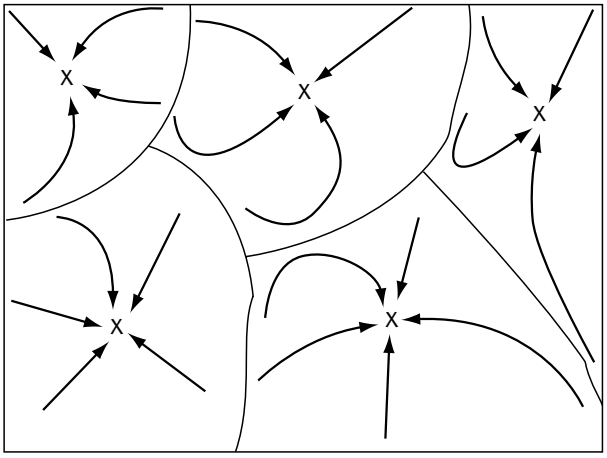

Figure 1. Attractor basins in an imaginary network. The x, y axes represent activations of two of the units, in this case, continuous valued.

For multiple patterns, we just overlay the weight prescription of each pattern:

$$w_{ij} = \frac{1}{N} \sum_p x_i^p x_j^p \tag{7}$$

where p ranges over all of the patterns. This is called the *outer product rule* or *Hebb rule* after Donald Hebb (1949), who proposed a similar idea in his classic book, *The Organization of Behavior*. If one imagines that these patterns are imposed (say, via perception) on the set of units, then this rule sets the weights according to the correlation between their firing. In neuroscience, the slogan is, 'neurons that fire together wire together'.

In a learning setting, we can imagine that upon presentation (or imposition) of a pattern (i.e., all y_i are set to the corresponding x_i^p), starting from some random initial weights, each weight is updated by:

$$w_{ij} := w_{ij} + \eta y_i y_j \tag{8}$$

where η is a (usually small) learning rate parameter. Over many presentations of the patterns, the weights will become proportional to the correlation between the elements of the patterns. They will also grow without bound, a problem that can be addressed by artificially limiting the size of the weights, or by adding a 'weight decay' (or 'forgetting') term that moves the weights slowly back towards 0.

Intuitively, we can think of the weights in the network as *constraints* between the units. Suppose,

for the sake of exposition, some unit represents the feature 'happy' and another unit represents the feature 'has a big smile'. We would like both of these units to be 'on' ($y_{happy} = 1, y_{smile} = 1$), or both of these units to be 'off' ($y_{happy} = -1, y_{smile} = -1$) in a stable pattern. Then they should have a positive weight between them, since the features are correlated. On the other hand, these units should have a negative connection to a unit representing 'sad'. Then if $y_{sad} = 1$, it will tend to try to turn off y_{happy} and vice versa. Hence the weights represent the way that features may 'vote' for their friends (positive weights) and vote against their enemies (negative weights).

Returning to the rule for the weights given in equation 7, the requirement for stability of a pattern becomes:

$$g\left(\sum_j w_{ij} x_j^p\right) = x_i^p \quad \forall i, p \tag{9}$$

Note that we can decompose the sum into:

$$\begin{aligned}\sum_j w_{ij} x_j^p &= \frac{1}{N} \sum_j \sum_{p'} x_i^{p'} x_j^{p'} x_j^p \\ &= x_i^p + \frac{1}{N} \sum_j \sum_{p' \neq p} x_i^{p'} x_j^{p'} x_j^p \end{aligned} \tag{10}$$

The second term is called the *crosstalk* term. The pattern will be stable if the crosstalk term is the same sign as x_j^p for all j, or if its magnitude is less than 1, so that it does not overwhelm x_j^p.

The question now becomes: what is the capacity of such a network? That is, how many such patterns can reliably be stored? First, by 'stored' we simply mean that the pattern is stable, not that a partial pattern will complete to a full pattern. Also, there are several ways in which we might define 'reliably'. For example, we might require that the patterns remain exactly as stored, or that they change only a small percentage of their bits, or that they are stable with some probability and some amount of distortion. It also matters how correlated the patterns are with one another. The details are beyond the scope of this article, but the general result agrees with Hopfield's empirical finding in his original article that the capacity is about $0.15N$. The most quoted figure for the capacity is $0.138N$, which corresponds to about 1.6% of the bits in a pattern changing to an incorrect setting before it stabilizes (Hertz *et al*., 1991). This means that to store, say, one pattern from every day of our lives until we reach 50 years, we would need of the order of 132,000 units. Looked at another way, given that we have 10^{11}–10^{12} brain cells, we could store of the order of 10^{10}–10^{11} memories – if the brain were a Hopfield network, and if it had to do nothing but store memories. However, even if we used only 1% of our brains for memory, we would still be able to store around 100 million memories by this calculation. So perhaps the view that they have small capacity is not such an worry.

ENERGY FUNCTIONS AND CONVERGENCE

One of the novel contributions of Hopfield's original paper was the proof of convergence of a Hopfield network. *Convergence* here means that when the network starts in some state of activation, using the update equations 1–3, the network will reach a point where no activations change. Note that this does not mean that it will converge to one of the stored memories! It simply means that the network will not oscillate, or become chaotic. The proof relies on the notion of an *energy function*, also known in physics as a *Lyapunov function*. The idea is that the energy function is a real-valued function of the state of the network, that it is bounded from below, and that the update equations of the network always make this number stay the same or go down. If one can come up with a Lyapunov function for a system, one can infer that the system reaches a point where nothing changes. (This is speaking rather loosely. There may be updates that move the state of the system to another state with the same energy value. However, in the proof below, we assume that only one unit changes its state, which avoids this problem.) The particular Lyapunov function Hopfield proposed is:

$$E = -\frac{1}{2} \sum_{ij} w_{ij} y_i y_j \tag{11}$$

This expression, without the negation sign, has also been called the 'goodness' function of the network by Rumelhart *et al*. (1986b), in which case it always goes up or stays the same.

Here we have excluded the contribution of any external input to the network, which can be easily incorporated into this expression. Given a set of weights, E clearly has a minimum value (it is bounded from below). Intuitively, we can think of this as a representation of how many constraints have been violated by the current activation state. That is, suppose two units are connected by a positive link. Then the constraint between them is that they should both be on or both be off, as in the 'happy/smile' example above. This 'constraintlet'

is represented by two terms (redundantly) in the above sum, $w_{happy\,smile} y_{happy} y_{smile}$ and its dual. If both units were on, then that would be a positive component of the sum, which would mean a more negative overall energy (more constraints satisfied). If one of them was 1 and the other -1, then the energy would be higher, all other things being equal. Similarly, if w_{ij} is negative, then the energy is lower when y_i and y_j are of opposite sign, versus when they have the same sign.

Another way to conceive of this is to imagine the values of E for different activation values of the network. If there are just two units in the network, we can lay out the possible states of the system in a plane. For some values of the units, E will be high, and for others, E will be low. Doing some injustice to the fact that we have only four discrete states, we can imagine that E forms an *energy landscape* over this two-dimensional state space of the system, as shown in Figure 2. The surface shows the height of the energy. The state of the network can be thought of as a ball on this surface. Updating the network state will cause the ball to roll downhill. This is just a more detailed picture of the same phenomenon shown in Figure 1.

Going back to the equation for E, it is intuitively clear why the operation of the network dynamics (equations 1–3) lowers this number. For example, if a unit's current value is -1, and the input from the rest of the network is positive, the unit will update its state to be $+1$, which will violate fewer constraints. To see this formally, suppose that a unit changes state upon updating (if it does not change state, the energy remains the same). Let y_i' represent the new state of unit i. Then the difference in energy with y_i in its new state, E', and the previous E only involves the terms with y_i and y_i' in them:

$$\begin{aligned} E' - E &= -\sum_j w_{ij} y_i' y_j + \sum_j w_{ij} y_i y_j \\ &= -y_i' \sum_j w_{ij} y_j + y_i \sum_j w_{ij} y_j \\ &= (y_i - y_i') \sum_j w_{ij} y_j \\ &= (y_i - y_i') u_i' \end{aligned} \tag{12}$$

By assumption, u_i' is of opposite sign to y_i, and must be the same sign as y_i'. Hence the difference is negative, and E' must therefore be of lower energy than E, as required.

BOLTZMANN MACHINES

One possible problem with Hopfield networks is that, since the update equation is deterministic, the energy always decreases. This means that the network will always move to the lowest nearby minimum, even if there is a better minimum

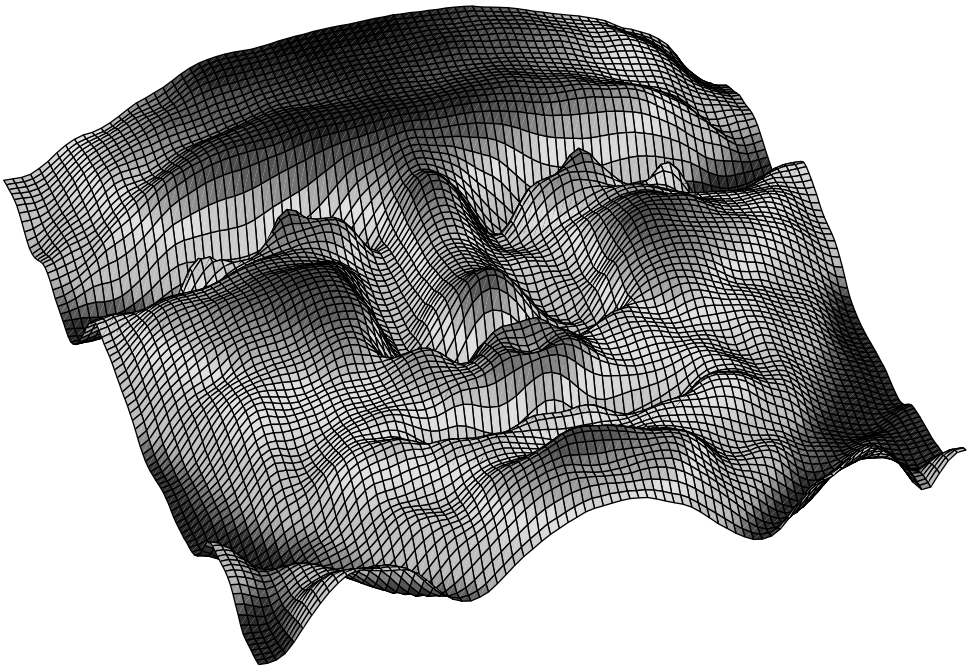

Figure 2. [*Figure is also reproduced in color section.*] An imaginary energy landscape.

somewhere else. The situation where this matters is where some of the units in the network are *clamped* – that is, their activation values are held fixed – and the problem is to find the 'best completion' of the pattern, given the constraints encoded in the network weights. One possible fix to this problem is to have the network sometimes go *uphill* in energy with some small probability. *Boltzmann machines* are one embodiment of this notion (Hinton and Sejnowski, 1986). The formulation of Boltzmann machines is somewhat different from the standard Hopfield network. First, the units are *stochastic*, and have states that are either 0 or 1:

$$s_i = \begin{cases} 1 \text{ with probability } g(u_i) \\ 0 \text{ with probability } 1 - g(u_i) \end{cases} \quad (13)$$

The probability of a unit being 1 is usually taken to be a *sigmoidal* function of the input:

$$g(u_i) = \frac{1}{1 + exp(\frac{-u_i}{T})} \quad (14)$$

The parameter T is called the *temperature*, because of an analogy between the operation of the system and spin glass models in statistical physics. It controls the steepness of the function g. T can be thought of as a noise parameter. The bigger T is, the less each unit will respond to the input from other units (the function g will be very flat). If T were infinite, each unit would flip between 0 and 1 with 50% probability. Thus, the basic idea in the operation of a Boltzmann machine is to start with a high T, and slowly lower T until it is near 0 and the system is practically deterministic (the function g will be very close to a threshold unit as in equations 1–3). Hinton has described the idea as follows (paraphrasing). Suppose you have a black box with a surface like that in Figure 2 inside, and a ball is dropped into the box. Your job is to get the ball to the lowest spot on the surface, obviously without being able to see inside the box. One way to do this is to shake the box vigorously, then slowly shake it less and less. The energetic shaking should get the ball into the largest well in the box, and as the shaking subsides, it should get into the lowest spot. One can prove that if you shake the box for an infinitely long time, and slow your shaking appropriately, then the ball will end up in the lowest spot in the box.

Another way to think about what T does is that when it is big, it smooths out the bumps in the energy landscape, as if you are squinting at it. As it is lowered, the smaller bumps will emerge, and the ball's behavior will depend more on the fine details of the landscape. It should be clear that no one is proposing that your brain 'heats up' as you are recalling memories! However, the idea that noise may help in reaching better states is not so far-fetched. It has been shown that laughing in the middle of a test improves performance.

Another novelty in Boltzmann machines is the idea of *hidden units* in the network. These are units that are not part of the stored patterns (which are placed on the *visible units*), but can be used to differentiate between patterns that might otherwise be confused because they are too similar. The introduction of a set of units that are not part of the stored patterns makes the use of the Hebb rule problematic, as the states of the hidden units are not specified. However, learning in Boltzmann machines nevertheless turns out to be relatively simple conceptually, but tends to be very slow. (Recently, Hinton has developed a relatively fast learning algorithm for a special case of Boltzmann machines (Hinton, 2002), but it is beyond the scope of this article.) The basic idea is to have two phases. In one phase, the patterns that are to be stored are clamped on the visible units. The network is run for a long time, while statistics are collected on how often units are on and off together. Then the network is run again without the patterns clamped. The weights are updated according to:

$$w_{ij} = \eta(< y_i^+ y_j^+ > - < y_i^- y_j^- >) \quad (15)$$

where the angle brackets mean averages over time, η is a learning rate parameter, y_i^+ refers to the clamped phase, and y_i^- refers to the unclamped phase. Notice that this rule will still result in symmetrically connected networks. Intuitively, one is subtracting off the statistics of the network running 'on its own' from the statistics of the network when the desired pattern is present. This has been compared to an 'awake' state (where the network is clamped by its perceptions of the environment) versus a 'sleep' state (the unclamped phase). Such evocative imagery has not yet been verified by neuroscientists, but one really wants it to be true.

One advantage of such networks is that, if they learn successfully, operating them without inputs will result in the network displaying on the visible units the entire *distribution* of the training environment. Unlike deterministic networks, then, these networks can be thought of as *generative models* of their environment. Also, if one thinks of the networks as simply learning by exposure to an environment, they can be thought of as *unsupervised* models that learn (on the hidden units) efficient encodings (features) of their environment. This has appeal as a model of how humans learn from 'mere exposure' to the environment. Of course, we

start with a highly structured neural network, based upon millions of years of evolution. Integrating such pre-structuring of the network with appropriate learning rules is the subject of a great deal of current research.

SEQUENTIAL ATTRACTORS: BACKPROPAGATION THROUGH TIME

While the networks described so far are attractive as models of pattern completion memory, they also seem flawed as a model of how brains might work. First of all, they require the connections in the network to be symmetric. There is little evidence that the neurons in brains, human or otherwise, are so connected. Second, if one takes seriously the notion of finding a stable state of the network, the idea that our neurons settle to a stable state is not particularly palatable. As Walter Freeman has remarked, 'the only stable neuron is a dead neuron'. One would like a model that perhaps reaches stable states transiently, and then progresses to a new state. While there has been some work in this area for Hopfield networks (see Hertz *et al*. (1991) for examples), there has been more work on training networks to go through sequences of states using *supervised*, or *error-correction*, learning techniques. The standard approach is called *backpropagation through time* (BPTT). While the full details are beyond the scope of this article, we can summarize some of the main points.

First, note that if we eschew stable states, the networks must *not* be symmetrically connected. Otherwise, there would be a Lyapunov function to describe their dynamics. Second, if one wants the network to go through different states, it must be told, in some way or another, what those states are. Hence, the training must be supervised – states are specified for the trajectory of the network, and the network is required to pass through those states in the order specified. We may retain the notion of attractors if we generalize it to cyclical behaviors. This means that, for example, if the network is somehow pushed out of the trajectory it has been trained to produce, it will move back towards that trajectory. Finally, such systems usually use *continuous* units, that take values in the range [0,1]. A standard equation for the activity of such units is the logistic equation:

$$g(u_i) = \frac{1}{1 + exp(-u_i)} \tag{16}$$

which bears a remarkable resemblance to the equation for the probability of a unit being 'on' in a Boltzmann machine. However, here this produces not a probability, but the actual activation of the unit. Otherwise, the u_i is calculated in exactly the same way as in equations 1–3.

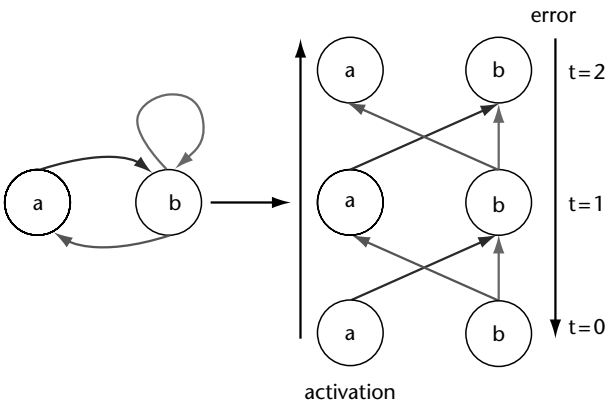

Figure 3. [*Figure is also reproduced in color section*.] Backpropagation in time.

BPTT uses the idea illustrated in Figure 3. On the left of the figure, there is a simple asymmetric recurrent network. This network is converted into a so-called feedforward network by 'unrolling' it in time, as shown on the right. Backpropagation (Rumelhart *et al*., 1986a) is a supervised learning technique that adjusts the weights in a network in order to reduce the error in the state of the network. Errors, in the form of target states, can be 'injected' into the network at any time step, and the weights are adjusted to make the state of the network closer to the target state. Errors are then propagated backwards through the network (hence the name 'backpropagation'), in this case through time (hence the name, BPTT).

The weighted links are color-coded to show how the links in the feedforward version relate to the links in the recurrent version. Also, since links of the same color in the feedforward version are, conceptually, the *same* link, this means that any weight adjustments to one link must be made to all of the links of the same color. Essentially, in BPTT, the weight changes to each link are added together for links of the same color. One of the most striking examples of BPTT in action was its use to train a system to back up a semi-tractor trailer, which required many steps and is a complex task that requires a very skilled human operator to perform (Nguyen and Widrow, 1989).

PHASE-SPACE LEARNING

BPTT in its basic form has problems in training systems with complicated attractors, especially if

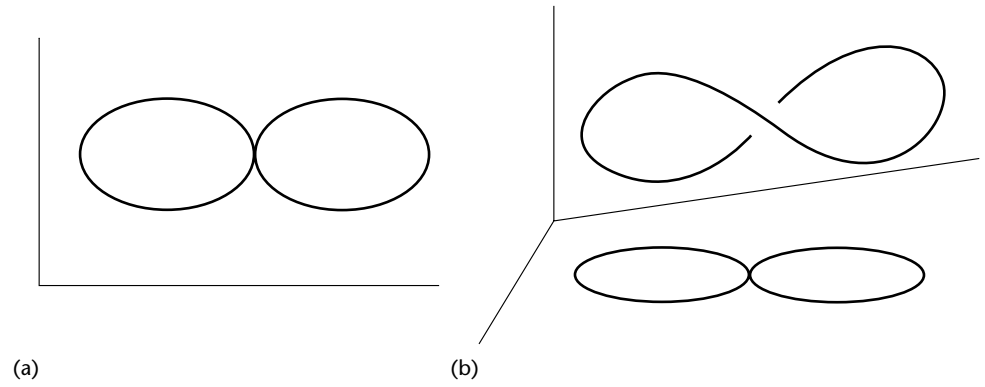

Figure 4. Embedding a '∞' from 2-D into 3-D.

one wants multiple sequential attractors in the same system (see Tsung and Cottrell (1995) for a discussion). A mild variation on BPTT produces surprising results. Tsung and Cottrell (1995) introduced a variation that applies in the case where the desired system dynamics are deterministic, which is often the case (an example where this is not the case is in machine translation; for example, the Spanish *casa* can be translated into English as *house* or *home*). It uses two ideas. The first, borrowed from time-series prediction, is to perform a *delay-space embedding* of the desired trajectory. This is useful in cases where the observed behavior does not appear deterministic, but could be, if more dimensions were introduced. Take, for example, a figure 8 shape. If the two visible units of a system (represented by the two axes in Figure 4(a)) are supposed to describe a figure 8 with their behavior, what happens at the middle point of the 8 is not determined – the system could go one of two ways. However, if there was a third dimension that basically raised one of the curves above the other (think of a raised highway), then the system would be deterministic. The idea is shown in Figure 4(b). Note that the 'shadow' of the trajectory in 2-D is still a figure 8 shape, but the system has a third variable that allows the crossing point to be separated in space.

Delay-space embedding is a technique for adding more state variables to avoid such crossing points, basically by taking the desired trajectory and adding more variables that are simply the ones we already have, but delayed in time. The skill is in picking the amount of delay, and the number of extra variables formed this way (Kennel *et al*., 1992). An important property of a proper embedding is that each point on the trajectory uniquely determines the next point on the trajectory. The space that the system is embedded into is called a *phase space*. In this space, time is represented by movement through the space. For example, the picture given in Figure 1 is a phase space picture: movement along the arrows is movement in time for the system. In this case, the memories given by the Xs in that picture are called *fixed point* attractors. We are interested here in attractors that may involve, for example, closed loops in phase space, which correspond to oscillations. An example of this has already been shown in Figure 4.

The second idea is, once the system has been made deterministic in this way, the mapping from one point to another is a *map*; i.e., there is some function, let's call it f, that produces the next point on the trajectory given the current point. Introducing t, a time variable, $f(\vec{y}(t)) \rightarrow \vec{y}(t + \delta t)$, for some increment δt of our choosing. We can use a feedforward neural network to learn f from examples. Essentially, we are doing BPTT only one δt step back in time. However, given the way we have arranged things via delay-space embedding, this is all that is needed. Now, given this map, we may *iterate* it. That is, once we start from some point, $\vec{y}(0)$, and obtain $f(\vec{y}(0)) = \vec{y}(\delta t)$, we can apply f again, to get the next point, and so on. The final idea is that we can make any trajectory an attractor by training the network to start from points near the desired attractor and making the target closer to the attractor. Tsung and Cottrell (1995) noted that this function f may be arbitrarily complex, so that hidden units between the input and the output may be needed. The idea is shown in Figure 5.

Thus, *phase-space learning* consists of: (1) embedding the trajectory to avoid crossing points, (2) sampling trajectory elements near the desired trajectory, and (3) training a feedforward network on these trajectory elements. Since feedforward

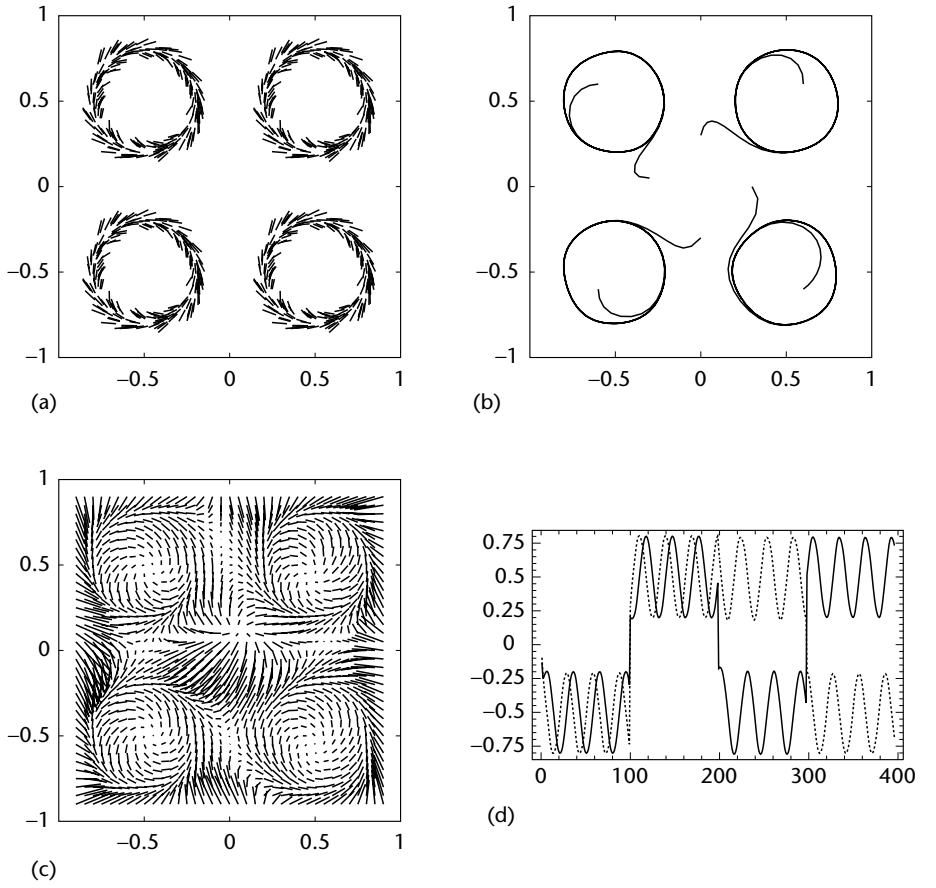

Figure 6. Learning four coexisting periodic attractors. The network had 2-20-20-2 units and was trained using back-propagation with conjugate gradient for 6000 passes through the training set: (a) the training set: 250 data pairs for each of the attractors; (b) eight trajectories of the trained network delineate the four attractors; (c) vector field of the network: this shows, for every little arrow, where the network would go next; (d) graph of the activations of the two visible units over time, as they are 'bumped' into different attractor basins. From Tsung and Cottrell (1995), reprinted by permission of MIT Press.

networks are universal approximators (Hornik *et al*., 1989), we are assured that, at least locally, the trajectory can be represented. The trajectory is recovered from the iterated output of the pre-embedded portion of the visible units (the ones we started with – e.g., the 'shadow' of the embedded system in the original space, as in Figure 4(b)). Additionally, we may extend the phase-space learning framework to also include time-varying inputs that affect the output of the system, as shown in Figure 5, bottom right.

The phase-space learning approach has no difficulties storing multiple attractors. Learning multiple attractors can be done in the same way a single attractor is trained; one simply includes a sufficient number of trajectory segments near all of the desired attractors. Figure 6 shows the result of training four coexisting oscillating attractors, one in each quadrant of the two-dimensional phase space. The underlying feedforward network has two inputs, two layers of 20 hidden units each, and two outputs. The network will remain in one of the oscillating regimes until an external force pushes it into another attractor basin. Such oscillating attractors are called *limit cycles* in dynamical systems theory.

Similarly, such a system can be used to avoid the problems inherent in standard Hopfield networks. The author has used phase-space learning to create a standard fixed-point attractor network to store 'meaning' patterns derived from co-occurrence counts. Specifically, 233 word vectors were used that were processed versions of vectors obtained from Curt Burgess at UC Riverside (Lund *et al*., 1995). The words were those used by Chiarello *et al*. (1990) in their priming experiments. They represented various words from 'ale' to 'wool'. The structure of the vectors was such that, for example, all of the food words were similar, all of the clothing words were similar, etc. The vectors were 36-dimensional (hence 36 visible units would be required to store them), and the elements were $+/-1$. Hence they were perfect for storing in a Hopfield network, except for one thing: there were over six times as many vectors as units, and a Hopfield network with 36 units should be able to store about five vectors. Instead, the author used phase-space learning, in the following way: a 36-70-36 feedforward network was used – that is, there were 36 inputs, 70 hidden units, and 36 outputs. On every training trial, one of the vectors was chosen to present on the input. 25% of the bits in the vector were probabilistically set to 0. The network was trained to produce the original vector from this nearby vector.

Once trained, it could be iterated by copying the outputs back to the inputs. One can think of this network as a recurrent network of 36 units, with 70 hidden units, by 'folding over' the output onto the input. The activation starts at the input, flows to the hidden units, and back to the input. There were also direct connections from the units to themselves (from the input to the output in the original network). This network was trained in about 10 minutes of Cray time (circa 1995), and produced the correct vector about 98% of the time. This demonstrates that the capacity of such networks is much higher than that of standard Hopfield networks.

CONCLUSION

There is not space in this article to cover several related topics. In particular, the reader should be aware that there are continuous-valued Hopfield networks (Hopfield, 1984); a deterministic Boltzmann learning algorithm (Hinton, 1989) that learns much faster than the standard algorithm; and recurrent networks that both recognize and produce sequences (Elman, 1990; Jordan, 1986) in cases where deterministic methods such as phase-space learning do not apply.

Backpropagation

Intermediate article

Paul Munro, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

CONTENTS

Backpropagation is a supervised training procedure for feedforward connectionist networks that is widely used by cognitive scientists to model learning phenomena.

LEARNING AND GENERALIZATION IN NEURAL NETWORKS

Initial approaches to developing general-purpose learning machines have generally been restricted to a form of learning known as supervised learning, i.e. abstracting the properties that underlie an input–output relation given a sample of input–output pairs. A standard test of successful learning is the ability of the system to generalize, which is measured by the average correctness of the system's responses to a set of novel stimuli.

Since the response properties of a neural network depend on the weights, or connections between pairs of units, models of learning are generally framed in terms of how the weights change as a function of experience. Donald Hebb (1949) suggested that changes in the biological correlates of these weights, the synapses between neurons, underlie human learning. In the late 1950s and early 1960s, learning rules were developed for networks. These rules were computationally limited, since both the units and the network architectures were simple (Rosenblatt, 1958; Widrow and Hoff, 1960). While the design of more powerful networks was well within the scope of scientific knowledge at that time, there was no known method for training them. (*See* **Hebb Synapses: Modeling of Neuronal Selectivity**; **Hebb, Donald Olding**)

A simple change to the processing function in the individual units led directly to the development of a learning rule for feedforward networks of arbitrarily complex connectivity. Notions from statistics can be applied to derive a learning procedure for networks with complex architectures. This was first done by Paul Werbos (1974), but his results went unnoticed by the scientific community until their almost simultaneous rediscovery by LeCun (1985), Parker (1982), and Rumelhart *et al*. (1986).

SINGLE-LAYER CONNECTIONIST NETWORKS WITH LINEAR THRESHOLD UNITS

The computational power of a connectionist network depends on the computational power of each unit and on the connectivity among the units. Early learning rules applied to the 'linear threshold unit' (LTU) model, which can respond to a stimulus pattern with one of just two possible values (usually these are 0 and 1). Each LTU performs a 'categorization' function on the space of possible stimuli: it divides the set of stimuli into those that generate a response of 1 and those that generate a response of 0. For an LTU, the boundary between these regions is linear. A 'layer' of LTUs performs independent categorization tasks. A category whose stimuli can be separated from stimuli outside the category by a linear boundary, and which is thus computable by an LTU, is called linearly separable (LS) in the stimulus space. Some LS categorization tasks are shown in Figure 1, along with some that are not LS. (*See* **Connectionism**)

LEARNING IN SINGLE-LAYER NETWORKS

Learning by an LTU is a process whereby the weights change in order to improve the placement of the category boundary. A 'supervised learning rule' operates on the parameters of a system (in this

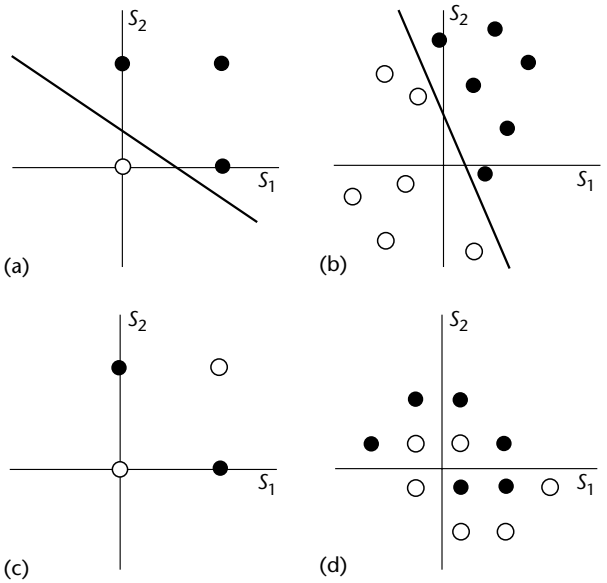

Figure 1. Linear separability. The graphs illustrate four categorization tasks in which patterns are plotted according to the stimulus coordinates (s_1, s_2). Filled dots represent stimuli that are in the category, and open dots represent stimuli not in the category. Categorization boundaries are drawn for the two linearly separable tasks: (a) the 'Boolean OR' task, and (b) a real-valued task. Two tasks that are not linearly separable are also shown: (c) the 'Boolean XOR' task, and (d) a 'double spiral' task.

case, the weights of the network) under the assumption that a set of labeled data (i.e. stimulus points for which the correct categorizations are known) is available. This 'training set' is used to tune, or train, the network weights in the hope that the system will generalize from the training so that it will classify novel stimuli appropriately. This approach resembles standard regression techniques from statistics.

Figure 2 illustrates weight changes of a linear threshold unit and the resulting categorizations on a two-dimensional stimulus space. Note that, in the initial state, some responses of the network are correct and some are incorrect. Eventually, the system finds a classification boundary that solves the given task as well as possible.

MULTI-LAYER NETWORKS

A network built of LTUs can compute a more general class of functions than a single LTU, which is restricted to computing functions that are LS. A typical network structure is the 'multi-layer perceptron' (MLP), originally proposed by Rosenblatt (1958). The MLP architecture first computes the responses of several units, each with different weights (the first layer) to a common stimulus. The pattern of responses is fed as a stimulus to a second layer, and so forth until the final (output) layer. The layers that precede the output layer are known as 'hidden layers'.

An MLP can compute functions that are not LS. Note that each unit in an MLP performs a linear separation on its direct input, but the category it computes on the network input might be more complex. By introducing one or more layers between the network stimulus and the ultimate response, the stimulus pattern is transformed to another 'representation'. A task that is not LS using the representations given at the stimulus level may become LS at a hidden layer. Thus, an MLP can compute a complex categorization task by changing the representation of the task. What is needed is to find a transformation under which the hidden-layer representations are LS. An example is shown in Figure 3.

BACKPROPAGATION OF ERROR

Until the publication of the 'backprop' procedure, there was no technique for training an MLP with more than a single layer. Like standard regression techniques, the derivation of backprop begins with the definition of an 'error measure' E which quantifies how closely the network approximates the given data as a function of its weight parameters.

The well-known 'gradient descent' technique is used to modify each weight, by an amount that is proportional to the derivative of E with respect to that weight. This approach eluded researchers in the 1960s, because of the abrupt shift in the value of the threshold function at the threshold, which renders the required derivatives undefined. The insight that enables the use of gradient descent is to replace the threshold function with a function that is differentiable but retains the important features of the threshold function (Figure 4).

The backpropagation learning rule is derived by applying the gradient descent technique to fit a feedforward network of sigmoid units to a set of data. The rule can be implemented as a process whereby an error value is first computed for each output unit. Subsequently, these errors are 'propagated backwards' through the weights of the network to determine an 'effective error' for all the hidden units in the network.

In its simplest form, the backprop procedure is implemented as follows (compare with the single-layer learning procedure described above):

	S_1	S_2	r	T
A	0	6	1	1
B	2	0	0	1
C	3	2	0	1
D	4	5	1	1
E	1	–4	0	0
F	–1	3	1	0
G	–3	4	1	0
H	–5	–1	0	0

	S_1	S_2	r	T
A	0	6	1	1
B	2	0	0	1
C	3	2	0	1
D	4	5	1	1
E	1	–4	0	0
F	–1	3	1	0
G	**–3**	**4**	**0**	**0**
H	–5	–1	0	0

	S_1	S_2	r	T
A	0	6	1	1
B	2	0	1	1
C	3	2	1	1
D	4	5	1	1
E	1	–4	0	0
F	–1	3	0	0
G	–3	4	0	0
H	–5	–1	0	0

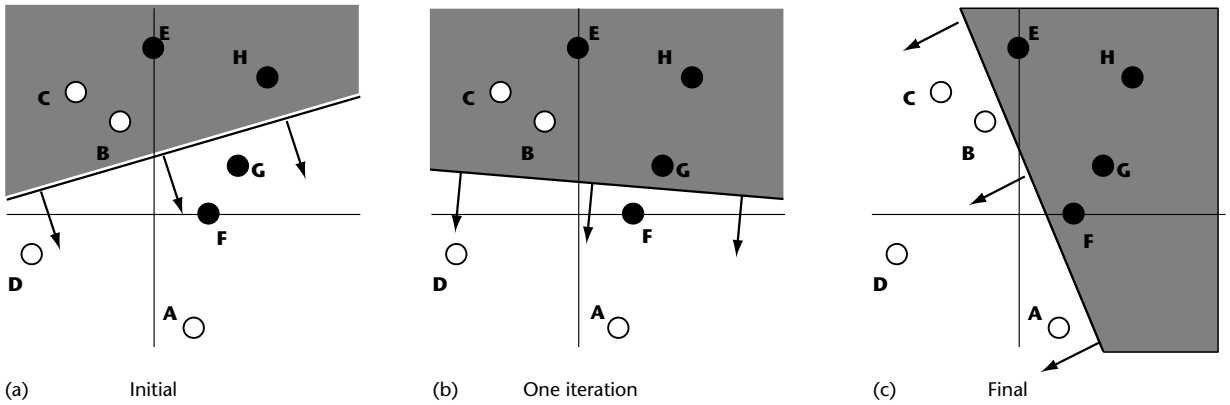

Figure 2. Learning by an LTU. Three stages during the learning process are shown. At each stage a table lists the stimulus values (s_1, s_2), the target (T), and the actual response (r), for the eight elements (A to H) of the training set. Each element is plotted according to its stimulus values, and is either open or filled depending on its target value. The line shows the discrimination boundary at each stage. (a) The initial (random) state. (b) The state after presentation of the first pattern, G. (c) The final state: all patterns are correctly classified.

	s_1	s_2	h_1	h_2	r
A	0	0	0	0	0
B	0	1	1	0	1
C	1	0	1	0	1
D	1	1	1	1	0

Figure 3. A simple MLP. (a) The network shown computes the 'XOR' function of the stimulus, which is not a linearly separable function. The intermediate (hidden) layer has two LTUs, which compute responses using the weights (arrow labels) and thresholds (θ) shown in the diagram. (b) The table shows the responses (h_1, h_2) of the hidden units and the response r of the output unit for each stimulus (s_1, s_2). (c) The linear classification boundaries of the hidden units are shown in 'S-space', in which the stimulus patterns are plotted. (d) The linear classification boundary of the output unit is shown in 'H-space', in which the representations of the patterns at the hidden layer are plotted.

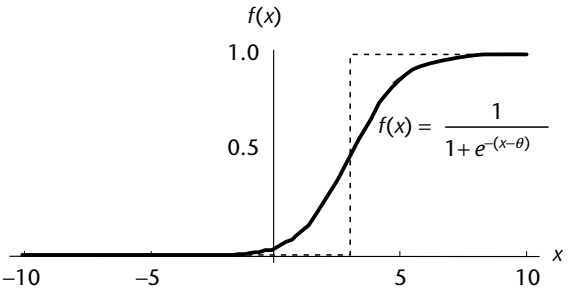

Figure 4. A sigmoid function. Backprop requires units that use differentiable functions. A sigmoid function is differentiable and has many of the important properties of the threshold function. Here, a sigmoid function is plotted (solid line) with a threshold function (dotted line). The value of θ is 3 for both functions. The sigmoid function only approaches its bounds asymptotically. The most common function used for this purpose is the 'logistic' function $f(x) = \frac{1}{1+e^{-x}}$.

1. Initialize the weights to random values.
2. Choose a random data item from the given set (stimulus and categorization value).
3. Compute the activities of the hidden units (first mapping), and from these the activities of the output units (second mapping). This is the 'forward propagation' of neural activity.
4. Compare the output responses with the target values and assign an error value to each output unit.
5. Compute the 'effective error' for each hidden unit as a function of the output unit errors and the hidden–output weights. This is the 'backward propagation' of error.
6. Modify the weights and biases.
7. Test the network on all items in the set of labeled data. If the number of incorrect classifications is acceptable, or if the number of iterations hits the maximum allowed, then stop – otherwise, go back to step 2.

Table 1 gives a more detailed description of the computations.

DEVELOPING INTERNAL REPRESENTATIONS FROM EXPERIENCE

In order for backprop to converge to a state that computes a 'difficult' task (such as one that is not LS), the mapping from the input to the hidden layer must give representations that simplify the task (e.g. rendering the task LS). Not only is convergence dependent on finding an appropriate set of internal representations, but so is the ability to generalize appropriately. Although backprop is not guaranteed to find an appropriate mapping of this kind, it does converge to a solution in many cases. In addition, it should be noted that an 'almost perfect' solution is acceptable for modeling many phenomena.

MODELING COGNITION

Networks have been trained with backprop to simulate cognitive functions ranging from perceptual tasks to high-order processes. These models address a broad range of scientific questions. In many cases, particularly in linguistics, the models have been used as counterexamples to assertions that certain cognitive capabilities must be innate or must require specific types of symbolic manipulation. Generally, backprop is used as an example of how a 'neural-like' system can extract statistical regularities from the environment, so that the performance of the system appears to follow 'rules' without any explicit encoding of those rules. The following examples from linguistics demonstrate the facility of backprop for developing models of cognitive tasks at several levels.

Mapping Text to Speech

In their simulation 'NetTalk', Sejnowski and Rosenberg (1987) trained a network to map English text to the corresponding phonological representation. Unlike some more regular languages, the correct pronunciation of a given letter in English is not always the same. However, it is not completely arbitrary, but depends in large part on the letters in the same neighborhood. Consider, for example, the pronunciations of the letter 'c' in the three nonword strings 'stince', 'stinch', and 'stinck'. The fact that most readers of English would agree on the pronunciation, even though they have never heard the words read aloud, indicates that there are 'rules' for pronunciation rather than arbitrary correspondences between letters and phonemes. NetTalk is trained on a corpus of text, and eventually is able to pronounce not only text from the

Table 1. The backprop algorithm

Algorithmic step	*Formulae*	*Pseudocode*

Hidden unit activities	$h_j = \frac{1}{1+e^{-x}}$
	where $x = b_j^{\text{hid}} + \sum_i w_{ij} s_i$
		`for j := 1 to nhid`
		`arg[j] := hidb[j] ;`
		`for i := 1 to ninput`
		`arg[j] := arg[j] + w[i,j] * s[i];`
		`h[j] := f(arg[j]) ;`
		`end`

Output unit responses	$r_k = \frac{1}{1+e^{-x}}$
	where $x = b_k^{\text{out}} + \sum_j v_{jk} h_j$
		`for k := 1 to noutput`
		`arg[k] := outb[k] ;`
		`for j := 1 to nhid`
		`arg[k] := arg[k] + v[j,k] * h[j] ;`
		`r[k] := f(arg[k]) ;`
		`end`

Output unit errors	$\delta_k^{\text{out}} = (T_k - r_k) r_k (1 - r_k)$	`for k := 1 to noutput`
		`dout[k] :=`
		`(T[k] – r[k]) * r[k] * (1 – r[k]) ;`

Hidden unit errors	$\delta_j^{\text{hid}} = \left[\sum_k v_{jk} \delta_k\right] h_j (1 - h_j)$	`for j := 1 to nhid`
		`dhid[j] := 0 ;`
		`for k := 1 to noutput`
		`dhid[j] := dhid[j] + v[j,k] * d[k] ;`
		`dhid[j] := dhid[j] * h[j] * (1 – h[j]) ;`
		`end`

Weight and bias adjustments	$\Delta w_{ij} = \eta \delta_j s_i$
	$\Delta v_{jk} = \eta \delta_k h_j$
	$\Delta b_j^{\text{hid}} = \eta \delta_j$
	$\Delta b_k^{\text{out}} = \eta \delta_k$
		`for j := 1 to nhid`
		`bhid[j] := bhid[j] + q * dhid[j] ;`
		`for i := 1 to ninput`
		`w[i,j] := w[i,j] + q * dhid[j] * s[i] ;`
		`for k := 1 to noutput`
		`bout[k] := bout[k] + q * dout[k] ;`
		`for j := 1 to nhid`
		`v[j,k] := v[j,k] + q * dout[k] * h[j] ;`

training corpus, but also text unseen during the training process. It extracts the mapping from text to speech without an explicit representation of the rules (see Figure 5).

Generating the Past Tense

The generation of past-tense verbs has been the subject of study by developmental psychologists because children almost universally go through similar stages on the path to adult competence in this task. A network simulation developed by Rumelhart and McClelland (1986), which did not use backprop, required a carefully designed representation in order to learn the task of mapping verbs from their present-tense forms to their past-tense forms. Their simulation successfully generalized from the training examples to novel verbs, both regular (e.g. *jump* and *jumped*) and irregular (e.g. *sing* and *sang*). In addition, it was able to mimic certain developmental stages of language learning in children over the course of its training. With the development of backprop, these results have been replicated in multi-layered networks that develop the requisite representations, rather than having them specified (Plunkett and Marchman, 1991).

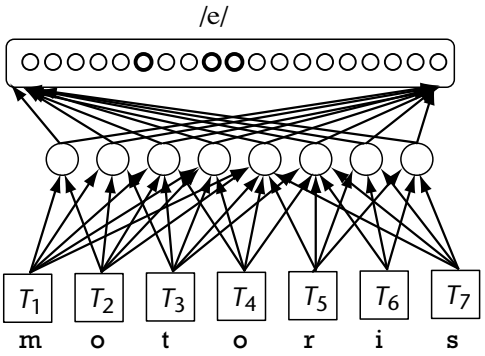

Figure 5. NetTalk. A sliding 7-character window of text (T_1, T_2, T_3, T_4, T_5, T_6, T_7) is presented as input to a network that is trained to generate a phonological representation of the central character (T_4). There are 29 input nodes for each of the 7 character positions (26 letters, space, period, and comma), a single hidden layer, and output units representing phonemic features.

Evolution of Language

Over the course of centuries, languages undergo subtle incremental changes that tend to reinforce regularity (Quirk and Wrenn, 1957) – that is, exceptions to rules are gradually lost, especially for verbs that occur with low frequency. Hare and Elman (1993) offer an explanation and support it by training a succession of networks on the past-tense task using backprop. The first network in their simulation is trained on present–past verb pairs from Old English. Before it achieves perfect performance, a second 'child' network is trained using the first network's computed past tenses. This process proceeds iteratively, each network learning imperfectly from its parent, and so the language evolves. While the process does not precisely follow the evolution of English, it exhibits similar properties with respect to increased regularization and the influence of word frequency.

ENHANCEMENTS TO BACKPROP

As a technique for training feedforward networks for classification tasks in many domains and for developing models of cognitive processes, backprop has been very successful. However, as a gradient-descent procedure, the pure form of the backprop procedure (commonly known as 'vanilla backprop') has some flaws, which can make it an inelegant, or even useless, approach. Some of these are discussed below.

Local Minima

Gradient-descent processes proceed along a path through the state space that reduces the objective function (in this case, the error), like water being driven down a hillside by gravity. The process converges to a state that is a local minimum, from which any direction leads uphill. Thus, the final value of the error is dependent upon the initial state, just as some mountain streams can lead to a high-altitude lake, while others flow to the sea. One imperfect, but simple, remedy is to add a 'momentum' term to the learning rule, which reinforces those components of weight changes that are common across learning trials.

Overfitting Training Data

The input–output items used for training are generally 'noisy'; that is, the output is not perfectly dependent on the input. A system with many adjustable parameters can be trained to fit noisy training data exactly, but only at the expense of its ability to generalize. By monitoring network performance on a set of 'test data' (consisting of items not used for training, but representative of the same sample set), training can be stopped before the system overfits the training data (Figure 6).

Slow Convergence

Gradient-descent processes tend to be slow. Learning of this kind is often criticized as a model of human learning for its inability to learn an item from a single exposure. The slow convergence is exacerbated by the complexity of the input–output relationship and the number of parameters. The speed of convergence is closely related to the value of the learning rate η.

Network Architecture

The determination of the best number of hidden units and their connectivity is a challenge, for which guesswork and trial-and-error are often relied upon. There are two primary approaches to optimizing network architecture. Networks can be 'grown' by starting with a minimal architecture and incrementally adding hidden units (Ash, 1989; Fahlman and Lebiere, 1990; Hanson, 1990) when the generalization error stops decreasing. At some point, the addition of more hidden units no longer benefits the network, or may even be a negative contribution.

Alternatively, one can begin with many more hidden units than are required and then 'prune'

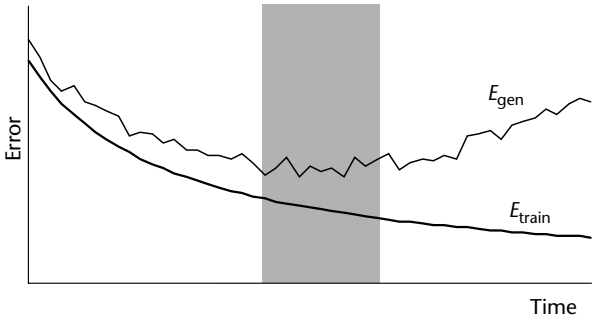

Figure 6. Two error measures. The error measured over the training set, E_{train}, steadily decreases over time. The error with respect to a set sampled from the same population, E_{gen}, also decreases during the first period of learning. Typically, for data sets with noise, E_{gen} eventually begins to steadily increase. Learning should be stopped when E_{gen} is at a minimum (at some point in the shaded region).

units that are deemed to have a low 'relevance' to the network task (Chauvin, 1989; Mozer and Smolensky, 1989; Le Cun *et al*., 1990; Hassibi and Stork, 1991; Demers and Cottrell, 1993). With each removal, the network is retrained and the generalization error is measured. The cycle of pruning and retraining is continued until the generalization performance begins to deteriorate. The objective function (the function minimized by the gradient descent) is typically augmented by an additional term related to the number of active hidden units.

LEARNING TO PERFORM TEMPORAL TASKS

The first implementations of backprop were confined to feedforward networks with static inputs and static outputs. Temporal processes are more naturally accommodated by networks that have recurrence (i.e. they are not feedforward). The fact that many cognitive processes are temporal in nature has led to the development of strategies to enable the application of backprop to temporal tasks. Three main approaches are described below.

Time Delay Neural Networks

In a 'time delay neural network' (TDNN), the input nodes encode consecutive items from a discrete temporal sequence. The sequence is shifted one item at a time, presenting the network with a sliding window on the entire temporal pattern. The NetTalk architecture (Figure 5) is a TDNN that processes a sliding window of text as input and produces a stream of phonemes as output. While a TDNN combines signals from different points in time to interact at the input level, the temporal interaction is limited by the size of the window.

Simple Recurrent Networks

Jordan (1986) introduced the idea of cycling the output back to the input in order to learn sequences. The next step was Elman's (1990) *simple recurrent network* (SRN), which learns to recognize patterns within a sequence by storing 'temporal context' in the hidden layer. With each iteration of the learning procedure, the hidden unit activities from the previous iteration are treated as if they were part of the input to the network (Figure 7(a)). Thus, the hidden layer acts as a memory that can retain information over several time steps. Servan-Schreiber *et al*. (1989) explored grammar learning by an SRN. They showed that the SRN could not only detect errors (with 100% accuracy in a simple grammar), but could generate novel sequences as well.

Backpropagation Through Time

The functionality of a given recurrent network **R** with N nodes can be approximated for T timesteps by a feedforward network **F** that has T layers with N nodes per layer (see Figure 7(b)). In the 'backpropagation through time' procedure (Williams and Zipser, 1989), each layer of **F** represents one timestep of **R**. Thus there are T units in **F** corresponding to each unit in **R**. Each connection from a unit i to a unit j in **R** is replicated by a number of copies in **F**. The implementation of backprop on **F** is subject to the constraint that the replicants of a given weight in **R** have the same value.

UNSUPERVISED LEARNING WITH BACKPROPAGATION

Simply defined, the *autoencoder* is a network trained to compute an identity map; that is, the target pattern is the same as the input. The standard form is a strictly-layered network (i.e. there are only connections between adjacent layers) with a single hidden layer of K units, and an equal number (N) of input and output units. Typically, $K < N$, and since the output layer only has access to the hidden layer, it must reconstruct the input pattern from the reduced (encoded) representation. In order to learn this task successfully, the hidden unit representations must evolve such that each pattern is unique.

One of the most obvious applications of this (assuming $K < N$) is to reduce the dimensionality of data representation. Any data item that can be successfully generated by the network can be stored in a compressed form, simply by presenting it as input to the network and storing the hidden-unit representation. The well-known data compression technique of principal components analysis is mathematically similar, though not exactly the same (Baldi and Hornik, 1989). The original item can be reconstituted at the output by activating the hidden layer with the compressed representation (see Figure 8). With this technique, the data compression is 'lossy': that is, the reconstructed data are not guaranteed to be accurate.

Some applications of auto-encoders trained with back propagation are described below.

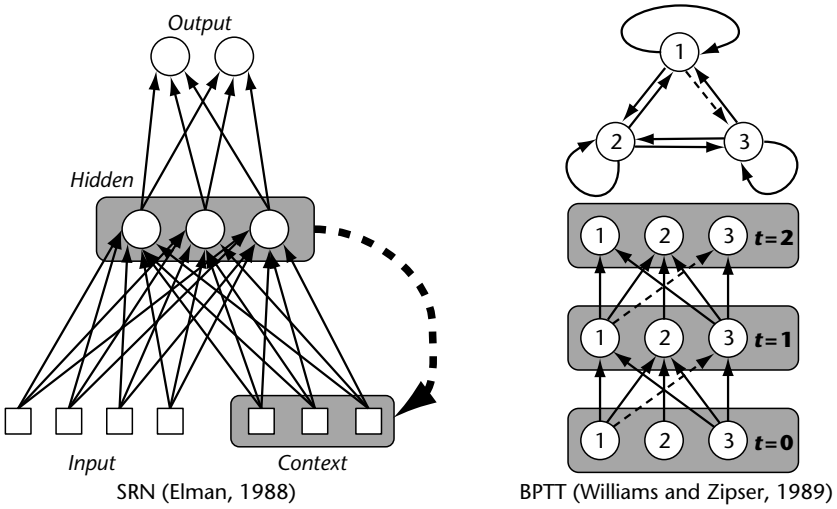

Figure 7. Architectures for temporal tasks. *Left* The simple recurrent network (SRN) maintains a history of the input sequence at the hidden layer by including the previous pattern of hidden unit activity as if it were part of a new input. *Right* A recurrent network (top) is approximated by a three-layer feed-forward architecture (bottom), where every node is replicated at every layer, and each layer corresponds to a different time step.

Image Compression

Cottrell *et al*. (1989) trained an auto-encoder on image data. After training, the network was able to represent the image using only 25% of the space required for the bitmap version. The reconstructed images had a very small deviation from the originals.

Novelty Detection

For some classification tasks, there are not enough data of one class to train a standard classifier (whether connectionist or not). After training an auto-encoder on items from the one class with sufficient data, any test item that shows low reconstruction error is classified as a member of the class used for training. If the reconstruction is poor, the item is classified as a member of the other class (we assume only two classes here). This approach has been used for predicting failure of electric motors using data from normally functioning motors only (Petsche *et al*., 1996).

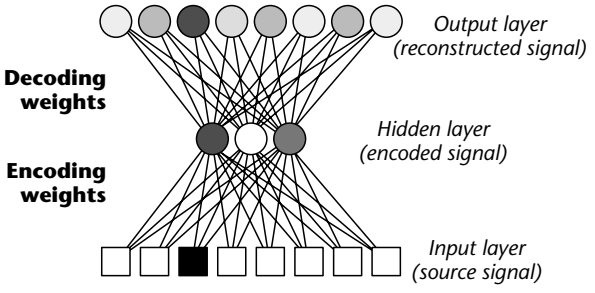

Figure 8. The autoencoder. This network is trained to reconstruct the input pattern at the output layer. Accurate reconstruction depends upon sufficient information in the hidden units, since they supply the only information available to the output units. Thus, the input is encoded by the input-hidden weights. The hidden unit representation is decoded by the hidden-output weights.

Random Access Auto-associative Memory

Pollack (1990) presented a technique by which an auto-encoder could develop a representation for a binary tree. In his scheme, each node in the tree is represented by an n-dimensional pattern of activity. An auto-encoding network with $2n$ input units, n hidden units, and $2n$ output units is used. Such 'random access auto-associative memories' have been applied as models of grammar learning and mental representations of music (Large *et al*., 1995).

BACKPROPAGATION AS A MODEL OF HUMAN LEARNING

Generally, there are two aspects of backprop training that are of potential interest to cognitive scientists: the dynamic process of learning, and the properties of the network after learning. While it is recognized as an important technique for cognitive modeling, the application of backprop to account for cognitive phenomena has been criticized on several grounds. These include: biological implausibility, the nature of the teaching signal,

and interference between learning old and new information.

Biological Plausibility

In part, the appeal of the neural-network approaches in artificial intelligence and cognitive science is their connection with biology. While there is ample neurobiological support for the notion that synaptic modification underlies learning, there is no specific mechanism known that corresponds to the error transmission implied by backprop. Furthermore, backprop has the inherent property of allowing weights to change sign, which would be analogous to an excitatory synapse becoming inhibitory or vice versa. A more biologically plausible procedure that is similar to backprop has been suggested by O'Reilly (1996). (*See* **Long-term Potentiation and Long-term Depression**)

Teaching Signals

In its pure form, backprop requires an explicit teaching signal to every output unit with every pattern presentation. However, a great deal of learning takes place with feedback that is much less specific, or entirely absent. A network with multiple output units can be trained with the minimal feedback of a scalar reward signal by introducing a second network that predicts the reward as a function of the first network's response (Munro, 1987).

Catastrophic Interference

If a network is trained with backprop on a set A of input–output pairs, and then trained on an independent set B, with no further training on the items from A, the performance on A deteriorates quickly. Eventually the items in A are forgotten (although they are on average more easily relearned than completely novel patterns). Partial remedies to the problem include: using two types of weights that change at different speeds (Hinton and Plaut, 1987); various forms of rehearsal (Ratcliff, 1990; Robins, 1995); and enforcing sparser hidden-layer representations (French, 1992; Krushke, 1993).

SUMMARY

Backprop has generated much attention, both inside and outside the cognitive science community. As a tool for cognitive modeling, it is still the best technique for abstracting the statistics of a task into a structure, and studying the internal representations that emerge and their influence on generalization performance. Thus, the acquisition of knowledge by the artificial system can be compared with human learning in several ways and over many modalities.

Aside from any relevance it has to cognition, backprop is also now a standard tool for machine learning, and performs well compared with other techniques. Variants of backprop are used in software in a broad range of application domains, from recognition of handwritten characters, to financial forecasting, to medical diagnosis. Of course, developers of commercial software are not concerned with cognitive and biological plausibility. They are generally more concerned with minimizing error rates than with emulating human patterns of error.

CONTENTS

THE MATHEMATICS OF INDUCTIVE LEARNING

Inductive learning is the process of coming to statistical conclusions based on past experiences. Unlike deduction, with induction one is never perfectly sure of one's conclusion, instead arriving at a (hopefully highly probable) guess. Inductive learning is performed by the human brain continually: almost all of a brain's conclusions, from the 'simplest' ones involved in sensor-motor decisions, to the most 'sophisticated' ones concerning how one should live one's life, are based at least in part on inductive learning. Even science is ultimately inductive in nature, with the 'past experiences' its conclusions are based on being previous experimental data, and its 'conclusions' being theories that are always open to revision.

A lot of work has been directed at implementing inductive learning algorithmically, in computers. 'Adaptive computation', involving neural networks, fuzzy logic, and computational statistics, can be viewed as a set of attempts to do this. The topic of algorithmic induction also looms large in other fields, like artificial intelligence and genetic algorithms. Recently this work has fostered new research on the mathematical underpinnings of inductive learning. A thorough understanding of those would not only result in improvements in our applied computational learning systems; it would also provide us with insight into the scientific method, as well as human cognition.

This article surveys 'Bayesian learning theory' and 'computational learning theory'. These are the two principal mathematical approaches that have been applied to supervised learning, a particularly important branch of inductive learning. The form of supervised learning considered in this article is simplified, the aim being to highlight the distinctions between these two learning theories rather than to present either in its full form.

A mathematical framework that can encapsulate both learning theories is the 'extended Bayesian framework' (EBF) (Wolpert, 1997). A simplified version of it, sufficient for current purposes, can be roughly described as follows. Say we have a finite '*input space*' X and a finite '*output space*' Y, and a set of m input–output pairs $d = \{d_X(i), d_Y(i)\}$. Call d a '*training set*', and assume it was created by repeated noise-free sampling of an $X \to Y$ '*target function*' f. More formally, assume that the '*likelihood*' governing the generation of d from f is $P(d \mid f) = \prod_{i=1}^{m} \pi(d_X(i))\delta(d_Y(i), f(d_X(i)))$, where $\delta(.,.)$ is the Kronecker delta function, which takes the value 1 if its arguments are equal and equals 0 otherwise, and π is the '*sampling distribution*'. $P(f)$ is known as the '*prior distribution*' over targets, and $P(f \mid d)$ is known as the '*posterior distribution*'.

Let h be the $X \to Y$ function our learning algorithm produces in response to d. As far as learning accuracy is concerned, that learning algorithm is described by $P(h \mid d)$: the details of how the algorithm generates h from d are irrelevant. (One of the major reasons why formalisms other than EBF have limited scope is that they do not use $P(h \mid d)$ to describe the learning algorithm; there is no other quantity that can capture all possible learning algorithms.) When discussing multiple learning algorithms – i.e., multiple distributions $P(h \mid d)$ – we will sometimes distinguish the different algorithms with the notation $\gamma_1, \gamma_2, \ldots$. Note that learning algorithms only ever see d, never f (although they often make assumptions concerning f). Accordingly, $P(h \mid d, f) = P(h \mid d)$. Also note that $P(h) = \sum_{d,f} P(h \mid d)P(d \mid f)P(f)$, and in general need not equal the prior $P(f)$ evaluated for $f = h$.

Take s to be the fraction of $d_X(i)$ such that $d_Y(i) = h(d_X(i))$; i.e., s is the learning algorithm's average accuracy on the training set. We use c to

indicate an error value, with its dependence on the other variables indicated by $c(h,f,d)$. In particular, we write c_O for the average (according to π) across all $x \in X$ lying outside the training set of whether h and f agree on x. We call c_O the '*off training set*' (OTS) error; it is a measure of how well our learning algorithm generalizes from the training set. An alternative error function, indicated by c_I, is the 'independent, identically distributed' (IID) error function. It is the same average, but not restricted to $x \notin d_X$, so that a learning algorithm gets some credit simply for memorizing what it's already seen.

Extensions of these definitions to allow for other kinds of error functions – noise in the target, uncertain sampling distributions, different likelihoods, infinite input and output spaces, etc. – are all straightforward, though laborious; see Wolpert (1997). The next section presents some theorems which will help us to compare the Bayesian and computational theories of supervised learning.

A FORMALIZATION OF INDUCTIVE BIAS

We start with the following theorem (Wolpert, 1995), which specifies the expected generalization error after training on some particular training set:

Theorem 1. The value of the conditional expectation $E(c \mid d)$ can be written as a (non-Euclidean) inner product between the distributions $P(h \mid d)$ and $P(f \mid d)$: $E(c \mid d) = \sum_{h,f} c(h,f,d)P(h \mid d)P(f \mid d)$.

(Similar results hold for $E(c \mid m)$, etc.)

Theorem 1 says that how well a learning algorithm $P(h \mid d)$ performs is determined by how 'aligned' it is with the actual posterior, $P(f \mid d)$, where 'alignment' is quantified by the error function. This theorem allows one to ask questions like 'for what set of posteriors is algorithm γ_1 better than algorithm γ_2?' It also means that, unless one can somehow prove from first principles that $P(f \mid d)$ has a certain form, one cannot prove that a particular $P(h \mid d)$ will be aligned with $P(f \mid d)$, and therefore one cannot prove that the learning algorithm generalizes well.

There are a number of ways to formalize this impossibility of establishing the superiority of some particular learning algorithm with a proof from first principles, i.e. with a proof that is not implicitly predicated on a particular posterior. One of them is in the following set of '*no free lunch*' theorems (Wolpert, 1996a):

Theorem 2. Let $E_{\gamma i}(.)$ indicate an expectation value evaluated using learning algorithm i. Then for any two learning algorithms γ_1 and γ_2, independent of the sampling distribution:

1. Uniformly averaged over all f, $E_{\gamma_1}(c_O \mid f,m) - E_{\gamma_2}(c_O \mid f,m) = 0$.
2. Uniformly averaged over all f, $E_{\gamma_1}(c_O \mid f,d) - E_{\gamma_2}(c_O \mid f,d) = 0$ for any training set d.
3. Uniformly averaged over all $P(f)$, $E_{\gamma_1}(c_O \mid m) - E_{\gamma_2}(c_O \mid m) = 0$.
4. Uniformly averaged over all $P(f)$, $E_{\gamma_1}(c_O \mid d) - E_{\gamma_2}(c_O \mid d) = 0$, for any training set d.

According to these results, by any of the measures $E(c_O \mid d)$, $E(c_O \mid m)$, $E(c_O \mid f,d)$, or $E(c_O \mid f,m)$, all algorithms are equivalent, on average. The uniform averaging that goes into these results should be viewed as a calculational tool for comparing algorithms, rather than as an assumption concerning the real world. In particular, the proper way to interpret statement 1 is that, appropriately weighted, there are 'just as many' targets for which algorithm 1 has better $E(c_O \mid f,m)$ as there are for which the reverse is true. Accordingly, unless one can establish *a priori*, before seeing any of the data d, that the f that generated d is one of the ones for which one's favorite algorithm performs better than other algorithms, one has no assurances that that algorithm performs any better than the algorithm of purely random guessing.

This does not mean that one's algorithm must perform no better than random guessing in the real world. Rather it means that, formally, one cannot establish superiority to random guessing without making some assumptions. Note in particular that you cannot use your prior experience – or even the billion years or so of 'prior experiences' of your genome, reflected in the design of your brain – to circumvent this problem, since all that prior experience is, formally, just an extension to the training set d.

As an important example of the foregoing, consider assessing the validity of a hypothesis by using experimental data that were not available when the hypothesis was created. In the form of 'falsifiability', this is one of the primary tools commonly employed in the scientific method. It can be viewed as a crude version of a procedure that is common in applied supervised learning: choose between the two hypothesis functions $h_{\gamma 1}$ and $h_{\gamma 2}$, made by running two generalizers γ_1 and γ_2 on a training set d_1, by examining their accuracies on a distinct 'held out' training set d_2 that was generated from the same target that generated d_1.

Such a procedure for choosing between hypotheses seems almost unimpeachable. Certainly its crude implementation in the scientific method has

resulted in astonishing success. Yet it cannot be justified without making assumptions about the real world. To state this more formally, take any two learning algorithms γ_1 and γ_2, and consider two new algorithms based on them, S and T. S uses an extension of the choosing procedure outlined above, known as '*cross-validation*': given a training set d, S breaks d into two disjoint portions, d_1 and d_2; trains γ_1 and γ_2 on d_1 alone; sees which resultant hypothesis is more accurate on d_2; and then trains the associated learning algorithm on all of d and uses the associated hypothesis. In contrast, T uses anti-cross-validation: It is identical to S except that it chooses the learning algorithm the accuracy of whose associated hypothesis on d_2 was worst. By the 'no free lunch' theorems, we know that T must outperform S as readily as vice versa, regardless of γ_1 and γ_2. It is only when a certain (subtle) relationship holds between $P(f)$ and the γ_1 and γ_2 one is considering that S can be preferable to T (see Theorem 1). When that relationship does not hold, T will outperform S.

This result means in particular that the scientific method must fail as readily as it succeeds, unless there is some *a priori* relation between the learning algorithms it uses (i.e. scientists) and the actual truth. Unfortunately, next to nothing is known formally about that required relation. In this sense, the whole of science – not to mention human cognition – is based on a procedure whose assumptions not only are formally unjustified, but have not even been formally stated.

BAYESIAN LEARNING THEORY

Intuitively, the Bayesian approach to supervised learning can be viewed as an attempt to circumvent the 'no free lunch' theorems by explicitly making an assumption for the posterior. Usually, to do this it first restricts attention to situations in which the likelihood is known (which in the context of this article means there is no 'noise'). It then makes an assumption about the prior distribution, $P(f)$. Next Bayes' theorem is invoked to combine the prior with the likelihood to give us our desired posterior: $P(f \mid d) \propto P(d \mid f)P(f)$, where the proportionality constant is independent of f. (Besides these kind of assumptions concerning the prior, there are other kinds of assumptions which, when combined with the likelihood, fix the posterior (Wolpert, 1993). However, such assumptions have not yet been investigated in any detail.)

Given such a posterior, the value of $E(C \mid d)$ that accompanies any particular learning algorithm $P(h \mid d)$ is determined uniquely (see Theorem 1). In particular, one can solve for the $P(h \mid d)$ that minimizes $E(C \mid d)$. This is known as the '*Bayes-optimal*' learning algorithm. This algorithm is given by the following theorem (which is rather more general than we need):

Theorem 3. Let $c(h,f,d) = \sum_{x \in X} \pi'(x) G(h(x),f(x))$ for some real-valued function $G(.,.)$ and some real-valued $\pi'(.)$ that is nowhere negative (and may or may not equal the distribution $\pi(.)$ arising in $P(d \mid f)$). Then the Bayes-optimal $P(h \mid d)$ always guesses the same function h^* for the same d:

$$h^* = \{x \in X \rightarrow \arg\min_{y \in Y} \Omega(x,y)\}, \text{where}$$
$$\Omega(x,y) \equiv \sum_f G(y,f(x)) P(f \mid d).$$

(The function $\pi'(.)$ is allowed to vary with d, as it does in OTS error.)

$\Omega(x,y)$ is the contribution to the posterior expected error that arises if the learning algorithm outputs (an h having) the value y at point x. So intuitively, Theorem 3 says that for any x, one should choose the $y \in Y$ that minimizes the average 'distance' from y to $f(x)$, where the average is over all $f(.)$, according to the distribution $P(f \mid d)$, and 'distance' is measured by $G(.,.)$. Note that this result holds regardless of the form of $P(f)$, and regardless of what (if any) noise process is present: all such considerations are taken care of automatically, in the $P(f \mid d)$ term. Note also that h^* might be an f with zero-valued posterior: in the Bayesian framework, the output h of the learning algorithm does not really constitute a 'guess for the f which generated the data'.

This is all there is to the Bayesian framework, as far as foundational issues are concerned (Berger, 1985; Loredo, 1990; Buntine and Weigend, 1991; Wolpert, 1995). Everything else in the literature concerning the framework involves either philosophical or calculational issues. The philosophical issues usually concern what $P(f)$ 'means' (Wolpert, 1993). In particular, some Bayesians do not view the $P(f)$ they use to derive their learning algorithm as an assumption for the actual $P(f)$, which may or may not correspond to reality. Rather, in general they interpret the probability of an event as one's 'personal degree of belief' in that event, and therefore in particular they interpret $P(f)$ that way. According to this view, probability theory is simply a calculus for forcing consistency in one's use of probability to manipulate one's subjective beliefs. Accordingly, no matter how absurd a Bayesian's prior, under this interpretation practitioners of non-Bayesian approaches to supervised learning are by definition always going to perform worse

than that Bayesian (since the Bayesian determines $P(f)$ and therefore $P(f \mid d)$, and accordingly guesses in an optimal manner – see Theorem 1).

Unfortunately, there are algorithms that cannot be cast as the Bayes-optimal algorithm for some implicit prior and likelihood (Wolpert, 1996b). Accordingly, even if one accepts the 'fundamentalist' Bayesian's view of what $P(f)$ 'means', the rigidity of the framework makes it ill-suited to broad analysis of algorithms. More generally, often our prior knowledge does not concern targets directly, but rather concerns the relative performances of various (possibly non-Bayesian) algorithms, or the efficacy of a scheme (like cross-validation) for choosing among those algorithms. The conventional Bayesian framework provides no way to exploit that prior knowledge. In general, we need to introduce the random variable h for such an analysis – which is what is done in EBF. (See, however, Wolpert (1993) for a discussion of how one can sometimes employ Bayes' theorem to exploit such knowledge directly.)

Some of the calculational issues in the Bayesian framework involve evaluating the Bayes-optimal algorithm, given knowledge of the posterior $P(f \mid d)$. The problem is that using the Bayes-optimal algorithm requires evaluating (and then minimizing) the sum giving $\Omega(x, y)$. Since this can be difficult, people often settle for approximations to finding $\arg\min_{y \in Y} \Omega(x, y)$. For example, the 'maximum *a posteriori*' (MAP) estimator is $h(x) = [\arg\max_f P(f \mid d)](x)$. Evaluating it involves finding a peak of a surface (namely $P(f \mid d)$) rather than performing a sum, and is often simpler.

Even if one is willing to use a MAP estimator, there might still be difficulties in evaluating the surface $P(f \mid d)$. For example, if we have a 'hierarchical' likelihood, then $P(d \mid f) = \sum_\lambda P(d \mid \lambda, f)\, P(\lambda)$, where λ is a 'hyperparameter'. (An example is where we know that the data are generated via a particular kind of noise process, but don't know the noise level in advance – that noise level is a hyperparameter.) Sums being difficult, often we can't even evaluate such a hierarchical likelihood (and therefore can't evaluate the associated posterior, $P(f \mid d)$). Instead, often one makes an ad hoc estimate of the hyperparameter, λ', and replaces $P(d \mid f)$ with $P(d \mid \lambda', f)$. (See the discussion of empirical Bayes and ML-II in Wolpert (1995).)

COMPUTATIONAL LEARNING THEORY

The computational learning framework takes a number of forms, the principal ones being the statistical physics, PAC and VC (uniform convergence) approaches (Baum and Haussler, 1989; Vapnik, 1982; Wolpert, 1995). All three can be cast as bounds concerning a probability distribution that involves IID error, and that is conditioned on f (in contrast to the Bayesian framework, in which f is not fixed). In their most common forms they all have m rather than d fixed in their distribution of interest (again, in contrast to the Bayesian framework). This means that they do not address the question of what the likely outcome is for the training set at hand. Rather, they address the question of what the likely outcome would be if one had different training sets from the actual d. Such varying of quantities that are in fact fixed and known has been criticized by Bayesian practitioners on formal grounds, as violating any possible self-consistent principles for induction. (See Wolpert (1993), and the discussion of the 'honesty principles' in Wolpert (1995), for an overview of the conflict between the two learning theories.)

For purposes of illustration, we will focus on (a pared-down version of) the VC framework. Start with the following simple result, which concerns the '*confidence interval*' relating c and s, for the case where $H^\sim$, the h-space support of a learning algorithm's $P(h)$, consists of a single h (Wolpert, 1995):

Theorem 4. Assume that there is an h' such that $P(h \mid d) = \delta(h - h')$ for all d. Then:

$$P(c_{\mathrm{I}} > s + \varepsilon \mid f, m) < 2e^{-m\varepsilon^2}$$

(Recall that s is the empirical misclassification rate.) Note that this bound is independent of f, and therefore of the prior $P(f)$.

If $H^\sim$ instead consists of more than one h, the bound in Theorem 4 still applies if one multiplies the right-hand side by $\mid H^\sim \mid$, the number of functions in $H^\sim$. The major insight behind the '*uniform convergence*' framework was how to derive even tighter bounds by characterizing $P(h \mid d)$ in terms of its VC dimension (Baum and Haussler, 1989; Vapnik, 1982; Wolpert, 1995). (It is important to distinguish between this use of the VC dimension and its use in other contexts, as a characterization of $P(f)$.) For $Y = \{0, 1\}$ and our error function, the VC dimension is given by the smallest m such that, for any d_X of size m, all of whose elements are distinct, there is a d_Y for which no h in $H^\sim$ goes through d. (The VC dimension is this smallest number minus one.)

Common to all such extensions of Theorem 4 is a rough equivalence (as far as the likely values of c are concerned) between: (1) lowering s; (2) lowering the expressive power of $P(h \mid d)$ (i.e., shrinking its

VC dimension, or shrinking $|H^{\sim}|$); and (3) raising m. Important as these extensions of Theorem 4 are, to understand the foundational issues underpinning the uniform convergence framework it makes sense to restrict attention to the scenario in which there is a single h in $H^{\sim}$.

In general, since we can measure s and want to know c_{I} (rather than the other way around), a bound on something like $P(c_{\mathrm{I}} > k \,|\, s, m)$, perhaps with $k \equiv s + \varepsilon$, would provide some useful information concerning generalization error. With such a bound, we could say that if we observe the values of m and s to be M and S, then with high probability c_{I} is lower than $U(M, S)$ for some appropriate function $U(.,.)$. However, since both f and (for our learning algorithm) h are fixed in the probability distribution in Theorem 4, c_{I} is also fixed there, for IID error. (By contrast, in the Bayesian framework, c_{I} is only probabilistically determined.) In fact, in Theorem 4 what is varying is d_X (or more generally, when there is noise, d). So Theorem 4 does not directly give us the probability that c_{I} lies in a certain region, given the training set at hand. Rather, it gives the probability of a d_X (generated via experiments other than ours) such that the difference between the fixed c_{I} and (the function of d_X) s lies in a certain region.

It might seem that Theorem 4 could be modified to provide a bound of the type we seek. After all, since the value of c_{I} is fixed in Theorem 4, that theorem can be written as a bound on the 'inverse' of $P(c_{\mathrm{I}} > k \,|\, s, m)$, $P(s < \kappa \,|\, c_{\mathrm{I}}, m)$, where $\kappa \equiv c - \varepsilon$. How does $P(s \,|\, c_{\mathrm{I}}, m)$ relate to what we wish to know, $P(c_{\mathrm{I}} \,|\, s, m)$? The answer is given by Bayes' theorem: $P(c_{\mathrm{I}} \,|\, s, m) = P(s \,|\, c_{\mathrm{I}}, m) P(c_{\mathrm{I}} \,|\, m) / P(s \,|\, m)$.

Unfortunately, this result has the usual problem associated with Bayesian results: it is prior-dependent. Nor does it somehow turn out that that prior has little effect. Depending on $P(c_{\mathrm{I}})$, $P(c_{\mathrm{I}} > s + \varepsilon \,|\, s, m)$ can differ markedly from the bound on $P(s < c_{\mathrm{I}} - \varepsilon \,|\, m, c_{\mathrm{I}})$ given in Theorem 4. Even if, given a truth c_{I}, the probability of an s that differs substantially from the truth is small, it does not follow that given an s, the probability of a truth that differs substantially from that s is small.

To illustrate this point, suppose we have two random variables, A and B, which can both take on the values 'low' and 'high'. Suppose that the joint probability distribution is proportional to: $P(A = \text{high}, B = \text{high}) = 100$, $P(A = \text{high}, B = \text{low}) = 2$, $P(A = \text{low}, B = \text{high}) = 1$, $P(A = \text{low}, B = \text{low}) = 1$. Then the probability that A and B differ is quite small (3/104); we have a tight confidence interval relating them, just as in Theorem 4. Nonetheless, $P(A = \text{high} \mid B = \text{low})$ is 2/3: despite the tight confidence interval, if we observe $B = \text{low}$, we cannot infer that A is low as well. Replace 'A' with 'c_{I}', and 'B' with 's', and we see that results like Theorem 4 do not imply that having observed a low s, one can conclude that one has a low c_{I}.

A more concrete example of this effect in the context of supervised learning is the following result, established in Wolpert (1995):

Theorem 5. Let $\pi(x)$ be flat over all x and $P(f)$ flat over all f. For the noise-free IID likelihood, and the learning algorithm of Theorem 4:

$$P(c_{\mathrm{I}} \,|s, m) = \left[\binom{m}{sm} c_{\mathrm{I}}^{sm} (1 - c_{\mathrm{I}})^{m - sm}\right] \times \left[\binom{n}{nc_{\mathrm{I}}} (|Y| - 1)^{nc_{\mathrm{I}}}\right]$$

where $|Y|$ is the number of values in Y.

Theorem 5 can be viewed as a sort of compromise between the likelihood-driven 'something for nothing' results of the VC framework, and the 'no free lunch' theorems. The first term in the product has no c_{I}-dependence. The second and third terms together reach a peak when $c_{\mathrm{I}} = s$; they 'push' the true misclassification rate towards the empirical misclassification rate, and would disappear if we were using OTS error. These two terms are closely related to the likelihood-driven VC bounds. However, the last two terms, taken together, form a function of c_{I} whose mean is $1/|Y|$. They reflect the fact that any f is allowed with an equal prior probability, and are closely related to the 'no free lunch' theorems (despite the fact that IID error is being used). In this sense, our result for $P(c \,|\, s, m)$ is just a product of a 'no free lunch' term with a VC-type term.

In response to the formal admonitions of these theorems, one is tempted to make the following intuitive reply: 'Say we have a function f and a given hypothesis function h' that have no *a priori* relation with one another. A sample point is drawn from f, and it is found that h' correctly predicts that point. Then another sample point is drawn, with the same result. Based on such a sequence of points, you guess that h' will correctly predict the next sample point. And lo and behold, it does. You keep extending the original sequence this way, always getting the same result that h' makes the correct prediction (since s is small, and the full training set d consists of the extended sequence, not the original one). In other words, the generalizer given by the rule "always guess h'" has excellent cross-validation error. In this situation, wouldn't you believe that it is unlikely for h' and f to disagree on future sample points, regardless of the "no free lunch" theorems?'

To disentangle the implicit assumptions behind this argument, consider it again in the case where h' is some extremely complex function that was formed by a purely random process. The claim in the intuitive argument is that h' was fixed independently of any determination of f, d, or anything else, and is not biased in any way towards f. Then, so goes the claim, f was sampled to generate d (the sequence of points), and it just so happened that f and h' agree on d. According to the intuitive argument presented above, we should conclude in such a case that h' and f would agree on points not yet sampled. Yet in such a situation our first suspicion might instead be that the claims that were made are wrong, that cheating has taken place and that h' is actually based on prior knowledge concerning f. After all, how else could the 'purely random' h' agree with f? How else could there be agreement when h' was supposedly fixed without any information concerning d, and therefore without any coupling with f?

If, however, we are assured that no cheating is going on, then 'intuition' might very well lead one to say that the agreements between f and h' must be simple coincidence. They have to be, since, by hypothesis, there is nothing that could possibly connect h' and f. So intuition need not proclaim that the agreements on the data set mean that f and h' will agree on future samples. Moreover, if cheating did occur, then to formulate the problem correctly, we have to know about the *a priori* connection between f and h' in order to properly analyze the situation. This results in a (prior-dependent) distribution different from the one investigated in the uniform convergence framework. (In the real world, of the two alternatives of coincidence and cheating, the reason for low s is almost always 'cheating'. Almost always one uses prior knowledge of some sort to guide the learning, rather than generate hypotheses purely at random.)

CONCLUSION

In all forms of reasoning that do not proceed by strict logical deduction, some kind of statistical algorithm must be employed. One of the major types of such reasoning is 'supervised learning'. In this type of reasoning one is provided with a training set of input–output pairs, and must make a guess for the entire input–output function in such a way as to minimize the error between that guess and the actual function that generated the data.

Apart from conventional sampling theory statistics, there are two principal mathematical approaches to supervised learning: the Bayesian framework and the computational learning framework. We have examined the foundations of these two approaches, especially in light of the 'no free lunch' theorems which limit what *a priori* formal assurances one can have concerning a learning algorithm without making assumptions concerning the real world.

In the Bayesian framework the assumptions concerning the real world arise explicitly, as 'prior probabilities' to be used to calculate the optimal guess. Unfortunately, the fact that the formalism concentrates solely on this assumption-driven calculation prevents it from allowing easy and broad investigation of what happens when those underlying assumptions are incorrect. In particular, Bayesian analysis cannot be used to analyze most learning algorithms that do not make their assumptions explicit; its scope is limited by construction. In particular, this restricts the framework's ability to analyze perhaps the most common algorithm in science, cross-validation.

In contrast, the simplest version of the computational learning framework makes no explicit assumptions about the nature of one's learning algorithm, or about the priors. In this sense it is universally applicable. Whereas the Bayesian framework skirts the 'no free lunch' theorems by forcing the underlying assumptions concerning the problem domain to be explicit, the strategy of the computational learning framework is to instead focus on the counterfactual scenario in which one's data are not fixed (to whatever the data set currently in front of you happens to be), but are averaged over. Unfortunately, the resulting bounds on learning error cannot be modified to concern some particular scenario a learning practitioner is confronted with; they are by their nature concerned with an average over multiple scenarios, when only one actually exists.

Bayesian Belief Networks

Intermediate article

Brendan J Frey, University of Toronto, Toronto, Canada

CONTENTS

A "Bayesian belief network" is a directed acyclic graph that specifies how stochastic variables in a complex system interact. The joint distribution is equal to the product of a set of conditional distributions. There is one conditional distribution for each node of the graph and each conditional distribution is conditioned on the parents of the corresponding node. Unlike Markov random fields, Bayesian networks do not require a partition function.

REASONING UNDER UNCERTAINTY

An intelligent agent that makes decisions in a realistic environment should take into account the uncertainties in the environment and the uncertainties introduced by incomplete knowledge of the environment. Also, a mathematical description of a physical system for inference should account for the uncertainties in physical systems.

Probability theory provides a way to account for uncertainty. A system is described by a set of random variables, and an instantiation of the variables is called a *configuration*. A numerical probability between 0 and 1 is associated with each configuration and this number corresponds to the relative frequency with which the configuration occurs, or possibly, in the Bayesian view, the chance that the configuration *will* occur. The sum over the probabilities of all configurations must be 1. If we are interested in only a subset of the variables, we can derive the probability of each sub-configuration by summing the probabilities of all configurations that have matching sub-configurations. In this way, a system can be viewed as being 'consistent' with a larger system. So, when building or inferring a system, we need not include all variables in the universe, but can instead include only a smaller, more tractable, subset.

For example, we may use $P(T=1)$ to represent the probability of the event that there is a tiger in the field of view of an intelligent agent, and $P(T=0)$ to represent the probability that there is not a tiger. In this case, $P(T=1)$ is equal to the sum over the probabilities corresponding to all configurations of the universe for which there is a tiger in the field of view of the intelligent agent.

It is often convenient to express probabilities in functional form. For example, the probabilities that $T=1$ and $T=0$ can be written $P(T)$. If we set $T=1$, then $P(T)$ is the probability that $T=1$. We refer to $P(T)$ as a *probability distribution*.

We use the conditional probability distribution

$$P(T|V=v) \tag{1}$$

to represent the probabilities that there is and is not a tiger, given that the random variable V representing the agent's visual input has the value v. If $P(T=1|V=v) \gg P(T=0|V=v)$, there is very probably a tiger in the scene and the agent ought to seriously consider running away.

It is natural to represent the random variable for the agent's visual input by a continuous vector (e.g., a vector of real-valued pixel intensities). For brevity, we will assume that all variables are discrete. In the case of continuous variables, probabilities can be replaced with probability density functions, and summations can be replaced by integrals. Many computations involving seemingly continuous quantities are in fact discrete (e.g., floating point computations on a computer), so not too much is lost by assuming the variables are discrete.

Suppose v is a visual scene containing black and orange stripes, and the probability of a scene containing black and orange stripes is greater if there is a tiger than if there is no tiger:

$$P(V=v|T=1) > P(V=v|T=0) \tag{2}$$

After observing $V=v$, it is tempting to conclude that there is probably a tiger in the scene, but this may not be so.

The probability that there is a tiger in the scene is given by the posterior probability distribution

$P(T|V=v)$. The posterior distribution can be computed from the values of $P(V=v|T=1)$ and $P(V=v|T=0)$ using Bayes' rule:

$$P(T|V=v) = \frac{P(V=v|T)P(T)}{\sum_{t=0,1} P(V=v|T=t)P(T=t)} \tag{3}$$

In this expression, $P(T|V=v)$ is called the *posterior distribution*, $P(T)$ is called the *prior distribution*, and $P(V=v|T)$ is called the *likelihood function*. Notice that all three expressions are functions of the unknown random variable T.

For example, on a jungle tour in India, we may have $P(T=1)=0.2$ and $P(T=0)=0.8$. However in Canada, we may have $P(T=1)=0.001$ and $P(T=0)=0.999$. So, for the scene with orange and black stripes, even though $P(V=v|T=1) > P(V=v|T=0)$, it may turn out that $P(T=1|V=v) < P(T=0|V=v)$, depending on the prior distribution over T.

MAKING DECISIONS UNDER UNCERTAINTY

Even though $P(T=1|V=v) < P(T=0|V=v)$, it may be a good idea to leap aside if orange and black stripes appear in the visual scene.

For every configuration of the unknown random variable ($T=1$ and $T=0$), we can specify a utility (benefit, negative cost) for every action, say 'Leap' and 'NoLeap'. Leaping aside when there is a tiger may mean survival, whereas not leaping aside when there is a tiger may mean death:

$$U^{\text{Leap}}(T=1) >>> U^{\text{NoLeap}}(T=1) \tag{4}$$

Leaping aside when there is no tiger will waste some energy, so

$$U^{\text{Leap}}(T=0) < U^{\text{NoLeap}}(T=0) \tag{5}$$

However, notice that there is much less difference in this inequality than in the previous inequality.

The agent can maximize its expected utility by choosing the decision that has highest expected utility. For Leap and NoLeap, we have

$$EU^{\text{Leap}} = \sum_{T=0,1} U^{\text{Leap}}(T)P(T|V=v) \tag{6}$$

$$EU^{\text{NoLeap}} = \sum_{T=0,1} U^{\text{NoLeap}}(T)P(T|V=v) \tag{7}$$

So, even in Canada, the second term in each formula may dominate, in which case the agent should leap aside if orange and black stripes appear in the visual scene.

BAYESIAN NETWORKS

Instead of a real tiger, orange and black stripes could be caused, say, by a child's stuffed toy tiger. Further, in a toy store, the cause is more likely to be a stuffed toy. In a zoo, the cause is more likely to be a real tiger. These random variables influence each other in a structured way, and Bayesian networks provide a graphical description of this structure.

A *Bayesian network* (Pearl, 1988) is a graphical description of the probability distribution on a system of random variables. It is a directed acyclic graph (DAG) on vertices corresponding to the random variables, along with a specification of the conditional distribution for each variable given its parents in the graph. In the context of directed graphs, 'acyclic' means there aren't any cycles *when edge directions are followed*. The probability distribution on the system of random variables is equal to the product of all of the conditional distributions. If the conditional distributions are not specified, the Bayesian network refers to the set of all probability distributions that can be derived by choosing numbers for the conditional distributions in the network. Further, all distributions described by the network satisfy certain conditional independence properties that can be determined directly from the graph.

Suppose $S=1$ indicates there is a stuffed toy tiger in the scene, whereas $S=0$ indicates there is not a stuffed toy tiger in the scene. The presence of orange stripes in the scene can be caused by either a tiger or a stuffed toy tiger. Figure 1(a) shows one possible Bayesian network that can be used to describe the relationship between the random variables T, S, and V. (Pearl uses an example where a burglar alarm is tripped by either a burglar or an earthquake.) This network describes the set of probability distributions that satisfy

$$P(T,S,V) = P(T)P(S)P(V|T,S) \tag{8}$$

the product of the conditional distributions for each child given its parents. Note that since T does not have parents, its 'conditional distribution' is written $P(T)$.

As described in Pearl (1988), the network can be examined to determine that all distributions described by the network have the property that T and S are independent random variables. This

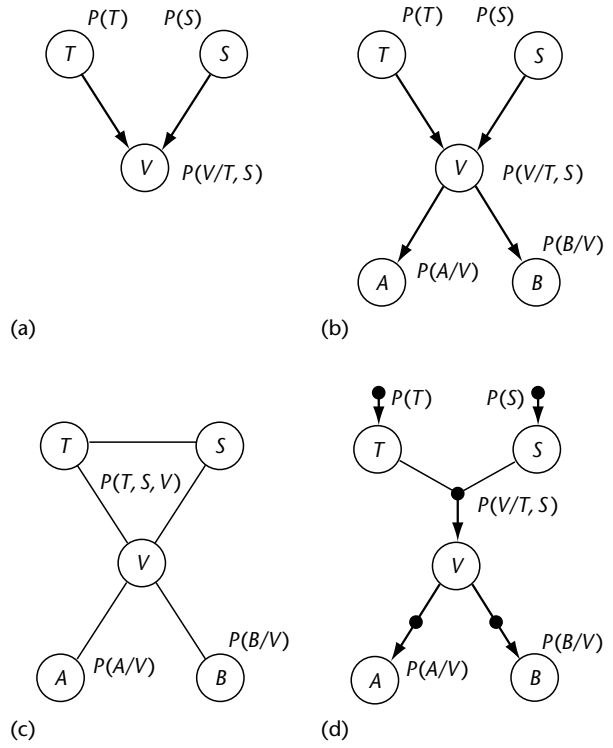

Figure 1. (a) A Bayesian network describing the probability distribution $P(T, S, V) = P(T)P(S)P(V|T, S)$ for the binary indicator variables tiger T, stuffed toy S, and a variable V that indicates the presence of orange stripes in the visual scene. (b) The network in (a) is extended to include variables that indicate whether Alice (A) and Bob (B) leap aside when orange stripes are present in the same scene. The joint distribution is $P(T, S, V, A, B) = P(T)P(S)P(V|T, S)\ P(A|V)P(B|V)$. (c) A Markov network, and (d) a factor graph that describe the same joint distribution.

example is simple enough that we can show this is true by summing over V to obtain the distribution $P(T, S)$:

$$P(T,S) = \sum_V P(T,S,V) = \sum_V P(T)P(S)P(V|T,S)$$
$$= P(T)P(S) \qquad (9)$$

It follows that $P(T|S) = P(T)$ and $P(S|T) = P(S)$, so T and S are independent. For example, the distribution over T is the same, whether or not S is known.

A particular distribution $P(T, S, V)$ is determined by specifying the numerical values of the conditional probability tables; e.g., $P(V = v|T = t, S = s)$ for all values of v, t, and s. Suppose $V = 1$ indicates the presence of orange stripes in the visual scene and $V = 0$ indicates that orange stripes are not present. In Canada, where toy tigers are more abundant than real tigers, we may have the following conditional probability tables:

$P(T)$	
$T = 0$	$T = 1$
0.999	0.001

$P(S)$	
$S = 0$	$S = 1$
0.999	0.001

		$P(V\|T,S)$	
T	S	$V = 0$	$V = 1$
0	0	0.999	0.01
0	1	0.5	0.5
1	0	0.1	0.9
1	1	0.05	0.95

Now, suppose the agent is accompanied by two other agents, Alice and Bob, and that in response to the presence of orange stripes in the scene, Alice and Bob independently choose to leap aside. $A = 1$ indicates that Alice has leapt aside, whereas $A = 0$ indicates that Alice has not leapt aside. Similarly, B indicates Bob's behavior. Figure 1(b) shows a Bayesian network that includes the behavior of Alice and Bob. The conditional probability table for $P(A|V)$ gives the probability that Alice leaps aside given the presence or absence of orange stripes in the scene.

This Bayesian network indicates that the joint distribution factorizes as follows: $P(T, S, V, A, B) = P(T)P(S)P(V|T, S)P(A|V)P(B|V)$. Also, various conditional independencies can be determined by studying the graph, as described in Pearl (1988). For example, Alice's and Bob's behaviors, A and B, are generally not independent. Their behavior is a consequence of a common cause, V. However, Alice's and Bob's behaviors are independent given the visual scene, V.

MARKOV RANDOM FIELDS

Like Bayesian networks, *Markov networks* (Markov random fields) provide a graphical description of the structure of the joint distribution. Unlike Bayesian networks, they are undirected.

A Markov network (Kinderman and Snell, 1980) is an undirected graph on vertices corresponding to the variables, along with a specification of potential functions defined on the variables in maximal *cliques*. A clique is a set of variables that are completely connected. A maximal clique is a clique that cannot be expanded to include an additional variable, without violating the condition that the variables be completely connected. Each potential function is a nonnegative function of the appropriate set of variables. Assuming all potentials are strictly positive, the probability distribution on the system of random variables is equal to the product of all of the clique potentials, multiplied by a normalizing constant.

The conditional independencies indicated by a Markov network are quite different from those indicated by a Bayesian network. In a Markov network, given the neighbors of a variable (the Markov blanket), the variable is independent of all other variables in the network. For a given set of variables, it is possible that there is a Bayesian network that can represent conditional independencies that cannot be represented by a Markov random field. The converse is also true.

For example, the Markov network for the above example is shown in Figure 1(c). The factor $P(V|T,S)$ requires that at least one maximal clique contain V, T, and S. Consequently, by examining the network without reference to the potentials, it is not possible to determine that T and S are independent.

FACTOR GRAPHS

Factor graphs subsume Bayesian networks and Markov networks, in the sense that there is a unique Bayesian network (or Markov network) for every factor graph. However, for a given Bayesian network (or Markov network), there may be multiple factor graphs. Since the Bayesian networks or Markov networks corresponding to the multiple factor graphs are the same, the different factor graphs do not indicate different conditional independencies. However, they can indicate more detailed factorizations of the joint distribution. Also, factor graphs have an extra set of nodes that identify factorization sites, and, in the algorithm described in the next section, computation sites for message-passing algorithms.

A *factor graph* (Kschischang *et al*., 2001) is a bipartite graph on *function vertices* and *variable vertices*. For each function vertex, a *local function* is specified, which is a function of the variables connected to the function vertex. 'Bipartite' means that each edge connects a variable vertex and a function vertex. The local functions may correspond to the conditional distributions in the Bayesian network, the clique potentials in the Markov network, or something else. The probability distribution on the system of random variables is equal to the product of all of the local functions, multiplied by a normalizing constant, if necessary.

If a local function is a conditional distribution over a variable, the edge connecting the local function to the variable may be directed toward the variable, to graphically indicate that the local function is a conditional distribution. This notation is useful for converting a factor graph to a Bayesian network.

Figure 1(d) shows a factor graph corresponding to the Bayesian network in Figure 1(b), where variable vertices are shown as white discs and function vertices are shown as black discs. This graph indicates that the joint distribution factors into the product $P(T)P(S)P(V|T,S)P(A|V)P(B|V)$.

A Bayesian network is converted to a factor graph by creating one variable vertex for each variable, creating one function vertex for each variable, connecting the function vertex for each variable to the variable and its parents, and setting the local function for each function vertex to P (variable|parents) from the Bayesian network. A factor graph is converted to a Bayesian network by removing the function nodes and using the directed edges to identify the child–parent relationships. Compare Figure 1(b) and Figure 1(d).

A Markov network is converted to a factor graph by creating one variable vertex for each variable, creating one function vertex for each clique potential, setting the local function for each function vertex to the corresponding clique potential, and connecting the function vertex to the variables on which it depends (i.e., to the variables in the corresponding clique of the Markov network). A factor graph is converted to a Markov network by considering each local function in turn, and creating a maximal clique from all variables connected to the local function. Compare Figure 1(c) and Figure 1(d).

From the above descriptions, it is clear that a factor graph has a unique Markov network, and it has a unique Bayesian network as well, if edge directions are provided.

PROBABILISTIC INFERENCE

From a joint distribution, we can compute the conditional distribution of one subset of variables given another subset of variables. To do this, we use the *chain rule*

$$P(A,B) = P(A|B)P(B) \tag{10}$$

and the rule for marginalization

$$P(A) = \sum_{B} P(A,B) \tag{11}$$

For the example where $P(T,S,V) = P(T)P(S)P(V|T,S)$, we can compute $P(T|V=v)$ as follows:

$$\begin{aligned} P(T|V=v) &= \frac{P(T,V=v)}{P(V=v)} \\ &= \frac{\sum_s P(T,S=s,V=v)}{\sum_{t,s} P(T=t,S=s,V=v)} \\ &= \frac{\sum_s P(V=v|T,S=s)P(T)P(S=s)}{\sum_{t,s} P(V=v|T=t,S=s)P(T=t)P(S=s)} \end{aligned} \tag{12}$$

While this 'direct' approach works for small problems, the number of additions needed grows exponentially with the number of variables. So, the direct approach becomes intractable when there are more than a few dozen binary variables, since the summations will then involve many billions of terms.

PROBABILITY (BELIEF) PROPAGATION, OR THE SUM–PRODUCT ALGORITHM

Probability propagation provides a way of computing the distribution of one variable given a set of observed variables. This computation is usually not as straightforward as the direct application of Bayes' rule, since there may be many other variables that must be properly accounted for. For example, to compute $P(A|B)$ from a distribution $P(A,B,C)$, we first sum over C to get $P(A,B) = \sum_c P(A,B,C)$.

The algorithm is easily understood from an example. Suppose the distribution over variables $A, B, \ldots, F$ factorizes as follows:

$$P(A,B,C,D,E,F) = P(A|B)P(B|C)P(C|D)P(D|E)P(E|F)P(F) \quad (13)$$

(Note that the Bayesian network, Markov network, and factor graph for this distribution all have the form of a chain.) Say we would like to compute the marginal distribution, $P(A)$:

$$P(A) = \sum_B \sum_C \sum_D \sum_E \sum_F \big(P(A|B)P(B|C)P(C|D) P(D|E)P(E|F)P(F)\big) \quad (14)$$

Computing this distribution directly takes roughly 2^5 multiplications and additions.

The distribution can be computed more efficiently by distributing the summations over the products:

$$P(A) = \sum_B P(A|B)\Bigg(\sum_C P(B|C)\Bigg(\sum_D P(C|D) \Bigg(\sum_E P(D|E)\Bigg(\sum_F P(E|F)P(F)\Bigg)\Bigg)\Bigg)\Bigg) \quad (15)$$

Computing the distribution $P(A)$ by successively computing 'partial distributions' takes roughly 2×5 summations, an exponential speed-up over the direct approach.

The computation of each 'partial distribution' can be thought of as a procedure that takes in messages, combines them with a conditional probability (or a potential or local function), performs a summation, and produces a new message. In the above example, the summation $\sum_F P(E|F)P(F)$ produces a message that is a real-valued function of E.

Probability propagation has a very simple form in factor graphs, so we describe the algorithm using factor graphs. Using the procedures described above, Bayesian networks and Markov networks can easily be converted to factor graphs. Also, the Bayesian network or Markov network corresponding to a given factor graph is quite obvious, so working with the factor graph does not obfuscate the original model.

Probability propagation consists of passing messages (implemented in a computer as short vectors of real numbers) on edges in the factor graph. Both function vertices and variables vertices combine incoming messages to produce outgoing messages on each of their edges. Each edge in the factor graph can pass a message in either direction, but *the number of values in a message is equal to the number of values its neighboring variable can take on*. For any edge, this number is unique, since in a factor graph, each edge is connected to only one variable vertex. So, we can think of each message as being a function of its neighboring variable.

For now, we'll assume that we are given a *message-passing schedule* that specifies which messages should be updated at each timestep. Think of each edge in the factor graph as having two message buffers (memory to store two messages) – one for each direction. Initially, we set all the messages (all the elements of all the vectors used to store the messages) to 1.

There are three types of computation that are performed in probability propagation:

1. *Propagating variable-to-function messages*. To produce an outgoing message on an edge, a variable computes the element-wise product of incoming messages on the other edges. For example, in Figure 2(a), $f(V)$ is the message sent from function 4 to variable V (note that it is a function of its neighboring variable, V). Let $g(V)$ be the message sent from function 5 to variable V. The message sent from variable V to function 3 is computed from:

$$h(V) = f(V)g(V) \quad (16)$$

That is, for each value of V, the corresponding elements $f(V)$ and $g(V)$ are multiplied together. Note that if a variable has just one edge (e.g., A in Figure 2(a)) its outgoing message is set to 1.

Propagating observations. If variable V is observed and has the value v, then an outgoing message is computed in the same fashion as described above, *except* that for all values $V \neq v$, we set the outgoing

message to *zero*. So, in the above example, we compute $h(V)$ as follows:

$$h(V) = \begin{cases} f(V)g(V) & \text{if } V = v \\ 0 & \text{if } V \neq v \end{cases} \quad (17)$$

2. *Propagating function-to-variable messages*. To produce an outgoing message on an edge, a function takes the product of its associated local function (conditional probability function, in the case of Bayesian networks, potential, in the case of Markov networks) with the incoming messages and sums over all variables in the conditional probability function, *except* the variable to which the message is being sent. For example, in Figure 2(b), $f(T)$ is the message sent from variable T to function 3 (note that it is a function of its neighboring variable), and $g(S)$ is the message sent from variable S to function 3. The message sent from function 3 to variable V is computed from

$$h(V) = \sum_T \sum_S P(V|T,S) f(T) g(S) \quad (18)$$

3. *Fusion*. Suppose the *incoming* messages to variable V are $f(V)$, $g(V)$ (from Figure 2(a)) and $h(V)$ (from Figure 2(b)). Variable V can fuse its incoming messages to compute an estimate of the *joint* probability of V and the observed variables:

$$\hat{P}(V, \text{Observations}) = f(V)g(V)h(V) \quad (19)$$

If V is observed to have the value v, we use

$$\hat{P}(V, \text{Observations}) = \begin{cases} f(V)g(V)h(V) & \text{if } V = v \\ 0 & \text{if } V \neq v \end{cases} \quad (20)$$

If $\hat{P}(V, \text{Observations})$ is then normalized with respect to V, we obtain an estimate of the *conditional* probability of V *given* the observed variables:

$$\hat{P}(V|\text{Observations}) = \hat{P}(V, \text{Observations}) / \sum_V \hat{P}(V, \text{Observations}) \quad (21)$$

Exact Inference Using Probability Propagation

If the factor graph is a tree, and if the messages arriving at a variable, say V, are based on the input from every other vertex in the graph (variable vertices and function vertices), then

$$\hat{P}(V, \text{Observations}) = P(V, \text{Observations}) \quad (22)$$

and

$$\hat{P}(V|\text{Observations}) = P(V|\text{Observations}) \quad (23)$$

That is, the fused messages give *exact* probabilistic inferences.

The Generalized Forward–Backward Algorithm

Suppose we wish to infer the probability for each and every variable in the network, given the observations. Clearly, for each and every variable in the network to receive messages from each and every other variable, at least roughly $2E$ messages must be computed, where E is the number of edges in the factor graph. (Slightly less than $2E$ messages may be needed, since, for example in Figure 2(a), we needn't pass a message from variable T to function 1.) The following procedure, called the *generalized forward–backward algorithm*, shows how we can achieve this bound – infer the probability for each and every variable in the network by passing $2E$ messages.

First, arbitrarily pick a vertex in the factor graph and call it the 'root'. Form a tree by arranging the vertices in layers, with the root at the top. Now, pass messages layer by layer *up* from the bottom to the top and then pass messages layer by layer *down* from the top to the bottom. Clearly, this procedure computes $2E$ messages and the messages arriving at each variable contain the input from each and

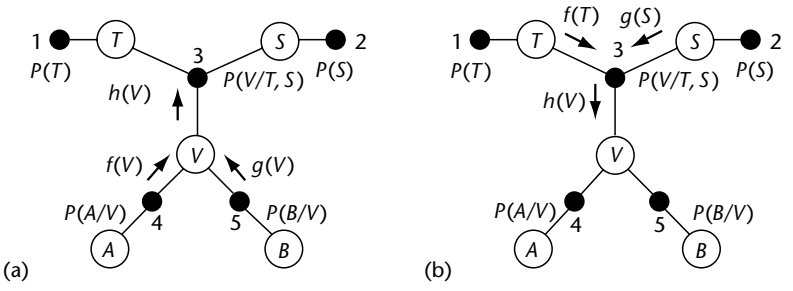

Figure 2. (a) Computing a variable-to-function message in the factor graph from Figure 1(d). The edge directions in the factor graph are dropped for visual clarity. (b) Computing a function-to-variable message.

every other vertex in the factor graph. Note that in this case, we need not initialize the messages.

Approximate Inference Using Probability Propagation

If the messages arriving at a variable do not contain the input from each and every other vertex in the factor graph, then $\hat{P}(A, \text{Observations})$ may not equal $P(A, \text{Observations})$. However, it *may* be a good estimate and in some cases can even be exactly correct. A more interesting case is when the factor graph is not a tree, but contains lots of cycles. In this case, even if the messages arriving at a variable contain the input from each and every other vertex in the factor graph, $\hat{P}(A, \text{Observations})$ will usually not be equal to $P(A, \text{Observations})$, because of the cycles. However, there are some very impressive applications where the approximation is astonishingly good (Frey and MacKay, 1998; Freeman and Pasztor, 2000; Frey *et al*., 2001). Also, new analysis is emerging that partly explains the approximation (Weiss and Freeman, 2001; Yedidia *et al*., 2001; Wainwright *et al*., 2002).

Binding Problem

Intermediate article

Jacques P Sougné, University of Liège, Liège, Belgium

CONTENTS

The binding problem is the problem of how a cognitive system (a brain or a computational model) groups a set of features together, associates a filler with a role, a value with a variable, an attribute with a concept, etc.

OVERVIEW OF THE BINDING PROBLEM

Humans effortlessly recognize objects, faces, sounds, tastes and so on, all of which are composed of many features. For example, a red ball has a particular shape and color. Since shape and color are not processed in the same cortical areas, there must be a mechanism able to bind the round shape with the red color and differentiate them from a blue cube nearby. A particular face is composed of a set of properties that have to be linked but must also be bound to a particular name and be distinguished from other faces and other names. Representing a predicate and its arguments in 'John loves Mary' requires correctly binding the filler 'John' to the role of 'lover', and the filler 'Mary' to the role of 'lovee', without confusing them. Representing a rule 'if *a* then *b*' requires correctly binding '*a*' to the antecedent and '*b*' to the consequent part of the rule. As these examples show, binding is an essential mechanism in a wide range of cognitive tasks.

How can an artificial neural network perform binding? Early critiques of connectionism raised this problem. How could a connectionist network represent the simple fact that 'the red rose is on a green table'? Since 'red', 'green', 'rose' and 'table' have distributed overlapping representations in the system, the problem is to correctly associate 'rose' with 'red' and 'table' with 'green' while avoiding 'crosstalk', i.e. avoiding the spurious associations between 'table' and 'red' and between 'rose' and 'green'.

The first idea that comes to mind for solving the problem in a connectionist setting is to increase the connection weights between 'rose' nodes and 'red' nodes and between 'table' nodes and 'green' nodes while decreasing other connection weights. But once these connection weights have been set, linked nodes cannot individually participate in other representations. Nodes must be reusable for representing another object like 'yellow rose'. Binding, therefore, must occur dynamically.

Fodor and Pylyshyn (1988) point out a difficulty that arises from the binding problem. They question the value of connectionism as a model of cognition since, according to them, connectionist models cannot display what they call 'systematicity'. The examples they give make reference to the binding problem. They point out that there are no people able to think that 'John loves Mary' but unable to think that 'Mary loves John'. Nobody is able to infer that 'John went to the store' from 'John, Mary, Susan and Sally went to the store' but unable to infer that 'John went to the store' from 'John, Mary and Susan went to the store'. One can define systematicity as the ability to apply a particular structure to any content.

Symbolic systems achieve systematicity very efficiently, but human systematicity does not prevail for complex logical forms. The ability to deduce $\sim A$ from the two statements $\sim B$ and $(A \supset B)$ is not linked to the ability to deduce A from the two statements B and $(\sim A \supset \sim B)$. These two inferences are both obtained by applying the same deduction rule (modus tollens), but they are not cognitively equivalent. Research in cognitive psychology has demonstrated that the first inference is easier (e.g. Evans, 1977; Wildman and Fletcher, 1977). Furthermore, children learning to talk do not display systematicity in their predicate use. (*See* **Symbolic versus Subsymbolic**)

BINDING IN SYMBOLIC SYSTEMS

Binding is not a problem in symbolic systems. A variable is defined and a value is associated with

('bound to') that variable. The lack of constraints on binding means that symbolic systems would not encounter the problems that humans sometimes have when doing binding.

For example, when the time of visual presentation is short, 'illusory conjunctions' are frequent. Illusory conjunction occurs when a particular feature of one object is incorrectly bound to another object. When people are rapidly shown a scene containing a blue ball and a yellow vase they may report having seen a yellow ball. Illusory conjunction is even more frequent if objects share common features.

While most connectionist systems of the 1980s were unable to do binding at all, symbolic systems were clearly too efficient in solving the binding problem compared with humans. Even if one could constrain the performance of a symbolic system with a parameter that would stochastically perturb binding, this would be far less psychologically persuasive than having binding be constrained as an emergent consequence of the architecture of the system.

Before examining the binding problem for connectionist systems, we will briefly review how the brain might achieve binding.

HOW THE BRAIN MIGHT ACHIEVE BINDING

How are neuron assemblies constituted? How are different assemblies bound and differentiated? How can we, as external observers, understand the messages involved in neural patterns of activity – and what code is used by the brain? There are two main hypotheses concerning this code: rate codes and pulse codes.

Rate Codes

There are three ways of considering rate coding, each of which uses a different averaging procedure.

Rate can be computed for a single cell firing over time. In this case, spikes are counted and their number divided by the time elapsed. The objection to this code is that behavioral reaction times are sometimes too small to allow the system to compute an average. If neurons fired at regular intervals, averages could theoretically be computed after two spikes. But noise is also a factor. To obtain a good estimate of the rate, it is necessary to compute the average over a longer period.

The second procedure for evaluating neural firing rate is to repeatedly average single cell spikes. The experimenter repeatedly records the spikes of a cell before and after a stimulation. The average is obtained by dividing the total number of spikes by the number of repetitions and the length of the recording intervals. However, this measure cannot be the code used by the organism to process information, since the reactions of most organisms are the consequence of single stimulus presentations.

The third procedure for computing rate involves recording several neurons before averaging. This rate represents the activity of a population of neurons. Some populations seem to react to particular classes of stimuli. If, after stimulation, an experimenter records the firing of each of these neurons and divides the sum by the number of neurons and by the length of the recording time window, a rate measure is obtained. The advantage of this procedure is that it allows the rate to be calculated for a short time window.

Rate coding has received empirical support. For example, Thomas *et al*. (2001) found that what was crucial for categorization was not category-specific neurons, but rather those neurons that respond more (at a higher rate) to one category than to another.

Pulse Codes

Pulse codes are based on precise timing of spikes. One possible pulse code is latency. The idea behind this is that the time separating a stimulus from the first spike of a neuron can carry information. Gawne *et al*. (1996) recorded activity of striate cortex cells and showed that spiking latency was a function of the visual stimulus contrast.

A second possible pulse code is phase coding. Oscillation of a population activity has been found in the hippocampus and cortical areas. This background oscillation can serve as a reference signal. A particular firing of a neuron can be compared to this background oscillation, and its location on the oscillation curve can serve as a code. This coding scheme has received empirical support. O'Keefe and Recce (1993), for example, showed that phase codes contained spatial information independently of spike rate in the rat hippocampus.

A third possible pulse code is synchrony. Neurons corresponding to microfeatures of a stimulus fire at the same time, and thereby allow the representation of the whole stimulus. This hypothesis has also received empirical support. Engel *et al*. (1991) showed that if several objects make up a scene, distinct clusters of synchrony are formed, each associated with a particular object in the scene. Synchrony is often associated with

oscillation since it has been shown that gamma oscillations enable synchronization.

It is important to note that rate codes and pulse codes are not mutually exclusive. Synchrony within a population of neurons over a short period of time also means that the population firing rate is high. It is also possible that different kinds of information could be coded by different coding schemes.

A final problem is how the brain reads the code expressed by neurons. People are capable of describing and observing their own thoughts, but exactly how this is done is not known.

CONNECTIONIST SOLUTIONS TO THE BINDING PROBLEM

Grandmother Cells

The first solution to the binding problem is to use one node for each possible binding. According to this purely localist solution, a binding is represented by a single cell which responds whenever this particular binding is used. This unique cell is called a 'grandmother cell'. This kind of representation poses a number of problems. First, imagine a soccer player banging his head against the goalpost and losing his 'soccer ball' cell. What would this player do after getting up? Would he no longer know anything at all about soccer balls? Second, an enormous number of feature combinations are necessary for representing the multitude of objects, concepts, etc., that humans deal with. If every specific combination had a particular corresponding cell, such a representation would require an impossibly large number of neurons. A final problem is generalization. If every new object would need a new representing neuron, similar objects cannot help in representation building.

Coarse–Fine Coding

At the opposite end of the spectrum from grandmother cells representations are fully distributed representations in which every node may participate in every object representation. Such representations also pose problems. Suppose that a particular object (a ball) has a representation and a particular color (blue) has another representation. Since every node participates in every representation, the conjunction 'blue ball' cannot be represented, since activations coming from 'blue' will be added to activations coming from 'ball' and the subsequent activations will not necessarily represent 'blue ball', 'blue' or 'ball', but could represent nothing or a ghost representation which can correspond to 'pear' or anything else. A solution to this problem is to use a finer coding in which a subset of the population is used to code a particular value. A node becomes active if the input falls in its receptive field. This partially distributed coding needs fewer nodes than purely localist codes to represent the same amount of information, therefore avoiding the problem faced by grandmother cells representation of needing an impossibly large number of cells. However, this solution, at least in its simplest form, only allows one variable to be bound at a time. This solution can represent the conjunction 'blue ball' as the set of 'blue' – responding nodes and 'ball'-responding nodes, but adding a 'yellow vase' to the scene to be represented would make everything bind together. Consequently, we would not be able to detect which color is associated with which object.

Tensor Products

Smolensky (1990) proposed the use of a tensor product representation of binding. Tensor products are similar to outer products of vectors (Figure 1a)). The outer product of two n-dimensional vectors $\mathbf{u}$ and $\mathbf{v}$ is the product $\mathbf{u}\mathbf{v}^{\mathrm{T}}$ of $\mathbf{u}$ and the transpose of $\mathbf{v}$ ($\mathbf{v}^{\mathrm{T}}$ is a matrix with one row and n columns). This is an $n \times n$ matrix. If one has to encode 'John loves Mary', the 'John' filler must be bound to the 'lover' role. John in the role of lover will be represented by the outer product of 'John' and 'lover' vectors. This solution can encode bindings, but it does not allow inferencing. It is also not clear what the neural correlate of outer products might be. One disadvantage of the tensor product is the increase of dimensionality for each additional tensor product (the tensor product of two vectors is a 2D array, the tensor product of a vector and a 2D array is a 3D array, etc.). To overcome this problem, other techniques have been proposed in which the binding of two vectors results in a vector (e.g. convolution – correlation: Plate, 1995). (*See* **Convolution-based Memory Models**)

Values Associated with Roles and Fillers

In the model ROBIN (Lange and Dyer, 1989) each filler has an associated node that outputs a particular constant value (called its signature). Each role has an associated object node or binding node. When a role object node has the same activation as that of a symbol's signature, this symbol is bound to the role (Figure 1(b)). A similar solution

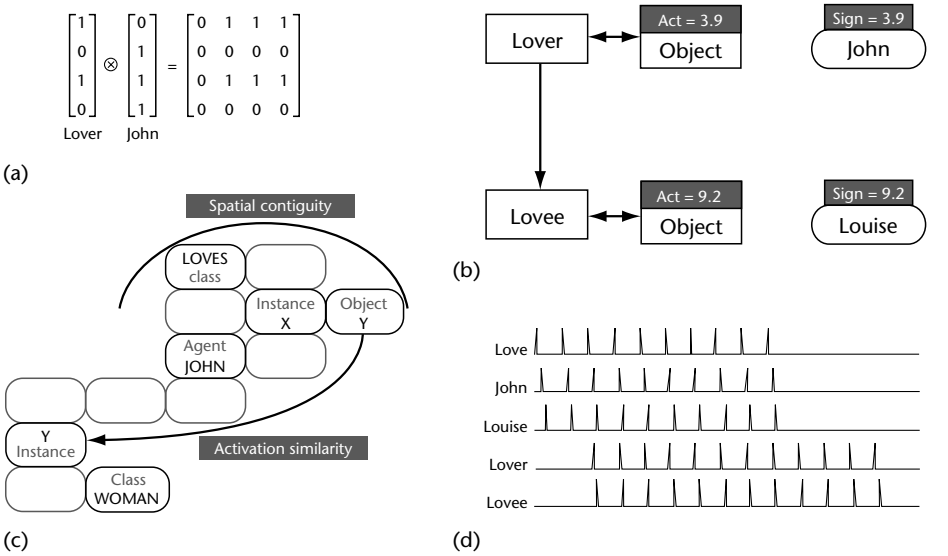

Figure 1. Connectionist solutions to the binding problem. (a) Tensor product representation (Smolensky, 1990) of 'John' bound to 'lover': 'lover' is represented by the (column) vector [1010] and 'John' by the (column) vector [0111]; their binding is represented by their outer product. (b) Values associated with role and filler, as in the model ROBIN (Lange and Dyer, 1989) in which binding is achieved by a match between activation of role object node and filler signature. For representing 'John loves Louise', the activation of the 'lover' object node has the same value as the signature of the 'John' node while the activation value of the 'lovee' object node has the same value as the signature of the 'Louise' node. (c) COMPOSIT binding by activation similarity and spatial contiguity, the representation of 'John loves some woman' in working memory. The register that contains the 'instance' flag with the X symbol denotes a particular instance of the adjacent 'loves' class. The agent of this loving situation is found in the adjacent register containing the 'agent' flag: 'JOHN'. The object of that loving instantiation is found in the adjacent register that contains the 'object' flag 'Y'. By activation similarity, 'Y' points to another register with the same 'Y' symbol and the 'instance' flag. This instance is adjacent to another register that contains the 'class' flag and the 'WOMAN' symbol, denoting that the object of the loving relation is some undefined woman. (d) Binding by synchrony. For representing 'John loves Louise', the firings of the nodes associated with the predicate 'Love' are followed by the 'John' nodes firing in synchrony with the 'lover' nodes while the 'Louise' nodes fire in synchrony with the 'lovee' nodes.

was proposed by Sun (1992) with his hybrid model CONSYDERR, which consists of a localist network and a distributed network. The localist network is composed of nodes representing symbols and links between these symbols representing rules. Each symbol node is linked to several nodes in the distributed network. The nodes of the distributed network represent the features of the symbol. Variable binding is achieved by the use of a particular value which is passed from a role node to a filler node along a link. These solutions lack psychological plausibility since the number of separated bindings is not constrained.

Activation Similarity and Spatial Contiguity

The model COMPOSIT (Barnden and Srinivas, 1991) uses two systems, a long-term memory and a working memory, both of which are connectionist networks. In this model, working memory is composed of several registers filled with activation patterns from long-term memory. Fillers and their roles are stored in registers as two vectors. One vector (the symbol vector) represents the filler and the other vector (the highlighting vector) represents the role. Predicates, related roles, and fillers are stored contiguously and thus constitute a distinguishable set that can be linked to a particular role pertaining to another predicate (Figure 1(c)). A role can be linked to another role by the similarity of their highlighting vectors. This is a very efficient solution that permits recursive predication. However, it is not clear what neural mechanism might correspond to the loading of registers.

The above solutions have various advantages and limitations, but they all lack neural plausibility. We will now explore more neurally plausible solutions.

Binding by Temporal Frequency

Lange and Dyer (1989) proposed the use of temporal frequency (instead of signatures) for binding, each signature being an unique frequency of node

spike. Nodes having the same firing frequency would be bound together. This model has not yet been explored by cognitive scientists, though there are neurobiological data that seem to be consistent with it. However, if the activation of a node is considered to be its firing rate, then binding by activation, as in CONSYDERR and ROBIN, can fall into this category.

Binding by Synchrony

For systems using temporal synchrony for variable binding, nodes can be in two different states: they can be firing ('on'), or they can be at rest ('off'). A node fires at a precise moment and transmits activation to other connected nodes. When a node's activation reaches threshold, it fires. Whenever two nodes (or two sets of nodes) representing two objects fire simultaneously, these objects are temporarily associated (Figure 1(d)). On the other hand, if two nodes (or two sets of nodes) fire in succession, they are distinguished. This is how the systems Shruti (Shastri and Ajjanagadde, 1993) and INFERNET (Sougné, 2001) solve the binding problem.

Synchrony has been used as a binding mechanism in various cognitive models, for perception, for attention, for spatial cognition, for memory, and for different types of inference. These models fit human data well, mainly because the number of distinguishable entities in these systems is constrained by the precision of synchrony. However, it is not clear how these models could represent recursive structures.

The Binding Problem and Distributed Representations

Most of the above models used localist representations. Binding in a fully distributed network is problematic, because as soon as two symbols are required at the same time, their representations may overlap, which could lead to crosstalk.

This problem is greatly reduced by using partially distributed representations, where each symbol is represented by an assembly. This solution avoids problems of 'grandmother' cells, and, since some assemblies share nodes, similarity effects related to binding can be achieved (Sougné, 2001).

THE PROBLEM OF MULTIPLE INSTANTIATION

Multiple instantiation involves the simultaneous use of the same parts of the knowledge base in different ways. Knowing that 'John is the father of Peter' and that 'Peter is the father of Paul', one can readily infer that John is the grandfather of Paul. To derive this conclusion, one must simultaneously instantiate the predicate 'father of' and the object 'Peter' twice. Precisely how this is done is the problem of multiple instantiation. This problem is also called the type–token problem. It is closely related to the binding problem. Solving the binding problem is not by itself sufficient to solve the problem of multiple instantiation; it is, however, necessary.

Symbolic models load copies of pieces of knowledge into a working area before processing them. For these models, there is no problem of multiple instantiation: they simply make several copies of the same content from the long-term knowledge base (LTKB) and store them in the working area. By contrast, for connectionist models that use the knowledge base itself as the place where symbols are associated and processed, multiple instantiation is a serious problem. How can the same object be associated with different roles at the same time without making several copies of this object? In general, multiple instantiation poses significant problems for distributed representations. Two closely related objects will, in principle, share nodes. Therefore, if both objects are needed simultaneously (for different roles), their common nodes must be associated with two different clusters of nodes.

People are able to cope with multiple instances of the same concept, unlike most connectionist models, but their performance when doing so is diminished. There is no naturally arising decrease in performance for symbolic models doing multiple instantiation.

Multiple Instantiation in Neural Networks

For localist networks (where each symbol is represented by a single node) that can represent predicates with more than one argument, the problem of multiple instantiation arises if two instantiations of a predicate have different bindings of their arguments. For example, 'John likes tennis and John likes football' does not require separate instances of the predicate 'likes' since this statement is equivalent to 'John likes tennis and football', in which 'tennis' and 'football' are bound to the same role. However, when two sets of two fillers must be associated with identical pairs of roles, the system must be able to handle two copies of the predicate and argument slots. For example, 'John likes football and Mary likes tennis' cannot be reduced to 'John and Mary like football and tennis',

because if it is one can no longer distinguish who likes what.

In distributed networks the problem of multiple instantiation arises as soon as one node must be used by clusters that have to be differentiated. If a predicate with more than one argument has to be represented, and if either the predicate's arguments or any of the arguments' fillers need to use a common node, then this node will have to be bound to different roles.

Relevance for Cognitive Science

In some sense, the connectionist limitations regarding the problem of multiple instantiation could be a blessing in disguise, because some tasks involving multiple instantiation are precisely those tasks that cause problems for humans. Empirical evidence of these difficulties comes from relational reasoning, from repetition blindness, and from the effects of similarity on working memory and on perception. These data show that multiple instantiation can indeed cause problems for humans and animals. In short, when confronted with multiple instantiation, people tend to be slower or to make more mistakes. A good model should not only be able to deal with multiply instantiated symbols, but should also reflect the difficulties that humans have with them.

Connectionist Solutions

There are three types of solution to the problem of multiple instantiation. The first type of solution is to use two systems, an LTKB and a working area into which copies of pieces of the LTKB are loaded. The second type of solution uses several copies of the same symbol in the LTKB. The third relies on superposing frequencies of oscillation.

Multiple copies loaded in a working area

The first solution is borrowed from symbolic models. Each additional instance of a symbol that is required will be represented by an additional copy of the symbol inside short-term memory (STM). An example is the COMPOSIT model (Barnden and Srinivas, 1991), illustrated in Figure 2(a). This solution is probably the most powerful one, and allows a broad range of high-level inferencing capabilities.

Unfortunately, however, this solution inadequately reflects the difficulties people have when they perform multiple instantiation. For these models, even if the STM has a limited capacity, it is as easy to load one copy as to fill the STM with copies of the same content (unless, of course, this is explicitly prevented). Other solutions have been developed, however, in which the STM is the activated part of the LTKB.

Multiple copies inside the LTKB

Lange (1992) describes a potential solution designed to handle multiple instantiation inside ROBIN. This solution involves each symbol having more than one signature and each role more than one activation (Figure 2(b). Multiple instantiation in Shruti (Shastri and Ajjanagadde, 1993) is achieved by the use of a bounded set of copies or banks of predicates and their argument slots (usually at most three).

One difficulty with the solution involving multiple copies inside LTKB is that the number of allowable copies is arbitrary. Another difficulty is the abrupt loss of performance. As long as a copy is available, performance will be perfect, but when no more copies are available, performance will decrease abruptly. This behavior does not accurately reflect human performance.

Period doubling

Sougné (2001) describes another solution to the problem of multiple instantiation. In INFERNET, nodes pertaining to a doubly instantiated object will support two oscillations while those singly instantiated will support one oscillation (Figure 2(c)). This makes doubly instantiated object nodes fire twice while singly instantiated objects fire once. This means that each new instance will occupy a new place in STM, thus avoiding crosstalk.

This solution can be compared to the neural phenomenon of bifurcation by period doubling, whereby a stable oscillatory state can lose its stability, giving rise to a new stable state with doubled period. Similar period doubling was obtained experimentally, *in vivo*, by Ishizuka and Hayashi (1996). They recorded cell activity in the somatosensory cortex of rats while increasing the stimulation frequency on a medial lemniscus fiber. As stimulation frequency increased, successive period doublings occurred, finally leading to a chaotic firing pattern.

It is therefore reasonable to assume that multiply instantiated symbol nodes could receive a higher frequency of input than singly instantiated ones; so that increasing the number of instantiations would increase the chance of period doublings.

Another advantage of this solution is its psychological plausibility. As the number of instantiations increases, cognitive performance decreases. The

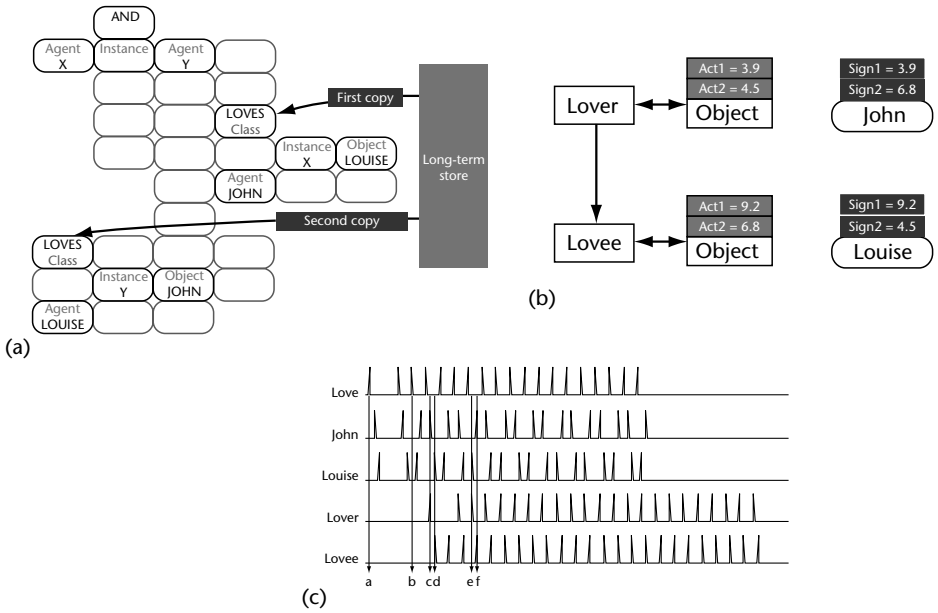

Figure 2. Connectionist solutions to the problem of multiple instantiation. Examples of how different solutions could encode 'John loves Louise and Louise loves John'. (a) The solution of the COMPOSIT model (Barnden and Srinivas, 1991), borrowed from symbolic artificial intelligence. Each additional instance occupies a new place in the 'working memory' area. The 'AND' symbol is instantiated and has two adjacent agents 'X' and 'Y' each pointing to their own instantiation of 'loves'. The register that contains the 'instance' flag with the 'X' symbol denotes a particular instance of the adjacent 'loves' class. The agent of this loving situation is found in the adjacent register containing the 'agent' flag: 'JOHN'. The object of that loving instantiation is found in the adjacent register that contains the 'object' flag: 'LOUISE'. The register that contains the 'instance' flag with the 'Y' symbol denotes a particular instance of the adjacent 'loves' class. The agent of this loving situation is found in the adjacent register containing the 'agent' flag: 'LOUISE'. The object of that loving instantiation is found in the adjacent register that contains the 'object' flag: 'JOHN'. (b) Multiple copies inside a long-term knowledge base. Handling multiple instantiation inside ROBIN requires that each symbol has more than one signature and each role more than one activation (Lange, 1992). For representing 'John loves Louise' and 'Louise loves John', one activation of the 'Lover' object node has the same value as one of the signatures of the 'John' node, and one activation of the 'Lovee' object node has the same value as one of the signatures of the 'Louise' node. Additionally, one activation of the 'Lover' object node has the same value as one of the signatures of the 'Louise' node, and one activation of the 'Lovee' object node has the same value as one of the signatures of the 'John' node. (c) Multiple instantiation by period doubling (Sougné, 2001). The fact 'John loves Louise' is introduced at time a. This pattern starts oscillating. At time c 'John' begins to fire in synchrony with 'Lover' and at time d 'Louise' starts firing in synchrony with 'Lovee'. The statement 'Louise loves John' is introduced at time b. This pattern starts oscillating. At time e 'Louise' begins to fire in synchrony with 'Lover' and at time f 'John' starts firing in synchrony with 'Lovee'. Therefore, the 'Love', 'John', 'Louise', 'Lover', and 'Lovee' nodes sustain two oscillations, enabling the 'John' and 'Louise' nodes to bind alternatively to 'Lover' and 'Lovee' nodes.

model can also simulate various similarity effects that humans display. However, it has not yet been proved to be able to simulate recursive predication.

SUMMARY

When looking at a field of poppies on a sunny day, how can we correctly associate the color red with the poppies, green with the grass, and blue with the sky, and avoid associating the color red with the grass and the color blue with the poppies? If we see Louise picking a red poppy, how can we correctly associate Louise with the picker and the red poppy with the picked object, without making the opposite and incorrect association? As long as the number of distinct ensembles remains small, these associations are easy for us, but how does the brain perform them correctly? The question of how a connectionist system binds a set of features together, associates a filler with a role, a value with a variable, an attribute with a concept, etc., is what is called 'the binding problem'. Related to this problem is the problem of multiple instantiation.

Catastrophic Forgetting in Connectionist Networks

Intermediate article

Robert M French, University of Liège, Liège, Belgium

CONTENTS

Unlike human brains, connectionist networks can forget previously learned information suddenly and completely ('catastrophically') when learning new information. Various solutions to this problem have been proposed.

INTRODUCTION

The connectionist paradigm in artificial intelligence came to prominence in 1986 with the publication of Rumelhart and McClelland's two-volume collection of articles entitled *Parallel Distributed Processing: Explorations in the Microstructure of Cognition*. Some 20 years earlier, research on an elementary type of neural network, known as perceptrons, had come to a sudden halt in 1969 with the publication of *Perceptrons*, Minsky and Papert's careful mathematical analysis of the capacities of a particular class of single-layered perceptrons. Minsky and Papert's work demonstrated a number of fundamental theoretical limitations of elementary perceptrons. Multi-layered perceptrons and new learning algorithms, which overcome these limitations, were developed over the course of the next two decades. These new networks were able to do many tasks that presented serious problems for traditional symbolic artificial intelligence programs. For example, they were able to function appropriately with degraded inputs, they could generalize well, and they were fault-tolerant. In the late 1980s there were many attempts to apply these networks to tasks ranging from underwater mine detection to cognition, from stock market prediction to bank loan screening.

At the end of the 1980s, however, a problem with these multi-layered networks came to light. McCloskey and Cohen (1989) and Ratcliff (1990) showed that the very property – namely, using a single set of weights as the network's memory – that gave these networks such power caused an unsuspected problem: catastrophic interference. Grossberg (1982) had previously cast this problem in the more general context of 'stability–plasticity'. In short, the problem was to determine how to design network architectures that would be sensitive to new input without being overly disrupted by it.

Catastrophic interference occurs when a network has learned to recognize a particular set of patterns and is then called upon to learn a new set of patterns. The learning of the new patterns modifies the weights of the network in such a way that the previously learned set of patterns is forgotten. In other words, the newly learned patterns suddenly and completely – 'catastrophically' – erase the network's memory of the previously learned patterns.

CATASTROPHIC VERSUS NORMAL FORGETTING

Catastrophic forgetting is significantly different from normal human forgetting. In fact, catastrophic forgetting is almost unknown in humans. Barnes and Underwood (1959) conducted a well-known series of experiments in human forgetting. Subjects begin by learning a set of paired associates *A–B*, each consisting of a non-word and a word (e.g., *pruth–heavy*). Once this learning is complete, they learn to associate a new word with each of the original non-words (*A–C*). At various points during the learning of the *A–C* pairs, they are asked to recall the originally learned *A–B* associates. McCloskey and Cohen (1989) conducted a similar experiment using addition facts on a standard connectionist network. After five learning trials in the *A–C* condition, the network's knowledge of the *A–B* pairs had dropped to 1 per cent, and after 15 trials it had disappeared. The newly learned pairs

had catastrophically interfered with the previously learned pairs.

The problem for connectionist models of human memory – in particular, for those models with a single set of shared multiplicative weights (e.g. feedforward back propagation networks) – is that catastrophic interference is hardly observed in humans. This raises a number of issues of significant practical and theoretical interest. Arguably, the most important issue for cognitive science is understanding how the brain manages to overcome the problem of catastrophic forgetting. The brain is, after all, a distributed (or partially distributed) neural network, yet it does not exhibit anything like the catastrophic interference seen in connectionist networks. What neural architecture allows the brain to overcome catastrophic interference, and what characteristics of neural networks in general will allow them to overcome it?

At present, in order to avoid catastrophic interference, most connectionist architectures rely on learning algorithms that require the network to cycle repeatedly through all the patterns to be learned, adjusting the weights by a small amount at a time. After many cycles (called 'epochs') through the entire set of patterns, the network will (usually) converge on an appropriate set of weights for the set of patterns that it is supposed to learn. Humans, however, do not learn in this way. In order to memorize ten piano pieces, we do not play each piece once and then cycle repeatedly through all the pieces until we have learned them all. We learn piano pieces – and just about everything – sequentially. We start by learning one or two pieces thoroughly, then learn a new piece, then another, and so on. If a standard connectionist network were to do this, each new piece learned by the network would probably erase from its memory all previously learned pieces. By the tenth piece, the network would have no recollection whatsoever of the first piece. In order for connectionist networks to exhibit anything like human sequential learning, they must overcome the problem of catastrophic interference.

MEASURES OF CATASTROPHIC INTERFERENCE

The two most common measures of catastrophic interference are known as 'exact recognition' and 'relearning'. In both cases, the network is first trained to a given level on a set of patterns. It is then given a second set of patterns to learn. Once it has learned this second set of patterns, we use one of the two measures of forgetting to determine the effect on the original learning of having learned the second set of patterns. The exact recognition measure depends on the percentage of the original patterns that can still be recognized by the network. (We give the input part of the pattern to the network; and if it produces the correct output, it is considered to have 'recognized' the pattern.) The relearning measure, first proposed by Ebbinghaus for human memory in the late nineteenth century, depends on how long it takes the network to relearn the originally learned patterns. Thus, even if the rate of exact recognition is very low, the knowledge might lie 'just below the surface' and the network might be able to relearn it very quickly. The studies by McCloskey and Cohen (1989) and Ratcliff (1990) used an exact recognition measure. A study by Hetherington and Seidenberg (1989) using the relearning measure showed that, at least in some cases, catastrophic interference might be less of a problem than was thought because the network, even if it could not recognize the originally learned patterns exactly, could relearn them very quickly.

SOLUTIONS TO THE PROBLEM

As soon as the problem came to light, there were many attempts to solve it. One of the first was the suggestion by Kortge (1990) that the problem was due to the back propagation learning algorithm. He proposed a modified learning algorithm using what he called 'novelty vectors' that did, in fact, decrease catastrophic interference. The basic idea of novelty vectors was 'blame assignment'. Kortge's learning rule was developed for auto-associative networks, i.e., networks that, starting from a random weight configuration, learn to produce on output the vectors that they received on input. Each pattern to be learned was fed through the network and the output was compared with the intended output (i.e., the input). Kortge called the resulting difference vector a 'novelty vector' because the bigger the activation differences at each node, the more novel the input – for vectors that the network had already learned there would be little difference between output and input. The novelty vector indicated by how much to change the weights: the greater the novelty activation, the more the weights were changed. This technique significantly reduced catastrophic interference, but it applied only to auto-associative networks.

French (1992) argued that catastrophic forgetting was in large measure due to excessive overlap of internal representations. He claimed that the

problem lay with the fully distributed nature of the network's internal representations, and suggested that by developing algorithms that produced 'semi-distributed' internal representations (i.e., representations whose activation was spread only over a limited subset of hidden nodes) catastrophic interference could be reduced. To this end he suggested a learning algorithm, 'node sharpening', that developed much sparser internal representations than standard back propagation. The result was a significant reduction in catastrophic interference. However, the overly sparse representations developed by this technique resulted in a significant decrease in the network's ability to discriminate categories. What was needed was a means of making representations both highly distributed and well enough separated.

Brousse and Smolensky (1989) and McRae and Hetherington (1993) showed that the problem was closely related to the domain of learning. In domains with a high degree of internal structure, such as language, the problem is much less acute. McRae and Hetherington managed to eliminate the problem by pretraining the network on a random sample of patterns drawn from the domain. Because of the degree of structure in the domain, this sample was enough to capture overall regularities of the domain. Consequently, the new patterns to be learned were perceived by the network to be variants of patterns, already learned and did not interfere with previous learning.

The early attempts to solve the problem of catastrophic interference concentrated on reducing representational overlap on input or internally. Kortge (1990) and Lewandowsky (1991) modified the input vectors in an attempt to achieve greater mutual orthogonalization (this is equivalent to reducing the overlap among input vectors). French (1992), Murre (1992), Krushke (1992) and others developed algorithms that reduced internal representational overlap, thereby significantly reducing the amount of catastrophic interference.

Some researchers (e.g. Carpenter, 1994) have laid the blame for the problem of catastrophic interference on a particular architectural feature of the most widely used class of connectionist networks, namely their use of multiplicative connection weights. In the ART family of networks (Carpenter and Grossberg, 1987), new input does not interfere with previously learned patterns because the network is able to recognize new patterns as being new and assigns a new set of nodes for their internal representation.

Hopfield networks, and related architectures, have been shown to have critical saturation limits beyond which there is a steep fall in memory performance. For these networks, forgetting is gradual until the memory becomes saturated, at which point it becomes catastrophic.

REHEARSAL AND PSEUDOREHEARSAL

Most connectionist networks learn patterns concurrently. In terms of human cognition, this is a contrived type of learning. For a given set of n patterns $\{P_1,\ldots P_n\}$, the network will successively adjust its weights by a very small amount for all of the patterns and then will repeat this process until it has found a set of weights that allow it to recognize all n patterns. This, in itself, is a way of learning foreign to humans. In addition, if a new set of patterns $\{P_{n+1},\ldots P_m\}$ must then be learned by the network, the standard way of handling the situation is to mix the original set of patterns with the new set of patterns to be learned, creating a new set $\{P_1,\ldots P_n, P_{n+1},\ldots P_m\}$, and then train the network on this new expanded set. In this way, the new patterns will not interfere with the old patterns, but there is a major problem with this technique: namely, that in the real world, the originally learned patterns are often no longer available and cannot simply be added to the set of new patterns to be learned.

In 1995 Anthony Robins made a major contribution to research on catastrophic forgetting with a technique based on what he called 'pseudopatterns' (Robins, 1995). His idea was simple and elegant. Suppose that a connectionist network with n inputs and m outputs has learned a number of input–output patterns $\{P_1, P_2,\ldots P_N\}$ generated by some underlying function f. Assume that these original input–output vectors are no longer available. How could one determine, even approximately, what function the network had originally learned? One way would be to create a number M of random input vectors of length n, $\{\hat{\imath}_1,\ldots \hat{\imath}_M\}$. These pseudo-input vectors would be fed through the previously trained network, producing a corresponding set of outputs $\{\hat{o}_1,\ldots \hat{o}_M\}$. This would result in a set of 'pseudopatterns' $S = \{\psi_1, \psi_2,\ldots \psi_M\}$ where ψ_k: $\hat{\imath}_k \rightarrow \hat{o}_k$. This set of pseudopatterns would approximate the prior learning of the network. The accuracy of the pseudopatterns in describing the originally learned function would depend on the nature of the function. Thus, when the network had to learn a new set of patterns, it would mix in a number of pseudopatterns with the new patterns.

The pseudopattern technique was the basis of the dual memory models developed by French (1997) and Ans and Rousset (1997), which loosely

simulate the hippocampal–neocortical separation, considered by some to be the brain's way of overcoming catastrophic interference (McClelland *et al*., 1995). These models incorporate two separate, continually interacting, pattern processing areas, one for early processing and one for long-term storage, information being passed between the areas by means of pseudopatterns. This technique allows them to forget gradually and to perform sequential learning appropriately. Somewhat unexpectedly, these dual memory networks also exhibit over time a gradual representational 'compression' (i.e., fewer active nodes) of the long-term internal representations. If this can be shown to occur also in humans, it might help explain certain types of category-specific deficits commonly observed in amnesiacs (French and Mareschal, 1998).

OTHER TECHNIQUES FOR ALLEVIATING CATASTROPHIC FORGETTING IN NEURAL NETWORKS

A number of other techniques have been developed to address the problem of catastrophic interference. Notably, there have been attempts to combine auto-associative architectures with sparse representations. Some architectures use two different kinds of weights on the connections between nodes, one that decays rapidly to zero and another that decays much more slowly. Convolution-correlation models such as CHARM and TODAM, which are mathematically equivalent to certain types of connectionist networks (sigma–pi networks) seem to be relatively immune to catastrophic interference, at least up to a point. Cascade-correlation learning algorithms have also been tried as a means of alleviating catastrophic interference, with some success. For a more complete review of the various models that have been developed to handle the problem of catastrophic interference in connectionist networks, see (French, 1999).

SUMMARY

The problem of catastrophic interference in connectionist networks has been known and studied since the early 1990s. Sequential learning of the kind done by humans cannot be achieved unless a solution is found to this problem. In other words, network models of cognition must, as Grossberg has stressed, be sensitive to new input but not so sensitive that the new input destroys previously learned information. Certain types of patterns, such as those found in highly structured domains, are less susceptible to catastrophic interference than patterns from less well structured domains. Nature seems to have evolved a way of keeping new learning (hippocampal learning) at arm's length from previously learned information stored in the neocortex (neocortical consolidation), thus physically preventing new learning from interfering with previously learned information. Connectionist models have been developed that simulate this cerebral separation. This is certainly not the only way to tackle the problem of catastrophic interference, but its close relationship with the way in which the brain may have solved the problem makes further exploration of these dual memory models of particular interest.

Classifier Systems

Intermediate article

Lashon B Booker, MITRE Corporation, McLean, Virginia, USA

CONTENTS

A classifier system is a parallel, message-passing, rule-based system designed to learn and use internal models of complex environments. Classifier systems are useful to cognitive modelers because they build representations that have both connectionist and symbolic qualities.

OVERVIEW

Real-world environments seldom provide salient, timely, complete, and unambiguous information. Therefore the correspondence between the unfolding complexity of the world and the representations used by a cognitive system cannot be taken for granted. Environmental properties, particularly complexity and uncertainty, are an important constraint on cognitive behavior. A complex environment may overwhelm a system with large amounts of information, not all of which is directly relevant to the system's appointed task. In order to function at all, a cognitive system must be discriminating and selective about what information it stores and uses. An uncertain environment is one in which it is unlikely that input configurations can be discerned or predictions made with accuracy. Under such circumstances, the only viable information-processing strategies are those capable of making pragmatic 'good guesses' about the true state of the world. In order to cope with both complexity and uncertainty, one must resist the temptation to try to know the environment in explicit detail. A system must focus on learning the basic concepts and regularities in the environment, their relationships, and their relevance to system goals. It is precisely this kind of economical, orderly arrangement of knowledge that constitutes an internal model of the environment. The notion that organisms can benefit from the use of internal models has long been recognized by psychologists as a powerful idea (Craik, 1943; Tolman, 1948).

Inductive processes generate and revise the constituent elements of internal models. Learning that leads to the development of an internal model can therefore be viewed as a pragmatic cognitive strategy for successful functioning in the real world. For this reason, induction is a central topic in cognitive science. In a comprehensive discussion of induction from this perspective, Holland *et al*. (1986), viewing induction broadly as any inferential process that expands knowledge in the face of uncertainty, describe a rule-based framework that seeks to answer the question: 'How can a cognitive system process environmental input and stored knowledge so as to benefit from experience?' Classifier systems are general-purpose rule-based systems designed to learn and use internal models in a manner consistent with this framework.

CLASSIFIER SYSTEMS AND COGNITIVE MODELING

Several properties of this framework for induction, and classifier systems in particular, are well suited to support cognitive modeling. In order to see why, it is helpful to begin with a broad characterization of internal representations and the mental operations that use them. The discussion by William James (1892) remains one of the most useful such characterizations available. James distinguishes two important aspects of cognitive representations and processes that are relevant here. Firstly, internal representations are dynamic, composite descriptions of the current situation and the expectations associated with it. The constituent elements of representations are associated with the many different aspects of the current stimuli and the overall context. The simultaneous, context-dependent activation of some combination of these elements constitutes the system's interpretation of the current situation. Secondly, the various elements that are candidates to participate in a representation interact with each other to determine which elements become active. The nature of these interactions is determined by the network

of associations connecting the elements together, and by mechanisms that direct the flow of activity from one element to another.

This notion of distributed representations emerging from dynamic patterns of interactions among large numbers of primitive elements is common to many connectionist approaches to cognitive science. The framework for induction proposed by Holland *et al*. takes a similar notion of representation, but uses simple condition–action rules as the basic elements. Rules interact by passing messages, and many rules can be active simultaneously. Inductive mechanisms organize rules into clusters that provide a multifaceted representation of the current situation and the expectations that flow from it. The structure of a concept is modeled by the organization, variability, and strength of the rules in a cluster. Simple rules thereby become building blocks for representing complex concepts, constraints, and problem-solving behaviors. Knowledge can be represented at many levels of organization, using rules and rule clusters as building blocks of different sizes and complexities. Because constituent elements compete to become active, aspects of a representation are selected only when they are relevant in a given context. Moreover, since rules are activated in parallel, new combinations of existing rules and rule clusters can be used to dynamically represent novel situations. (*See* **Connectionism**; **Distributed Representations**)

Because the framework for induction uses symbolic rules as representational primitives, there are important differences between this approach and the typical connectionist approach to cognitive modeling. The most obvious difference is that it is easier to construct representations having symbolic expressiveness. Another significant difference is in the way inductions are achieved. Modification of connection strengths is the only inductive mechanism available in most connectionist systems. Moreover, the procedures for updating strength are part of the initial system design, and cannot be changed, except perhaps by adjusting a few parameters. The framework for induction, on the other hand, permits a range of inductive mechanisms, from strength adjustments to analogies. In principle, many of these mechanisms can be controlled by or easily expressed in terms of condition–action rules. These rules can be evaluated, modified and used to build higher-level concepts. Overall, this paradigm offers a set of potential cognitive modeling capabilities that occupy an important middle ground between subsymbolic connectionist systems and the traditional symbolic paradigms of artificial intelligence.

Classifier systems were originally proposed as a rule-based implementation of this approach to cognitive modeling. The earliest proposals (Holland, 1976) and experiments (Holland and Reitman, 1978) described simple cognitive systems designed to adapt to their environment under sensory guidance. Most subsequent work has focused less on developing cognitive architectures and more on the algorithms and computational techniques needed to implement architectures of this kind. The remainder of this article discusses these algorithms and their properties from the standpoint of cognitive modeling.

ALGORITHMIC DESCRIPTION OF CLASSIFIER SYSTEMS

A classifier system is a parallel, message-passing, rule-based system designed to permit nontrivial modifications and reorganizations of its knowledge as it performs a task. The typical operating principles for a classifier system can be briefly summarized as follows. In the simplest version, all information processing is accomplished using messages that are encoded as binary strings of fixed length k. The set of messages to be processed at any given moment is stored on a 'message list'. Classifier systems process these messages using a population of rules, called 'classifiers'. Every classifier is a fixed-length string having the form

$$s_1, s_2, \ldots, s_n \Rightarrow m \qquad (1)$$

Each s_i is an input condition, represented as a string of length k in the ternary alphabet {0, 1, #}. The action part m is also a string of length k in this ternary alphabet. A condition is satisfied by a message whenever there is a 'match' – that is, whenever the 0 and 1 symbols in the condition are identical to the bit values at corresponding positions of the message. The # symbol is a 'don't care' place holder that matches any message bit value at the designated position. A classifier is eligible to become active only if each of its conditions matches a message on the message list. Once a classifier is activated, the action part of the rule specifies a message m which the rule will 'post' on the message list on the next timestep. When the # symbol appears in the action part it is interpreted as a 'pass through' place holder. This means that the designated position in the posted message is assigned the value of the corresponding bit from a message that matched one of the classifier's conditions.

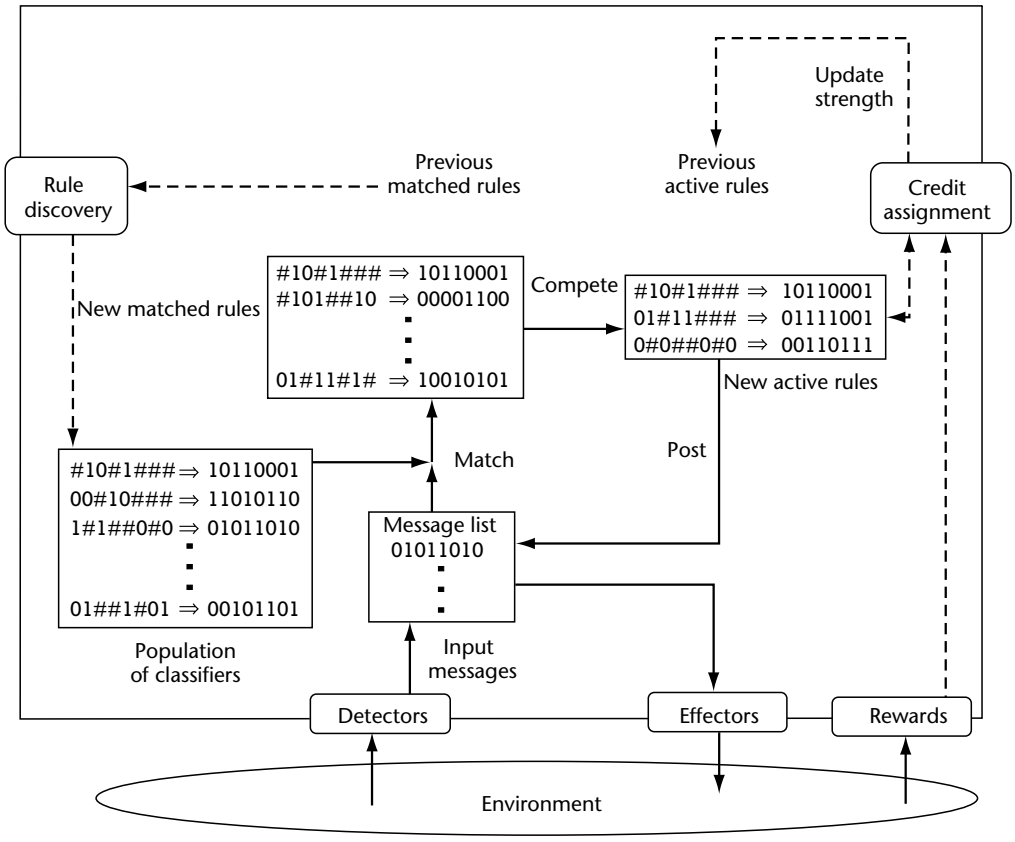

Figure 1. The organization of a typical classifier system. See the text for a detailed explanation.

In more detail, the typical classifier system can be described in terms of three interacting subsystems: a 'performance' system, a 'credit assignment' system, and a 'rule discovery' system (see Figure 1). The performance system is responsible for interacting with the external environment and generating behavior. It is assumed that an input interface is available to translate the state of the environment into messages (e.g. by using a set of detectors) and that an output interface interprets relevant messages as action specifications (e.g. by using a set of effectors). It is also assumed that the environment occasionally gives the system explicit performance feedback in the form of pay-off or reinforcement. Given these assumptions, the basic execution cycle for the performance system proceeds as follows:

1. Place messages from the input interface on the current message list.
2. Compare all messages to all conditions and conduct a competition among matching classifiers to determine which ones will become active.
3. For each active classifier, generate one message for the new message list.
4. Replace the current message list with the new message list.
5. Process the current message list through the output interface to produce system output.
6. Return to step 1.

Two important aspects of the performance system are worth noting here. Firstly, the system is highly parallel. Many classifiers can be active simultaneously. Since different classifiers match different subsets of messages, the classifiers can be thought of as building blocks which can be activated in many combinations to represent a variety of situations. Secondly, matching classifiers must compete to become active. This competition makes it possible to avoid imposing any consistency requirements on posted messages, and allows the system to insert new rules smoothly without disrupting existing capabilities. Classifiers are treated as tentative hypotheses about the effects of posting a message given the current conditions. Each of these 'hypotheses' is repeatedly tested according to the system's experience with the environment.

The competition mechanism assumes that a reliable assessment of the plausibility of each

hypothesis is available. The credit assignment system is responsible for computing those assessments. It is difficult to assign credit for successful problem-solving behavior in a system that uses many rules over several timesteps to generate behavior. The difficulty is even more pronounced when overt feedback from the environment is intermittent or rare. The only realistic strategy for classifier systems is to evaluate performance for behavioral sequences in local terms for each classifier involved. The most straightforward approach is to rely on a simple reinforcement principle: strengthen a hypothesis whenever the associated message leads to a favorable or rewarding situation. A considerable amount of theoretical work in psychology, adaptive control, and machine learning has used this principle as a starting point for understanding how to solve difficult credit-assignment problems. One computational approach designed for classifier systems is the 'bucket brigade' algorithm (Holland *et al*., 1986), one of many algorithms from the reinforcement learning literature that are suitable for this purpose. (*See* **Reinforcement Learning: A Computational Perspective**)

Credit assignment is only one of several learning mechanisms that are needed for a successful inductive process. It is also necessary to have a mechanism that can generate plausible new hypotheses. For rule-based systems this means generating new rules as candidates to replace existing rules that have not been particularly useful. In the classifier system framework, the rule discovery system is responsible for generating plausible new classifiers. 'Plausibility' in this context is tied to the notion of 'building blocks' mentioned in the discussion of parallelism above. The simple syntax used in classifier conditions makes it straightforward to view classifiers as strings composed of readily identifiable parts. One easily-specified and useful set of parts can be defined as follows. In each classifier condition and action, there are many 'components' which can be identified by specific combinations of symbols at designated positions. For example, the condition `0#011### ... 1#` begins with a `0` in position 1 and a `#` in position 2. This combination defines a template, or 'substring schema', which can be denoted by the string `0#****** ... **` (where the symbol `*` indicates positions not involved in the definition). Any condition beginning with this two-symbol prefix contains the corresponding substring schema as one of its parts. The utility of such a part can be estimated by the average strength of the rules containing that part. A new rule can be considered 'plausible' to the extent that it is composed of parts, or building blocks, having above-average utility. Thus, the rule-discovery process can generate plausible new rules by favoring above-average building blocks in the construction of new rules.

Note that every condition or action of length k uses 2^k distinct building blocks. Even given a moderately sized population of classifiers, it is computationally infeasible to evaluate explicitly and use information about all of the building blocks in all of the classifier conditions and actions. It is possible, however, to devise procedures that implicitly make use of this information. The mechanism used most often for this purpose in classifier systems is a 'genetic algorithm'. A genetic algorithm is a general-purpose search procedure that uses sample-based induction (Holland *et al*., 1986) to conduct the search. The algorithm repeatedly selects a sample of rules (the 'parents') from the population and recombines their building blocks to construct new rules (the 'offspring'). The new elements are constructed using genetic operators such as recombination and mutation. The selection criterion for parents is biased to favor high-strength classifiers, and new classifiers replace low-strength classifiers in the current population. (*See* **Evolutionary Algorithms**)

REPRESENTATIONS IN CLASSIFIER SYSTEMS

The starting point for representing knowledge in the classifier system framework is the use of simple message-passing rules as primitive elements. Each rule condition specifies a basic equivalence class or category of messages that match the condition. Because of parallelism and recombination, higher-level representations built using these primitives have an inherently composite nature. Rather than construct a syntactically complex representation of a symbolic concept that might be difficult to use or modify, a classifier system is designed to use clusters of rules as representations. The implementation of this approach to representing knowledge in classifier systems relies on principles and mechanisms operating at two levels of organization: rules and rule clusters. Each rule offers a range of representational power that is determined by the way messages are matched, encoded and processed. The representational power of rule clusters is determined by the way rules are organized in relation to each other and by their competitive and cooperative interactions. These issues are discussed briefly below.

Rule Syntax, Message Encoding and Matching

An input message is a string of feature values or primitive attributes describing some state configuration in the environment. Condition–action rules are a convenient way to represent states and transitions between states in the environment, generate predictions, and specify simple procedures. Rule conditions provide generalizations of messages that correspond to useful regularities and attribute-based concepts. These generalizations are the lowest-level building blocks available for constructing new rules. The generalizations that are possible in a classifier system depend on the classifier rule syntax and on the way messages are encoded and matched.

In the basic classifier 'language', conditions are fixed-length ternary strings that correspond to generalizations given by simple conjunctions of attribute values. Because the syntax is so simple, no extra mechanisms are needed to specialize or generalize these conditions. Specialization only requires changing a # to a 0 or 1, while generalization is accomplished by changing a 0 or 1 to a #. Changes of this kind are routinely generated by the genetic algorithm in the rule discovery system. Note, however, that simple classifier conditions of this kind cannot be used to express arbitrary, general relationships among structured attributes. There are two ways to increase the expressive power of these classifier conditions.

First, by using multiple conditions and multiple rules, it is possible to represent concepts involving the logical conjunction and disjunction of simple clauses. A classifier with multiple conditions can be activated only when each condition matches a message on the message list. The posting of that classifier's message therefore indicates an input configuration in which the conjunction of those conditions is true. When two or more classifiers have different conditions but identical actions, the posting of that particular message indicates an input configuration in which at least one of the conditions is true (disjunction) Additional expressive power is obtained by allowing some conditions to be satisfied when no matching message is on the list. This provides a way to represent logical negation, making it possible to represent arbitrary Boolean expressions.

The second way to increase the expressive power of individual classifiers is to use more powerful encoding schemes for messages. In the simplest encoding, each message bit corresponds to a single attribute–value pair or predicate. This encoding is adequate for categories defined by a set of critical features whose presence or absence is mandatory for category membership. More sophisticated encodings support generalizations about the range of ordinal values and disjunctions of nominal values. These encodings provide capabilities that compare favorably to the primitive language constructs used in many symbolic learning paradigms. Moreover, the basic building blocks supporting these generalizations can be easily recombined and otherwise manipulated by the genetic algorithm and other local, syntactic rule modification algorithms.

Even with more expressive encodings, however, there are limits to what can be represented with conditions using the standard syntax. For example, although continuous input values can be represented as bit strings, classifier conditions can only represent a subset of the generalizations that may be useful or required. Moreover, the standard matching algorithm does not allow for generalizations that require variable binding or parametrization. This means that it is not possible to express simple relations between subfields in a single condition or across multiple conditions. In order to overcome these limitations, some classifier system implementations have utilized more sophisticated symbolic expressions in rule conditions. This can be problematic, though, because it is not always clear what the buildings blocks are in these complex representations. One of the important open research questions is how to increase the expressive power of classifier conditions without sacrificing the efficiency and well-chosen building blocks characteristic of the basic classifier language syntax.

Multiple Rules and Default Hierarchies

As noted above, the expressive power of rule conditions can be enhanced by using a set of rules to represent disjunctive clauses in the description of an attribute-based concept. This is a form of implicit cooperation among rules, whereby different subsets of rules are responsible for different aspects of the overall representation. Many forms of cooperative interactions among rules are possible.

For example, another useful form of implicit cooperative interaction is tied to the competition mechanism. The competition for the right to post messages is usually implemented with a bias towards selecting the 'specific' rules whose conditions contain the most detail about the current situation. This makes it possible for rules to become organized into 'default hierarchies'. The simplest example of a rule-based default hierarchy consists

of two rules. The first ('default') rule has a relatively general condition and provides an action that is sometimes incorrect. The second (exception) rule is satisfied only by a subset of the messages satisfying the default rule, and its action generally corrects errors committed by the default. That is, the exception rule uses additional information (its more specific condition) to distinguish situations that lead the more general default rule astray. When the exception wins the competition it prevents the default from making a mistake and losing strength under the credit assignment mechanism. There is consequently a kind of symbiotic relationship between the two rules. Note that the default may have other exceptions, and each exception may, in turn, have exceptions, resulting in a hierarchy of interactions. Default hierarchies are an important feature of classifier systems from the standpoint of cognitive modeling. Classifier systems with default hierarchies have been used to model a wide variety of conditioning phenomena (Holyoak *et al*., 1990) and human performance on simple discrimination tasks (Riolo, 1991).

Another useful implicit interaction among rules is based on patterns of conditions and actions. If the action posted by rule R_1 matches the condition of another rule R_2, then the activation of R_1 will tend to result in the activation of R_2. In this case the two rules are said to be 'coupled'. Since rule coupling implies sequential activation, classifier systems can use representations in which the constituent rules are activated over more than one match–compete–post execution cycle. This is the first step needed to go beyond simple reactive behavior to a mode in which internal information processing can be used to generate responses. Only a few classifier systems have exploited implicit coupling for cognitive modeling purposes. Booker (1988) describes a system that learns a simple internal model in which the goal-relevance of environmental states can be retrieved from memory using internal messages.

Complex Knowledge Structures

The coupling mechanism becomes even more useful when the rule interactions are organized explicitly. Particular bits incorporated into a rule's condition – such as a suffix or prefix – can be used as a kind of identifier or address, called a 'tag'. Messages can be directed to a rule explicitly by incorporating the appropriate tag into those messages. If there are several rules sensitive to the same tag, then they will be activated together as a cluster. Consequently, any rule that contains that tag in its action part will be explicitly coupled to the entire cluster. Tags are the building blocks for representing sequences and associations. Because tags are simple parts of messages and rules, associations among rules can be constructed and modified with the standard repertoire of rule discovery mechanisms.

Moreover, a tag can be given semantics as a label indicating the origin (e.g. the input interface) or destination (e.g. the output interface) of a message. By identifying tags with semantic content, we can impose a hierarchical organization on classifier representations. Tags become identifiers for relationships within and between levels in a hierarchy, and for relationships between hierarchies. In principle, the use of semantically useful tags to couple rules makes classifier systems a powerful framework for representing complex knowledge structures. For instance, it has been shown (Forrest, 1991) that the knowledge contained in a standard semantic network description (e.g. KL-ONE or NETL) can be mapped into a set of classifiers that support the same information-retrieval operations. It remains to be seen whether these kinds of complex knowledge structures can be learned by a classifier system as a result of its experiences in an environment. However, experiments have demonstrated that classifier systems can learn simple associative knowledge structures (Riolo, 1990; Stolzmann and Butz, 2000). (*See* **Semantic Networks**)

PROBLEM SOLVING USING CLASSIFIER SYSTEMS

Problem solving in the classifier systems framework differs from more conventional approaches to problem solving in that a strong emphasis is placed on flexibly modeling the problem-solving context. The rationale for this emphasis on flexible problem representations is that cognitive systems are often confronted with problems that are poorly defined – that is, various aspects of the initial problem specification may be unknown or partially known. Instead of relying on stand-alone procedures for reformulating such problems, classifier systems can use building blocks, together with the simultaneous activation and combination of multiple representations, to recategorize the problem components. In this way, the system conducts a search for solutions to a problem both in the problem space and in the space of alternative problem representations.

The starting point for this approach is a good model that allows for prediction-based evaluation of the knowledge base, and the assignment of credit

to the model's building blocks. This makes it possible to modify, replace, or add to existing rules via inductive mechanisms such as the recombination of highly rated building blocks. After repeated experiences solving instances of a problem, the inductive mechanisms generate rules which are specialized or generalized as needed to adequately represent the typical elements of the problem space. Maintaining a varied repertoire of useful specific and general rules is essential to achieving problem-solving flexibility. When a novel situation is encountered, there is some chance that it will be matched by general rules that provide some useful, though perhaps imperfect, guidance about how to proceed. The simultaneous activation of specific and general rules defines an implicit default hierarchy in which default expectations can be overridden whenever a specific exception occurs. Novel situations can also be handled by activating associations that suggest recategorizations of structured concepts and relations. By coordinating multiple sources of knowledge, hypotheses and constraints in this way, problem solving can proceed opportunistically, guided by the integration of converging evidence and building on weak or partial results to arrive at confident conclusions.

In simple cases, problem solving can be achieved by learning a direct mapping between inputs and outputs. A large body of research within the reinforcement learning paradigm has been devoted to solving Markovian decision tasks using this strategy, and classifier systems can achieve comparable results. However, classifier systems used in this way are simple reactive systems that do not require any cognitive processing beyond basic categorization. One particularly sophisticated problem-solving mechanism that has been implemented in a classifier system is based on Baum's (Baum and Durdanovic, 2001) approach, which views rule clusters as 'post-production systems'. The system learns algorithms that solve instances of Rubik's cube and arbitrary block-stacking problems. (*See* **Markov Decision Processes, Learning of**)

SUMMARY

Classifier systems can be thought of as connectionist systems that use rules as the basic epistemic unit. Using simple rules in this way makes it possible to enjoy the advantages of distributed representations, and at the same time to represent nontrivial symbolic concepts and employ flexible problem-solving mechanisms. Consequently, classifier systems have the potential to occupy an important middle ground between the symbolic and connectionist paradigms. In order to realize this potential, more work must be done to understand how classifier systems might dynamically construct and modify the kinds of multifaceted representations described here. Research on small systems and simple problems has been a promising first step towards that goal.

CONTENTS

A collection of interacting autonomous entities, called 'agents', may be capable of creating complex cognitive processes and behaviors, which could not be achieved by a single agent, without the need for outside centralized coordination or control.

INTRODUCTION

Several theories of cognition, most notably Minsky's 'society of mind', posit that intelligent behavior can be seen as the result of the interaction of simple processes. Minsky states: 'Very few of our actions and decisions come to depend on any single mechanism. Instead, they emerge from conflicts and negotiations among societies of processes that constantly challenge one another' (Minsky, 1986). The central tenet of such theories of cognition and behavior is that complex system-level behavior can emerge from the interaction of multiple, possibly numerous, components.

A canonical example of such emergence is the function of the human brain. The brain itself is made up of billions of simple neurons organized into a massively connected network (Nicholls *et al*., 2001). In general, an individual neuron acts as a comparatively simple processing unit that receives signals from a set of neighboring input neurons, and under appropriate conditions transmits signals to a set of its neighboring output neurons. From this network of interacting neurons emerges the complexity of human cognition and behavior. No single neuron or subset of neurons is responsible for this complexity; rather, it is the result of their interactions.

Several disparate research fields are actively involved in investigating the principles of interaction among a collection of components. These include cognitive science, computer networks, distributed systems, artificial life, collective robotics, multi-agent systems, as well as others. The rest of this article aims to explain conceptually, and show through examples, how complex cognition and behavior can emerge from the interaction of individual components and how those emergent behaviors can be used in a variety of ways.

AGENTS

The term 'agent' has become a popular choice for a nontrivial component of a system with many interacting components that result in emergent behavior. Precisely defining an agent remains difficult, as agents come in many guises. An agent could be a piece of software, a specific computer on the Internet, a mobile robot, or even a person. In general, an agent is an autonomous entity, situated in an environment, and equipped with some degree of intelligence.

Being 'situated' places a number of constraints on how the agent can operate (Brooks, 1991; Maes, 1990). It implies that the agent has some means of sensing its environment, but the sensing may be limited and inaccurate. For example, a mobile robot may be situated in an office environment and have a means of sensing the distance to nearby objects; thus its sensing capabilities are both limited and prone to error and noise. Situatedness also implies an interaction with the environment. Thus, the same robot may be able to drive around, affecting the environment with its placement, and perhaps move objects, intentionally or otherwise. Conversely, the actions of a situated agent are influenced by the environment. The objects the robot encounters affect what it senses and how it behaves. Another implication of being situated is that an agent is constrained by environmental

characteristics. For example, a mobile robot cannot drive through walls nor can it avoid falling if it drives down a set of stairs. Finally, the agent's characteristics – its computational, sensory, and actuation capabilities – influence how it interacts with its environment, which includes other agents.

SOCIETIES OF AGENTS

A collection of interacting agents is referred to as a 'society of agents'. Using this metaphor, a brain is a society of agents, as is a team of mobile robots cooperating on a task. Such agent societies are interesting for a number of reasons. First, for certain tasks and/or environments, a society of agents is the only viable or efficient solution. Second, even for tasks that can be handled by an individual agent, there may be more efficient, adaptive, and robust solutions performed by a society of agents.

A society of agents may consist of a homogeneous or heterogeneous collection of agents. In a homogeneous society, all agents are identical, while in a heterogeneous society, agents may have different characteristics. The variations in capabilities may result in hierarchies, specializations, or various other forms of social organization. Consequently, heterogeneous societies are generally more complex to control but are typically capable of a larger set of tasks.

The human immune system (Segel and Cohen, 2001) is an excellent example of a society of heterogeneous yet simple agents. It is capable of protecting the body against infection and invasion by foreign substances of all kinds, whether bacteria, virus, parasite, etc., which can be viewed as a very large set of different defensive 'tasks' to be accomplished. Each agent in this society is very specific, but the large number of agents of each kind and in total, combined with the ability to generate additional agents when needed, produces an unprecedented defensive functionality.

AGENT INTERACTION

Agents situated in a shared environment have ample opportunity to interact, by directly sensing each other, communicating, coordinating actions, and even competing. The shared environment in which the interactions take place may be an abstract data space, the physical world, or anything in between. A society of software agents may interact through a personal computer or even the entire Internet. Likewise, a society of mobile robots may interact in an office environment or on the surface of Mars. Furthermore, multiple environment types may be spanned in a single multi-agent system. For example, in multi-robot systems using behavior-based control (Matarić, 1994), individual robots are controlled by a collection of internal agents that interact through a computational environment, while the society of physical robots that contains them interacts in and through the physical world. The nature of the interactions in a society of agents depends upon such factors as agent capabilities, environmental constraints, and desired local and global behavior.

The spectrum of agent interaction is broad. At one end are methods that employ large numbers of simple, identical agents, connected together in patterns which lead to useful computation as a result of data flow through the system. At the other end are systems of complex, specialized agents which explicitly negotiate for task assignments and resources. Mechanisms for agent interaction can be broadly classified as fitting into the following, often overlapping categories: interaction through the environment, interaction through sensing, and interaction through communication. Each is described in turn.

Interaction Through the Environment

The first mechanism for interaction among agents is through their shared environment. This form of interaction is indirect in that it consists of no explicit communication or physical interaction between agents. Instead, the environment itself is used as a medium of indirect communication. This is a powerful method of interaction that can be utilized by very simple agents with no capability for complex reasoning or for direct communication.

Stigmergy is an example of interaction through the environment employed in a variety of natural insect societies. Originally introduced in the biological sciences to explain some aspects of social insect nest-building behavior, stigmergy is defined as 'the process by which the coordination of tasks and the regulation of constructions does not depend directly on the workers, but on the constructions themselves' (McFarland, 1985; Holland and Melhuish, 1999). The notion was originally used to describe the nest-building behavior of termites and ants (Franks and Deneubourg, 1997). It was shown that the coordination of building activity in a termite colony was not inherent in the termites themselves. Instead, the coordination mechanisms were found to be regulated by the task environment, in this case the growing nest structure. A location on the growing nest

stimulates a termite's building behavior, thereby transforming the local nest structure, which in turn stimulates additional building behavior of the same or another termite.

Examples of artificial systems in which agents interact through the environment include distributed construction (Bonabeau *et al*., 1994), sorting (Deneubourg *et al*., 1990), clustering (Beckers *et al*., 1994), optimization problems (Dorigo *et al*., 1999), object manipulation (Donald *et al*., 1993), analysis of network congestion (Huberman and Lukose, 1997), and phenomena such as the spread of computer viruses (Minar *et al*., 1998).

Interaction Through Sensing

The second mechanism for interaction among agents is through sensing. As described by Cao *et al*. (1997), interaction through sensing 'refers to local interactions that occur between agents as a result of agents sensing one another, but without explicit communication'. This form of interaction is also indirect, as there is no explicit communication between agents; however, it requires each agent to be able to distinguish other agents from miscellaneous objects in the environment.

Interaction through sensing can be used by an agent to model the behavior of another agent or to determine what another agent is doing in order to make decisions and respond appropriately. For example, flocking birds use sensing to monitor the actions of other birds in their vicinity in order to make local corrections to their own motion. It has been shown that effective flocking results from quite simple local rules followed by each of the birds in the society (flock), responding to the direction and velocity of the local neighbors (Reynolds, 1987). Such methods of interaction through sensing can be found in use in mobile robot flocking, following, and foraging (Matarić, 1995), robot soccer (Werger, 1999), robot formations (Fredslund and Matarić, 2002), and simulations of behaviorally realistic animations of fish schooling (Tu and Terzopoulos, 1994). Other applications of interaction through sensing include human-like physical or visual interaction between physical agents (Murciano and del R. Millan, 1996; Michaud and Vu, 1999; Nicolescu and Matarić, 2000), including the ability to understand and influence the motives of other physical agents (Breazeal and Scassellati, 1999; Ogata *et al*., 2000).

Interaction Through Communication

The third mechanism for interaction among agents is through direct communication. Unlike the first two forms of interaction described above, which were indirect, in interaction through communication agents may address other agents directly, either in a system-specific manner or through a standard agent communication protocol such as KQML (Finin *et al*., 1996) or CORBA (Vinoski, 1997). Such agent-directed communication can be used to request information or action from others or to respond to requests received from others. Communication may be task-related rather than agent-directed, in which case it is made available to all (or a subset) of the agents in the environment. Two common task-related communication schemes are blackboard architectures (Schwartz, 1995; Gelernter, 1991) and publish/subscribe messaging (Arvola, 1998). In blackboard architectures, agents examine and modify a central data repository; in publish/subscribe messaging, subscribing agents request to receive certain categories of messages, and publishing agents supply messages to all appropriate subscribers. In some domains, such as the Internet, communication is reliable and of unlimited range, while in others, such as physical robot interaction, communication range and reliability are important factors in system design (Arkin, 1998; Gerkey and Matarić, 2001).

FROM AGENT INTERACTION TO COGNITION AND BEHAVIOR

Given a society of interacting agents, how is complex system-level behavior achieved? Interaction among the society members is not sufficient in itself to produce an interesting or useful global result. In order for the interacting agents to produce coherent global behavior, there must be some overarching coordination mechanism that appropriately organizes the interactions in both space and time.

There are many coordination mechanisms by which to organize the various interactions among agents in order to produce coherent system-level behavior. Self-organization techniques are based on a 'set of dynamical mechanisms whereby structures appear at the global level of a system from interactions among its lower-level components. The rules specifying the interactions among the system's constituent units are executed on the basis of purely local information, without reference to the global pattern, which is an emergent property of the system rather than a property imposed upon the system by an external ordering influence' (Bonabeau *et al*., 1997). Methods such as genetic algorithms (Holland, 1975), machine learning techniques such as reinforcement learning (Sutton and Barto, 1998), and distributed constraint

satisfaction (Clearwater *et al*., 1991) can all be used to design agents and their interactions such that the resulting behavior meets desired system-level goals. Agents may also explicitly negotiate with each other for resources and task assignments in order to coordinate their behavior.

One such approach, employed in human as well as synthetic agent societies, is 'market-based' coordination, where individual agents competitively bid for tasks, which they must either complete or report as broken contracts. Auctions are a common coordination method in market-based techniques. In auctions, the most appropriate agents are continuously selected and (re)-assigned to various non-terminating roles (Tambe and Jung, 1999; Werger and Matarić, 2000). In contrast, more symbolic negotiation protocols based on distributed planning involve multiple stages, in which agents first share their plans, then criticize them, and finally update them accordingly (Bussmann and Muller, 1992; Kreifelt and von Martial, 1991; Lesser and Corkill, 1981). Game-theoretic approaches to negotiation have proven effective in situations where agents may be deceptive in their communication (Rosenschein and Zlotkin, 1994). In most complex models of negotiation-based coordination, agents reason about the beliefs, desires, and intentions of other agents, and influence those using specialized techniques (Brandt *et al*., 2000).

CONCLUSION

As was stated earlier, in systems where complex global behavior emerges from the interactions of a society of simple agents, as the complex function of the brain emerges from the interactions of a large society of neurons, the resulting complexity cannot be attributed to any single agent but instead to the interaction of all agents. Agents and their, often local, interactions with each other and with the environment generate the resulting global behavior of the system – no additional external coordination mechanism is needed. Interaction in the agent society can take place through several mechanisms, including interaction through the environment, through sensing, and through communication. In lieu of a central coordinator, a society of agents coordinates its interactions to produce desired system-level behavior through such mechanisms as self-organization, machine learning techniques, or more complex negotiation mechanisms.

The notion that complex behavior can arise from the interaction of simple agents has powerful and far-reaching implications. Many fields, ranging from biology, to artificial intelligence, computer networking, and business management, all find inspiration and motivation from these principles.

Computability and Computational Complexity

Introductory article

Patrick Doyle, Stanford University, Stanford, California, USA

CONTENTS

Processes that can be specified precisely can be formalized as algorithms. The theory of algorithm analysis determines important properties of these algorithms, such as the resources they consume, and the theory of computational complexity categorizes the problems these processes solve according to those properties, revealing the fundamental limitations of computation.

MEASURING THE DIFFICULTY OF INFORMATION PROCESSING PROBLEMS

The major tasks of a computational system are the retrieval, processing, and presentation of information. The processing of information involves some set of operations designed to transform it from one form into another. A spreadsheet program may add up a column of numbers to determine a month's expenses. A mathematics package might compute the area under a curve. A buyer of a new car might analyze several alternative models to decide which has the best combination of features, safety, speed, and cost.

Some of these tasks are simpler than others. Most people would find it easier to add up a column of numbers than to compute the area under a curve. There are also usually many different ways to solve a particular problem, but some are preferable to others because they consume fewer valuable resources.

In order to solve a problem, there must be a procedure that will generate the answer to the problem, and that procedure must be executed. The branch of computer science known as the theory of algorithms deals with the analysis of such procedures, and attempts to find meaningful measures for comparing one procedure with another. The study of computational complexity extends this theory by organizing problems into categories according to the difficulty of the procedures needed to solve them.

WHAT IS AN ALGORITHM?

In order to solve a problem, some organized sequence of operations must be performed – some sort of procedure, process, routine, or recipe. These terms all capture an intuitive notion of algorithm, but in order to apply formal analysis, it is necessary to be more precise about just what such an activity entails.

An algorithm is a finite sequence of effective and exact instructions for transforming any set of appropriately expressed pieces of information (the input) into another set of pieces of information (the output) in a finite amount of time.

Consider the problem of sorting a hand of playing cards. The goal is to sort the cards from lowest rank to highest. One algorithm to solve this problem works as follows: given a hand of cards, go through the hand and find the card with the lowest rank (if there is more than one, take the first one). Place that card on top of a separate pile. Repeat this process until no cards are left in the hand. Now the pile contains the sorted cards.

This procedure, while inefficient, meets the criteria of an algorithm. The inputs and outputs are well defined as sequences of playing cards. The instructions are effective for a human being to

execute, since they involve moving cards in a hand. They are also exact, since they precisely and unambiguously explain what to do next in each case. The algorithm is guaranteed to terminate since there are only finitely many cards in a hand, and at each repetition of the loop there is one fewer card to examine.

The particular language in which an algorithm is written does not matter much. Generally, in computer science one finds algorithms described in formal programming languages that are designed for this purpose. However, so long as it meets the above requirements, it does not matter whether the algorithm is written as a flowchart, a Java program, English prose, or a Japanese haiku. It is only important that the environment in which the algorithm is to be executed can interpret and follow its instructions exactly and unambiguously. The above description of the card sorting algorithm, for example, is sufficient for an English-speaking human being, but not for a computer.

There are several natural questions about algorithms that have important and surprisingly complex answers. First: does every problem have an algorithm that will solve it? Second: are some algorithms 'better' than others for solving a certain problem? Last, and most practically: is there a way to measure the 'goodness' of an algorithm? The modern theory of computation is a result of the attempt to answer these questions.

COMPUTABILITY AND DECIDABLE PROBLEMS

In the early twentieth century, before the first electronic computers were built, several different formal models of computation were proposed. One of the simplest, and the one most used in computer science today, is the Turing machine, introduced by the mathematician Alan Turing in 1936. (*See* **Turing, Alan**)

A Turing machine is an imaginary mechanical device with three components: an infinitely long tape of paper, divided into cells that may each hold one of a finite set of symbols; a read–write head that can read and modify the contents of a cell; and a controller that may be in any of a finite set of states. The machine's behavior is directed by a fixed set of rules (the machine's program) that depend only on the current state and the symbol under the read–write head. The machine operates by repeatedly cycling through four steps:

1. Examine the symbol in the current cell.
2. Change the internal state (possibly to the same state it already occupies).
3. Write a symbol in the cell (possibly the same symbol already there).
4. According to the rules, move the head one cell to the left or to the right, leave it where it is, or halt the computation.

Although a Turing machine is a simple device, it has all the power and generality of a modern computer. That is, any problem that a modern computer can solve, a Turing machine could also solve. The Church–Turing thesis asserts that the Turing machine (or any equivalent model) exactly captures the notion of 'effective computability'.

A computable function is one for which there is an algorithm that will, for any input it is designed to understand, produce the correct output in a finite amount of time. Thus, according to the Church–Turing thesis, a Turing machine can solve any problem for which an algorithm can be provided. This thesis is only a hypothesis, however. It cannot be proven, since the notion of algorithm is not mathematically rigorous. The Church–Turing thesis says that our intuition about computability is captured by these formalisms.

Because their operations are so simple, Turing machines are frequently used in proving properties of computation. One important area of research into these properties deals with a special class of problems called decision problems. These are problems that have only 'yes' or 'no' answers. Any problem can be cast as a decision problem, and it is often simpler to prove properties of the decision version of a problem than to prove properties of the original problem directly. A decision problem may be 'decidable', 'semi-decidable', or 'undecidable'.

A problem is decidable if there exists some algorithm that is guaranteed either to accept (with a 'yes') or reject (with a 'no') any instance of the problem. Many obvious problems have decidable algorithms. Even the game of chess is a decidable problem: since there are only finitely many games (assuming no boundless repetition of useless moves), it is possible to find a strategy that will play perfectly just by exhaustively examining every possible game. The amount of computation is entirely impractical, but in principle, questions such as 'is white guaranteed to win in this position?' can be answered.

Semi-decidable problems have algorithms that are guaranteed to accept all 'yes' instances. If the instance is a 'no', the algorithm may reject the instance, or it may run forever without being able to determine that the instance should be rejected. An

example of a semi-decidable problem is the problem of determining whether a given number is the difference of two primes. If a problem has no algorithm that can be guaranteed to accept all 'yes' instances, it is said to be fully undecidable. Many important questions, even some about algorithms themselves, are undecidable.

GÖDEL'S INCOMPLETENESS RESULTS AND THE ALGORITHMIC NATURE OF COGNITION

At the beginning of the twentieth century, the mathematician David Hilbert posed the problem of finding an algorithm that could determine whether any mathematical proposition, expressed in the language of logic, was true or false. This question remained open until 1931, when the mathematician Kurt Gödel published his famous 'Incompleteness Theorem'. This theorem states that, in any sufficiently powerful logical system such as mathematics, there are propositions that cannot be proved true or false within the system itself. Gödel showed that mathematics is fundamentally incomplete because there are true propositions in mathematics that cannot be proved using the axioms of mathematics. Thus Hilbert's algorithm could not exist.

When Alan Turing introduced the Turing machine and its definition of computability in 1936, he used a version of Gödel's argument to show that there are certain problems that are not computable, in the sense that there exist no algorithms that can compute their solutions. Specifically, Turing proved that no Turing machine could solve the so-called halting problem, a decision problem that asks whether a given Turing machine will eventually halt on a given input.

The proof can be described informally. Suppose there does exist a Turing machine $D(M, x)$ that decides whether Turing machine M would halt when run on input x. Now construct a Turing machine $N(M)$ that takes a machine M as input. N operates as follows. First, $N(M)$ runs $D(M, M)$; that is, N uses D to decide whether machine M would halt when fed its own design as its input. If D replies that M would halt on input M, N enters an infinite loop. If D replies that M would never halt on input M, N halts.

What happens if N is run on itself? If D says that N would halt on input N, N actually enters an infinite loop. If D says that N is would not halt, N actually halts. This is a contradiction of the assumption that D can correctly decide the halting problem, so that assumption must be false. No such machine D can exist.

These remarkable results have led to philosophical debates about algorithms and their relationship to human information processing. Do human beings think in ways that can be expressed in algorithms, or is there some other kind of computation taking place? If humans do use algorithms, are they therefore bound by the same limitations as computers, and logically incapable of performing certain kinds of tasks? (*See* **Artificial Intelligence, Gödelian Arguments against**)

Several prominent philosophers have argued against this. Their arguments range from John Searle's 'Chinese room' argument that computation cannot produce understanding, to Roger Penrose's hypothesis that the brain has certain quantum-mechanical properties that allow it to function in ways no computer could mimic. These arguments have not convinced many computer scientists, and the branch of computer science known as artificial intelligence is devoted to building computers with abilities that equal or exceed those of human beings. (*See* **Artificial Intelligence, Philosophy of**; **Chinese Room Argument, The**; **Computation, Philosophical Issues about**)

ORDER OF MAGNITUDE AND COMPLEXITY MEASURES IN SPACE AND TIME

Given a problem together with an algorithm for solving it, the next task is to analyze the resources that the algorithm consumes. With each instance of the problem, we associate a 'size', which is the number of symbols required to describe the instance. The resources the algorithm consumes when operating on an instance of the problem can then be expressed in terms of the size of the instance. Generally the resource of interest is either the time it takes to run or the space the algorithm needs to perform its computations.

Recall the simple algorithm for sorting a hand of playing cards. It looks for the highest-ranked card and moves it to a separate pile. It repeats this process with each succeeding card until all the cards are sorted. If there are n cards in the hand, the first card must be compared against all $(n-1)$ remaining cards, the second card against $(n-2)$ cards, and so on down to the last two cards, which require only one comparison. This approach requires $(n-1)+(n-2)+\ldots+1=(n^2-n)/2$ comparisons altogether.

To determine how much time this algorithm would actually take would require detailed information about the computer on which it is run, including how much time it takes to read the input,

make a comparison, and so on. Ordinarily algorithm analysis is not interested in this level of detail; it is enough to determine the rate of growth, or order of growth, of the algorithm, a more abstract measure that will be identical on all machines that share the same fundamental principles of operation.

Several simplifying assumptions are made to find the algorithm's order of growth. First, constant-time overhead costs are ignored. Only operations that grow in number as the size of the input grows are considered. Second, only the dominant term ($\frac{1}{2}n^2$ in the above example) in the number of operations is used. As the size of the input grows, this term overwhelms the others: when $n = 10$, $\frac{1}{2}n = 5$ and $\frac{1}{2}n^2 = 50$; when $n = 1000$, $\frac{1}{2}n = 500$ but $\frac{1}{2}n^2 = 500\,000$. Finally, any coefficients on the dominant term are ignored, since such constants are less important than the overall rate of growth. This leaves n^2 as the term of interest. This order-of-growth bound is written as $O(n^2)$. This O notation is commonly used to describe the worst-case complexity of an algorithm, which is the amount of effort it will require on the most difficult possible input.

This formulation makes it straightforward to compare algorithms without having to consider the details of a particular computer or minor factors in the algorithm that do not have a significant effect on its overall efficiency. For the card-sorting problem, for example, there are many known algorithms, and the most efficient comparison algorithms have an order of growth of $O(n \ln n)$, a considerable improvement over $O(n^2)$ for large hands.

PROBLEM REDUCTION AND COMPLEXITY EQUIVALENCE CLASSES

The kind of analysis used in the previous section is helpful when examining a single algorithm, or comparing several algorithms, but the theory of computational complexity is concerned with understanding fundamental distinctions between classes of algorithms. There are two especially important classes, known as P and NP, which intuitively divide problems into 'easy' and 'hard'.

P is the class of all decision problems that take an amount of time that is polynomial or better in the size of the input, such as $O(n \ln n)$, $O(n^2)$ or $O(n^{357})$. These problems are regarded as 'easy' or 'tractable' because the amount of time grows relatively slowly with the size of the input.

The other important basic complexity class is called NP, for nondeterministic polynomial time. NP consists of decision problems whose answers can be verified in polynomial time. That is, given some instance of a problem and a guess for an answer, there is an algorithm that can check in polynomial time whether that guess is correct.

Clearly P is a subset of NP, since any problem that can be solved in polynomial time can have its solution checked in polynomial time. However, there are many NP decision problems for which no polynomial-time algorithm has been found: it is known how to check their solutions in polynomial time, but the best-known algorithms for solving them take exponential time, such as $O(2^n)$, or worse. These problems are in NP but seemingly not in P.

Many other complexity classes have been studied. Some deal with different time bounds: for example, EXP consists of problems solvable by exponential-time algorithms, and is a strict superset of NP. Others measure different resources, such as space. PSPACE is a class of problems whose algorithms are polynomially bounded (in the size of the problem instance) in the amount of space they use rather than in the number of operations they perform.

Proving that a decision problem is in a certain complexity class can be difficult. An important concept in complexity analysis is that of reducing one problem to another. In order to determine the complexity of some problem A, one can often show that it can be transformed into another problem B whose complexity is already known. Then the complexity of A is no worse than the complexity of B plus the complexity of turning instances of A into instances of B. Computer scientists have built up a large library of problems with known complexities, making this approach a common way to determine the complexity of a new problem.

NP-COMPLETE PROBLEMS AND THE 'P = NP' QUESTION

In 1971, Stephen Cook proved that there is a certain problem in NP, called the satisfiability problem, such that any other problem in NP can be reduced, in polynomial time, to an instance of it. Hence, if there is a fast algorithm for satisfiability, then there would be a fast algorithm for every problem in NP; conversely, if any problem in NP is intractable, then satisfiability is intractable.

The satisfiability problem can be stated informally as follows. Given a set of variables that can be either 'true' or 'false', and a formula combining

those variables with the logical connectors 'and', 'or' and 'not', is there an assignment to each variable that makes the entire formula true? For example, '((v_1 and v_2) or (v_2 and not v_3))' is true when either both v_1 and v_2 are true or when v_2 is true and v_3 is false. Any instance of any problem in NP can be rewritten, in polynomial time, as an instance of satisfiability.

Since Cook's proof, many other problems in NP have also been shown to have this property. Such problems are called NP-complete. They are, in a sense, the 'hardest' problems in NP, since finding a fast algorithm for any one of them would mean finding a fast algorithm for all problems in NP.

As mentioned above, the class P is contained within NP. Surprisingly, it is still not known whether P is actually equal to NP: that is, whether every problem in NP actually has a polynomial-time algorithm, and we have just not yet found one for any NP-complete problem.

If P = NP, then the huge range of important problems in NP for which no tractable algorithms have been found must all have tractable algorithms. After decades of research, however, it is widely believed that P $\neq$ NP. Many modern cryptographic systems base their security on the assumption that certain problems in NP are too difficult to solve in any reasonable span of time. Whether these classes are equivalent or not, a proof either way will have widespread implications for complexity analysis and algorithm design. This is one of the great unsolved questions in computer science.

COMBINATORIC EXPLOSIONS IN COMMON COGNITIVE TASKS AND THE USE OF APPROXIMATION ALGORITHMS

There are many important problems that are in NP. Many common cognitive tasks fall into this category, and yet human beings are able in their daily lives to perform tasks that are theoretically too difficult to solve in any reasonable time. One explanation is that humans perform a fundamentally different kind of computation than computers do. But there are some other possibile explanations.

A problem that is in NP may still be tractable in practice. There exist problems in NP for which algorithms with very low exponents are known; for example, $O(2^{0.00001n})$ might be an acceptable order of growth in most cases.

Another possibility is using a fast algorithm that provides an approximate solution to the problem. Often it is possible to find an algorithm in P that is guaranteed to provide solutions that are within some bounded range of the best solution. One well-known example is the travelling salesman problem, which provides a map of cities and the distances between them, and asks for the most efficient route for visiting all the cities. This problem is in NP, but there is a known polynomial-time algorithm that is guaranteed to find a route no worse than twice the length of the most efficient route. In many cases these approximation algorithms are good enough for practical needs, and they are useful when the exact algorithms are impractical.

STRONG COMPLEXITY CONSTRAINTS ON COGNITIVE MODELS

Complexity measures ordinarily assume that computations are being performed on a serial machine – that is, steps in the algorithm are executed one after another and one at a time. However, there are strong arguments that this is not a reasonable model of human cognition. One prominent argument, given by Jerome Feldman and Dana Ballard, is contained in what is called the '100-step rule'.

Simple cognitive tasks, such as identifying and naming an object, take human beings something on the order of half a second (500 ms) to perform. Since neurons, which are the basic computational components of the brain, take around 5 ms to act, the 100-step rule declares that these cognitive tasks cannot take more than about 100 sequential neuronal operations. (*See* **Computational Models of Cognition: Constraining**)

However, although a single neuron may take several ms to act, our brains contain many billions of neurons. Inspired by the structure of the brain, connectionist models of computation consist of many independent processors that are connected together, and that perform their computations in parallel, rather than serially. As long as the serial algorithm can be redesigned so that each one of the individual parallel processors has something to do in each time step, its speed can be improved by as many times as there are processors – in the case of the human brain, a parallel algorithm might run billions of times faster than a serial one. (See **Connectionist Architectures: Optimization**; **Connectionism**)

Although parallel algorithms can be more complex to design, the same tools that are used for ordinary serial algorithms can be applied. The complexity analyses on time and space are the same for

both parallel and serial systems, since a parallel machine only improves over a serial one by a constant factor, and such constant terms are ignored in order of magnitude analysis. However, in practice a linear speed-up of billions of times significantly increases the range of problems that can be solved.

SUMMARY

The design of algorithms is fundamental to computer science. The theory of algorithm analysis makes it possible to determine the amount of a resource that an algorithm requires. This allows the comparison of different algorithms to determine which are best in what situations. The theory of computational complexity has led to categorizing problems according to their difficulty, with the polynomial-time P problems being intuitively 'easy' and the nondeterministic polynomial-time NP-complete problems 'hard'. Many important problems have been shown to be NP-complete, but often it is possible to develop approximation algorithms that will give good, if not necessarily the best, answers to these problems. These concepts can be applied to algorithms that attempt to explain human brain processes. However, since the brain contains many billions of slow neurons operating in parallel, rather than a few fast processors, some argue that they may not be appropriate measures for human cognition.

Computation, Formal Models of

Introductory article

Arun Jagota, University of California, Santa Cruz, California, USA

CONTENTS

This is the study of abstract machines that compute, and of what they compute. This is also a study that characterizes what problems can be computed in principle, and which of the computable problems can be computed in practice.

THE MIND AS MACHINE?

For centuries, philosophers have wondered whether the mind is a 'mere' machine. We are no closer to answering this question now, at the beginning of the twenty-first century, than we were then. On the other hand, we have made tremendous progress in building and understanding *machines*. Now we are even able to put together ones that work in ways that might be considered somewhat intelligent. (*See* **Computational Models: Why Build Them?**)

THE BENEFITS OF A FORMAL MATHEMATICS OF COMPUTATION

The advances in building and understanding mind-like machines would not have occurred without the theoretical and algorithmic foundations provided by formal models of computation. Formal models of computation establish the limits of what can and cannot be computed. For a problem that is computable, complexity theory tells us whether it can be computed *efficiently* or not. Automata theory tells us what types of computations different types of machines can perform. Formal language theory presents to us a hierarchy of languages of increasing sophistication. A remarkable correspondence is found between the automata of automata theory and the languages of formal language theory. One of the most powerful abstract models of computation is the Turing machine. The study of its properties has led to major results, including the theory of NP-completeness.

Upto this point we have discussed only sequential models of computation. Parallel computation on the other hand can be much faster. Brain-inspired models of massively parallel computation have been developed and are now widely studied and used. A fundamentally different type of model of parallel computation – the quantum computer – is being studied in the abstract. Should it be realizable, it would radically transform the nature of computation as we know it today.

AUTOMATA

The word *automaton* really only means 'machine'. However, it is used to convey a sense that our interest lies in the computational properties of the machine, especially those that may be characterized formally. This section considers automata that recognize languages. Such an automaton reads a string of input symbols and returns 'yes' if the string is in the language associated with the automaton and 'no' if not.

There are three broad classes of automata: *finite-state automata (FSA)*, *pushdown automata (PDA)*, and *Turing machines (TMs)*. Finite-state automata are the simplest and, not surprisingly, the least powerful. Pushdown automata have more features; this makes them more powerful than finite-state automata. Turing machines have even more features; this makes them the most powerful. The power of a class of automata is measured by the richness of the class of languages associated with it (see the last paragraph of this section for more on this).

To appreciate the issues we need to understand what we mean by *features* in a machine, and what we mean by *power* of a machine. The features of a machine may be roughly classified as type of *memory*, and the *instruction set*. For instance, the only memory in a finite-state machine resides in its *states*. The only instruction that a finite-state automaton has is one that reads the next input symbol in the current state, and makes a transition to the next state. Both issues are illustrated in Figure 1.

In this diagram, let us imagine that we are presently in state A. This is the memory we are talking about. That is, the FSA *knows* that we are in state A. However, the FSA does *not* know how we got there; i.e. it does not remember states, if any, that were visited prior to reaching state A. Next, the machine reads the next letter in the input. If the letter is a 0, it moves to state B. If the letter is a 1, it moves to state C. These are the only types of actions this machine can take.

A pushdown automaton on the other hand has a more sophisticated memory mechanism – its memory resides not only in the present state it is in, but also in a *stack* that it is allowed to use. To make effective use of the stack, the PDA also has a richer instruction set, specifically, instructions to push items onto, and pop items off, the top of the stack as illustrated in Figure 2.

In this diagram, let us imagine that we are presently in state A. If the next letter in the input is a 0 and the top of the stack contains a Y, then we replace the Y on the top of the stack by Z and move to state B. If, on the other hand, the next letter in the input is a 1 and the top of the stack contains a W, then we replace the W on the top of the stack by X and move to state C. From this example, we see that the instructions of a PDA are more sophisticated than those of an FSA. It may appear that, like an FSA, the PDA also does not remember which states it visited before reaching A. This is not true. We can record these states in the stack. In fact, creative use of the stack is what endows a PDA with its added power over an FSA.

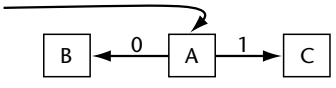

Figure 1. Finite-state automaton.

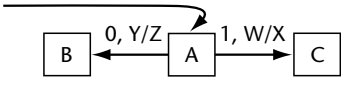

Figure 2. Pushdown automaton.

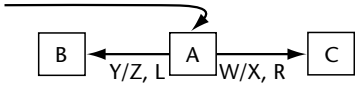

Figure 3. Turing machine.

One wonders whether a stack is enough to compute anything that is computable. Interestingly, it turns out that it is not. The Turing machine, which *is* enough, has an even more flexible memory, and instructions to go with it. A TM has a *tape*, which can be read in *both* directions. (By contrast, one can only push items onto, and pop items off, the top of a stack.) Figure 3 illustrates the use of this tape, especially the instructions that read, write, and use it. (*See* **Turing, Alan**)

In this diagram, let us imagine that we are presently in state A. Also, the tape head is on top of a certain cell on the tape (the tape is divided into cells). If the current cell – that the tape head is scanning – contains a Y, we replace this cell's content (Y) by Z, and move the tape head one cell to the left (this is what L means). If the current cell contains a W, we replace this cell's content by X, and move the tape head one cell to the right. From this example we see that, unlike an FSA or a PDA, a TM does not explicitly read the external input – it is assumed to be already on the tape before the TM execution is begun. We see that the TM has a richer feature set than a PDA, both in its memory and in its instructions.

Now one would hope that the automata with the richer feature sets are strictly more powerful than the ones with the poorer feature sets. Indeed this is the case. We explain this in the following setting. We measure computing power of an automaton in its use as a *language recognizer*. In this use, TMs recognize all languages that are decidable (the recursive languages), PDAs recognize only a *proper* subset of these languages (the context-free languages), and FSAs recognize only a *proper* subset of the languages that PDAs recognize (the regular languages). Various classes of languages mentioned above – recursive, context-free and regular – are discussed in the next section.

FORMAL LANGUAGES AND THE CHOMSKY HIERARCHY

As everyone knows, language is essential to communication. What one might not realize is that language is also essential to computation.

The Chomsky hierarchy of formal languages was a landmark event in linguistics and, as it turns out, also in computation. This hierarchy defines classes

of languages of strictly increasing power. In what follows we will let Σ denote the alphabet, Σ^* the set of all strings on the alphabet, and $L \subseteq \Sigma^*$ a language on Σ. (Notice that a language is a *particular subset* of all possible strings on an alphabet.)

At the lowest level in the hierarchy is the class of *regular languages*. This class, R, may be defined as follows. The language $L = \emptyset$ that contains no strings is in R. The languages $L = \{a\}, a \in \Sigma$ are in R. (Each of these languages contains a one-letter string, comprised of an alphabet symbol.) The language $L = \{\wedge\}$, which contains just one element – the empty string – is in R. If languages L_1, L_2 are in R then so are the languages $L_1 \cup L_2$, $L_1 \circ L_2$, and $L_1{}^*$. Here $L_1 \circ L_2 = \{x \circ y | x \in L_1, y \in L_2\}$ where the small circle symbol ($\circ$) denotes the concatenation of two strings, and $L_1{}^* = \bigcup_{i=0,\ldots,\infty} L_1^i$ where $L_1^i = \underbrace{L_1 \circ L_1 \circ \ldots \circ L_1}_{i \text{ times}}$. In other words, a regular language is built from simpler languages by the union of two regular languages, the concatenation of two regular languages, or the repeated concatenation – zero or more times – of the same language.

This simple structure suggests that regular languages should be easy to parse. Indeed this is the case. Regular languages are parsed by *regular expressions*. Regular expressions mirror the structure of the definition of the class of the regular languages; specifically they are composed of operators that correspond to the union and the concatenation of two languages and an operator for repeated concatenation of the same language.

Despite being at the lowest rung of the Chomsky hierarchy, a regular language can have a rich structure. On the other hand, precisely because the language is regular, this structure can be efficiently parsed by computer methods. These two facts collectively explain why regular languages are so popular, having many applications. These include free-text searches, especially in Unix and on the web, and computational biology. (*See* **Finite State Processing**)

At the next level in the hierarchy is the class of *context-free languages*. Every regular language is a context-free language. On the other hand, there are context-free languages that are not regular. The language formed by the set of all palindromes (say on the alphabet $\Sigma = \{0, 1\}$) is one such example. (A palindrome is a string that coincides with its reverse.)

Before we give a formal definition for this class of languages, it will help us to examine the closely related notion of a grammar. A *grammar* for a language is a set of rules which collectively allow us to determine which strings are in the language and which are not. A grammar is itself written in a *meta-language*. By imposing different restrictions on what forms the rules can take in this meta-language, we get different classes of grammars, hence different classes of languages.

In a *context-free grammar* we can have rules only of the type $A \Rightarrow x$. Here A is a single non-terminal symbol and x a string, possibly empty, composed of non-terminal and/or terminal symbols. The terminal symbols in the grammar are the alphabet symbols in the associated language.

Let us use an example to explain what a non-terminal symbol is, and how the set of rules comprising a grammar is applied to test whether a given string is in the language associated with the grammar or not. Here is one context-free grammar for the language of palindromes mentioned earlier.

$$S \Rightarrow 0S0 \quad S \Rightarrow 1S1 \quad S \Rightarrow 0 \quad S \Rightarrow 1 \quad S \Rightarrow \wedge$$

In this grammar, S is the only non-terminal symbol, 0 and 1 are the terminal symbols, and $\wedge$ denotes the empty string. This grammar has five rules. Let us now apply this grammar to verify that 0110 is a palindrome. We do this by starting with the non-terminal symbol S and applying a certain sequence of rules which transforms this S to the string 0110. This process is called a *derivation*. The derivation in this example is:

$$S \rightarrow 0S0 \rightarrow 01S10 \rightarrow 0110$$

Which rules were applied when is not made explicit in this derivation. In our example though, we can easily infer this from our derivation.

A context-free language may now be defined as one that is recognized by a context-free grammar.

At the next level in the Chomsky hierarchy is the class of *context-sensitive languages*. Every context-free language is a context-sensitive language. On the other hand, there are context-sensitive languages that are not context-free. The language $L = \{xx | x \in \Sigma^*\}$ is one such example.

A context-sensitive language is associated with a grammar in which we can have rules only of the type $xAy \Rightarrow xzy$. Here A is a non-terminal symbol and x, y, and z are strings composed of non-terminal and/or terminal symbols. (x and/or y can be empty, but z cannot be.) The meaning of this rule is that 'when A occurs with x on its left and y on its right, it may be replaced by the string z'. Notice that this rule is more general than one for a context-free grammar; the latter does not permit context-dependent replacement.

Finally, a *recursive language* is one whose characteristic function is decidable. That is, given a string x in Σ^*, there is an effective procedure for determining whether x is in the language or not.

THE CORRESPONDENCE BETWEEN AUTOMATA AND FORMAL LANGUAGES

What solidifies the connection between languages and computation is the precise correspondence between formal languages of the Chomsky hierarchy and the automata that we saw in a previous section. Specifically, it turns out that FSAs recognize regular languages, PDAs recognize context-free languages, and TMs recognize recursive languages. In fact, even context-sensitive languages have their automaton counterpart – the linear-bounded automaton, which is realized by imposing certain restrictions on a TM.

THE TURING MACHINE

To this point, we have described the Turing machine as a language recognizer. Unlike FSAs and PDAs, however, a Turing machine may also be used as a more conventional type of computer, to read input, do some task, and produce output. This is done in much the same way as a language would be recognized, the main difference being that after reading the input and doing its computation, the TM places the output on the tape at a specific location.

THE UNIVERSAL TURING MACHINE

A TM runs a particular program. This is cumbersome; to run different programs, one needs to construct different TMs, one for each program. The universal Turing machine (UTM) is a fix to this. A UTM accepts, as its input, both the program P and the input x to P. The UTM then runs the program P on input x, and writes out, to the tape, the output that P would have produced, on input x.

THE VON NEUMANN ARCHITECTURE

The von Neumann architecture may be thought of as a practically-inclined realization of the idea of a universal Turing machine. This architecture uses the key notion of a 'stored program concept'. A program, like data, is stored in memory. A program is indistinguishable from data, as it resides in memory. (*See* **von Neumann, John**)

In the von Neumann architecture, there is a 'central processing unit' that reads and executes the instructions of a program stored in memory, one by one. The data needed by an instruction is read from memory; the result produced by the instruction is written back to memory. For example, the instruction $z = x + y$ would be executed as follows. First, the instruction is read from memory. Next, the data items needed by the instruction, x and y, are read from memory. Then, the values of x and y are added together. Finally, the result is stored back into memory at location z.

INSTRUCTION SETS, COMPUTER LANGUAGES, AND THE IDEA OF THE 'VIRTUAL MACHINE'

The von Neumann architecture is the basis for every sequential computer built. The huge significance of the stored program concept – that it facilitates the execution of countless programs on the same computer – was recognized early on and profitably exploited since. Computers were developed with carefully designed instruction sets. The instruction sets had to be powerful enough so that any programs could be written in them. On the other hand, they had to be simple enough to keep the central processing unit from becoming overly complex.

These conflicting objectives were resolved by adopting 'minimalist' designs. Specifically, the instruction set was kept small, and composed of simple and 'orthogonal' instructions. The instructions were designed to be combinable. Thus, a user wanting a more elaborate instruction set could in effect create one by combining various instructions from the smaller set in various ways.

While this strategy solved the problem it was designed to solve, a different one remained. The instructions in a computer's instruction set were at a very low level; just right for the computer to understand them, but very tedious for humans to program in. A breakthrough came in the development of computer languages that humans could write in more easily. These languages had very high-level instructions. On the other hand, computers could not understand them. This dilemma was resolved by building translators, programs that take a program written in a high-level language and translate it to a program in the computer's (low- level) language.

Once we had freed ourselves from having to write programs at the level of the computer, we had also freed ourselves from its constraints to a considerable extent. Specifically, we no longer

needed to write programs that would fit in its memory, or use only its instructions. The translator in effect created a 'virtual machine' around the actual computer, one that was vastly richer. This notion of a 'virtual machine' revolutionized software development, freeing it to a great extent from the confines of a particular computer.

WHAT IS AN ALGORITHM?

An algorithm is a step-by-step procedure to solve a particular problem. An algorithm is required to terminate in any one run. How does this notion differ from that of a program? Well, for one thing, a program may not always terminate – loops in its control flow may cause it to run forever at times. Second, a program typically means a sequence of instructions (to do something) written in a particular language, while an algorithm is a higher-level, language-independent recipe for solving a problem in a particular way.

THE NOTIONS OF COMPUTABILITY AND COMPUTATIONAL COMPLEXITY

Is it possible to develop a program that can check whether or not any given program will terminate? This would be nice; we could use it to find 'infinite loops' in our programs. Unfortunately, it is impossible to do so. (On a practical computer with bounded resources such a program can be developed, though it will be impractical.) That is, the so-called halting problem is noncomputable.

More precisely, let us define a partial function $f{:}\mathrm{N} \rightarrow \mathrm{N}$ as a function that takes a natural number as input and returns a natural number $f(n)$ if f is defined on n, and returns 'undefined' if f is undefined on n. We say that a Turing machine T computes f if T reads the input n as 1^n and produces output $1^{f(n)}$ if $f(n)$ is defined and does not halt if $f(n)$ is undefined. We say that a partial function is computable if there exists a Turing machine that computes it. Since any given TM can compute at most one partial function, the number of TMs is countable, and the number of partial functions is uncountable, we see that there are many partial functions that are not computable.

The notion of computability establishes the limits of what can be computed in principle. It turns out that the limit of what can be computed in practice is far lower. The characterization of this limit is the subject of computational complexity.

Computational complexity is the study of the time needed to solve a particular problem as a function of the size of an instance of the problem. For example, consider the problem of factoring a composite number. An instance of this problem is specified by a particular positive integer. The size of an instance – the number n – is $\lceil \log_2 n \rceil$, the number of bits needed to describe n. The fastest known factoring algorithm runs in time exponential in n. The apparent difficulty of factoring has a very significant application: the development of public key cryptosystems such as those used at banks (and now for e-commerce over the internet) that seem unbreakable.

Now consider a different problem – of testing whether a given number occurs in a list of numbers. This problem can be easily solved in time proportional to n. If we assume that the instance size is also proportional to n – a valid assumption when the numbers are required to fit in a fixed word size – then this problem's computational complexity is linear.

Thus, we would conclude that factoring is computationally hard, while search is computationally easy.

How do we know that factoring is indeed computationally hard? Perhaps there is an efficient algorithm – we just have not found it. In the early 1970s this very sort of questioning led to the remarkable theory of NP-completeness. Informally speaking, the class NP-complete is the set of computable problems, none of which is known to be efficiently solvable, yet all are efficiently interconvertible (i.e. any NP-complete problem can be efficiently transformed into any other). This still does not mean that an NP-complete problem is definitely hard. However, the efficient interconvertibility yields an intriguing and significant property: If *any* NP-complete problem is easy, then *every* NP-complete problem is easy.

The practical import of this theory is as follows. Thousands of problems are known to be NP-complete. If one can show that a new problem of interest is NP-complete, then this suggests that it really is hard. If this problem were easy, then so would the thousands of other problems be. But since many able researchers have tried to devise efficient algorithms for many of these problems, over the past thirty years, and all have failed, this is highly unlikely.

PARALLEL COMPUTATION, ASSOCIATIVE NETWORKS, AND CELLULAR AUTOMATA

The von Neumann architecture, while pivotal to the evolution of computers, has one major drawback – it has a sequential bottleneck. Instructions must be

executed one at a time. On the other hand, everyone realizes that many algorithms are intrinsically parallel. For example, to test if a number x occurs in a list L of numbers, we could compare x against each number in L in parallel.

The observation that many algorithms are inherently parallel, coupled with the incessant need of humans to 'have things done faster', has spurred research on parallel computation. Many models of parallel computation have been proposed. Some have even been implemented. These days every computer – even a sequential one – is parallel. On your computer you can compose an e-mail message in one window at the same time that the computer is downloading a video off the internet. This is an example of parallel computation.

The brain has been one source of inspiration for many models of parallel computation. Many computations in the brain are massively parallel (many others are sequential). Groups of neurons fire in synchrony, or in asynchrony. Brain-inspired models such as artificial neural networks and cellular automata are composed of primitive computing elements interconnected together in various ways. (In the case of artificial neural networks, these are the neurons.) The power of these models arises from the precise way in which these primitive elements are interconnected. If we 'add up' the computations performed by the computing elements, they don't amount to much. If we now interconnect these same elements in particular ways, suddenly we have gained a lot of computing power. In these cases, the whole is indeed greater than the sum of its parts.

In artificial neural networks, the net input to neuron i is $n_i = \sum_j w_{ij} S_j$ where j indexes the neurons connected to neuron i, S_j is the output of neuron j, and w_{ij} is the weight of the connection from neuron j to neuron i. The output of neuron i is $S_i = g(n_i)$ where g is the neuron's transfer function, typically a sigmoid.

In a cellular automaton, the primitive computing element is a cell. By contrast to neural networks, the cells are usually interconnected in a lattice, typically with one or two dimensions (neural networks are typically more flexibly connected). A cell updates its state by examining the states of its neighbors on the lattice. Although a cellular automaton typically has more restricted connectivity than a neural network, the cells in a cellular automaton are more flexible in what they can compute. Specifically, their computations are not restricted to taking the weighted combinations of the outputs of their neighbors and following these by a transfer function.

QUANTUM COMPUTATION

Complexity theory tells us that there are many problems that seem to be inherently intractable. These results hold only on models of classical computation, however. Quantum computers, on the other hand, are capable of performing exponentially many computations in parallel, exponential in the size of the input. They are therefore able to break the intractability barrier of classical computation. However, not all NP-complete problems are known to be tractable on quantum computers. The class of tractable problems on quantum computers is still not well understood in relation to classical models.

Let us revisit the factoring problem discussed earlier. Recall that we mentioned that the best classical algorithm takes exponential time in the size $\lceil \log_2 n \rceil$ of the binary representation of the composite number n that is to be factored. By contrast, there exists an algorithm for factoring on a quantum computer that takes only roughly quadratic time in the size $\lceil \log_2 n \rceil$ of the input. Should quantum computation become a practical reality at some point in time, this would suggest that public key cryptosystems might be breakable. (The first famous paper demonstrating tractability of prime factorization on quantum computers is due to P. Shor.)

At this time, quantum computers are already a little more than an abstract model in that they have been realized in toy devices. It remains to be seen whether practical quantum computers can be built.

Computational Models of Cognition: Constraining

Intermediate article

Terry Regier, University of Chicago, Chicago, Illinois, USA

CONTENTS

Computational models of cognition may be constrained in various ways. The three primary benefits of constraining a computational model are: (1) parsimony; (2) avoiding over-flexibility; and (3) potentially stronger motivation for the elements of the model.

OVERVIEW

Computational models of cognition are an essential tool in the study of the mind. One advantage of such models is their explicitness. The computational researcher must specify a mental mechanism in sufficient detail to allow the resulting model to be instantiated on a computer, and run as a cognitive simulation. This often requires that theoretically important elements of the model be described very clearly: the theory must be explicit enough to be described as a machine.

But what sort of machine? Computational machines range from the inflexible to the very flexible. An inflexible machine performs only a single predetermined task, such as addition, or multiplication, or accepting 65 cents in coins and returning a can of soda. A very flexible or general machine, in contrast, may be used for a wide variety of functions. Significantly, there exists an abstract machine, the Turing machine, that is so general that it has been taken as the formal equivalent of the very broad informal notion of an algorithm – thus, a Turing machine is taken to be capable of implementing any algorithm at all (Lewis and Papadimitriou, 1981). Modern programmable computers are approximations to Turing machines. Thus, the flexibility of modern computers gives a sense of the generality of Turing machines, and of the potential generality of computational machines as a class.

What is the significance of these issues of computational generality and flexibility for models of cognition? Often, generality is taken as a strength in a scientific theory. One would like to be able to account for a broad array of data, from a variety of sources, rather than provide a micro-theory of a very limited domain of cognition. There is, however, a danger of over-generality in model construction. If data are accounted for by a model that is very general and flexible, it is not always clear what to make of the model's success. The problem is that such a general model could also perhaps have fit other data, of a sort never empirically observed. That is, it may have succeeded in accounting for the empirical data because of its extreme flexibility, rather than because of a systematic match between the structures of the model and the mental processes at play. In this sense, a model's computational power may undermine its explanatory power. A more constrained, less computationally powerful model may in some instances provide more insight into the mental processes under study.

THE BENEFITS OF CONSTRAINTS

There are three primary benefits of a constrained model. These are: a more parsimonious characterization, an avoidance of over-flexibility, and potentially stronger motivation for the elements of the model. To illustrate these benefits, let us turn to a simple example.

Consider the task of silently counting from zero up to a given positive integer, and then pressing a button when done. This task involves the mental process of counting, with no overt behavioral clues as to the nature of the process other than the total time required. This time is shown as a function of the target number in Figure 1. These are informally collected data, meant for illustrative purposes only. The data represent averages over five testing sessions, from one subject. The figure also shows the fits of two models, one more constrained than the other.

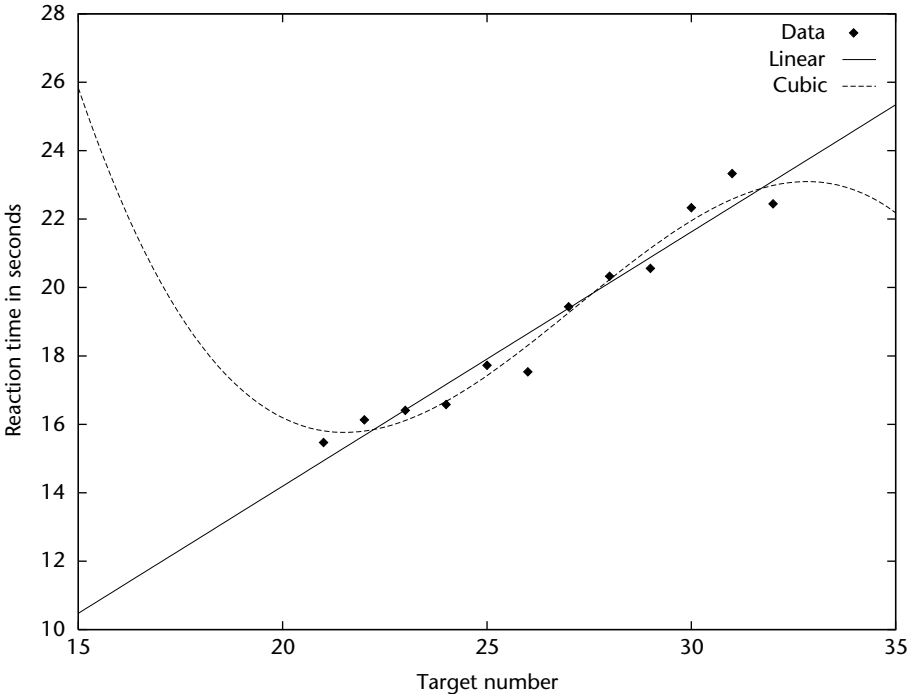

Figure 1. Mental counting. The data represent average time taken to count silently up to a given number. The best linear fit and best cubic fit are also shown.

The obvious computational characterization of mental counting is a simple iterative loop: begin with zero, then add 1 repeatedly until the target number is reached. We may reasonably assume that the counting will assume a rhythmic character, such that each iteration requires the same amount of time. Thus, overall reaction time T should be a linear function of the target number X:

$$T = aX + b \tag{1}$$

Here a and b are free parameters. Note that the parameter a has a straightforward psychological interpretation: the time taken for a single counting iteration. The parameter b denotes the amount of time needed to count from zero to zero – ideally this would be zero. Fitting this linear model to these data, we obtain a good fit, as shown in the figure ($R^2 = 0.9504$, $p < 0.0001$).

Let us compare this with the performance of a less constrained model, one based on a cubic function of the target number:

$$T = a_1X + a_2X^2 + a_3X^3 + b \tag{2}$$

This more general model provides a somewhat closer fit to the data ($R^2 = 0.9713$, $p < 0.0001$). The two new terms in the model approach significance. However, a comparison between the two models also highlights the three benefits of more constrained models.

Perhaps the most obvious benefit is that of parsimony. The linear model is simpler than the cubic model, which contains two terms in addition to those of the linear model. Model simplicity is aesthetically pleasing, and also makes the model easier to analyze.

A related issue is that the constrained model is less likely to be overly flexible. In this example, the less constrained cubic model overfits the data. With the obtained parameter settings, the cubic model predicts the observed data very well. But in doing so it also fits some of the noise, so that it generalizes poorly outside the observed range. As can be seen in the figure, this model predicts that it will take longer to count to 15 than to 30: an obviously false prediction. This problem is avoided by the more constrained linear model.

Finally, as we have seen, in this case the elements of the constrained linear model are motivated: they readily admit clear psychological interpretations, in the context of an iterative counting process. This is not true of the additional terms in the cubic model. The addition of such elements to a model, in the hope of increasing flexibility and thereby improving the fit to the data, comes at the price of arbitrariness.

These various benefits of constrained models need not all correlate perfectly. One could imagine, for instance, an ill-motivated model with few free parameters, or a well-motivated one with many. But the appeal of a constrained model lies in the prospect of accurately explaining a psychological phenomenon using a small number of well-motivated components.

These issues are relevant to a range of different styles of cognitive modeling, not just to simple models like that used in the example. Concerns about unconstrained models have been voiced in the context of symbolic models, and also in the context of connectionist or neural network models. For example, Miller *et al*. (1960) proposed a symbolic mental structure called a plan, which might be recursively created by other plans, yielding an overall system that was potentially quite complex and flexible. They anticipated that some might find their proposal too general and open-ended, and imagined their critics arguing as follows (quoted in Seidenberg, 1993):

> A good scientist can draw an elephant with three parameters, and with four he can tie a knot in its tail. There must be hundreds of parameters floating around in this kind of theory and nobody will ever be able to untangle them.

While Miller *et al*. defended their proposal against this critique, on the grounds that a complex system may in some instances be required, their sensitivity to the issue demonstrates an early concern with underconstrainedness in symbolic models. Another manifestation of the same concern may be found in Newell's (1990, p. 220) discussion of the computational universality of his production system framework SOAR, and the need for constraints in such a framework.

Some connectionist models have raised similar concerns. Massaro (1988) claimed that the multilayer perceptron – a commonly-used connectionist architecture – was too computationally powerful to be psychologically meaningful. His argument was based on the finding that a single connectionist model could simulate results generated by three mutually exclusive process models. Thus, the connectionist model appeared to Massaro to be overly flexible, and potentially unfalsifiable. And Cybenko (1989) showed formally that multi-layer perceptrons are in principle flexible enough to approximate arbitrarily well any continuous function over inputs that range from 0 to 1. Further discussion of constraints in connectionist models may be found in (McCloskey, 1991; Regier, 1996; Seidenberg, 1993; Siegelmann, 1995). We shall return to some of these issues below.

THE SOURCES OF CONSTRAINTS

There are many possible sources for constraints in a cognitive model. Four particularly important ones are treated here: constraints derived from known psychological structure, those derived from known biological structure, those derived from task structure, and those based on the nature of the input to the model.

Psychological Structure

It is natural for a computational model of one psychological phenomenon to be informed by – and constrained by – independent observations concerning another, related phenomenon. This would afford an explanation of the one mental process in terms of the other. For example, Gluck and Bower (1988) accounted for aspects of human categorization using a simple connectionist learning rule, the delta rule, which is ultimately motivated by studies of Pavlovian conditioning in animals (Rescorla and Wagner, 1972). This rule has known constraints: for example, it predicts blocking and overshadowing in learning. The strength of Gluck and Bower's presentation is that they find empirical evidence of these constraints in human category learning – thus mechanistically linking human categorization and animal conditioning. Another example of the use of psychological constraints may be found in Nosofsky's (1986) model of categorization. This model builds on an existing model of identification, or the discrimination of stimuli from one another (Shepard, 1957). Thus, the constraints of the original model – such as a monotonic decrease in generalization with increasing psychological distance – are incorporated into its successor. This implicity grounds an account of categorization in an existing account of identification.

Biological Structure

Biological constraints may also be brought to bear on cognitive models. This idea holds the potential of reduction, of explaining cognitive processes in terms of the neural structure that underlies them. Wilson *et al*. (2000) provide a concrete example. They present a model of how humans perceive the orientation of another person's head: whether the other person is facing one directly, or in partial profile. They are able to account for their empirical

findings in this domain using a model based on a population code of neurons found in area V4 of cortex, neurons sensitive to concentric and radial visual structure. Thus, the constraints of the underlying neural structure are used to explain a psychological phenomenon. Another example can be found in Regier and Carlson's (2001) study of spatial language. Participants were asked to rate the acceptability of linguistic spatial descriptions such as 'the dot is above the triangle', when shown pairs of objects in various spatial configurations. Their linguistic responses were well described by a model based in part on a neurobiological finding: the representation of overall direction as a vector sum. Thus, the linguistic data are partially grounded in a neurobiological constraint. More generally, one of the major appeals of connectionism as a modeling framework has been the prospect of bringing neural constraints to bear on psychological models (Feldman and Ballard, 1982; Seidenberg, 1993).

An important source of biological constraints is timing (Feldman and Ballard, 1982). Complex mentally-guided behavior can occur at a timescale of seconds. Assume, for example, that someone were to ask: 'Do you know where the registrar's office is?' It would take only a few seconds to hear the question, extract the intended meaning, recall where you believe the office is, prepare a linguistic response to the question, and deliver that response. Thus, a good amount of cognitive computational work is accomplished in a short timespan. But neurons, which are widely assumed to be the ultimate implementation of this computational work, operate on a timescale of a few milliseconds – relatively slowly by the standards of modern computers. Thus, the entire process of hearing and responding to the question must take place within only a few thousand neural computational timesteps. This constrains the number of iterations a model may realistically take when accomplishing such a behavioral or cognitive task. Since very little can be computed in a few thousand time steps using serial computation, this constraint strongly motivates parallel computation in cognitive models.

Task Structure

The nature of the psychological or behavioral task under study may also provide constraints on potential models. An example is the simple motor task of moving one's hand (or a pointer) to a target area of a specific size. Empirically, it has been found that the time required for this task varies as log (D/S), where D is the distance from starting point to end point of the motion and S is the size of the target region. This regularity is known as Fitts' law. An elegant model explaining this law has been given, based on the nature of the behavioral task. On this model, the most natural solution to the task is to launch the hand in the right general direction, and then iteratively correct during movement so as to bring the hand closer and closer to the target. This defines a recursion which, when solved analytically, yields the formula for Fitts' law (Keele, 1968; Meyer *et al.*, 1988; Newell, 1990). Another example is the simple mental counting task described earlier. Here, it is the intuitively obvious iterative nature of the counting task that motivates the linear model, the more constrained of the two models considered.

Input

An important source of constraint lying outside the model itself is the nature of the input supplied to it. Researchers investigating very flexible or general models often emphasize the constraints that reside in the model's input, at least as much as those residing in the structure of the model itself. Much connectionist modeling takes this approach. Specifically, as we have seen, multi-layer perceptrons are computationally quite general, and this generality has been a point of criticism. However, flexible mechanisms of this sort can be very useful scientifically, when considered together with the nature of the model input. A concrete example may be found in language acquisition. For many years, the study of language acquisition was dominated by the 'argument from poverty of the stimulus' (Chomsky, 1986). This view holds that the linguistic input heard by the language-learning child is too sparse, too impoverished to eventually give the child full knowledge of the syntactic structure of the language. Therefore, on this account, some elements of this knowledge must be innate. This account predicts that general-purpose learning mechanisms would not be able to learn the syntactic structure of natural language – as such mechanisms lack the requisite language-specific innate structure. This stance has been challenged recently. Very flexible, general-purpose connectionist networks have succeeded in learning artificial languages that resemble natural language in some important respects (Elman, 1993; Rohde and Plaut, 1999). This suggests that the input may not be as impoverished as had earlier been asserted, and that there may be no need to posit innate language-specific structure. Thus, the importance of these demonstrations lies

precisely in the unconstrainedness of the mechanism itself, and the substantial constraints present in the input.

Given this variety of possible sources of model constraints, is there a most appropriate source? Is there any reason to prefer a model constrained in one manner over a model constrained in another? The answer to this question ultimately lies in the nature of the scientific question being asked. A general mechanism with constrained input is useful in addressing the alleged necessity of innate structure. For other sorts of questions, however, it may be more informative to demonstrate that elements of already acknowledged mechanistic structure can explain a novel phenomenon, one to which they were not originally tied. In both cases, the data at hand are explained in terms of known and independently motivated constraints, whether these constraints reside in the mechanism itself or in environmental input.

SUMMARY

Over-generality is a potential danger in computational models of cognition. It is conceivable that a model may account well for a set of empirical data because of its extreme flexibility, rather than because of a clear match between its structures and those of the cognitive process under study. This possibility has been a concern in both symbolic and connectionist models of cognition. However, the problem can be avoided by constraining models in principled ways. This can yield a more parsimonious, less over-flexible, and more convincingly motivated model. There are several possible sources for constraints on cognitive models: existing knowledge concerning psychological or biological structure, the nature of the cognitive task itself, or the input to the model. The scientific question being posed will indicate the most appropriate source of constraint in a given modeling enterprise.

Computational Models: Why Build Them?

Introductory article

Herbert A Simon, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

CONTENTS

The term 'computational model' is used for a theory that is stated definitely enough that precise reasoning (not necessarily numerical) can be performed on it to infer the course of system behavior. Nowadays, such a theory is often expressed as a computer program, the computer tracing the system's path.

INTRODUCTION

A computational model traces a system's processes over time, determining its path from its present state and the influences impinging on it at each moment. By this definition, a clock, whose hour hand moves one degree of arc for every half-degree of rotation of the earth, is a computational model in astronomy. In physics, computational models commonly take the form of systems of differential equations: for example, Maxwell's equations for electromagnetism.

HOW COMPUTERS MODEL THE HUMAN MIND

Computational models are not new to the social sciences. Economics has been using them for more than a century and a half. Because much of economics is concerned with quantities and prices of commodities, many economic situations and can be translated directly into numerical form, and standard analytic methods, together with computer simulations, can be used to study them.

In cognitive science, simple numerical computational models have long been used in psychophysics and psychometrics: for example, in scaling stimulus–response relations and in factor analysis. A powerful new class of computational models, *physical symbol systems* (PSS), emerged when it was recognized (around 1950) that the patterns stored in computers could be used to represent not only numbers, but also symbols of any kind, including words in natural language or pictures and diagrams. A PSS, implemented by a computer program, may represent the successive states of the disks and pegs of a Tower of Hanoi puzzle while it is being solved, or successive states of the thought processes of the person solving it. This article focuses upon physical symbol systems, both serial and parallel (connectionist), which are the predominant forms of computational model in contemporary cognitive science; but it will comment on their relation to mathematical models as well.

To behave as a PSS, a computer carries out certain fundamental processes: receiving (*sensing*) patterns, encoding (*perceiving*) them, storing (*remembering*) them, evoking (*recognizing*) them on appropriate occasions, modifying symbol structures in memory (*reasoning*), and outputting symbol structures that initiate actions (*behaving*). Finally, the system's actions may depend upon what particular symbols it finds in memory (*branching* or *choosing*). In each case the symbolic process can be matched with the corresponding class of psychological processes.

Symbols, in this context, are any kinds of distinguishable patterns, which may be linguistic, diagrammatic, pictorial, or purely abstract-relational in character. Although 'symbol' is popularly used specifically for linguistic patterns, these have no privileged position in cognitive modeling. The essential characteristic of a pattern is that it be capable of denoting (pointing to) other patterns, as a line drawing may denote a cat, or a DNA sequence, or a protein.

The *physical symbol system hypothesis* postulates that any system possessing these capabilities, and only such a system, can be programmed, or

can program itself, to act intelligently. This is an empirical hypothesis to be confirmed or rejected by comparing the behaviors of such systems with human behavior, exactly as differential equations in physics are matched with physical systems.

A computer program, whether it processes numbers or non-numerical symbols, is formally a system of *difference equations*. Difference equations differ from differential equations only in that they move ahead by discrete increments of time instead of continuously (the increment being the time required to execute an instruction). Thus, the PSS hypothesis asserts that cognitive processes can be modeled by difference equations, numerical or symbolic or both in combination.

Computational models of cognition often not only simulate but actually carry out the solution process, and arrive at the solution (or fail to); they are both models of problem solving (or, more generally, thinking) and problem solvers. They describe and predict the course of thought, explaining its mechanisms while seeking to solve the problem. In this respect, they are different from the equations of physics, for equations representing the path of a planet do not move in such a path, but merely represent it, symbolically or graphically.

CONSTRUCTING AND TESTING MODELS

Some examples will show how models are constructed and what they do. Beginning with a very specific problem in algebra, the model is then generalized to a wide range of problems. This raises the question of how to accommodate the different ways in which different people may respond to the same problem: what invariants in cognitive processes constitute scientific laws of thinking?

An Algebraic Example

A program can model a student solving a linear equation in algebra, say, $7x - 15 = 3x + 9$. The solution takes the form $x = N$, where substitution of the number N for x satisfies the original equation. To discover the solution process, data are obtained from a student who writes down successive steps while talking aloud. In this case, she first adds 15 to both sides of the equation, obtaining $7x = 3x + 24$; then subtracts $3x$ from both sides, obtaining $4x = 24$. Finally, she divides both sides by 4, obtaining $x = 6$. At each step, she also collects terms (e.g. $9 + 15 = 24$). Each equation is transformed into another that has a closer resemblance to the final result.

A computer program can be constructed to follow this same procedure. The program applies a succession of *operators* that remove the differences between the current expression and the goal expression, leaving unchanged the number that satisfies the equation. The first step removes the unwanted number (-15) from the left side of the equation; the second step removes the unwanted term in x ($3x$) from the right side; the third step divides out the non-unitary coefficient of x (4). At each step the program performs the same operation on both sides of the equation and collects terms to simplify the result.

Deriving a More General Theory

Means–ends analysis and heuristic search

The method just described, *means–ends analysis*, is applicable to all sorts of problems, numerical or not. It is a powerful form of an even more general method called *heuristic search*. In heuristic search a problem is defined by a set of possible situations, or *problem space*. One of these is the *starting situation*, and any situation that satisfies a specified set of criteria is a *solution*. By applying a sequence of operators, the system can move through the space in search of a solution.

In the Tower of Hanoi we begin with three pegs *A*, *B* and *C* and a pyramid of disks, all stacked, say, on peg *A*. The disks must be moved, one by one, to other pegs, never placing a larger disk on a smaller one, until all have been moved to peg *C*. Each time a disk, starting with the largest, is moved successfully to peg *C*, a difference is removed between the initial and the final situation: fewer disks now remain to be relocated. The theory that people solve problems by using heuristic search, and means–ends analysis in particular, is captured in the computational model called the general problem solver (GPS). The theory has been shown to explain much human problem solving, but it clearly does not tell the whole story. More recently, GPS has been broadened into even more comprehensive models of cognition, including SOAR and the ACT-R family of programs.

Production systems

At a still more general level, the computational model proposes that the problem solving search is implemented by a mechanism called a *production system*. The choice of successive search steps results from the execution of 'if–then' rules (called *productions*), successors to the stimulus–response (S–R) pairs of behaviorist psychology. Whenever the

conditions of a rule ('ifs') are satisfied, its actions ('thens') are executed. The principal advance over S–R is that if–then rules, unlike S–R connections, can contain variables that are instantiated in each problem situation, and the stimuli and responses can be symbol structures within the brain as well as external sensory stimuli and motor responses. Thus, short-term memory at a given moment can supply one or more of the ifs of an if–then rule, and the action, the 'then', or part of it, may invoke knowledge in long-term memory. The algebraic problem described above might be solved mentally, holding the intermediate symbol structures internally and only writing down the answer.

Many problem spaces that humans search are very large. In chess, about 10^{20} branches emanate from each move. In the time available to make a move, a master can explore perhaps 1000 of these, a minute fraction. Similarly, in the algebraic problem, an infinite number of equations have the same value of x as the given one, and x has an infinite number of possible values. How does the student, after generating only three equations, find the right value?

The computer program of the example shows that knowledge of the operations of adding or subtracting the same quantity from both sides of an equation, and of multiplying or dividing both sides by the same quantity, combined with knowledge of means–ends analysis, is sufficient to solve the equation rapidly. The student's written work and verbal statements will show whether this is the process she used to solve it. Thus the computational model is a theory that can be tested in detail, and at several levels of generality, against the verbal and other behavior of human subjects, with a time resolution of about five seconds per action.

The model both tests the sufficiency of the theory's mechanisms to produce the observed behavior, and compares its information processes, point by point, with the observed processes of the human subject. This is precisely how we test any theory against data; a computational model is not special in this respect. The comparison tests its sufficiency to perform the task and the degree of its correspondence with human processes.

Model invariants

The model described above can only solve algebraic equations; but the architecture of the model, ignoring its knowledge of algebra, constitutes a broad theory of problem solving. The theory postulates that a problem solver defines a problem space for the given problem; then, operations appropriate to the problem domain, implemented as productions, search selectively through the space, guided by means–ends analysis. The validity of this architecture as a general theory of problem solving can be tested by constructing the appropriate problem spaces and if–then productions for various problem domains, then simulating the system's behavior for specific problems in these domains and comparing the behavior with that of human subjects.

The problem solving models, which make much use of information stored in semantic memory, can be joined to several programs, for example, the EPAM program, which serves as a perceptual 'front end', UNDERSTAND and ISAAC, which are capable of translating verbal problem statements into inputs to GPS-like problem solvers, and CaMeRa, which reasons from pictorial or diagrammatic information. In this way the theory can undergo successive stages of generalization.

Individual differences

Whereas laws of human behavior presumably describe invariants over our species, different people perform the same task differently, and a single person behaves differently on different occasions. A major source of variation is the difference between people's memory stores, which are augmented by new learning, and different subsets of which are invoked in each problem situation. There is also genetic and other variability in the biological structure of brains. Theories in cognitive science, including computational models, must somehow extract invariants from this variability.

Invariant relations may be obtained in several ways. Laws may describe nonidentical but similar behaviors: 'When people are hungry, they search for food.' This is a (weak) law of behavior. The food varies greatly between cultures, with availability, and from one time to another, as do the methods of search (hunting, fishing, visiting the supermarket, etc.). The invariant is that people take actions that are relevant to the goal of food gathering. A theory of problem solving (like those already discussed) must deal with goals, and with processes for attaining them, taking as boundary conditions the goal-arousing circumstances and priorities among competing goals, and as initial conditions the actor's knowledge of ways of attaining goals and skills in pursuing the paths that are seen.

Because much variability derives from differences in what subjects know and attend to, an important approach to variability, and to the independent estimation of the parameters needed for testing models, is to design experiments that

explicitly manipulate the knowledge available to subjects or modify the focuses of their attention or their goals, inducing them to adopt particular strategies.

These considerations are relevant whether behavior is studied at the level of symbolic processes or of neural activity. All human behavior is ultimately implemented by neurons, just as computer behavior is by chips. The neuronal activity is just as susceptible to individual variation deriving from inheritance, experience, and focus of attention as is the more aggregated symbolic activity it produces.

The variations in a system's structure, knowledge, and attention serve as initial and boundary conditions for a computational model, and (like parameter values in numerical models) must be supplied before the model can simulate the behavior of a particular subject in a particular situation. Of course, in many tasks, members of a group (say, college sophomores) will all behave in much the same way. To the extent that this is so, we can construct a model of a 'typical' subject by averaging over subjects in each experimental condition.

Unified theories of cognition

A model may contain so many parameters that it can fit almost any data, hence predict nothing. One solution to this problem is to identify a range of tasks throughout which a certain set of parameters play a significant role, then fit a single set of parameter values to data from all the tasks. This strategy can be pursued within unified theories of cognition, which aim to embody the whole range of cognitive processes, hence are testable in almost all task environments. For such theories, the ratio of number of data points to number of parameters will increase with the range of tasks.

A more conservative strategy is to take advantage of the cognitive system's subsystems, and to construct computational models of the subsystems, with the aim of ultimately joining them. This strategy reaps the usual dividends of 'divide and conquer', but needs to be carried out with due attention to the compatibility of the component models, so that they can later be joined, and to defining components that are capable of performing a variety of tasks, the more the better. As an example of design for compatibility, the UNDERSTAND system was constructed some years after GPS with the condition that the output of the former should be a suitable input to the latter. With respect to range of tasks, the EPAM system, using the same set of parameter values throughout, has been applied to perceptual, learning and expert memory tasks, and tasks of categorization and concept attainment.

The two most significant efforts to move towards a unified system are the Soar system of Newell, Rosenbloom and Laird, and J. R. Anderson's ACT systems. The 'divide and conquer' strategy has motivated the development of the set of programs that includes GPS, EPAM, UNDERSTAND, CaMeRa, and a model of scientific discovery.

All the problems that human variability, the complexity of the cognitive system and the multiplication of parameters pose for cognitive modeling are present to the same degree in other modes of theorizing about cognition. Vagueness may create the illusion of lawfulness; it cannot create the reality. Without the discipline of modeling, the sources of variability are not likely to be recognized as clearly or dealt with as carefully. The rigor and unambiguity of cognitive models brings these problems forcibly to mind, and allows them to be addressed with precision and clarity.

MODELS OF LEARNING

Because human (and animal) responses are highly modifiable, learning processes play a major role in cognitive psychology, and many computational models are theories of learning. In fact, learning processes are generally closer than task behaviors to being invariants of behavior, although learning processes are also modifiable as people learn to learn. Among the models of learning mechanisms are *adaptive production systems* (APS), *parallel distributed processors* (PDP), the 'elementary perceiver and memorizer' (EPAM), the *chunking* mechanism of Soar, and a number of similar learning processes in the ACT-R system. Several or all of these different mechanisms (and perhaps others) may be required to account for the full range of human learning capabilities.

Adaptive Production Systems

The algebraic example discussed earlier will illustrate how an adaptive production system can learn. An APS constructs new productions, and inserts them in its memory along with those already there. These new productions will henceforth be executed along with those previously stored. In each new task environment, the APS mechanism calls for a distinct set of differences and operators for building the new if–then rules.

Suppose an APS is presented with a set of worked-out examples of problems like the

algebraic problem examined above, having learned previously what operations can legitimately be performed on an equation. It examines the first two lines of a worked-out example to discover what change was made in the equation, what operator was used to accomplish it, and what difference between initial expression and solution was removed. It then constructs a new production whose 'if' clause is the difference that was removed and whose 'then' clause is the operator used to remove it. The clauses are then generalized to permit any numbers to replace the specific numbers in the example. Thus, the APS initially constructs the production: 'If -15 appears on the left side of the equation, then add 15 to both sides and simplify.' It then generalizes it to: 'If a numerical term, N, appears on the left side of the equation, then add N to both sides and simplify.' The first APS with these capabilities was constructed by D. Neves.

Parallel Distributed Processors

Parallel distributed processors, which derive their original inspiration from Hebb's 'cell assemblies', use elements that somewhat resemble simplified neurons, or collections of neurons. Each such element consists of a link connecting two nodes. Each node has a modifiable level of stimulation, and each link an activation level. The links are typically organized into an input layer, one or more 'hidden' layers, and an output layer, the layers being arranged sequentially. A stimulus (a set of features) activates one or more nodes (each corresponding to a feature) in the input layer to varying levels of stimulation; each node then contributes to the activation of the links it is connected to; these links contribute to the stimulation of the input nodes of the hidden layer; and so on. Each final node in the output layer corresponds to a possible output, and the PDP responds with the output of the node that has the strongest total stimulation. A PDP model can learn to recognize distinct stimuli, and to conceptualize, by grouping them together, stimuli that share certain properties.

To learn, for example, to associate each letter of the Roman alphabet with a distinct set of input features, the system is given feedback on the correctness of its response to each set of features presented. A correct response increases the activation of the links that contributed to it, and decreases the activation of the other links; after an incorrect response, the reverse occurs. This simple scheme has been used to construct systems that can discriminate and conceptualize.

Discrimination Nets

Other kinds of learning which are closely related but organized in serial instead of parallel fashion, are modeled by the 'elementary perceiver and memorizer'. EPAM, in learning, grows a network of nodes and links. Each node contains a test for the value of some feature of the stimulus; the system tests this feature, then moves to a new node along the link that represents the stimulus's value on the test. If, for example, a test discriminated among various sizes of birds (wren-size, robin-size, chicken-size, etc.), then EPAM would move to a new node, following the link corresponding to the size of the bird being recognized. At the new node, EPAM tests another feature (the bird's color, say), and repeats the process until a terminal node was reached.

If given feedback when it is right or wrong, EPAM can learn to recognize large numbers of different patterns (an EPAM net has learned to distinguish 300 000 different patterns of chess pieces on chessboards). It can also store relevant information at each node in the net; hence it can serve, for example, as a medical diagnosis system which, at each node, has information about the disease whose symptoms would cause it to be sorted there. EPAM is a computational model of substantial breadth and power which has modeled a wide range of the phenomena that have been observed in memorization, discrimination, and categorization experiments.

Learning by Compilation ('Chunking')

Yet another learning mechanism is employed by Soar, an adaptive production system that can improve the functionality of new productions it has acquired by 'chunking' them. When two or more processes are frequently performed in sequence, their performance can be greatly speeded up by 'automating' them: that is, by removing time-consuming perceptual tests that would otherwise be used to determine what to do next, but which are unnecessary if the sequential process becomes automatic.

Comparing Learning Models

The existing evidence suggests that human learning probably employs all of the methods that have been examined here, and perhaps others as well. Nevertheless, close comparison of the behavior of different learning systems in approaching the same task can advance our understanding of the

contribution of each mechanism to their performance, and can detect commonalities of mechanism among them.

For example, the EPAM and PDP models perform almost identically in a well-rehearsed experiment that found that letters embedded in four-letter words are recognized more rapidly than letters embedded in nonsense words. An investigation into how two such different architectures (serial versus parallel, symbolic versus numerical) could arrive at the same predictions showed that both models recognize words by recognizing the letters of which they are composed: EPAM by first recognizing letters, then words, by a recursive process; PDP systems using two serially arranged hidden layers with feedback from the 'word' layer to the 'letter' layer. Comparisons like this, of different models in performing the same task, shed valuable light on the functional equivalence of apparently quite different processes, and separate those features of theories that are important for accounting for the phenomena, from those that are merely artefacts of implementation. Such comparisons are important for choosing among proposed models and mechanisms.

SYMBOLIC AND NUMERICAL MODELS

This article has emphasized symbolic rather than numerical models. Removing the necessity of expressing the qualitative differences among architectures in numbers greatly extends the range of systems and realistic detail of mechanisms that can be modeled. For example, traditional mathematical learning models applied to conceptualization tasks generally compare feature vectors of two stimuli, using some kind of correlation between them as a single measure of similarity. As we have seen, EPAM and PDP systems employ much more detailed mechanisms of comparison, hence can answer much more specific questions about the process. No one would propose that computation of correlations is the actual psychological mechanism of comparison, whereas EPAM and PDP systems embody plausible candidate mechanisms. Observations of behavior may allow such claims to be proven.

LEVELS IN COMPLEX SYSTEMS

Not all computational models describe cognition at the same level of detail or in terms of processes on the same timescale. A similar diversity of theory is familiar in the other sciences. In physics, we have classical thermodynamics, which theorizes about heat and temperature averaged over bodies of substantial size. On the other hand, kinematic theories describe interactions of individual particles like atoms or molecules; while statistical mechanics treats of similar detail, but only on a probabilistic basis.

Levels in Scientific Theory

In any science there exist theories (and usually important theories) at each of several levels. This is possible because most complex systems observed in the world are constructed in a hierarchy of levels, and the elements are joined in such a way that the interaction between elements at any single level can be described without specifying any but very general properties of the elements at the next level below, and without considering dynamics at the next level above.

For example, a car can be described in terms of ignition, engine, transmission, and wheels, without describing anything about these components except their functions and their mutual connections. The ignition, at the proper time, fires the fuel from which the engine obtains energy to turn the drive shaft. The latter, connected to the wheels by the transmission, turns them, moving the car down the road. However, we can also fill a book describing each of these components in terms of their subcomponents, but still without mentioning details about their atomic structure.

Levels in Cognitive Theory

The human mind and brain are also organized as a hierarchy of components, each of these components made up of subcomponents, and so on. Thus we speak of the brain, then of the cerebrum, the cerebellum, the hippocampus, and so on; or of long-term memory, short-term memory, visual senses, auditory senses, and so on. Components can be recognized because there are stronger and more frequent interactions among the elements of a component than between distinct components on the same level.

The elementary actions and events among components at any given level usually take place on the same general timescale, shorter times as we go lower in the hierarchy, longer times as we go higher. Thus, a simple reaction to a sensory stimulus may take half a second, a step in solving an algebraic problem a couple of seconds, solution of a homework problem ten minutes, performance of a sequence of scientific experiments three weeks.

As in the biological and physical sciences, a theory of cognition can be built at each broad level to describe and explain the phenomena and processes at that level without attention to the detailed structure of the levels below, treating the latter as already in steady state and treating the levels above as constant constraints for the time interval of interest. This near-independence between levels follows mathematically from the comparative independence of components from each other as compared with their high level of internal interaction. Typically, descriptions refer to events at a particular level, whereas explanations account for events at one level in terms of processes at the next level below.

Three major levels of theory have been identified in cognitive science: the knowledge (or representational) level, of events that are minutes or more in duration, the symbolic level, whose events are seconds or tenths of seconds in duration, and the neural level, whose events may endure for only milliseconds or tens of milliseconds. Both the symbolic and the neural levels are possibly divisible into sublevels. Computational models of various aspects of thinking have been built at all of these levels.

The knowledge level

The behavior of a goal-oriented organism can often be predicted, in first approximation, by asking what actions would be effective, in its given environment, to attain its current goals. This is like predicting the shape of jelly from the shape of the mould in which it set. It requires information only about the goal and the environment, and none about the processes used by the organism to select the goal-attaining behavior. In ignoring the mechanisms, it is predictive and descriptive, rather than explanatory.

For example, the dominant theory in twentieth-century economics was that economic decisions maximize achievement of a goal called *utility*. A real system can behave in this way only if it has capabilities for determining in any situation which of all the available choices would yield this maximum. To predict its behavior, the goals embodied in the utility function and their relative weights have to be specified. The term 'rational' is often reserved for behavior that satisfies these criteria.

In some situations in real life, where we know what people value (what has utility), and they know what alternative actions are available and how to implement them, rationality defined in this way can be a powerful tool for prediction. This level of theory is called the 'knowledge level', calling attention to the centrality of an actor's knowledge of the environment as both generating and limiting the possible actions for reaching goals and deriving utility. If the environment is simple enough and the actors are rational, then their behavior (like the behavior of the jelly) can be predicted from the shape of the environment (the mold), specifying no other characteristics of the actors than their goals. The fulfillment of knowledge-level predictions provides no information about the mechanisms of human thought, except that there exist mechanisms of making simple goal-oriented decisions in these situations.

Thus, if we bring a college student into the laboratory with instructions to point to the taller of a five-foot and a six-foot person standing in the room, we can generally predict which person will be selected. We are assuming that the student has the goal of performing the task and sensory and mental capabilities for picking the taller person. However banal these conditions, they are at the core of descriptions of behavior at the knowledge level.

Two examples of knowledge-level theory in psychology are J. J. Gibson's theory of affordances, and the 'rational' (R) component of J. R. Anderson's ACT-R model. Gibson, for example, characterized a pilot landing a plane in terms of the characteristics of the landing field's surface (e.g. the size variation of ground patterns with distance), implicitly assuming that these characteristics were visible to the pilot, who understood their implications for the position of the plane. Similarly, Anderson's ACT-R model has built-in assumptions that certain learning processes will use information optimally. No strong claim is made that the mechanisms in the model for these processes correspond to the real mechanisms (those that would be discovered by exploration at the symbolic or neural levels).

An important argument for analysis at the knowledge level is that evolutionary processes tend to produce a fit between environmental properties and the behaviors of adaptive organisms in response to them. If sitting is sometimes an important goal, then the organism will become able to recognize objects that afford 'sittability', perhaps logs and chairs among them.

The symbolic level

At the next level below the knowledge level – the information processing, or symbolic, level – the theory takes account not only of the goals and external environment, but also of the actor's knowledge, and ability to use that knowledge to recognize, search and reason. For example, most

means–ends analysis is at this level. PDP and other 'neural net' models are sometimes said to belong to the neural level, or sometimes to combine both levels, denying any separation in this range.

Information processing theories have been especially successful in modeling complex, often ill-structured, professional-level problem solving and design tasks, including chess playing, medical diagnosis, and scientific discovery. Such tasks require intuition, insight, and even creativity. Similar programs compose music, draw, or paint. All of these theories share a common core: they employ recognition and heuristic search as the basic mechanisms in problem solving. Hence, they are instances of a more general theory.

Bounded rationality

Knowledge-level theories, particularly those that assume optimization, have been criticized as ignoring the boundedness of human rationality: limited knowledge, and limited ability to compute consequences and compare incommensurate goals. Defenders of optimization reply that the bounded rationality viewpoint merely calls attention to the occurrence of human irrationality without proposing an alternative; and bounded rationality has sometimes been interpreted incorrectly as declaring that human behavior is largely irrational.

The principal contact between the proponents of knowledge-level optimization and the proponents of bounded rationality has been through research, often published in the fields of economics or decision theory, that attacks specific assumptions of economic theory, especially the consistency of the utility function.

By introducing the variability of human behavior, symbolic-level theories become less general and require the specification of numerous parameters before they can be applied to specific situations. This issue has already been discussed, and ways described of maintaining a high ratio of data points to parameters. It should also be noted that, in actual applications, most optimization models that ignore the limits on human rationality are (and must be) applied to complex real-world situations only after much abstraction and simplification of details, and that these approximations are generally carried out in a very unsystematic way without direct measurement of their effects.

The neural level

It is an important goal of science to connect theories at adjoining levels: for example, symbolic-level psychology with neuroscience, or neuroscience with biochemistry. The major explanatory theories in science use the mechanisms at one level to account for the mechanisms at the next level above without challenging the value of the theory at either level. The second half of the twentieth century saw a rapid growth in knowledge about human cognition at both symbolic and neural levels, as well as at the linkage between neural and biochemical levels. Understanding of the connections between symbolic and neural levels has developed more slowly, but in recent years, more attention has been paid to these connections, and the instruments for discovering them have been greatly improved. The modeling of such connections between levels is likely to receive much attention in the years immediately ahead.

SUMMARY

Cognitive science aims to understand systems as complex as physical and other biological systems. To reach that understanding, scientific representations are needed that provide the same kind of precision and reasoning power that physics, chemistry and biology get from mathematics and from the formal notations that describe chemical structures and processes. Psychology was severely handicapped by the looseness of the language and associated inference processes traditionally employed in its theories. In the past, a major deterrent to the employment of clear representations was that they could only be used if the phenomena were translated into mathematical language.

The modern computer created, to the surprise even of its inventors, a new set of formalisms appropriate for describing and analyzing information processing systems, without needing to cast these descriptions in numerical form. Computer programs can simulate cognition at the level of its information processes, even to the point of actually carrying out the cognitive tasks. Today, we have theories, in the form of operative programs, that give clear and precise accounts of most of the human cognitive processes at the symbolic level that enable people to perform complex, often ill-structured, tasks at professional, and sometimes creative, levels. These accounts may be incorrect in places. But we know that expert behavior derives from knowledge-based recognition and search processes, and we know how this is accomplished in an important collection of task domains.

In cognitive science today, our capabilities for stating theories at the symbolic level far exceed the power of our tools for actually observing the cognitive phenomena in the detail required to test the theories rigorously. As observational means

improve, for example, by advances in the temporal resolution of functional magnetic resonance imaging (FMRI) studies, one can hope that the balance can be restored between our theory building and our observational capabilities.

Computer Modeling of Cognition: Levels of Analysis

Introductory article

Michael RW Dawson, University of Alberta, Edmonton, Alberta, Canada

CONTENTS

According to Marr's three-level hypothesis, information processors must be described at the computational level, the algorithmic level, and the implementational level in order to be fully understood.

MODELING AT SEVERAL LEVELS: DESCRIBING COGNITION FROM MULTIPLE PERSPECTIVES

On 11 May 1997 a computer system called Deep Blue defeated world chess champion Garry Kasparov in a six-game match by a score of 3.5 to 2.5. For researchers interested in modeling high-level cognitive activities like thinking and problem solving, it is instructive to compare Deep Blue and Kasparov, and to consider in what ways these two chess players are different and in what ways they are similar.

At one level of analysis – that of their physical components – they are clearly quite different. Deep Blue is constructed from silicon circuitry, while Kasparov's chess playing ability is based in a biological brain. However, if we consider them from a more abstract perspective, we find that they are similar. At some level of description Deep Blue and Kasparov both fall into the same class of systems, because both can be described as 'chess players'. Furthermore, if one were to only observe a record of the moves made by these two systems, then it would appear that they were very similar because both played chess at a very high level of ability, and in many situations they would choose to make similar moves.

ANALYSIS OF TASK, ALGORITHM AND IMPLEMENTATION

From the example above, it is clear that when researchers wish to compare a computer model with a person or system being modeled, they must consider this comparison from a variety of perspectives. Similarly, when examining some phenomenon of interest in the hope of developing a computer simulation, the phenomenon must be investigated at a number of different levels of analysis.

The vision scientist David Marr argued convincingly that when information processors were being studied, three general levels of analysis were relevant. Each of these levels corresponds to asking a particular kind of question.

The first analysis proposed by Marr is at the *computational* level. At this level of analysis, a researcher is primarily concerned with the question: 'What information processing problem is being solved by the system?' In the chess example, this would involve specifying the abstract 'rules of chess', and classifying a system (e.g. Deep Blue or Kasparov) as being a chess player provided it obeyed those rules. Marr provided many examples in vision in which a computational analysis involved proving that the visual system could be described as solving a particular type of mathematical problem (such as a constrained optimization problem) when it was detecting some visual property (such as a pattern of motion). In general, because computational-level analyses often involve specifying abstract laws, they require researchers to use formal techniques such as mathematical or logical proof. In other words, the answer to the computational-level question is usually a mathematical statement that an information processing system is solving a particular problem; this statement can characterize the abstract laws that define the problem, or that impose constraints on how solutions to the problem are to be achieved. Such a statement can be applied either to a human subject or to a computer simulation.

The second analysis proposed by Marr is at the *algorithmic* level. At this level of analysis, a researcher is primarily concerned with the question: 'What procedures, program, or algorithm is being used by the system to solve the information processing problem?' There are many different ways of solving the same information processing problem. So, while Deep Blue and Kasparov may be equivalent when compared at the computational level, because they are both playing chess, they might at the same time be very different at the algorithmic level because they are using very different procedures to choose their next move.

Answering the algorithmic-level question is the primary goal of empirical cognitive scientists, such as experimental psychologists and psycholinguists. They use the research methodologies of the behavioral sciences to try and determine the procedures used by humans to solve information processing problems. This attempt usually separates into two different investigations. The first attempts to determine the general information processing steps (the program) being used to solve the problem. The second attempts to determine the primitive properties of symbols and the processes that act upon these symbols (the programming language). Many fundamental debates in cognitive science, such as the debate between proponents of symbolic connectionist models, are debates about the nature of the 'programming language' for human cognition. Zenon Pylyshyn has called this 'programming language' the functional architecture of cognition.

The third analysis proposed by Marr is at the *implementational* level. At this level of analysis, a researcher is primarily concerned with the question: 'What physical properties are responsible for carrying out the program or algorithm?' At the algorithmic level, it is sufficient to state what the components of the functional architecture are. At the implementational level, one has to explain how these components are 'brought to life' by an actual physical device. For human cognition, in which we assume that the brain is responsible for carrying out information processing, this requires researchers to determine how brain states and neural circuits are responsible for instantiating the functional architecture. Not surprisingly, the research methods of neuroscience provide the primary tools for answering the implementational-level question.

THE EXAMPLE OF COLOR PERCEPTION

To illustrate the three-level approach, let us consider color perception. In the seventeenth century, Sir Isaac Newton performed experiments with prisms and light and published the results in his book *Opticks*. As far as color vision was concerned, his great discovery was that some colors could be 'constructed' from combinations of others. Newton proposed that human color vision was based upon the perception of seven primary colors. Many alternative theories have been proposed. Goethe proposed a two-color theory in 1810; Young proposed a three-color theory in 1810; four-color theories were proposed by both Hering and Ladd-Franklin in the late nineteenth century.

The question of what is the minimum number of primary colors required for a complete theory of human color perception is a computational-level question. The physicist James Clerk Maxwell answered this question in 1856. Using a 'color solid' proposed by Newton, and an elegant geometric proof, Maxwell was able to show that any perceived color could be expressed in terms of three primary colors.

Maxwell's proof provides important information about color perception in principle, but leaves many unanswered questions about human color vision in practice. For instance, does the human visual system base itself upon the minimal number of primary colors? If so, what three primary colors does it use? These questions arise at the algorithmic level, and must be answered by experimental studies of human vision. In 1873, Helmholtz presented a series of lectures which popularized Young's three-color theory of color perception. This led to decades of psychophysical experimentation, such as having subjects differentiate pure colors from colors created by mixing combinations of light. The results of these experiments supported the Young–Helmholtz theory, indicated that Maxwell's proof applied to human color vision, and demonstrated that our perceptions of color arise from combining the sensations of the three primary colors red, green, and blue.

The answers to the algorithmic-level questions provide a great deal of information about the basic information processing steps used in color vision. However, they give no information about the physical mechanisms that are involved. Helmholtz himself was painfully aware of this. In 1873 he said: 'It must be confessed that both in man and in quadrupeds we have at present no anatomical basis for this theory of colors.' It wasn't until the second half of the twentieth century that a physical account of the Young–Helmholtz theory became possible. Researchers discovered three different kinds of cone cells in the retina, each containing a different light-sensitive pigment. A technique

called microspectrophotometry, in which a small beam of light is passed through individual receptors that have been removed from the retina, revealed that these pigments are sensitive to different wavelengths of light: one is most sensitive to red light, one to green light, and one to blue light.

This example illustrates two general points. First, it shows that a psychological phenomenon can be examined at a number of different levels. Indeed, complete understanding of a phenomenon requires computational, algorithmic, and implementational accounts. Second, this degree of understanding is not easy to achieve. Our detailed modern theories of color perception are based upon several centuries of research.

INVESTIGATING MIND AT A VARIETY OF SCALES

The three levels of analysis that have been described above are not the only approach to understanding and modeling cognitive phenomena. For example, neuroscientists have argued that cognitive science requires a complete understanding of the brain, and that this understanding requires that the brain be examined at a number of different levels. This means analyzing the brain at a number of different scales. The neuroscientist Gordon Shepherd calls these levels of organization. At the largest scale, one studies the behavior of the whole brain. Reducing the scale to the next level of organization, one studies large systems and pathways in the brain (e.g. sensory pathways). At the next level, one studies the properties of specific centers and local circuits. Reducing the scale once more, one studies the properties of neurons (for example, through single cell recording). At even more microscopic scales, one studies structures within neurons (for example, systems of connectivity involving dendrites or axons). Reducing the scale further, one studies individual synapses. Finally, one can study the molecular properties of membranes and ion channels.

Patricia Churchland and Terry Sejnowski have cited these levels of organization as an argument against the three-level approach proposed by Marr. They suggest that because there are so many levels of organization, one cannot talk about a single implementational level. Furthermore, because different implementational levels might have different task descriptions, there will be a multiplicity of algorithms, so that it is inappropriate to talk about a single algorithmic level.

However, Marr's three levels were proposed as properties of an investigation, and not of the system being investigated (that is, they are an epistemology, not an ontology). Marr did not claim that information processors 'have' an algorithmic level. Rather, he claimed that to understand an information processor, one must answer the algorithmic-level questions. These questions need not be applied monolithically to an entire system. Thus, one can ask Marr's three questions of any level of organization in the brain, provided the level in question can be usefully considered as being involved in information processing. The 'levels of analysis' and 'levels of organization' approaches are not mutually exclusive, but are complementary.

SMOLENSKY'S SYMBOLIC AND SUBSYMBOLIC LEVELS

An alternative view of levels has arisen from attempts to relate symbolic models of cognition to connectionist simulations. Paul Smolensky has argued that in the context of connectionist simulations one can distinguish between a symbolic account and a subsymbolic account. To say that a connectionist network is subsymbolic is to say that the activation values of its individual hidden units do not represent interpretable features that could be represented as individual symbols. Instead, each hidden unit is viewed as indicating the presence of a microfeature. Individually, a microfeature is unintelligible, because its 'interpretation' depends crucially upon its context (i.e., the set of other microfeatures that are simultaneously present). However, a collection of microfeatures represented by a number of different hidden units can represent a concept that could be represented by a symbol in a symbolic model. From this perspective, a symbolic account of a network is only an approximate account. A more accurate and complete account of how a network solves a problem can only be found by analyzing it at the subsymbolic level.

The distinction between symbolic and subsymbolic levels is both interesting and important. However, this distinction too is compatible with Marr's approach. One could argue that a subsymbolic account of a network (e.g. a description of its microfeatures) would represent a description of its functional architecture while a symbolic account of the network would represent a description of an algorithm (e.g. a description of symbolic representations), as well as how this algorithm is composed from the functional architecture (the microfeatures).

This observation shows that the three-level approach can be applied to connectionist models as

well as to more traditional symbolic computer simulations. Michael Dawson has argued that the three-level hypothesis applies equally to these two streams within cognitive science because connectionist and symbolic modelers both agree with the general assumption that cognition is information processing. This is an important point because many researchers are concerned that connectionist networks are not fully-fledged cognitive theories, but only provide an implementational account of cognitive phenomena.

SUMMARY

Information processing systems are very complex. In order to provide a complete account of an information processor, or to build a computer simulation of a cognitive phenomenon, three different levels of analysis are required. The computational level addresses the question: 'What information processing problem is being solved?' The algorithmic level addresses the question: 'What information processing steps are being applied to solve the problem?'. Thus the algorithm is distinguished from the functional architecture. The implementational level addresses the question: 'What physical properties are responsible for bringing these information processing steps into existence?' One reason why cognitive science is such a multidisciplinary undertaking is that the answers to these questions require vocabularies and methodologies from such diverse disciplines as mathematics, psychology and biology.

Computer Vision

Introductory article

John K Tsotsos, York University, Toronto, Canada

CONTENTS

Computer vision is a discipline whose major concern is the development of computational methods, in terms of both hardware and software, to acquire, process, and interpret visual images.

INTRODUCTION

Computer vision systems attempt to recover shapes of objects, illumination direction, motion, object structure and identity, composition, and so on, from a digital image of a scene. The purpose of such systems is either to help us understand the contents of the image or to elicit an appropriate response from an autonomous system such as a robot. The interpretative process often occurs in the context of a particular domain. The goal of research in computer vision is to devise methods that approach or even exceed the performance of human vision. In addition, many researchers use the language of computation to formalize theories of biological vision.

Computer vision is difficult. At least half of human (or primate) cerebral cortex is involved in visual processing: this represents a huge amount of neural processing power. Some specific reasons for the difficulty of computer vision are described below.

Problems Inherent in the Analysis of Images

A camera is used to acquire a two-dimensional digital image of a three-dimensional scene. Imagine viewing an unknown scene with one eye and trying to estimate distances in that scene: you cannot do so reliably. Explicit information about depth is not present in a single image. The depth of objects in the scene must be inferred either indirectly or by using a binocular camera system. Indirect inference may use cues in the image such as occlusion (one object being in front of another).

Nor does an image contain explicit information about where the source of illumination is located. The computer system must infer this by considering positions and shapes of shadows, highlights, and shading on surfaces.

Often knowledge of where the scene is located and what the participants in the scene are doing assists greatly with solving ambiguities. For example, if you see a picture of a soccer game that includes a number of players and a ball in the air, from what direction did the ball come and who kicked it? Knowledge of the objects outside the scene and of the timing of the actions that led up to the scene can help with such a question.

The geometry of the camera system presents a different sort of difficulty, because it distorts the image. Extreme perspective effects are commonly seen if a wide-angle lens is used. The image is distorted on a finer scale by sources of noise in the imaging system. Such noise adds small variations to the true values of image intensity and color. For example, image sensors quantize light levels; therefore they do not represent those levels precisely.

Finally, it must be remembered that digital images represent large amounts of information. These bits of information must be compared with one another and combined with one another, and decisions must be made on all possible combinations in order to arrive at an interpretation of the image contents.

Although vision seems effortless for normally-sighted humans, it requires a large amount of processing power. Because of these difficulties, many have questioned whether a computer vision system could ever perform at the level of the human visual system.

Can Vision be Modeled Computationally?

An often-debated question is whether or not human or primate vision – and, more broadly, perception – can be modeled computationally. If not, then research on models of biological vision based on computational principles is sure to fail.

A proof of *decidability* is sufficient to guarantee that a problem can be modeled computationally. A decision problem has the form: given an element of a countably infinite set A, does that element belong to the set B (a subset of A)? Such a problem is decidable if there exists a Turing machine that computes 'yes' or 'no' for each element of A.

Perception, in general, has not yet been formulated as a decision problem, but many subproblems have been so formulated. Visual search, an important subproblem, has been formulated as a decision problem, and is decidable: it is an instance of the 'comparing' Turing machine.

Even if some other aspect of perception were determined to be undecidable, it would not follow that all of perception is undecidable, or that other aspects of perception cannot be modeled computationally. For example, one of the most famous undecidable problems is whether or not an arbitrary Diophantine equation has integral solutions (Hilbert's 10th problem). But this does not mean that mathematics cannot be modeled computationally. Similarly, another famous undecidable problem is the halting problem for Turing machines: it is undecidable whether a given Turing machine will halt for a given initial specification of its tape. This has important theoretical implications, but it certainly does not mean that computation cannot exist.

THE COMPONENTS OF A COMPUTER VISION SYSTEM

The processing stages depend strongly on the problem to be solved. For example, methods for processing color images would not be needed if only grayscale images are received. Similarly, if images from a microscope are analyzed, there is no depth inherent in the domain, so depth-specific processes can be omitted. The following discussion will assume no such domain-specific restrictions, and will describe the stages and components one might consider in the design of a general-purpose vision system. Note, however, that although the phrase 'general-purpose vision system' is often used, and may represent the ultimate goal of research in the area, general-purpose functionality has so far been elusive.

Levels of Analysis

It has been claimed that any information processing system must be understood at three different levels: the computational level, the representational and algorithmic level, and the hardware implementation level. The computational level is concerned with the goal of the computation and with the logic of the solution strategy. The representational and algorithmic level deals with the representations for the input, the output, and the intermediate computations, and with the algorithm that implements the solution strategy. The hardware implementation level concerns the physical realizations of the representations and algorithms – whether in a computer or in a brain. These levels of analysis have become part of the basic computational framework for the study of perception.

Acquiring Images

Cameras with arrays of sensing elements capture digital images. Each sensing element captures the color and brightness over a small region of the scene and translates it to a single value. (This value does not correspond directly to human perception of color and light.) For example, the quantity measured as brightness is irradiance, or power of light per unit area.

The result is an array of picture element values, or pixels, representing the scene. Note that the image is not an exact representation of the scene. The imaging geometry determines the size of the cone of light that is digitized by each pixel sensor; if that cone is large then detail from the scene is lost. There are also noise sources from within the electronic sensors.

The geometry of the imaging system relative to the scene is important if one wishes to recover the elements of the scene from a single image. A computer vision system must assume a projection model. Usually, this is the perspective model, but sometimes, for convenience, one assumes an orthographic projection model whereby the image is formed by rays from the object that are parallel to the optical axis of the camera. Perspective and orthographic projections do not differ much if the distance to the scene is much larger than the variation in distance among objects in the scene. Whatever model is chosen, if computations are made with the origin of a coordinate system on the camera, the frame of reference for the vision system is known as the 'camera frame'.

Often a single image is insufficient to recover the characteristics of a scene. Even an object as simple

as a cube can present difficulties: if, for example, you could see only one face of it, you could not know if it was a cube, a pyramid or some other kind of solid. Edges of the object align with one another, and this alignment obscures the object structure. Only if you rotated the cube, or moved your head, could you confirm the shapes and sizes of the other faces. Using computer-controlled camera systems, researchers have studied this seemingly natural and obvious tactic for deciding between competing recognition hypotheses. In 'active perception', a passive sensor is used in an active fashion, its state parameters being changed according to sensing strategies. In such systems, intelligent control is applied to the data acquisition process in a way that depends on the current state of data interpretation, including recognition.

Active vision is useful in order to see a portion of the visual field that is otherwise hidden, to increase spatial resolution (by moving in closer, or zooming), and to disambiguate aspects of the visual world (for example by analyzing induced motion or lighting changes). In all these uses, some hypothesize-and-test mechanism must be at work. Only if hypotheses are available can a particular action actually yield benefits; otherwise the number of possible interpretations and actions is too large. Furthermore, in practical implementations of active perception, the additional cost imposed on a perceptual system must be considered.

Preparing for Analysis

The image acquisition process leads to a scene representation that contains errors and noise. Usually one attempts to model noise in such a way that algorithms can account for it and compensate for its effects. If it can be assumed that the noise is additive and random, there are algorithms that suppress, smooth or filter it. Such algorithms are usually either applied before any further processing or integrated into other processing stages.

A second major issue is camera calibration. Without calibration, it is impossible to tell, for example, the length of a line in the scene from the length of its representation in the image. If the image acquisition system is calibrated, knowledge of the camera system parameters is related to known coordinates in the three-dimensional scene. As a result, measurements in images can be related to measurements in the scene. Usually, in order to calibrate a camera system, a known target in a known position and pose is captured and the projection equations are solved for the resulting image.

Extracting Features from an Image

Image features are meaningful structures of an image, that is, they are strongly related to elements of the scene being imaged. There are two types of features: global properties, such as the average gray level across the image, and local properties, such as lines, circles, or textures. Each feature corresponds to a particular geometric arrangement of image values. Features that are preserved under some transformation are known as invariants with respect to that transformation. The length of an object, for example, is invariant with respect to rigid movement. Invariants are especially valuable as indices for databases of object models. (*See* **Vision, Early**)

We will now look at some of the most important image features.

Edges

Edges are sets of pixels around which image values exhibit a sharp variation, i.e., discontinuity. Edge detectors are designed to detect such pixels. The first generation of edge detectors simply calculated a discrete approximation to the first derivative of image intensity with respect to position; peaks in this derivative are then candidates for edge points. However, noise can both mask true peaks in the derivative and give rise to false ones.

The second derivative of image intensity, for an ideal step edge, is zero at the point of the step. On one side of the step the value is negative while on the other it is positive. If the step is corrupted by noise, the positive and negative regions of the second derivative may be similarly corrupted, but the zero is much more stable. Edge detectors using this idea have somewhat better properties than the first generation of detectors. They usually smooth the image with a mathematical operation designed to remove noise and then compute an approximation to the second derivative. This is sometimes known as the 'difference of Gaussians' method because the overall process can be modeled by subtracting two Gaussian functions with appropriate parameters. The scale of intensity structure in the image must be carefully considered: for good detection, the scale of the edge detector must be matched to the scale of the image structure.

Regions

'Image segmentation' is the partitioning of an image into regions, or subsets of pixels, that satisfy some homogeneity criterion. The partitioning is constrained so that all pixels are accounted for, there is no overlap between regions, and no two

adjacent regions can be merged into a larger one that still satisfies the criterion. The criterion may relate, for example, to intensity, color, texture, or combinations of these.

How can such a segmentation be computed? Start with an arbitrary segmentation – say, into individual pixels. At each iteration, each region may or may not satisfy the criterion. If it does, then look at those of its neighbors that also satisfy the criterion and try to merge those regions into one. If the new region still satisfies the criterion, keep it; otherwise do not.

If a region does not satisfy the criterion, then split it into smaller regions. Continue the merging and splitting process until no further merges or splits are possible. (Note that regions consisting of single pixels must satisfy the homogeneity criterion, so the process terminates.)

This is known as the split-and-merge algorithm. Such regions are also known as 'connected components'. Segmentation remains one of the more stubborn problems in computer vision owing to the difficulty in defining comprehensive homogeneity criteria that correspond to objects.

Texture

The texture of a surface can be described as a statistical property. Texture elements ('texels') are visual primitives with certain invariant properties that occur repeatedly in different positions, deformations, and orientations inside a given area. The simplest approach to texture is to consider the first-order gray-level statistics of the image ('first-order' statistics are statistics of single pixels, as opposed to groups of pixels). These can be captured by the gray-level histogram (which specifies the frequency of occurrence in the image of each gray-level value). However, such histograms are insensitive to permutations of pixel positions, and thus have limited utility.

Second-order statistics describe pixel pairs in fixed geometric relationships. For example, how many pixels in an image have a given gray level while another pixel, a given distance away along a given direction, has another given value? Such statistics can be computed and used to classify textures such as those corresponding to images of wood, corn, grass, and water. Edge pairs – perhaps requiring certain angular relationships – can also be used to represent textures. (A cloth with a herringbone weave illustrates this.) Texture characteristics can be used as part of a segmentation algorithm to represent properties of regions.

Color

Color can be represented by associating red, green, and blue values with each pixel. Intensity is then the average of these three values. Other color spaces, such as the CIE system or the hue–saturation–intensity system, are also in common use. Each has advantages for different applications.

A major challenge in color processing is to model color constancy, the fact that humans see object colors consistently under widely varying illumination. 'Physics-based' methods attempt to calculate the spectral power distribution of the illumination and the objects. The physics of how light interacts with objects, and how colors are reflected from surfaces, is important in the design of color processing algorithms. The appearance of a surface depends strongly on the type of illumination, the direction of the illuminant, and other ambient light reflected off nearby objects.

Color is often also used as an aid in image segmentation. One technique uses knowledge of object color to classify pixels. For example, in a scene containing a basket of fruit, yellow may indicate banana, red may indicate apple, and so on. The yellow pixels can be grouped together, and if they are in the proper geometric configuration, the region may represent a banana. (*See* **Color Vision, Philosophical Issues about**; **Color Vision, Neural Basis of**; **Color Perception, Psychology of**)

Shape from shading

A smooth opaque object produces an image with spatially varying brightness even if the object is illuminated evenly and is made of material with uniform optical properties. Shading thus provides essential information about object shape. A smooth yellow billiard ball, illuminated with a single light source, has a surface that appears increasingly shaded as the angle of incidence of the light from the perpendicular increases. This effect can be mathematically modeled, and the resulting equation, describing the amount of light emitted from the surface, is called the image irradiance equation. Surface orientation has two degrees of freedom, while brightness – what is measured by image irradiance – has only one. Therefore, one needs to add a constraint in order to solve the image irradiance equation. This constraint may come from an overall smoothness metric on the desired solution, or from the use of multiple images (a technique known as 'photometric stereo').

Shape from texture

If an object's surface is textured, the variation in texture can be used to determine surface shape. Imagine a large white cloth, patterned with blue polka dots. Drape the cloth over a surface so that it is not flat. You can easily deduce the shape of the cloth from the shapes of the polka dots and their variation from true circles in the image seen by your eye. Shape-from-texture algorithms use this variation. Uniformly textured surfaces undergo two types of distortions due to imaging: as a surface recedes from the observer, increasingly large areas of the surface are isotropically compressed onto a given area of the image; and as a surface tilts away from the frontal plane, foreshortening causes anisotropic compression of texture elements. The rate of change of the projected size of texture elements – called the texture gradient – constrains the orientation of the plane.

A surface orientation can be represented by the slant – the angle between the normal to the surface and the projection direction – and the tilt – the angle between the normal's orthographic projection onto the image plane and the x-axis. If we know that a surface has blue dots as texture, then the variation in appearance of those dots in an image can be expressed as a slant and tilt and used to represent changes of local orientation of the surface.

Stereoscopic disparity

Normally sighted humans have two eyes. If you hold a finger in front of you and look at it first with the right and then with the left eye, it appears to shift position. The amount of displacement is the horizontal 'disparity'. Your visual system compares the two images and relates the disparity to the depth of the object (in the simplest case, by solving for the triangle formed by your eyes and the object). If you observe a scene with both eyes (a convergent imaging system), there is a single point on which both eyes fixate. At that point, there is zero horizontal and vertical disparity. For convergent systems, vertical disparity is zero only on the $x = 0$ and $y = 0$ planes. Horizontal disparity is zero only on the circle which contains the fixation point and the two eyes. The major problem is how to match a feature in one eye's image with the same feature in the other eye's image (the correspondence problem). For example, if you view a white picket fence from a close-up position, so that the fence covers the entire field of view, and if you look with each eye separately, assuming there is a uniform scene behind the fence (say, blue sky, or a green lawn), then you do not have enough information to know where a given picket in either image lies.

The geometry of the binocular imaging system can help. Given a point in the left image, the corresponding point in the right image is constrained to lie within a line in the right image, called the epipolar line. (This can be derived using the perspective projection transformation from one image to the other image.) In general, three important constraints help with this problem: similarity of corresponding features in the two views; the viewing geometry which constrains corresponding features to lie on epipolar lines; and piecewise continuity of surfaces in scenes. In the picket fence example, if you are close enough to the fence, matching the edges of the pickets will solve the problem if you can make assumptions about the width of the pickets and your viewing distance. (*See* **Depth Perception**)

Motion

Movies are natural representations of changes in object position, shape, and so on, and humans have no difficulty interpreting the apparent motion in an image sequence as equivalent to real motion, if the images are taken close enough in time. The simplest strategy for computing motion from a sequence of images is to consider the differences between successive images. The problem is to determine which pairs of points correspond to each other from one image to the next. This is another correspondence problem. For example, if the image sequence depicts a car moving along a road, it is easy to see that the points corresponding to the door handle in one image belong to those of the same door handle in the second. What about points on a smooth surface? What about the points of light in a fireworks display? Which ones are in correspondence, and what is the algorithm that determines the correspondence? In general, there are six translation and rotation parameters to recover for an object in motion. From two perspective images in time sequence, a computer system can recover only relative translation and not absolute translation of objects in motion at the scene. If the depth of objects in the scene is known, then absolute translation can be recovered.

Velocity can be measured only perpendicular to the contour of the moving object (that is, only one component of the velocity vector can be measured). This is known as the aperture problem. If one can assume that all edges in an image belong to the same rigid surface patch and that motion has constant velocity on the patch, then one can determine

the full velocity vector by solving for the correct velocity in the equations that minimize the error of the measured velocity relative to the correct velocity. The field of velocity vectors thus obtained is known as the optical flow associated with the apparent motion in an image sequence.

If an image sequence contains several moving objects as well as a background, and perhaps a moving camera system, the problem is more complicated. Suppose motion vectors could be defined along the contours and internal structures of each of the objects and of the background. This set of vectors will then contain 'groupings' for each motion: each object produces its own distribution of motion vectors. So in order to determine which groups of vectors correspond to single objects, a mixture of distributions made up of several separate motions can be proposed. The groups of vectors that best fit the distributions would describe single objects in motion. (*See* **Motion Perception, Neural Basis of**)

Representations

How a computer system represents images, extracted features, domain knowledge, and processing strategies is critical to its performance. A number of representational schemes have been proposed whose value has been proven in practice.

Image pyramids

In an image pyramid, an image is represented as a number of layers, each layer being an image. Successive images have smaller numbers of pixels representing the whole image. Each layer computes image properties (at successively coarser resolutions), and each computation communicates only with computations occurring in layers immediately above or below or with computations within the layer. This representation helps to reduce the amount of computation required: the coarser layers constrain the processing in the more detailed layers.

Intrinsic images

Intrinsic images form an intermediate level of representation, between images and object models. They consist of a number of separate feature maps that interact so that they can be computed unambiguously. The features they describe may include surface discontinuities, range, surface orientation, velocity, and color. These representations seem to be related to the processing stages in the primate cortex, where different kinds of computations seem to be grouped together in separate, but interacting, brain areas.

Image sketches and visual routines

Progressions of successively more abstract representations are often useful for coding complex visual information. One commonly-used sequence consists of the 'primal' sketch, the 'two-and-a-half-dimensional' sketch, and the 'three-dimensional' sketch. The primal sketch represents intensity changes and their organization in a two-dimensional image. The two-and-a-half-dimensional sketch represents the orientation and depth of surfaces, and discontinuity contours. Finally, the three-dimensional sketch represents shapes and their spatial organization.

Given the large number of feature types that might be computed on an image, and the representations that arise from them, how can a vision system integrate this information in a meaningful manner? The idea of visual routines addresses this question. These routines extract abstract shape properties and spatial relations from the early representations. Shape properties are characteristics of single items (e.g. length, orientation, area), and spatial relations are characteristics of two or more items (e.g. 'above', 'inside', 'longer than'). Shape properties and spatial relations are important for object recognition, visually guided manipulation, and abstract visualizations. Using a fixed set of basic operations, the visual system might assemble different visual routines to extract a variety of shape properties and spatial relations. Several specific operations have been proposed, including shifts of attentional focus, indexing to an 'odd man out' location, bounded activation, boundary tracing, and marking.

Object representations

Vision systems require the explicit representation of points, curves, surfaces, and volumes. There are a number of schemes that are employed, but there is no consensus yet on what constitutes an adequate set of primitives for spatial representations. Several popular methods exist for representing an object, including 'generalized cylinders', 'deformable models', 'geons', and 'aspect graphs'.

Strategies for Recognition

Several methods have proved useful for recognition of objects in images. The three most important are model-based, invariant-based, and appearance-based methods. The problem of recognition remains unsolved in general. At an abstract level,

recognition of objects in an image given a database of object types seems solvable in principle. One needs only to locate groups of features that might be objects, and then match each group to a model in the database. This is a hypothesize-and-test strategy: you first make a hypothesis, then test it; if it is false, you refine it and test it again, and so on until you are successful. If the image object is an instance of one of the models, then this procedure will find it.

This is a search task. However, a problem common to many search tasks arises: if it is not known in advance which parts of an image match with which parts of a model in a database, then all possible combinations of pixels must be checked, which is computationally infeasible.

Selective attention is an important mechanism for dealing with this problem. A visual attention mechanism can help with the selection of a region of interest in the visual field, the selection of feature dimensions and values of interest, the shifting from one selected region to the next, the integration of successive attentional fixations, interactions with memory, indexing into model bases, etc. (*See* **Vision, High-level**; **Object Perception, Neural Basis of**; **Vision: Object Recognition**; **Audition, Neural Basis of**; **Spatial Attention, Neural Basis of**; **Selective Attention**; **Vision: Top-down Effects**)

Model-based recognition

It is common for systems to employ databases of models to help with recognition. Important subtasks in recognition include deciding which models in the database have instances in the image, where those instances are, and their orientations.

Recognition can be viewed as a process that proceeds from the general to the specific and that overlaps with, guides, and constrains the derivation of a description from the image. For example, a database of models can be constructed using volumetric primitives and organized using a specialization hierarchy as well as a decomposition hierarchy. Models can be selected according to the characteristics of the extracted volumetric primitives.

Interpretation trees represent methods that use features of objects for recognition. Each model in the database is described by its component features, and the description must include the constraints between features. The interpretation tree enumerates all possible ways in which a given set of features found in an image can be matched with features of particular objects in the model base. Methods for searching this tree focus on limiting search so that not all of the tree need be examined (the trees can grow exponentially). An assignment can be verified by back-projecting the resulting model into the image (using the positions of features, and modeling the image formation process to see whether the object actually looks like the one in the image).

Much work has been done on understanding scenes with polyhedral objects. Edges are found and connected, and the resulting sequences labeled as concave or convex with respect to the polyhedron; shadows, occluding boundaries, and so on are also hypothesized. Labeled edges can then be grouped into hypothesized whole objects, and these hypotheses can be confirmed within an interpretation tree.

Invariant-based recognition

Invariants are properties of geometric configurations that do not change under certain transformations. For example, the length of an edge of a solid, rigid object is an invariant property of that object. Suppose several such invariants for a set of objects are defined. The database of objects can then have a feature vector associated with each model, where the features of the vector are all invariants. These features can be used as indices into the database. For example, if objects have planar sides and lines are straight or simple conics, then sets of contours may participate as invariant features under projective transformation.

Appearance-based recognition

Images themselves can also be considered as features. In order to make such features usable, several images of each object, taken from different viewpoints (and illumination conditions, if relevant), are needed. Object models in a database are defined by such a set of images. Face recognition is a particularly good application of this method.

Suppose you have a set of pictures, say, passport photographs. The size of the face in each is about the same; there is only a single face in each; and the lighting is approximately the same in each. Suppose now that you compute the average image: add up the pixel values at each location from all the pictures and divide by the number of pictures. Each picture can then be redefined as the sum of this average picture and a representation of how the image differs from the average in terms of a relatively small set of 'principal components' of the image set. This provides an economical way of representing the images. For any new picture, you compute this representation. Representations can be compared: if the new image is sufficiently close

to one of the stored images, then they are taken to represent the same person.

Choosing a recognition strategy

In each of the above methods, the computer system must include representations that formalize the knowledge of a domain. Performance depends critically on the representation, the control strategy that uses this knowledge, and the quality of the knowledge. Only if the knowledge of how to solve the task can be extracted, codified in a suitable formalism, and used in drawing conclusions during processing, will the method work. The choice of recognition strategy thus depends on the kinds and qualities of domain knowledge available. If only very general knowledge of the domain is possible then an invaraint strategy might be the best choice. If explicit models are known, then model-based methods are preferable. If control over imaging conditions and scene positioning is possible, then appearance-based methods may be appropriate. The methods may also be combined.

The role of knowledge and its application to guide processing is critical. It can be shown that basic problems in vision such as matching are potentially intractable if no knowledge is used to guide processing: that is, there is no guarantee that those problems can be solved using any existing or future computational resources. The intractability is due solely to the difficulty of selecting which parts of the input image are to be processed: without knowledge, the number of such image subsets increases exponentially.

Task guidance can be implicit (as in positioning a person so that the face is imaged in a particular way) or explicit (as in annotating interesting portions of a scene by hand before computer processing). Attentional selection, using knowledge to optimize processing, may determine which image parts to attempt to process first; if the first few selections are good ones, a great deal of searching can be avoided.

CONCLUSION

Although computer vision has been an active discipline since the early 1960s, progress has been slow. The 1990s saw some promising developments, in part due to the advent of sufficiently powerful computers and the resulting ability to search through more possibilities and to test more complex theories. Computer vision is now widely used in commercial applications. Still, progress on finding theories that address the capabilities of human vision remains slow. This represents the greatest intellectual challenge in the field.

Concept Learning and Categorization: Models

Intermediate article

John K Kruschke, Indiana University, Bloomington, Indiana, USA

CONTENTS

Category learning involves generalizing from one learned case to another in appropriate ways. Models of category learning have been based on various representations, including exemplars, prototypes, rules, and hybrids thereof.

CATEGORIZATION IN COGNITION

Categories pervade our cognition. We classify variously shaped printed squiggles into different letter categories. We classify a spectrum of acoustic signals into phonemic categories. We categorize people, animals, plants, and artefacts, and we base our actions on how we categorize.

A central function of learned categories is generalizing from a particular learned instance to novel situations. If learned knowledge consisted merely of isolated facts with no generalization, then the knowledge would be inapplicable except for the unlikely exact recurrence of the learned situation. For example, learning that a four-legged, striped, 1.0-meter-tall animal is a tiger would not generalize to inferring that a four-legged, striped, 1.1-meter-tall animal is also a tiger. The consequence of this failure to generalize a category could be an eaten learner. At the opposite extreme, if learned knowledge were to generalize too broadly, then complementary errors could be committed: learning that a four-legged, striped, 1.0-meter-tall animal is a tiger would lead to inferring that a zebra is also a tiger. The consequence of this over-generalization could be a starved learner.

An equally crucial goal of learning categories is retaining previously learned knowledge while quickly acquiring new knowledge. For example, after having learned about zebras, it could prove disastrous if learning about tigers required dozens of exposures. It could also be disastrous if the learning about tigers erased valid knowledge about zebras.

Category learning is critically important because it underlies essentially all cognitive activities; yet it is very difficult because: (1) learned categories must generalize appropriately; (2) learning must occur quickly; and (3) new learning must not overwrite previous knowledge. Understanding how learners accomplish these feats is the topic of this article.

Any theory of category learning must specify: (1) what information from the world is actually retained in the mind; (2) how that information is used and learned; and (3) why that particular learning algorithm is useful. These three issues are addressed in turn, for different theories. Each type of theory is initially described informally, to convey the basic motivating principles of the theory. It is then described in formal, mathematical terms. By being expressed mathematically, the theory gains: quantitative precision rather than vague verbal description; publicly derivable predictions rather than theorist-dependent intuitively derived predictions; stronger support when predictions are confirmed in quantitative detail; greater explanatory power when the formal mechanisms in the model have clear psychological interpretations; and greater applicability because of precise specification of relevant factors.

EXEMPLAR THEORIES

Perhaps the simplest way to learn is just to memorize the experienced instances. For example, a learner's knowledge of the category *dog* might consist of knowing that the particular cases named Lassie, Rin-Tin-Tin, Old Yeller and Pongo are exemplars of dogs. There is no derived representation of a prototypical dog, nor is there any abstracted set

of necessary and sufficient features that define what a dog is. As new cases of dogs are experienced, these cases are also stored in memory. Notice, however, that just because these exemplars of dogs are in memory, the learner need not be able to distinctly recall every dog ever encountered. Retrieving a memory might be quite different from using it for categorization.

According to these exemplar theories of categorization, a new stimulus is classified according to how similar it is to all the known instances of the various candidate categories. For example, a newly encountered animal is classified as a dog if it is more similar to known exemplars of dogs than it is to known exemplars of cats or horses, etc. The notion of similarity, therefore, plays a critical role in exemplar theories.

Selective attention also plays an important role in exemplar theories. Not all features are equally relevant for all category distinctions. For example, in deciding whether a novel animal is a dog or a cat, it might be more important to pay attention to size than to number of legs, because dogs and cats tend be of different sizes, but have the same number of legs.

In principle, exemplar encoding can accurately learn any possible category structure, no matter how complicated, because the exemplars in memory directly correspond with the instances in the world. This computational power of exemplar models is one rationale for their use. On the other hand, the uniform application of exemplar encoding can make learning slow, if highly similar instances belong to different categories. One way around this problem is to associate exemplars with categories only to the extent that doing so will improve accuracy of categorization. Analogously, features or stimulus dimensions may be attended to only to the extent that doing so will reduce error. Error reduction is one rationale for theories of learning.

Formal Models of Exemplar Theories

In a prominent exemplar-based model (Kruschke, 1992; Medin and Schaffer, 1978; Nosofsky, 1986), a stimulus is represented by its values on various psychological dimensions. For example, a tiger might be represented by a large numerical value on the dimension of size, and by another large numerical value on the dimension of ferocity, along with other values on other dimensions. The psychological value on the d^{th} dimension is denoted $\psi_d{}^{\text{stim}}$. For the m^{th} exemplar in memory, the psychological value on the d^{th} dimension is denoted $\psi_{md}{}^{\text{ex}}$. These psychological scale values can be determined by methods of multidimensional scaling (e.g., Kruskal and Wish, 1978).

The similarity of the stimulus to a memory exemplar gets larger as the distance between the stimulus and the exemplar in psychological space gets smaller. For psychological dimensions that can be selectively attended to, the usual measure of distance between the stimulus, s, and the m^{th} memory exemplar is given by $\text{dist}(s,m) = \sum_i \alpha_i |\psi_i{}^{\text{stim}} - \psi_{mi}{}^{\text{ex}}|$, where the sum is taken over the dimensions indexed by i, and $\alpha_i \geq 0$ is the attention allocated to the i^{th} dimension. When attention on a dimension is large, then differences on that dimension have a large effect on the distance, but when attention on a dimension is zero, then differences on that dimension have no effect on the distance. The distance is then converted to similarity by an exponentially decaying function: $\text{sim}(s,m) = \exp(-\text{dist}(s,m))$. Therefore, when the stimulus exactly matches the memory exemplar, the similarity is 1.0, and as the distance between the stimulus and the memory exemplar increases, the similarity decreases towards zero. (Shepard (1987) provides a review of the properties of the exponential similarity function.)

Each exemplar then 'votes' for the categories. The strength of an exemplar's vote is its similarity to the stimulus, and the exemplar's selection of categories is a continuous weighting given by its associative strengths to the categories. The associative strength from exemplar m to category k is denoted w_{km}, and the total 'voting' for category k is $v_k = \sum_m w_{km} \text{sim}(s,m)$. The overall probability of classifying the stimulus into category k is the total vote for category k relative to the total of votes cast. Formally, the probability of classifying stimulus s into category k is given by $p_k = v_k / \sum_c v_c$.

In laboratory experiments on category learning, after the learner makes his or her guess as to the correct categorization of a given stimulus, he or she is given corrective feedback, and then tries to learn this correct answer. The same procedure applies to learning in the model. The model adjusts its associative weights and attention strengths to reduce the error between its vote and the correct answer. Error is defined as $E = \sum_k (t_k - v_k)^2$, where t_k is the 'teacher' value: $t_k = 1$ if k is the correct category, and $t_k = 0$ otherwise. There are many possible methods by which the associative weights and attention strengths could be adjusted to reduce this error, but one sensible method is 'gradient descent' on error. According to this procedure, the changes that make the error decrease most rapidly are computed according to the derivative of the error with

respect to the associative weights and attention strengths. The resulting formula for weight changes is $\Delta w_{km} = \lambda(t_k - v_k)\ \mathrm{sim}(s, m)$, where λ is a constant of proportionality called the learning rate. This formula states that the associative weight between exemplar m and category k increases to the extent that the exemplar is similar to the current input and the category teacher is under-predicted. Notice that after the weight changes according to this formula, the predicted category will be closer to the correct category; i.e., the error will have been reduced. The formula for attentional changes is slightly more complicated, but essentially it combines information from all the exemplars to decide whether attention on a dimension should be increased or decreased (Kruschke, 1992; Kruschke and Johansen, 1999).

Variants of this exemplar model have been shown to fit a wide range of phenomena in category learning and generalization (e.g., Choi *et al*., 1993; Estes, 1994; Kruschke and Johansen, 1999; Lamberts, 1998; Nosofsky and Kruschke, 1992; Nosofsky, Gluck *et al*., 1994; Nosofsky and Palmeri, 1997; Palmeri, 1999).

PROTOTYPE THEORIES

Instead of remembering every exemplar of a category, the learner might construct a representation of what is typical of the category. For example, the mental representation of *dog* might be an average of all the experienced instances. The dog prototype need not necessarily correspond to any actually experienced individual dog. Alternatively, the representative summary could be an idealized caricature or extreme case that is maximally distinct from other categories, rather than the central tendency of the category.

According to prototype theories of categorization, a new stimulus is classified according to how similar it is to the prototypes of the various candidate categories. A newly encountered animal is classified as a dog if it is more similar to the dog prototype than it is to other category prototypes.

One rationale for this approach to categorization is that it is efficient: the entire set of members in a category is represented by just the small amount of information in the prototype.

Formal Models of Prototype Theories

Prototypes can be formally described in a similar way to exemplars. The prototype for category k has psychological value on dimension i denoted by $\psi_{ki}^{\mathrm{proto}}$, and this value represents the central tendency of the category instances on that dimension. The model classifies a stimulus as category k in a manner directly analogous to the exemplar model, so that the probability of classifying stimulus s as category k is given by $p_k = \mathrm{sim}(s, k) / \sum_m \mathrm{sim}(s, m)$. The sum in the denominator is over all category prototypes, instead of over all exemplars.

In one kind of prototype model, each prototype must be tuned to represent the central tendency of the instances in its category. For the first experienced instance of a category, the prototype is created and set to match that instance. For subsequently experienced instances of the category, the prototype changes from its current values slightly towards those of the new case. By moving towards the instances of the category as they are experienced, the prototype gradually progresses towards the central tendency of the instances.

One way of formalizing the learning of central tendencies is the following algorithm, closely related to so-called 'competitive learning' or 'clustering' methods. The idea is that a prototype should be adjusted so that it is as similar as possible to as many instances as possible; in this way the prototype is maximally representative of the stimuli in its category. Define the total similarity of the prototypes to the instances as $S = \sum_{k,s} \mathrm{sim}(s, k)$, where $\mathrm{sim(s,k)} = \exp(-\sum_{\mathrm{i}} \alpha_{\mathrm{i}} [\psi_{\mathrm{i}}^{\mathrm{stim}} - \psi_{\mathrm{ki}}^{\mathrm{proto}}]^2)$. (This summation across all instances does not require that all the instances be stored in memory, nor that the instances be simultaneously available for learning.) The question then is how best to adjust $\psi_{ki}^{\mathrm{proto}}$ so that the total similarity increases. One way to do this is gradient ascent: the prototype values are adjusted to increase the total similarity as quickly as possible. The resulting formula, determined as the derivative of the total similarity with respect to the coordinates, yields $\Delta\psi_{ki}^{\mathrm{proto}} = \lambda\ \mathrm{sim}(s, k)\alpha_i(\psi_i^{\mathrm{stim}} - \psi_{ki}^{\mathrm{proto}})$. This formula causes each prototype's values to move towards the currently experienced stimulus, but only to the extent that the prototype is already similar to the stimulus, and only to the extent that the dimension is being attended to. In this way, prototypes that do not represent the stimulus very well are not much influenced by the stimulus.

Some models allow multiple prototypes per category, to capture multimodal distributions (Anderson, 1991), and use other learning methods derived from Bayesian statistics. In the extreme case, there can be one prototype per exemplar, and such models become equivalent to exemplar models (Nosofsky, 1991). In exemplar models,

however, the coordinates of the exemplars typically do not get adjusted from one trial to the next.

In several studies that compare prototype and exemplar models, it has been found that prototype models do not fit data better than exemplar models (e.g. Ashby and Maddox, 1993; Busemeyer *et al*., 1984; Busemeyer and Myung, 1988; Nosofsky, 1992; but cf. Reed, 1972), but some have found evidence for prototypes either early or late in learning (Homa *et al*., 1993; Smith and Minda, 1998). Prototype theory is, however, intuitively appealing, and a challenge for cognitive scientists is to discover phenomena that are naturally addressed by prototype models but that cannot be adequately accounted for by exemplar-based models, or by rule-based models, which are described next.

RULE THEORIES

Yet another way of representing categories is with rules that specify strict necessary and sufficient conditions for category membership. For example, something is a member of the category 'bachelor' if it human, male, unmarried and eligible. Many natural categories are very difficult to specify in terms of rules, however (e.g. Rosch and Mervis, 1975). For example, the category 'game' has no necessary and sufficient features (Wittgenstein, 1953). Nevertheless, people are prone to look for features that define category distinctions, and people tend to believe that such defining features exist even if in fact they do not (Brooks, 1978; Brooks *et al*., 1998).

Rules for category definition are typically a single threshold on a single dimension: for example, a building is a skyscraper if and only if it is taller than 10 floors. Rules can also be logical combinations of such thresholds: for example, a building is a skyscraper if and only if it is taller than 10 floors and its facade is at least 60% glass. In some rule-based theories, rules can be more complicated boundaries: for example, a building is a skyscraper if and only if the number of floors multiplied by the percentage of glass in the facade exceeds the value 6.0. (By this multiplicative rule, a building only seven floors tall would be classified as a skyscraper if it had at least 86% glass in its facade, because $7 \times 86\% > 6.0$.)

In principle, categorization rules are absolute, and there is no 'gray area' around the boundary of the category. In practice, however, most rule-based models do incorporate some mechanism for blurring the category boundary, to accommodate real performance data.

Formal Models of Rule Theories

Traditionally, rule models have been referred to as 'hypothesis testing' or 'concept learning' models (for a review, see Levine, 1975). In these sorts of models, individual features are tested, one at a time, for their ability to account for the correct classifications of the stimuli. For example, the model might test the rule 'if it's red then it's in category K'. As long as the rule works, it is retained, but when an error is encountered, another rule is tested. As simple rules are excluded, more complicated rules are tried. A recent incarnation of this type of model is also able to learn exceptions to rules, by testing additional features of instances that violate an otherwise successful rule (Nosofsky, Palmeri and Mckinley, 1994). This model is also able to account for differences in behavior between people, because there can be different sets of rules and exceptions that equally well account for the classifications of the stimuli.

For stimuli that vary on continuous dimensions, there is a well-studied class of models for which the decision boundary is assumed to have a shape that can be described by a quadratic function, because a quadratic describes the optimal boundary between two multivariate normal distributions, and natural categories are sometimes assumed to be distributed normally (e.g. Ashby, 1992). In this approach, there are three basic postulates: (1) the stimulus is represented as a point in multidimensional space, but the exact location of this point is variable because of perceptual noise; (2) a stimulus is classified according to which side of a quadratic decision boundary it falls on; (3) the decision boundary is also subject to variability because of noise in the decision process. Thus, although the classification rule is strict and there is no explicit role in the model for similarity gradients, the model as a whole produces a gradation of classification performance across the boundary because of noise in perception and decision. There are many variations on this scheme of models, involving different shapes of boundaries, deterministic or probabilistic decision rules, and so on. (Ashby and Alfonso-Reese, 1995; Ashby and Maddox, 1993).

HYBRID REPRESENTATION THEORIES

It is unlikely that any one of these types of representation can completely explain the complexity of human category learning. A variety of work has shown that neither rule-based nor prototype models can fully account for human categorization (e.g. Ashby and Waldron, 1999; Kalish and

Kruschke, 1997). In particular, exemplar representation must be supplemented with rules to account for human learning and generalization (Erickson and Kruschke, 1998). Therefore, some recent theories combine different representations. A model constructed by Vandierendonck (1995) combines rectangular decision boundaries with exponentially decaying similarity gradients. A model constructed by Ashby *et al*. (1998) combines linear decision boundaries that involve single dimensions (corresponding to verbalizable rules) with linear decision boundaries that combine two or more dimensions (corresponding to implicitly learned rules). A model constructed by Erickson and Kruschke (1998) combines exemplars with single-dimension rules.

The challenge for hybrid representation theories is specifying the interaction of the various types of representation. If there are several representational types available, under which conditions is each type used? In the model of Erickson and Kruschke (1998), for example, which combines rules with examples, the representations compete for attention, so that the type of representation that reduces categorization error most quickly is the type that is used for that instance. Hybrid models will probably proliferate in the future.

ROLE OF SIMILARITY

Similarity is critical in exemplar and prototype theories, and also appears in hybrid rule-based theories as distance from the boundary (e.g. Vandierendonck, 1995). Some researchers have criticized the notion of similarity as being internally incoherent, or have argued that similarity does not always correlate with categorization.

Similarity can be empirically investigated in several different ways. One method is simply to ask people to rate the similarity of two items; another is to measure discriminability between items. Usually these different assessments agree, but sometimes they do not (e.g. Tversky, 1977). Similarity can be context-specific: in the context of hair, gray is more similar to white than to black, but in the context of clouds, gray is more similar to black than to white (Medin and Shoben, 1988). In general, models of similarity presume which features or dimensions are used for comparing the objects, without any explanation of why those features or dimensions are selected. Models of similarity do have parameters for specifying the attention allocated to different features, but the models do not describe how these attentional values arise (Goodman, 1972; Murphy and Medin, 1985).

Similarity is not always a clear predictor of categorization. Consider the category *things to remove from a burning house*. The items 'heirloom jewellery' and 'children' are both central members of this category, yet they have little surface similarity (Barsalou, 1983). On the other hand, if attention is directed only to the features *irreplaceable* and *portable*, then children and heirloom jewellery bear a strong similarity. Once again the question of what to attend to is crucial, but not addressed by current theories of similarity.

Despite these complexities, there are strong regularities in similarity and categorization data that should yield to formal treatment. Excellent reviews of these topics have been written by Goldstone (1994) and by Medin *et al*. (1993).

SUMMARY

Categorization is central to cognition. Different theories of category learning posit different representations for the information underlying categorization. Research has shown that no single type of representation can account for the full range of categorization observed in humans. Instead, recent models combine different types of representations in hybrid systems. Challenges for future research include determining how different representations interact, and how attention influences and is influenced by category learning.

CONTENTS

Science must eventually explain how the properties of the brain determine cognitive behavior. Connectionist approaches to cognitive science are based on the belief that our present understanding of neural and brain physiology should guide cognitive research.

INTRODUCTION

Since the detailed anatomy of higher cognition is not known, most connectionist research involves mathematical and computational modeling of behavior. The same modeling techniques also have a wide range of biological, engineering and management applications, and the discipline called 'neural networks' or 'connectionism' now encompasses a wide range of efforts that have only a vague link to the brain or cognition. This article will describe the kinds of connectionist model used in cognitive science and their implications for how we think about thinking.

Connectionist computational models are almost always computer programs, but programs of a different kind from those used in, for example, word processing, or symbolic artificial intelligence (AI). Connectionist models are specified as networks of simple computing units, which are abstract models of neurons. Typically, a model unit calculates the weighted sum of its inputs from upstream units and sends to its downstream neighbors an output signal that is a nonlinear function of its inputs. Learning in such systems is modeled by experience-based changes in the weights of the connections between units.

EARLY DEVELOPMENTS

There is a distinguished prehistory to current connectionist modeling techniques. Many of the original papers are gathered in (Anderson and Rosenfeld, 1988).

Sigmund Freud and William James, arguably the greatest psychologists of the nineteenth century, both discussed explicit neural models of cognition. For much of the first half of the twentieth century, the Anglo-American study of cognition was dominated by the behaviorist paradigm, which rejected any investigation of internal mechanisms of mind. In the 1940s, there arose two new connectionist paradigms, which still shape the field. McCulloch and Pitts (McCulloch, 1988) emphasized the study of particular computational structures comprised of abstract neural elements, while Hebb (1949) focused on the properties of assemblies of cells. The study of bulk properties of abstract neural systems has continued through Hopfield networks (Hopfield, 1982) and the Boltzman machine (Ackley *et al*., 1985), but has had little impact in cognitive science. One lasting result of Hebb's work was the Hebbian model of learning, which will be discussed in the next section.

The notion of a computational model is now commonplace in all scientific fields and in many other areas of contemporary life. One builds a detailed software model of some phenomenon and studies the behavior of the model, hoping to gain understanding of the original system. While all fields use computational models, connectionist researchers also invent and study computational techniques for constructing models, presenting the results of simulations, and understanding the limitations of the simulation. From the time of the first electronic computers, people dreamed of making them 'intelligent' by two quite distinct means. The first is to build standard computer programs as models of intelligence. This remains the dominant paradigm in AI and has had considerable success. The second approach was to try to build hardware that was as brain-like as possible

and have it learn the required behavior, this was the origin of connectionist modeling.

LEARNING CONNECTION WEIGHTS

Connectionist models consist of simple computing units (or nodes) connected via weighted links. A node communicates with the rest of the network by transmitting its output to all the nodes immediately downstream of it. This output is a monotonic (and often nonlinear) function of the node's total input. The contribution of each input link to the receiving node's total input is the output of the node at its source multiplied by the weight of the link. The most commonly used input–output transfer functions compute the total input by summing the inputs contributed by all the weighted links and then passing this total input through a nonlinear function. An example of such a nonlinear function is the step function, whereby the node produces an output of 1 (i.e. fires) if and only if the total input exceeds a threshold. Another commonly used function is the sigmoid function, whereby the output of a node varies smoothly between -1 and $+1$ as a function of the total input (the shape of this response curve resembles a stretched S).

The behavior of a connectionist network is completely determined by the input–output transfer function, the pattern of interconnection among the nodes, and the link weights. Typically, the input–output transfer function is assumed to remain fixed for a given model. It is possible to 'sculpt' the interconnection pattern by starting with a completely connected network and then pruning it by setting the weights of certain links to zero. Thus, changes in the functionality of a connectionist network (learning) can be effected by changing only the link weights; and most mechanisms and theories of learning in connectionist networks focus on changes in link weights.

One of the most influential proposals about learning in neural networks was made by Hebb (1949) and is known as Hebb's rule. In its simplest form, this rule states that the weight of the link from node i to node j is strengthened if i repeatedly participates in the firing of j. This rule and its variants lie at the core of many learning rules investigated by neural network modelers and theorists. In its simplest form, the rule suffers from several technical difficulties. These include lack of specificity, and saturation (all link weights would increase until they eventually reached their maximum possible values). To tackle this problem, Hebb's rule has been supplemented with an anti-Hebbian learning rule which says that the weight from node i to node j decreases if node j fires but node i does not; or alternatively, if node i fires but node j does not. The 'BCM' rule (Bienenstock, Cooper and Munro, 1982) states that the weight vector of a node is tilted in the direction of the input vector if the output exceeds a threshold, or in the direction opposite to that of the input vector if the output is below that threshold. The threshold can be variable, and may depend on the time-averaged output of the node. Note that the weight vector of a node with n input links is simply the n-tuple consisting of the n link weights.

Another framework for modifying link weights is competitive learning (von der Malsburg, 1973; Grossberg, 1976; Rumelhart and Zipser, 1985). Informally, the competitive learning algorithm may be described as follows. Let each node compute its output to be the weighted sum of its inputs, and assume that weight and input vectors are normalized to one. Then the output of a node is given by $\cos \alpha$, where α is the angle between the weight vector and the input vector. Weight modification in response to external inputs proceeds as follows: (1) An input pattern is presented to the network; (2) the node with the highest response is identified (this can be achieved by a 'winner takes all' configuration (Feldman and Ballard, 1982)); (3) the weight vector of this winning node is rotated towards the input vector; (4) the weight vector is renormalized. These steps are repeated for each input pattern. As a result of this weight modification regime, the nodes in the network modify their link weights so as to respond maximally to frequently occurring input patterns. In effect, each cluster (or category) in the input space 'recruits' one or more nodes in the network that produce a strong response to input patterns from the associated cluster.

The competitive learning algorithm can be augmented by requiring that (1) nodes in the network are arranged in a low-dimensional lattice (for example, in a linear sequence, or in a two-dimensional grid) and (2) changes in the weight vector of a node are accompanied by similar changes in the weight vectors of neighboring nodes (for example, via lateral connections between neighboring nodes). Such an augmented neural network learning algorithm is called a self-organizing map (Kohonen, 1982). Self-organizing maps have been applied to a variety of problems in pattern recognition. They have the important capability of developing topology-preserving maps from a high-dimensional space to a low-dimensional space. Examples of such maps abound in the brain: for example, several visual features

(e.g., location in the visual field, orientation, direction of motion) are mapped to a layered two-dimensional cortex.

The 'adaptive resonance theory' architecture (Grossberg, 1980) also extends the competitive learning framework by incorporating several new features, such as separate layers for representing features and categories, top-down and bottom-up interactions between these layers, lateral inhibition, and mechanisms for regulating attention and detecting novelty. These mechanisms allow such models to control the granularity of classification, while achieving a balance between plasticity (the ability to learn new categories) and stability (the ability to retain categories that have already been learned).

All of the learning algorithms discussed above belong to the category of unsupervised, or self-organizing, algorithms, since their weight modification depends solely on the inputs. A different class of algorithms arises if the inputs are accompanied by some form of feedback indicative of the network's performance. This feedback can be used by the network to to guide the modification of link weights. Such feedback can be non-specific, providing a single measure of the network's performance (such as a simple positive or negative reinforcement signal); or highly specific, providing a detailed description of the desired network response (for example, a specification of the output pattern for each input pattern). Algorithms with non-specific feedback are called reinforcement learning algorithms (Sutton and Barto, 1998); while algorithms with specific feedback are called supervised learning algorithms (Rosenblatt, 1958; Block, 1962; Minsky and Papert, 1988; Rumelhart *et al*., 1986; Werbos, 1994).

In the most general terms, reinforcement learning means learning to act in a manner that maximizes the expected future reinforcement (reward). A simplified version of this problem can be formulated as follows. In a trial T, the system observes an input pattern (stimulus) $x(T)$ and responds by performing action $a(x(T))$. After a number of such moves, the system receives a positive or negative reinforcement. The objective of the learning algorithm is to discover a policy whereby at each trial, the system chooses an action that maximizes the expected total reward. This is difficult for several reasons. First, there is uncertainty associated with actions: given the complexity and variability of the environment, the result of action a_i in response to input $x(T)$ is not fixed. Second, there can be a significant delay between choosing an action and receiving a reinforcement. Third, examples of optimal actions are not provided and must be discovered by the system through trial and error. Several reinforcement learning algorithms have been developed. These include the 'temporal difference method' and 'Q-learning' (Sutton and Barto, 1998). The central idea in these learning algorithms is, for each reward signal, to assign appropriate credit or blame to the decisions that led to that signal. After enough training, the system acquires tables that list the best action (that which maximizes the expected reward) for each combination of state and input. These tables are taken to stand for weighted connections in a neural network.

Reinforcement learning is more plausible biologically than supervised learning, which requires a teacher to provide detailed answers rather than just a numerical score. It has been applied to models of motor control and related phenomena. But it is much slower than supervised learning in complex tasks, and has not been widely used in cognitive models.

THE PERCEPTRON AND ITS SUCCESSORS

The most striking early result about supervised learning was the perceptron learning theorem (Rosenblatt, 1958; Block, 1962; Minsky and Papert, 1988). The perceptron model uses a single layer of linear threshold units for categorizing simple visual patterns. Each unit calculates the weighted sum of its inputs and fires (outputs 1) if this sum is greater than the unit's threshold. The associated learning rule involves changing each weight if the unit's prediction about an input pattern was wrong. The theorem showed that any classification that could be computed by a perceptron could be learned by this simple rule.

This theorem gave rise to the belief that ever more complex behavior could be learned directly from feedback. This turned out to be overly optimistic as other scientists, notably Minsky and Papert (1988), showed that many simple distinctions could not be captured by such simple networks. This led to a relatively quiet period for connectionist modeling.

Around 1980, a variety of ideas from biology, physics, psychology, computer science and engineering coalesced to yield a 'new connectionist' approach to modeling intelligence, which has become a core field of cognitive science and also the basis for a wide range of practical applications (McClelland and Rumelhart, 1986). Among the important advances was a mathematical technique (back propagation) that extended the early work

on perceptron learning to a much richer set of network structures. Two ideas allowed error feedback to be used to train networks with multiple layers. The first idea was to replace the linear unit function of the perceptron with a smooth and bounded function, typically the sigmoid described above. The second idea exploits the chain rule for partial derivatives to assign appropriate amounts of credit and blame to model units that do not connect directly to the output nodes, where comparisons with training data are made. While it is theoretically possible to apply back propagation to arbitrary networks (McClelland and Rumelhart, 1986), this does not work well in practice, and essentially all of the back propagation work in cognitive science has been based on two architectural styles.

Most of the early connectionist learning models used strictly layered networks with no feedback at all (McClelland and Rumelhart, 1986). These have limited computational ability, but are still used as components of larger models, some of which can be quite elaborate (Plaut and Kello, 1999). A simple modification of the layer architecture (Elman *et al*., 1996) involves adding fixed-weight connections from a hidden layer at one timestep to the same layer at the next timestep. Because the feedback weights remain fixed, the back propagation learning algorithm remains the same, but these networks can learn some serial tasks beyond the capabilities of layered networks without feedback. Most of the current work on learning in unstructured tasks uses this architecture.

THE CONNECTIONIST APPROACH TO COGNITIVE SCIENCE

The basic connectionist style of modeling is now being used in different ways in neurobiology, in applications, and in cognitive science. Neurobiologists who study networks of neurons employ a wide range of computational models, from very detailed descriptions of the internal chemistry of the neuron to the abstract units described above.

In cognitive science, connectionist techniques have been used for modeling all aspects of language, perception, motor control, memory and reasoning. This universal coverage represents a potential breakthrough: previous computational models of, for example, early vision and of problem solving used entirely different mathematical and computational techniques. Since the brain is known to use the same neural computation throughout, it is not too surprising that models based on this paradigm can be applied to all behavior. The existing models are neither broad nor deep enough to ensure that the current set of mechanisms will suffice to bridge the gap between structure and behavior, but the work remains productive.

Connectionist models in cognitive science belong to two general categories, often called structured (or localist) and layered (or parallel distributed processor (PDP)) networks. Most connectionists are primarily interested in learning, which is modelled as experience-driven change in connection weights. There is a great deal of research studying different models of learning with and without supervision, different rules for changing weights, and so on. Since the focus of such an experiment is on what the network can learn, any imposed structure will weaken the results of the experiment. The standard approach is to use networks with unidirectional connections arranged in completely connected layers, sometimes with a very restricted additional set of feedback links. This kind of network contains a minimal amount of imposed structure and is also amenable to efficient learning techniques such as the back propagation method described above. Most researchers using totally connected layered models do not believe that the brain shares this architecture, but there is a controversy, which we will discuss later, about the implications of PDP learning models for theories of mind.

Structured connectionist models are usually focused less on learning than on the representation and processing of information. Essentially all the modeling done by neurobiologists involves specific architectures, which are known from experiment. For structured connectionist models of cognitive phenomena, the underlying brain architecture is rarely known in detail and sometimes not at all at the level of neurons and connections. The methodology employed is to experiment with computational models of the behavior under study that are consistent with the known biological and psychological data and are plausible in terms of the resources (neurons, computing time, etc.) they require. This methodology is very similar to what are called spreading activation models and are widely used in psycholinguistics. Some studies combine structured and layered networks (Regier, 1996) or investigate learning in networks with initial structure dependent on the problem area or the known neural architecture.

Another important difference between the structured and the layered approaches is that the

layered approach assumes that each 'item' (or mental object) is represented as a pattern of activity distributed over a common pool of nodes (van Gelder, 1992). This notion of 'holographic' representation suffers from some fundamental limitations. Consider the representation of 'John and Mary'. If 'John' and 'Mary' are represented as patterns of activity over the entire network such that each node in the network has two specific patterns for 'John' and 'Mary' respectively, then how can the network represent both 'John' and 'Mary' at the same time? The situation gets even more complex if the system has to represent relations such as 'John loves Mary', or 'John loves Mary but Tom loves Susan'. In contrast to the layered approach, the structured approach uses small clusters of nodes with distinct representational status.

An early example of a structured connectionist model was the interactive activation model for letter perception developed by McClelland and Rumelhart (1981). This model consisted of three layers of nodes, corresponding to visual features of letters, letters, and words. Nodes representing mutually exclusive hypotheses within the letter and word layers inhibited each other. For example, nodes representing letters in the same position inhibited each other, since only one letter can exist in a given position. A node in the feature layer was connected via *excitatory* connections (connections with positive weights) to nodes in the letter layer representing letters that contained that feature. Similarly, a node in the letter layer was connected via *excitatory* connections to nodes in the word layer representing words that contained that letter in the appropriate position. Additionally, there were reciprocal connections from the word layer to the letter layer. The interconnection pattern allowed bottom-up perceptual processing to be guided by top-down expectations. The model could explain a number of psychological findings about the preference of words and pronounceable non-words over other non-words and isolated letters. Other examples of early structured connectionist models included word sense disambiguation models (Cottrell and Small, 1983; Waltz and Pollack, 1985), and the semantic network model CSN (Shastri and Feldmanx, 1986). CSN encoded 'is a' relations using links, and property values using binder nodes that connected property, value and concept nodes. CSN could infer the most likely value of a specified property for a given concept, and find the concept that best matched a partial description.

The Binding Problem

A critical limitation of the early connectionist models was that they could not encode dynamic bindings. Consider the representation of the event 'John gave Mary a book'. This cannot be represented by simply activating the conceptual roles 'giver', 'recipient', and 'gift', and the entities 'John', 'Mary', and 'a book'. Such a representation would be identical to that of 'Mary gave John a book'. Unambiguous representation of an event requires the representation of bindings between the roles of an event (e.g., giver) and the entities that fill these roles in the event (e.g., John). In conventional computing, binding is carried out by variables and pointers, but these techniques have no direct neural counterparts.

Structured connectionist modelers have made significant progress towards neurally plausible solutions to the binding problem. Some of these models use the relative positions of active nodes and the similarity of firing patterns to encode bindings (Barnden and Srinivas, 1991). Some assign distinct activation patterns (signatures) and propagate these signatures to establish bindings (e.g., Lange and Dyer, 1989). Some models use synchronous firing of nodes to represent and propagate dynamic bindings (Shastri and Ajjanagadde, 1993; Hummel and Holyoak, 1997). The possible role of synchronous activity for feature binding had been suggested earlier by others (e.g., von der Malsburg, 1981), but a model called Shruti (Shastri and Ajjanagadde, 1993) offered the first detailed computational account of how such activity can be used to solve problems in the representation and processing of high-level conceptual knowledge and to carry out inference.

Shruti is a structured connectionist model that can encode semantic, causal, and episodic knowledge and perform inferences to establish referential and causal coherence. Shruti encodes relational knowledge using neural circuits composed of focal cell clusters. A systematic mapping between relations (and other rule-like knowledge) is encoded by highly efficacious links between focal clusters. Inference in Shruti results from the propagation of rhythmic activity across interconnected focal clusters. There is no interpreter or inference engine that manipulates symbols or applies rules of inference. In general, Shruti combines predictive inferences with explanatory (or abductive) inferences, instantiates new entities during inference, and unifies multiple entities by merging their phases of firing.

Recruitment Learning

In addition to incremental learning driven by repeated exposure to a large body of training data, structured models have also made use of one-trial learning using 'recruitment learning' (e.g., Feldman, 1982). Recruitment learning can be described as follows. Learning occurs within a structured network containing an unassigned group of randomly connected nodes. Recruited nodes in such a network acquire distinct 'meanings' (or functionality) by virtue of their strong connections to previously structured nodes. For example, a novel concept that is a conjunct of existing concepts x_1 and x_2 can be learned by (1) identifying free nodes that receive links from nodes representing both x_1 and x_2 and (2) 'recruiting' one or more such free nodes by strengthening the weights of links incident on such nodes from x_1 and x_2 nodes. In general, the recruitment process can transform a quasi-random network into a collection of nodes and circuits with specific functionalities.

It has been shown (Shastri, 1999) that recruitment learning can be firmly grounded in the biological phenomena of long-term potentiation and long-term depression, which involve rapid, long-lasting, and highly specific changes in synaptic strength.

Rules versus Connections

Perhaps the most visible contribution of connectionist computational models in cognitive science has been to provide a new conceptual framework for some long-standing debates on the nature of intelligence. Much of the current debate is being published in scientific journals. The question of nature versus nurture concerns how much of some trait, usually intelligence, can be accounted for by genetic factors and how much depends on postnatal environment and training. Some PDP connectionists have taken very strong positions suggesting that learning can account for everything interesting (Elman *et al*., 1996). In the particular case of grammar, an important group of linguists and other cognitive scientists take an equally extreme nativist position, suggesting that humans only need to choose a few parameters to learn grammar. A related question is the whether human grammatical knowledge is represented as general rules or just appears as the rule-like consequences of PDP learning in the neural network of the brain. There is ample evidence against both extreme positions, but the debate continues to motivate a great deal of thought and experimentation.

CURRENT AND FUTURE TRENDS

Quantitative neural models are playing a major role in cognitive science. The mathematical and computational ideas underlying learning in neural networks have also found application in a wide range of practical problems, from speech recognition to financial prediction. Given current computing power, back propagation and similar techniques allow large systems of nonlinear units to learn reasonably complex probabilistic relationships using labelled data. This general methodology overlaps not only with AI but also with mathematical statistics, and is part of a unifying theory called computational learning theory. There is also a large community of scientists and engineers who are working on neural networks and related statistical techniques for various tasks, and there are conferences and journals to support this effort.

The explosion of activity on the internet is affecting the whole field of computing. Two application areas that seem particularly important to cognitive science are intelligent web agents and spoken language interaction. As the range of users and activities on the internet continues to expand, there is increasing demand for systems that are both more powerful and easier to use. This is leading to increased efforts on the design of human–computer interfaces, including the modeling of users' plans and intentions – clearly overlapping with traditional concerns of cognitive science. One particularly active area is interaction with systems using ordinary language. While machine recognition of individual spoken words is relatively successful, dealing with the full richness of language is one of the most exciting challenges facing computing and cognitive science, and a problem of great commercial and social importance.

Looking ahead, technical work on connectionist modeling is likely to remain closely linked to statistics and learning theory. From the scientific perspective, it is likely that most interdisciplinary connectionist research in cognitive science will remain focused on specialized domains such as language, speech and vision. With the rapid advances in neurobiology, the field will increasingly connect with the life sciences, yielding great mutual benefits (e.g. Carter *et al*., 1998).

Connectionist Architectures: Optimization

Advanced article

Marcus Frean, Victoria University of Wellington, Wellington, New Zealand

CONTENTS

A key issue in using connectionist methods is the choice of which network architecture to use. There are a number of ways this choice can be made automatically, driven by the problem at hand.

INTRODUCTION

If one takes a training set in the form of input–output pairs and trains a large connectionist network on it, the result is generally 'overfitting'. There are many functions which exactly fit the existing data and the act of learning arrives at just one of them, somewhat arbitrarily. The problem is compounded where the data is noisy, in which case the network uses its extra degrees of freedom to fit the noise rather than the underlying function generating the data. Conversely, if the network is too small it 'underfits', which is equally unsatisfactory. The real aim is usually not to get the training set correct, but to generalize successfully to new data. The model selection problem is to arrive at the network that gives the best possible predictions on new inputs, using only the available training data and prior knowledge about the task. (*See* **Machine Learning**)

There are several ways of controlling the complexity of mappings learned by neural networks. These include varying the number of weights or hidden units by building up or paring down an existing network, and direct penalties (otherwise known as regularization) on model complexity, such as weight decay. Other ideas include partitioning the input space into regions which are locally linear as in 'mixtures of experts', or using genetic algorithms to choose between different architectures.

CRITERIA FOR NETWORK OPTIMALITY

The optimality or otherwise of a network is, in many cases, determined by its ability to generalize. Almost by definition this ability is not directly observable, so in practice we have to make an educated guess at it and use that to choose between networks.

The simplest method takes part of the available data and sets it aside. Once the network has been trained on the remaining data it can be 'validated' by seeing how well it performs on the withheld data, thus giving an estimate of how well it will generalize. This estimate won't be very good unless the hold-out set is large, which wastes a lot of the data that could otherwise be used for training. To minimize this effect, 'cross-validation' applies the same idea repeatedly with different subsets of the data, retraining the network each time. In k-fold cross-validation, for example, the data is divided into k subsets. One at a time, these serve as hold-out sets, and the validation performance is then averaged across them to give an estimate of how well the network generalizes. 'Leave-one-out' cross-validation uses $k = N$, the number of samples, but $k = 10$ is typically used.

Another general approach, from conventional statistics, is to attempt to quantify the generalization performance of trained networks without a validation set at all. One prefers networks with a low 'prediction error'

$$C = C_{data} + C_{net} \quad (1)$$

Here C_{data} is the usual training error, such as the sum of squared errors, and C_{net} is taken to be a measure of the complexity of the network,

proportional to the effective number of free parameters it has. Assuming a nonlinear network is locally linear in the region of the minimum, an approximation to C_{net} can be calculated (Moody, 1992; Murata *et al*., 1994) given the Hessian matrix of second derivatives $H_{ij} = \partial^2 C_{data}/\partial w_i \partial w_i$, which can be found using a number of methods (Buntine and Weigend, 1994). For large training sets, leave-one-out cross-validation and the above are essentially equivalent, with the latter giving the same effect for much less computational effort. These approaches assume a single minimum however, so the estimate can be strongly affected by local minima. On the other hand, leave-one-out cross-validation also gets trapped in local minima, in which case 10-fold cross-validation is preferable.

A third approach is to use Bayesian model comparison to choose between networks, as well as to set other parameters such as the amount of weight decay. Bayesians represent uncertainty of any kind by an initial or 'prior' probability distribution, and use the laws of probability to update this to a 'posterior' distribution in the light of the training set. In this view we should choose between models based on their posterior probabilities given the available data – again this does not require that any data be set aside for validation (MacKay, 1995). In the fully Bayesian approach, ideally we should use not one set of weights and one structure but many sets and many architectures, weighting the prediction of each by their posterior probability. To the extent this averaging can be done, deciding on an 'optimal' model (and indeed all learning as it is usually thought of) becomes unnecessary. (*See* **Reasoning under Uncertainty**; **Pattern Recognition, Statistical**)

Generalization performance is not the only measure of usefulness of a given network architecture. Other potentially important measures are its fault tolerance, training time on the problem at hand, robustness to 'catastrophic forgetting', ease of silicon implementation, speed of processing once trained, and the extent to which hidden representations can be interpreted. (*See* **Catastrophic Forgetting in Connectionist Networks**)

PRUNING OF UNIMPORTANT CONNECTIONS OR UNITS

Pruning algorithms start by training an overly complex network before trimming it back to size. In other words, we knowingly overfit the data and then reduce the number of free parameters, attempting to stop at just the right point. Clearly the general model selection schemes described above (cross-validation, estimated prediction error, and Bayesian model comparison) can be applied to prune overly large networks; however a number of ideas have been formulated that are specific to pruning. Pruning algorithms can remove weights or whole units, and one can think of the choice of which element to remove as being driven by a measure of 'saliency' for that element. Each algorithm uses a different form for this saliency.

A simple measure of saliency to use for weights is their absolute value. However, while it may be true that removing the smallest weight affects the network the least, it doesn't follow that this is the best weight to remove to improve generalization. Indeed this seems completely opposite to weight decay (see below), which in effect 'removes' large weights by decaying them the most, and it performs poorly in practice.

A more principled idea, known as 'optimal brain damage' (Le Cun *et al*., 1990), approximates the change to the error function that would be caused by removal of a given connection or unit, and uses this measure to decide which to remove. To make this approximation, one trains the network until it is at a minimum of the usual error function, and then calculates the Hessian H. Ignoring the off-diagonal elements of this matrix, the saliency of the weight is given by $H_{ii}w_i^2$.

This idea has been further developed in 'optimal brain surgeon' (Hassibi and Stork, 1993), which avoids the assumption that the Hessian is diagonal. Interestingly this gives a rule for changing all the weights, with the constraint that one of these involves the setting of a weight to zero. One must first calculate the full inverse Hessian matrix however, which can make the algorithm slow and memory intensive for large problems.

Statistical tests can also be applied to detect non-contributing units that could be made redundant. For example if two units are in the same layer and are perfectly correlated (or anti-correlated) in their activity, we know the network can perform the same mapping with one of them removed. A particularly simple case is when a unit has the same output all the time, making it functionally no different from the bias unit.

WEIGHT DECAY

In networks whose output varies smoothly with their input, small weights give rise to outputs which change slowly with the input to the net, while large weights can give rise to more abrupt changes of the kind seen in overfitting. For this reason one response to overfitting is to penalize

the network for having large weights. The most obvious way to do this is by adding a new term

$$C_{net} = \frac{\beta}{2}\sum_i w_i^2 \quad 0 < \beta < 1 \tag{2}$$

to the objective function being minimized during learning. The total cost $C = C_{data} + C_{net}$ can then be minimized by gradient descent. For a particular weight we have

$$\Delta w \propto -\frac{\partial C}{\partial w} = -\frac{\partial C_{data}}{\partial w} - \beta w \tag{3}$$

The first term leads to a learning rule such as back propagation (depending on the form of C_{data}), while the second removes a fixed proportion of the weight's current value. Hence each weight has a tendency to decay toward zero during training, unless pulled away from zero by the training data. The 'decay rate' β determines how strong this tendency is. Clearly a major question is how to set β, for which the general methods described earlier are applicable. (*See* **Backpropagation**)

Weight decay helps learning in other ways as well as its effect on generalization – it reduces the number of local minima, and makes the objective function more nearly quadratic so quasi-Newton and conjugate gradient methods work better.

From a Bayesian perspective, weight decay amounts to finding a *maximum a posteriori* (MAP) estimate given a Gaussian prior over the weights, reflecting our belief that the weights should not be too large. Weight decay is not usually applied to bias weights, reflecting the intuition that we have no *a priori* reason to suppose the bias offset should be small. Depending on the nature of the problem, this may not be a particularly sensible prior – for instance we may actually believe that most weights should be zero but that some should be substantially nonzero. One expression of this to use a different weight cost such as

$$C_{net} = \beta \sum_i \frac{w_i^2}{c^2 + w_i^2} \tag{4}$$

This has been called weight elimination, because it is more likely to drive weights towards zero than simple weight decay. Very small weights can then be eliminated. c is a second parameter which needs to be set by hand. An interesting alternative is 'soft weight sharing' (Nowlan and Hinton, 1992) which implements MAP with a prior that is a mixture of Gaussians. The means (which need not be zero) and variances of these Gaussians can be adapted by the learning algorithm as training proceeds.

GENERATIVE ARCHITECTURES

Generative architectures, also called constructive algorithms, build networks from scratch to suit the problem at hand. Once each unit is trained, its weights are 'frozen' before building the next unit. An important advantage of this is that only single layers of weights are being trained at any one time. Accordingly the learning rules involved need only be local to the unit in question (unlike back propagation), which tends to make learning particularly fast and straightforward.

For simplicity each algorithm is described here as it applies to a single output unit – multiple outputs are trivial extensions to this, as described in the cited papers.

Upstarts

The upstart algorithm (Frean, 1990) is a method for constructing a network of threshold units. Imagine a single linear threshold unit (perceptron) that is trained to minimize the number of errors it makes on the training set, and then frozen. This unit, which we will call u, makes two kinds of error: it is either wrongly on, or wrongly off. In the upstart algorithm these errors are dealt with separately by recruiting two new units, which we could call u_- and u_+, one for each type of error. These new units receive the same inputs, but their outputs go directly to u (see Figure 1(a)). The role of u_- is to correct the 'wrongly on' errors by the parent unit u so it has a large negative output weight, while the output weight of u_+ is large and positive since its function is to correct the wrongly off errors. (*See* **Perceptron**)

It is easy to derive appropriate targets for u_-, given the original targets and u's responses: u_- is to be given the target 1 whenever u is wrongly on, while in all other cases its target should be 0. Similarly the target for u_+ is 1 whenever u is wrongly off, and 0 otherwise. Notice that the output of u_- (u_+) does not matter if u was already correctly off (on), so these can be omitted from the child node's training set. Should the child units be free of errors on their respective training sets, u will itself be error-free. If, however, either u_- or u_+ still make mistakes of their own, these errors are likewise of two types and we can apply the same idea, recursively. The result is a binary tree of units, grown 'backwards' from the original output unit. Child nodes spend their time loudly correcting their parent's mistakes, hence the algorithm's name.

Suppose u_- has the output 1 for just one of the wrongly on patterns of u, and is zero in all other

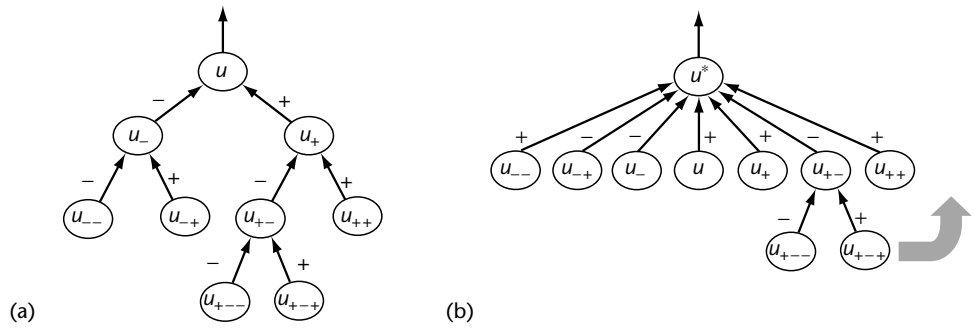

Figure 1. (a) A binary tree constructed by the upstart algorithm. All units have direct inputs, omitted here for clarity. The 'leaves' of the tree make no errors, so neither does the root node. (b) The same network being rearranged into a single hidden layer.

cases. For convex training sets (e.g. binary patterns) it is always possible to 'slice off' one pattern from the others with a hyperplane, so in this case it is easy for u_- to improve u by at least one pattern. Of course we hope that u_- and u_+ will confer much more advantage than this in the course of training. In practice a quick check is made that the number of errors by u_- is in fact lower than the number of wrongly on errors by u, to ensure convergence to zero errors.

Networks constructed using this method can be reorganized into a single hidden layer, if desired. That is, a new output unit can get zero errors by being connected to this layer with weights which are easily found, as shown in Figure 1(b).

For noise-free data this procedure usually produces networks that are close to the smallest that can fit the data, with attendant gains in generalization ability compared to larger networks. Notice however that the training set is learned without errors, so this is just as prone as any other algorithm to overfitting of noisy data (the idea has not been generalized to handle such noise, although there seems no reason why this couldn't be done). One can also use the same procedure to add hidden units to a binary attractor (Hopfield) network, thereby increasing its memory capacity from $\sim N$ to 2^N patterns.

The Pyramid Algorithm

Another algorithm for binary outputs is the pyramid algorithm (Gallant, 1993). One begins as before with a single binary unit, connected to the inputs and trained to minimize the number of errors. This unit is then 'frozen' and (assuming errors are still being made) a new unit is designated the output: this new unit sees both the regular inputs and any (frozen) predecessors as its input, as shown in Figure 2. (*See* **Perceptron**)

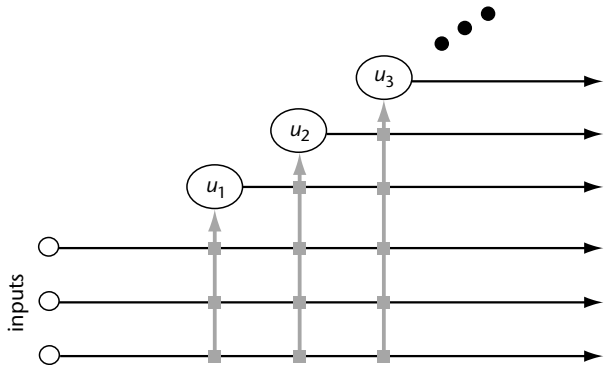

Figure 2. The architecture constructed by the pyramid algorithm. Vertical lines represent multiple connections (shown as squares) to the unit above. Each new unit assumes the role of output.

It is not hard to show that this new unit can achieve fewer errors than its predecessor, provided the input patterns are convex. If it sets its weights from the network inputs to zero and has a positive weight from the previous frozen unit, these two obviously make the same number of errors. As with upstarts, given convex inputs it could then easily reset its input weights so that this behavior was altered for just one input pattern where it was previously in error. This is the 'worst case' behavior, and appropriate weights can easily be predefined, to be improved by training (any method for arriving at good weights for a single unit is applicable). Despite its apparently 'greedy' approach to optimization and its extreme simplicity, the method can build concise networks. For example, given the N-bit parity problem (where the task is to output the parity of a binary input) the upstart algorithm generates a network with N hidden units, while the pyramid algorithm builds the apparently minimal network having only $(N+1)/2$

hidden units. Like the upstart algorithm, the method as it stands is prone to overfitting noisy data.

Cascade Correlation

Cascade correlation (Fahlman and Lebiere, 1990) can be applied to networks with real-valued outputs, and uses sigmoidal hidden units. We begin with a network having only direct connections between inputs and outputs, with no hidden units. These weights are trained using gradient ascent (the delta rule), or whatever learning procedure you like. We then introduce a hidden unit, with connections to the input layer. This unit sends its output via new weighted connections to the original output layer. In upstarts, the hidden unit is binary and is preassigned one of two roles, which determines how it is trained and the sign of its output weight – this is because being binary it can only correct errors of one type by the output unit, given its output weight. In this case, however, the hidden unit is real-valued and this means it can play a role in correcting errors of either sign by the output unit. Fahlman and Lebiere's idea is to train the hidden unit to maximize the covariance between its output and the existing errors by the output units. We can then use this gradient to learn input weights for the hidden unit in the usual way. When this phase of learning is deemed to have finished, all the output unit's connections are retrained, including the new ones. The process can now be repeated with a new hidden unit, with each such unit receiving inputs from the original inputs as well as all previous hidden units. Figure 3 shows the resulting cascade architecture.

A potential problem is that the output can make a lot of errors yet, after averaging, the correlation with a hidden unit can be very small. Despite this the method seems to work well in practice, and can be extended to recurrent networks.

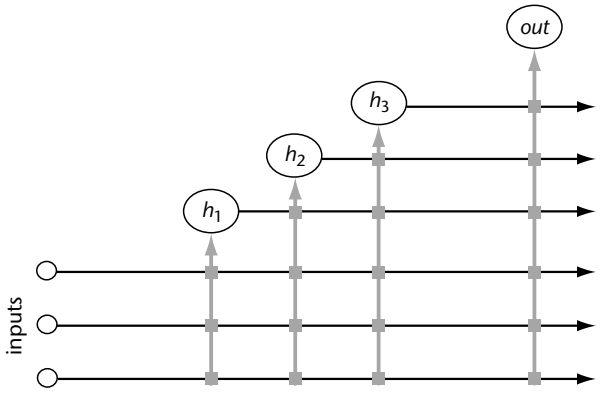

Figure 3. The architecture constructed by cascade correlation.

ADAPTIVE MIXTURES OF EXPERTS

In conventional back propagation networks, each sigmoid unit potentially plays a part in the network's output over its entire range of inputs. One way of restricting the power of the network is to partition the input space into distinct regions, and restrict the influence of a given unit to a particular region. Ideally we would like to learn this partition rather than assume it from the beginning.

A particularly appealing way to do this is known as the 'mixture of experts' architecture (Jacobs *et al.*, 1991). Each 'expert' consists of a standard feedforward neural network. A separate 'gating' network, with as many outputs as there are experts, is used to choose between them. The output of this network is chosen stochastically using the softmax activation function at its output layer,

$$Pr(i = 1) = \frac{e^{\phi_i}}{\sum_j e^{\phi_j}} \tag{5}$$

where ϕ_i is the weighted sum into the ith output unit. This reflects the fact that only one of the outputs is active at any given time. All of the nets (including the switch) are connected to the same inputs as shown in Figure 4, but only the expert that happens to be chosen by the switch is allowed to produce the output. A learning procedure can be found by maximizing the log likelihood of the network generating the training outputs given the inputs, in the same way as the cost function for back propagation is derived. Indeed the learning rule for the 'experts' turns out to be simply a weighted version of back propagation. During learning each expert network gets better at generating correct outputs for the input patterns that are

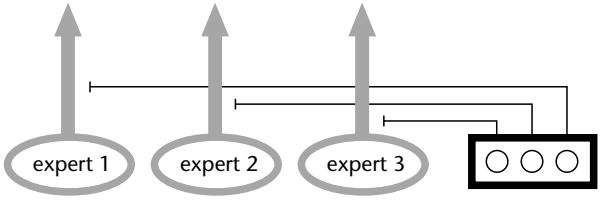

Figure 4. The mixtures of experts architecture. Each expert consists of a separate network, and may have multiple outputs. A separate gating network acts as a switch, allowing just one of the experts to generate the output. All of the experts, together with the gating network, have access to the input pattern.

assigned to it by the switch. At the same time, the switch itself learns to apportion inputs to the best experts. One can think of the switch as performing a 'soft' partition of the input space into sections which are learnable by individual experts. (*See* **Backpropagation**)

A further possibility is to treat each expert as a mixture of experts system itself (Jordan and Jacobs, 1994). A form of hierarchical decomposition of the task can thus be repeated for as many levels as desired. If simple linear units are used for the leaf nodes of the resulting tree-structured network, training can be achieved using a version of the expectation-maximization (EM) algorithm rather than gradient descent.

USING GENETIC ALGORITHMS TO EVOLVE CONNECTIONIST ARCHITECTURES

One criticism of both pruning and constructive algorithms is that they alter networks in only very limited ways, and as such they are prone to getting stuck in local optima in the space of possible architectures. Genetic algorithms offer a richer variety of change operators in the form of mutation and crossover between encodings (called 'chromosomes') of parent individuals in a population. The hope is that networks which are more nearly optimal may be found by evolving such a population of candidate structures, compared to making limited incremental changes to a single architecture. (*See* **Evolutionary Algorithms**)

In generating new candidate architectures, genetic algorithms choose parents based on their performance ('fitness'), which may be evaluated using the techniques described previously for determining network optimality. The main contribution of genetic algorithms then is their more general change operators, principally that of crossover, which operate on the chromosome rather than the network directly. Accordingly, the way in which architectures are mapped to chromosomes and vice versa is of central importance (Yao, 1999).

One approach is to assume an upper limit N to the total number of units and consider an $N \times N$ connectivity matrix, whose binary entries specify the presence or absence of a connection. Any units without outputs are effectively discarded, as are those lacking inputs. A population of such matrices can then be evolved, by training each such network using a learning algorithm initialized with random weights. To apply genetic operators, each matrix is simply converted to a vector by concatenating its rows. Restriction to feedforward networks is straightforward: matrix elements on and below the diagonal are set to zero, and are left out of the concatenation.

A drawback of this approach (though by no means unique to it) is that the evaluation of a given network is very noisy, essentially because the architecture is not evaluated on its own but in conjunction with its random initial weights. Averaging over many such initializations is computationally expensive, and one solution is to evolve both the connections and their values together. In this case an individual consists of a fully specified architecture together with the values of weights. On the other hand cross-over makes little sense for combining such specifications (unless the neural network uses localist units such as radial basis functions) because it destroys distributed representations.

Less direct encodings can be used, such as rules for generating networks, rather than the networks themselves. Evolutionary algorithms have also been used to change the transfer functions used by units (such as choosing between sigmoid and Gaussian for each unit), and even to adapt the learning rules used to set the weights.

Connectionist Implementationalism and Hybrid Systems

Intermediate article

Ron Sun, University of Missouri, Columbia, Missouri, USA

CONTENTS

We may incorporate symbolic processing capabilities in connectionist models, including implementing such capabilities in conventional connectionist models and/or adding additional mechanisms to connectionist models.

INTRODUCTION

Many cognitive models have incorporated both symbolic and connectionist processing in one architecture, apparently going against the conventional wisdom of seeking uniformity and parsimony of mechanisms. It has been argued by many that hybrid connectionist–symbolic systems constitute a promising approach to developing more robust and powerful systems for modeling cognitive processes and for building practical intelligent systems. Interest in hybrid models has been slowly but steadily growing. Some important techniques have been proposed and developed. Several important events have brought to light ideas, issues, trends, controversies, and syntheses in this area. In this article, we will undertake a brief examination of this area, including rationales for such models and different ways of constructing them.

MODELING DIFFERENT COGNITIVE PROCESSES WITH DIFFERENT FORMALISMS

The basic rationale for research on hybrid systems can be succinctly summarized as 'using the right tool for the right job'. More specifically, we observe that cognitive processes are not homogeneous: a wide variety of representations and processes seem to be employed, playing different roles and serving different purposes. Some cognitive processes and representations are best captured by symbolic models, others by connectionist models (Dreyfus and Dreyfus, 1987; Smolensky, 1988; Sun, 1995). Therefore, in cognitive science, there is a need for 'pluralism' in modeling human cognitive processes. Such a need leads naturally to the development of hybrid systems, in order to provide the necessary computational tools and conceptual frameworks. For instance, to capture the full range of skill-learning capabilities, a cognitive architecture needs to incorporate both declarative and procedural knowledge. Such an architecture can be implemented computationally by a combination of symbolic models (which capture declarative knowledge) and connectionist models (which capture procedural knowledge). The development of intelligent systems for industrial applications can also benefit greatly from a proper combination of different techniques, because currently no one technique can do everything successfully. This is the case in many application domains.

The relative advantages of connectionist and symbolic models have been argued at length. (See, for example, Dreyfus and Dreyfus, 1987; Smolensky, 1988 and Sun, 1995 for various views.) The advantages of connectionist models include: massive parallelism; graded representation; learning capabilities; and fault tolerance. The advantages of symbolic models include: crisp representation and processing; ease of specifying detailed processing steps; and the resulting precision in processing. With these relative advantages in mind, the combination of connectionist and symbolic models is

easy to justify: hybrid systems seek to take advantage of the synergy of the two types of model when they are combined or integrated.

Psychologists have proposed many cognitive dichotomies on the basis of experimental evidence, such as: implicit versus explicit learning; implicit versus explicit memory; automatic versus controlled processing; incidental versus intentional learning. Above all, there is the well-known dichotomy between procedural and declarative knowledge. The evidence for these dichotomies lies in experimental data that elucidate various dissociations and differences in performance under different conditions. Although there is no consensus regarding the details of the dichotomies, there is a consensus on the qualitative difference between two types of cognition. Moreover, most researchers believe in the necessity of incorporating both sides of the dichotomies, because each side serves a unique function and is thus indispensable. Some cognitive architectures have been structured around some of these dichotomies.

Smolensky (1988) proposed a more abstract distinction of conceptual versus subconceptual processing; and he related the distinction to that between connectionist and symbolic models. Conceptual processing involves knowledge that possesses the following three characteristics: public access; reliability; and formality. This is what symbolic models capture. There are other kinds of cognitive capacities, such as skill and intuition, that are not expressible in linguistic forms and do not share the above characteristics. It has proved futile to try to model such capacities with symbolic models. These capacities should belong to a different level of cognition: the subconceptual level. The subconceptual level is better modeled by connectionist subsymbolic systems, which can overcome some of the problems faced by symbolic systems modeling subconceptual processing. Therefore, the combination of the two types of models can capture a significantly wider range of cognitive capacities. These ideas provide the justification for building complex hybrid cognitive architectures. For detailed accounts of a variety of examples of the synergistic combination of connectionist and symbolic processes, see Dreyfus and Dreyfus, 1987; Sun, 1995; Waltz and Feldman, 1986; and Wermter and Sun, 2000.

INTEGRATING CONNECTIONIST AND SYMBOLIC ARCHITECTURES

Hybrid models are likely to involve a variety of types of processes and representations, in both learning and performance. Therefore, they will involve multiple heterogeneous mechanisms interacting in complex ways. We need to consider how to structure these different components; in other words, we need to consider architectures. Questions concerning hybrid architectures include:

- Should hybrid architectures be modular or monolithic?
- For modular architectures, should we use different representations in different modules, or the same representations throughout?
- How do we decide whether the representation of a particular part of an architecture should be symbolic, localist, or distributed?
- What are the appropriate representational techniques for bridging the heterogeneity likely in hybrid systems?
- How are representations learned in hybrid systems?
- How do we structure different parts to achieve appropriate results?

Although many interesting models have been proposed, including some that correspond to the cognitive dichotomies outlined above, our understanding of hybrid architectures is still limited. We need to look at the proposed models and analyze their strengths and weaknesses, to provide a basis for a synthesis of the existing divergent approaches and to provide insight for further advances. Below we will provide a broad categorization of the existing architectures.

Architectures of hybrid models can be divided into 'single-module' and 'multi-module' architectures. Single-module systems can be further divided according to their representation types: symbolic (as in symbolic models); localist (i.e. using one distinct node for representing each concept – see, for example, Lange and Dyer, 1989; Sun, 1992 and Shastri and Ajjanagadde, 1993); and distributed (i.e. using a set of overlapping nodes for representing each concept – see, for example, Pollack, 1990 and Touretzky and Hinton, 1988). Usually, it is easier to incorporate prior knowledge into localist models, since their structures can be made to directly correspond to that of symbolic knowledge. On the other hand, connectionist learning usually leads to distributed representation (as in the case of back-propagation learning). Distributed representation has some useful properties.

Multi-module systems can be divided into 'homogeneous' and 'heterogeneous' systems. Homogeneous systems are similar to the single-module systems discussed above, except that they can contain several replicated copies of the same structure, each of which can be used for processing the same set of inputs, to provide redundancy for various reasons; alternatively, each module (of the

same structure) can be specialized for processing inputs of a particular type (of content).

For heterogeneous multi-module systems, several distinctions can be made. First, a distinction can be made in terms of the representations of the constituent modules. There can be different combinations of types of constituent modules: for example, a system may be a combination of localist and distributed modules (as in CONSYDERR, described in (Sun, 1995), or it may be a combination of symbolic and connectionist modules, either localist or distributed (as in CLARION, described in (Sun and Peterson, 1998)).

Second, a distinction can be made in terms of the coupling of modules: a set of modules may be loosely or tightly coupled. In loosely coupled architectures modules communicate with each other, primarily through message passing, shared memory locations, or shared files. This allows for some loose forms of cooperation among modules. One form of cooperation is in terms of the type of processing: while one or more modules take care of preprocessing (e.g. transforming input data) or postprocessing (e.g. rectifying output data), another module focuses on the main part of the task. Preprocessing and postprocessing are commonly done using a neural network, while the main task is accomplished by symbolic methods. Another form of cooperation is through a master–slave relationship: while one module maintains control of the task at hand, it can command other modules to handle some specific aspects of the task. For example, a symbolic expert system, as part of a rule, may invoke a neural network to make a specific classification decision. Yet another form of cooperation is an equal partnership of multiple modules. In this form, the modules (the equal partners) may represent complementary processes; functionally equivalent but structurally and representationally different processes; or differentially specialized and heterogeneously represented 'experts'.

In tightly coupled architectures on the other hand, the constituent modules interact through multiple channels (for example, various possible function calls); or they may even have node-to-node connections between modules (as in CONSYDERR (Sun, 1995) and ACT-R (Anderson and Lebiere, 1988)). As in the case of loosely coupled systems, there are several possible forms of cooperation among modules.

TIGHTLY COUPLED ARCHITECTURES

Let us examine briefly a tightly coupled, heterogeneous, multi-module architecture: CONSYDERR (Sun, 1995). It consists of a concept level and a microfeature level. The representation is localist at the concept level, with one node for each concept, and distributed at the microfeature level, with an (overlapping) set of nodes for representing each concept. Rules are implemented, at the concept level, using links between nodes representing conditions and nodes representing conclusions, and weighted sums are used for evaluating evidence. Rules are diffusely duplicated at the microfeature level in a way consistent with the meanings of the rules. Rules implemented at the concept level capture explicit and conceptual knowledge that is available to a cognitive agent, and diffused representations of rules at the microfeature level capture (to some extent) associative and embodied knowledge. Figure 1 shows a sketch of the model. There are two-way (gated) connections between corresponding representations at the two different levels;

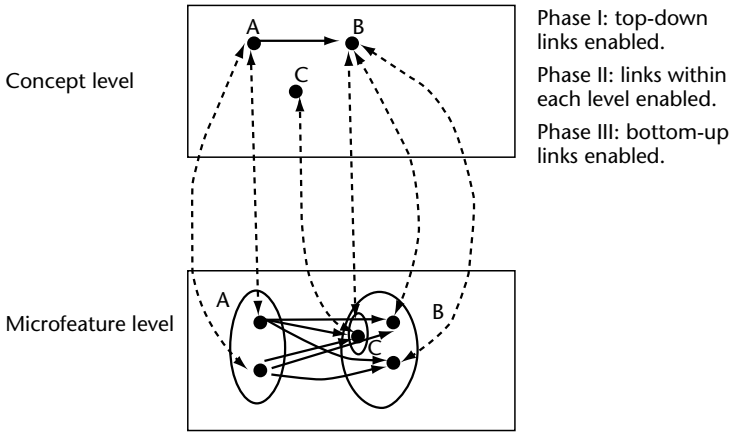

Figure 1. The CONSYDERR architecture.

that is, each concept is connected to all the related microfeature nodes, and vice versa. The operation of the model is divided into three phases: the top-down phase, the settling phase, and the bottom-up phase. In the top-down phase, microfeatures corresponding to activated concepts are themselves activated, enabling similarity-based reasoning at the microfeature level. In the settling phase, rule-based reasoning takes place at each level separately. Finally, in the bottom-up phase, the results of rule-based and similarity-based reasoning at the two levels are combined.

Because of the interaction between the two levels, the architecture is successful in producing, in a massively parallel manner, a number of important patterns of common-sense human reasoning: for example, evidential rule application, similarity matching, mixed rule application and similarity matching, and both top-down and bottom-up inheritance (Sun, 1995).

COMPLETELY INTEGRATED ARCHITECTURES

An even tighter coupling between symbolic and connectionist processes exists in ACT-R (Anderson and Lebiere, 1998). ACT-R consists of a number of symbolic components, including declarative memory (a set of structured chunks), procedural memory (a set of production rules), and goal stacks. Retrieval in declarative memory is controlled by activations of chunks, which spread in a connectionist fashion and are affected by the past history of activations, similarity-based generalization, and stochasticity. Learning of associations among chunks and selection of procedural knowledge also happen in a connectionist fashion. Thus, the learning and the use of symbolic knowledge are partially controlled by connectionist processes. Through this tight integration of the two types of process, ACT-R has been successful in modeling human learning in areas such as arithmetic, analogy, scientific discovery, and human–computer interaction.

LOOSELY COUPLED ARCHITECTURES

Loosely coupled multi-module architectures, unlike the tightly coupled models discussed above, involve only loose and occasional interaction among components. For example, CLARION (Sun and Peterson, 1998), a model for capturing human skill learning, consists of two levels: a symbolic rule level and a connectionist network level. The two levels work rather independently, but their outcomes are combined in decision-making. The network level consists of back-propagation networks, which work through spreading activation and learn by reinforcement. The rule level works according to symbolic rules, which are learned by extracting information from the network level. Through the loose, outcome-based interaction of the two types of processes, the system is able to model a variety of types of human skill learning.

LOCALIST IMPLEMENTATIONS OF RULE-BASED REASONING

Among single-module or homogeneous multi-module models, localist implementations of symbolic processes, especially rule-based reasoning, stand out as an interesting compromise between connectionist networks and purely symbolic models. The representational techniques described below are shared by a number of localist models of rule-based reasoning (see, e.g. Lange and Dyer, 1989; Sun, 1992 and Shastri and Ajjanagadde, 1993).

The simplest way of mapping the structure of a rule set into that of a connectionist network is by associating each concept in the rule set with an individual node in the network, and implementing a rule by connecting each node representing a concept in the condition of the rule to each node representing a concept in the conclusion of the rule. The weights and activation functions can be set to carry out binary logic or fuzzy evidential reasoning.

To express relations, especially relations between large numbers of variables, we need to introduce variables into rules in connectionist implementations. We can represent each variable in a rule as a separate node. We assign values to these variable nodes dynamically and pass values from one variable node to another, based on links that represent variable binding constraints. Such values can be simple numerical signs (Lange and Dyer, 1989; Sun, 1992) or activation phases (Shastri and Ajjanagadde, 1993).

For example, in first-order predicate logic, each argument of a predicate is allocated a node as its representation; a value is assigned to represent an object (i.e., a constant in first-order logic) and thus is a sign of the object. This sign can be propagated from one node to other nodes, when the object that the sign represents is being bound to other variables from an application of a rule.

For each predicate in the rule set, an assembly of nodes is constructed. The assembly contains $k + 1$ nodes if the corresponding predicate contains k arguments. We link up assemblies in accordance

with rules. With this network, we can perform forward-chaining inference. We first activate the assemblies that represent known facts; then activations from these assemblies will propagate to other assemblies to which they are connected. This propagation can continue to further assemblies. For backward chaining, we first try to match the hypothesis with conclusions of existing rules; if a match is found, then we use the conditions of the matching rule as our new hypotheses to be proved: if these new hypotheses can be proved, the original hypothesis is also proved. To implement backward chaining in assemblies, we need, in addition to a predicate node, another node for indicating whether the predicate node is being considered as a hypothesis. Backward flow of activation through hypothesis nodes leads to backward-chaining inference.

Why should we use connectionist models (especially localist ones) for symbolic processing, instead of symbolic models? There are two reasons in particular why researchers explore such models. First, connectionist models are believed to be a more apt framework for capturing many (or even all) cognitive processes (Waltz and Feldman, 1986). The inherent processing characteristics of connectionist models often make them more suitable for cognitive modelling. Second, learning may be more easily incorporated into connectionist models than symbolic models: using, for example, gradient descent and its various approximations, expectation maximization, or the Baun–Welch algorithm. This is especially true of distributed models, but is also true of localist ones to some extent.

DISTRIBUTED IMPLEMENTATIONS OF RULE-BASED REASONING

A stronger notion of integration emphasizes developing symbolic processing capabilities in truly connectionist models, rather than juxtaposing symbolic codes with neural networks, or adopting a compromise as in localist implementations. This approach is more parsimonious explanatorily and thus potentially a more interesting form of cognitive modelling if it can be properly developed. Hence there is considerable interest in symbolic processing capabilities of distributed (or 'true') connectionist models.

An early example is Touretzky and Hinton's (1988) DCPS, which implements a production system in connectionist models. There is a working memory, which stores initially known facts and derived facts; there are two clause components, each of which is used to match one of the two conditions of a rule (each rule is restricted to have two conditions); there is a rule component, which is used to execute the action of a matching rule in the working memory; and a bind component is used to enforce constraints that may exist in a rule regarding variables. Each component is a connectionist network. See Figure 2.

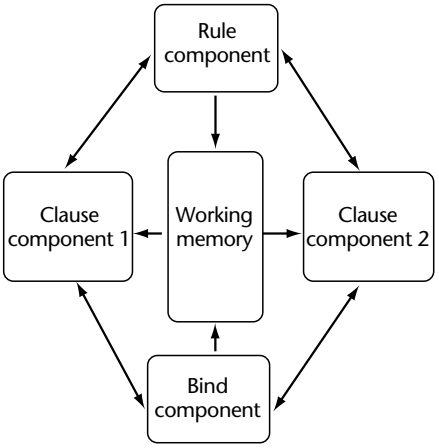

Figure 2. The overall structure of a connectionist production system.

The working memory consists of a large number of nodes, each of which has a randomly assigned 'receptive field'. A *triple* (a fact) is stored in the working memory by activating all the nodes that include the triple in their receptive fields. Many such triples can be stored in the working memory. The two clause components are used to 'pull out' two triples that can match two conditions of a rule. That is, they are used to match triples (in the working memory) with rules (in the rule component). Each node in working memory is connected to a corresponding node in each clause component. A clause component is a kind of 'winner takes all' network.

The rule component is made up of mutually inhibiting clusters. It is also a kind of 'winner takes all' network. Each rule is represented in the rule component by a cluster of identical nodes. The connections from the rule component to the clause components are used to help to pull out the triples that match a rule. In turn, these pulled-out triples also help a particular rule to win in the rule component. After successfully matching a rule with two triples in working memory, actions of the rule are carried out by the gated connections from rule nodes (in the rule component) to nodes in working memory. If the action of the rule includes adding a triple, then the gated connections will excite those nodes in the working memory that

represent the triple; if the action includes deleting a triple, then the gated connections will inhibit those nodes in the working memory that represent the triple to be deleted. Overall, it is a complex system designed specifically to implement a limited production system.

EXTRACTION OF SYMBOLIC KNOWLEDGE FROM CONNECTIONIST MODELS

Many hybrid models involve extracting symbolic knowledge, especially rules, from trained connectionist networks. For example, some researchers proposed a search-based algorithm to extract conjunctive rules from networks trained with backpropagation (see Fu, 1989 and Wermter and Sun, 2000). To find rules, the algorithm first searches for all the combinations of positive conditions that can lead to a conclusion; then, with a given combination of such positive conditions, the algorithm searches for negative conditions that should be added to guarantee the conclusion. In the case of three-layered networks, the algorithm can extract two separate sets of rules, one for each layer, and then integrate them by substitution. Other researchers (e.g. Towell and Shavlik, 1993) tried rules of an alternative form, the 'N of M' form: 'If N of the M conditions $a_1, a_2, \ldots a_M$ are true, then the conclusion b is true.' (It is believed that some rules can be better expressed in such a form, which more closely resembles the weighted-sum computation in connectionist networks, in order to avoid the combinatorial explosion and to discern structures.) A four-step procedure is used to extract such rules, by first grouping similarly weighted links and eliminating insignificant groups, and then forming rules with the remaining groups.

These early rule extraction algorithms are meant to be applied at the end of the training of a network. Once extracted, the rules are fixed; there is no modification 'on the fly', unless the rules are completely extracted again after further training of the network. In some more recent systems, rules can be extracted and modified dynamically. Connectionist learning and rule learning can work together, simultaneously. Thus the synergy of the two processes may be utilized to improve learning (Sun and Peterson, 1998). Dynamic modification is also suitable for dealing with changing environments, allowing the addition and removal of rules at any time.

SUMMARY

Overall, we can discern two approaches toward incorporating symbolic processing capabilities in connectionist models: combining symbolic and connectionist models; and using connectionist models for symbolic processing. In the first approach, the representation and learning techniques from both symbolic processing and neural network models are used to tackle complex problems, including modeling cognition, which involves modeling a variety of cognitive capacities. The second approach is based on the belief that one can perform complex symbolic processing using neural networks alone, with, for example, tensor products, RAAM, or holographic models (see Wermter and Sun, 2000). We may call the first approach 'hybrid connectionism' and the second 'connectionist implementationalism'.

Despite the differences between them, both approaches strive to develop architectures that bring together symbolic and connectionist processes, to achieve a synthesis and synergy of the two paradigms. Many researchers in this area share the belief that connectionist and symbolic methods can be usefully combined and integrated, and that such integration may lead to significant advances in our understanding of cognition.

Constraint Satisfaction

Intermediate article

Rina Dechter, University of California, Irvine, California, USA
Francesca Rossi, Università di Padova, Padova, Italy

CONTENTS

Constraints are a formalism for the representation of declarative knowledge that allows for a compact and expressive modeling of many real-life problems. Constraint satisfaction and propagation tools, as well as constraint programming languages, are successfully used to model, solve, and reason about many classes of problems, such as design, diagnosis, scheduling, spatio-temporal reasoning, resource allocation, configuration, network optimization, and graphical interfaces.

INTRODUCTION

A constraint satisfaction problem (CSP) consists of a finite set of variables, each associated with a domain of values, and a set of constraints. Each constraint is a relation, defined on some subset of the variables, called its scope, specifying their legal combinations of values. Constraints may be described by mathematical expressions, or by computable procedures.

A solution is an assignment of a value to each variable from its domain such that all the constraints are satisfied. Typical constraint satisfaction problems are to determine whether a solution exists, to find one or all solutions, and to find an optimal solution relative to a given cost function.

An example of a constraint satisfaction problem is the well-known k-colorability problem. The task is to color, if possible, a given graph with k colors only, in such a way that any two adjacent nodes have different colors. A constraint satisfaction formulation of this problem associates the nodes of the graph with variables; the sets of possible colors are their domains; and the 'not equal' constraints between adjacent nodes are the constraints of the problem.

Another well-known constraint satisfaction problem in logic concerns 'satisfiability', which is the task of finding a truth assignment to propositional variables such that a given set of clauses are satisfied. For example, given the two clauses $(A \vee B \vee \neg C)$, $(\neg A \vee D)$, the assignment of 'false' to A, 'true' to B, 'false' to C and 'false' to D is a satisfying truth value assignment.

The structure of a constraint problem is usually depicted by a 'constraint graph', whose nodes represent the variables. Two nodes are connected if the corresponding variables participate in the same constraint scope. In the k-colorability problem, the graph to be colored is the constraint graph. In the satisfiability problem above, the constraint graph has A connected with D, and A, B and C connected with each other.

Constraint problems have proved successful in modeling many practical tasks, such as scheduling, design, diagnosis, and temporal and spatial reasoning. The reason is that constraints allow for a natural, expressive and declarative formulation of what has to be satisfied, without the need to say how it should be satisfied.

In addition, many cognitive tasks, such as language comprehension, default reasoning and abduction, can be naturally represented as constraint satisfaction problems. Historically, constraints and constraint satisfaction have been used in many cognitive tasks related to vision (Waltz, 1975).

When an observer looks at a two-dimensional representation of a three-dimensional geometrical scene, each line and line intersection can be interpreted in many ways, but the physical world together with the laws of geometry put restrictions. It is natural to model lines as variables, with three possible values, indicating that a line can represent a convex, concave, or boundary line, and to have constraints among the lines which are incident to the same junction, forcing the usual laws of three-dimensional geometry.

This representation provides a natural modeling, and is useful for finding a geometrically plausible three-dimensional interpretation of the two-dimensional scene. In fact, by looking at just one constraint, one can automatically eliminate values from the domains of its variables, if such values do not agree with the constraint. This can trigger a chain reaction in which other constraints are considered (one at a time) and other values are deleted in the domains of other variables, until nothing more can be deleted. At this point, we are often left with just one value for each variable, that is, the only plausible interpretation of the scene.

This (generally incomplete) method is usually called 'arc consistency' and belongs to the class of constraint propagation techniques that we will describe in greater detail below.

In linguistics, there are constraint-based views of a language (Chomsky and Lasnik, 1992), constraints over the logic of typed feature structures and relations which are used to describe principles of phrase grammars (Pollard and Sag, 1994), and constraint-based linguistic theories, which perform constraint-assisted searches for deductive proofs, in the spirit of constraint logic programming languages (see below).

It should be noted, however, that constraints and constraint satisfaction are sometimes understood in different ways by computer scientists on one hand and linguists and cognitive scientists on the other. In fact, in most cognitive science applications, a constraint is usually interpreted as being universally quantified over all its entities (e.g., linguistic signs), while this is not the way constraints are defined and used in computer science.

CONSTRAINT SATISFACTION AS SEARCH

Complexity of Constraint-related Tasks

In general, constraint satisfaction tasks (like finding one or all solutions, or the best solution) are computationally intractable (NP-hard). Roughly, this means that there are likely to be problem instances requiring all the possible variable instantiations to be considered before a solution (or best solution) can be found, and this can take a time exponential in the size of the problem. However, there are some tractable classes of problems that allow for efficient solution algorithms of all the problems in the class. Moreover, even for intractable classes, many techniques exhibit a good performance in practice in the average case.

Techniques for Solving CSPs

The techniques for processing constraint problems can be roughly classified into two categories: search (also called conditioning), and consistency inference (or propagation). However, techniques can be combined, and in practice, constraint processing techniques usually contain aspects of both categories.

These two methods have a cognitive analogy in human problem solving. Conditioning search uses the basic operation of guessing a value of a variable and trying to solve a subproblem with the guess. Inference corresponds instead to thinking and deduction, with a view to simplifying the problem.

Search algorithms traverse the space of partial instantiations, building up a complete instantiation that satisfies all the constraints, or else they determine that the problem is inconsistent. By contrast, consistency inference algorithms reason through equivalent problems: at each step they modify the current problem to make it more explicit without losing any information (that is, maintaining the same set of solutions). Search is either systematic and complete, or stochastic and incomplete. Likewise, consistency inference algorithms may achieve complete solutions (e.g., by variable elimination), or incomplete solutions. The latter are usually called local consistency algorithms because they operate on local portions of the constraint problem.

Backtracking search

The most common algorithm for performing systematic search for a solution of a constraint problem is the so-called backtracking search algorithm. This algorithm traverses the space of partial solutions in a 'depth first' manner, and at each step it extends a partial solution (that is, a variable instantiation of a subset of variables which satisfies all the relevant constraints) by assigning a value to one more variable. When a variable is encountered none of whose possible values are consistent with the current partial solution (a situation referred to as a dead end), backtracking takes place, and the algorithm reconsiders one of the previous assignments. The best case occurs when the algorithm is able to successfully assign a value to each variable without encountering any dead ends. In this case, the time complexity is linear in the size of the problem (often identified with the number of its variables). In the worst case, the time complexity of this algorithm is exponential in the size of the problem. However, even in this case the algorithm requires only linear space.

Look-ahead schemes

Several improvements to backtracking have focused on one or both of the two phases of the algorithm: moving forward to a new variable ('look-ahead' schemes) and backtracking to a previous assignment ('look-back' schemes) (Dechter and Pearl, 1987). When moving forward to extend a partial solution, some computation (e.g., arc consistency) may be carried out to decide which variable, and which of the variable's values, to choose next in order to either fail quickly if there is no solution, or not fail at all if there is one. Variables that maximally constrain the rest of the search space are usually preferred, and therefore, the most constrained variable is selected. This method follows the so-called 'first fail' heuristics, which aim to force failures as early as possible, in order to cut down on the amount of backtracking. By contrast, for value selection, the least constraining value is preferred, in order to maximize future options for instantiations (Haralick and Elliot, 1980). A well-known look-ahead method is 'forward checking', which performs a limited form of consistency inference at each step, ruling out some values that would lead to a dead end. A currently popular form of look-ahead scheme, called MAC (for 'maintaining arc consistency'), performs arc consistency at each step and uses the revealed information for variable and value selection (Gaschnig, 1979).

Look-back schemes

Look-back schemes are invoked when the algorithm encounters a dead end. These schemes perform two functions. The first is to decide how far to backtrack, by analyzing the reasons for the current dead end, a process often referred to as 'backjumping' (Gaschnig, 1979). The second is to record the reasons for the dead end in the form of new constraints so that the same conflict will not arise again, a process known as 'constraint learning' and 'no-good recording' (Stallman and Sussman, 1977).

Local search

Stochastic local search strategies were introduced in the 1990s and are popular especially for solving propositional satisfiability problems. These methods move in a hill-climbing manner in the space of all variables' instantiations, and at each step they improve the current instantiation by changing the value of a variable so as to maximize the number of constraints satisfied. Such search algorithms are incomplete, since they may get stuck at a local maximum and they are not able to discover that a constraint problem is inconsistent. Nevertheless, when equipped with some heuristics for randomizing the search, or for revising the guiding criterion function (e.g., constraint reweighting), they have been shown to be reasonably successful in solving many large problems that are too hard to be handled by a backtracking search (Selman *et al*., 1992). A well-known local search algorithm for optimization tasks is called 'simulated annealing'.

Evaluation of Algorithms

The theoretical evaluation of constraint satisfaction algorithms is accomplished primarily by worst-case analysis, that is, determining a function of the problem's size that represents an upper bound of the algorithm's performance over all problems of that size. However, the trade-off between constraint inference and search is hardly captured by such analysis. This is because worst-case analysis, by its nature, is very pessimistic, and often does not reflect the actual performance. Thus in most cases an empirical evaluation is also necessary. Normally, an algorithm is evaluated empirically on a set of randomly generated problems, chosen in such a way that they are reasonably hard to solve (this is done by selecting them from the phase transition region (Selman *et al*., 1992)). Several benchmarks, based on real-life applications such as scheduling, are also used.

CONSTRAINT PROPAGATION

Constraint propagation (or local consistency) algorithms (Montanari, 1974; Mackworth, 1977; Freuder, 1982) transform a given constraint problem into an equivalent one which is more explicit, by inferring new constraints which are added to the problem. Therefore, they can make explicit inconsistencies that were implicitly contained in the problem specification. Intuitively, given a constraint problem, a constraint propagation algorithm will make any solution of a small subproblem extensible to some surrounding variables and constraints. These algorithms are interesting because their worst-case time complexity is polynomial in the size of the problem, and they are often very effective in discovering local inconsistencies.

Arc and Path Consistency

The most basic and most popular propagation algorithm, called arc consistency, ensures that any value in the domain of a variable has a legal

match in the domain of any other variable. This means that any solution of a one-variable subproblem is extensible in a consistent manner to any other variable. The time complexity of this algorithm is linear in the size of the problem. Another well-known constraint propagation algorithm is path consistency. This algorithm ensures that any solution of a two-variable subproblem is extensible to any third variable. As would be expected, it is more powerful than arc consistency in discovering and removing inconsistencies. It also requires more time: its time complexity is cubic in the number of variables.

i-Consistency

Arc and path consistency can be generalized to *i*-consistency. In general, *i*-consistency algorithms guarantee that any locally consistent instantiation of $i - 1$ variables is extensible to any i^{th} variable. Thus, arc consistency is just 2-consistency, and path consistency is just 3-consistency. Enforcing *i*-consistency can be accomplished in time and space exponential in *i*: if the constraint problem has n variables, the complexity of achieving *i*-consistency is $O(n^i)$.

Global Consistency

A constraint problem is said to be globally consistent if it is *i*-consistent for every *i*. In this case, a solution can be assembled by assigning values to variables (in any order) without encountering a dead end, that is, in a backtrack-free manner.

Adaptive Consistency as Complete Inference

In practice, global consistency is not necessary to have backtrack-free assignment of values: it is enough to have directional global consistency relative to a given variable ordering. For example, an 'adaptive consistency' algorithm, which is a variable elimination algorithm, enforces global consistency in a given order only, so that every solution can be extracted with no dead ends along this ordering. Another related algorithm, called tree clustering, compiles the given constraint problem into an equivalent tree of subproblems whose respective solutions can be efficiently combined into a complete solution. Adaptive consistency and tree clustering are complete inference algorithms that can take time and space exponential in a parameter of the constraint graph called the 'induced width' (or 'tree width') (Dechter and Pearl, 1987).

Bucket Elimination

Bucket elimination (Dechter, 1999) is a recently proposed framework for variable elimination algorithms which generalizes adaptive consistency to include dynamic programming for optimization tasks, directional resolution for propositional satisfiability, Fourier elimination for linear inequalities, and algorithms for probabilistic inference in Bayesian networks.

Constraint Propagation and Search

Some problems that are computationally too hard for adaptive consistency can be solved by bounding the amount of consistency enforcing (e.g., applying only arc or path consistency) and embedding these constraint propagation algorithms within a search component, as described above. This yields a tradeoff between the effort spent in constraint propagation and that spent on the search, which can be exploited and which is the focus of empirical studies.

TRACTABLE CLASSES

In between search and constraint propagation algorithms, there are the so-called structure-driven algorithms. These techniques emerged from an attempt to topologically characterize classes of constraint problems that are tractable (that is, polynomially solvable). Tractable classes are generally recognized by realizing that enforcing low-level consistency (in polynomial time) guarantees global consistency for some problems.

Graph-based Tractability

The basic constraint graph structure that supports tractability is a tree. This has been observed repeatedly in constraint networks, complexity theory and database theory. In particular, enforcing arc consistency on a tree-structured constraint problem ensures global consistency along some orderings. Most other graph-based techniques can be viewed as transforming a given network into a meta-tree. Among these, we find methods such as tree clustering and adaptive consistency, the cycle cutset scheme, and the biconnected component decomposition. These lead to a general characterization of tractability that uses the notion of induced width (Dechter and Pearl, 1987).

Constraint-based Tractability

Some tractable classes have also been characterized by special properties of the constraints, without

any regard to the topology of the constraint graph. For example, tractable classes of temporal contraints include subsets of the qualitative interval algebra, expressing relationships such as 'time interval A overlaps or precedes time interval B', as well as quantitative binary linear inequalities over the real numbers of the form $X - Y \leq a$ (Meiri *et al.*, 1990). In general, we exploit notions such as tight domains and tight constraints, row-convex constraints (van Beek and Dechter, 1995), implicational and max-ordered constraints, and causal networks. A connection between tractability and algebraic closure has been discovered and intensively investigated in recent years, yielding a nice theory of tractability (Cohen *et al.*, 2000).

SOFT CONSTRAINT SATISFACTION AND CONSTRAINT OPTIMIZATION

Constraint processing tasks include not only problems of constraint satisfaction, but also problems of constraint optimization. Such problems arise when the solutions are not equally preferred. The preferences among solutions can be expressed via a cost function (also called an objective function), and the task is to find the best-cost solution or a reasonable approximation to it.

For example, we may have the constraints $X \leq Y$ and $Y \leq 10$, with the objective function $f = X + Y$, to be maximized. The best solution (unique in this example) is: $X = 10,\ Y = 10$. All other solutions (e.g. $X = 5,\ Y = 6$), although satisfying all the constraints, are less preferred. Cost functions are often specified as a sum of cost components, each defined on a subset of the variables.

Branch and Bound

Adapting the backtracking search algorithm for the task of selecting the most preferred (best cost) solution yields the well-known branch and bound algorithm. Like backtracking, branch and bound traverses the search tree in a 'depth first' manner, pruning not only partial instantiations that are inconsistent, but also those that are estimated to be inferior to the current best solution. At each node, the value of the current partial solution is estimated (by an evaluation function) and compared with the current best solution; if it is inferior, search along the path is terminated. When the evaluation function is accurate, branch and bound prunes substantial portions of the search tree.

Soft Constraints

One way to specify preferences between solutions is to attach a level of importance to each constraint or to each of its tuples. This technique was introduced because constraints in real problems often cannot be described by a set of 'true or false' statements only. Often constraints are associated with features such as preferences, probabilities, costs, and uncertainties. Moreover, many real problems, even when modeled correctly, are overconstrained. Constraints that have varied levels of importance are called soft constraints. There are several frameworks for soft constraints, such as the semi-ring formalism (Bistarelli *et al.*, 1997), whereby each tuple in each constraint has an associated element taken from a partially ordered set (a semi-ring); and the valued constraint formalism, whereby each constraint is associated with an element from a totally ordered set. These formalisms are general enough to model classical constraints, weighted constraints, 'fuzzy' constraints, and overconstrained problems. Current research effort is focused on extending propagation and search techniques to these more general frameworks.

CONSTRAINT PROGRAMMING

The constraint satisfaction model is useful because of its mathematical simplicity on the one hand, and its ability to capture many real-life problems on the other. Yet, to make this framework useful for many real-life applications, advanced tools for modeling and for implementation are necessary. For this reason, constraint systems (providing some built-in propagation and solution algorithms) are usually embedded within a high-level programming environment which assists in the modeling phase and which allows for some control over the solution method.

Logic Programming

Although many programming paradigms have recently been augmented with constraints, the concept of constraint programming is mainly associated with the logic programming (LP) framework (Lloyd, 1993). Logic programming is a declarative programming paradigm whereby a program is seen as a logical theory and has the form of a set of rules (called clauses) which relate the truth value of an atom (the 'head' of the clause) to that of a set of other atoms (the 'body' of the clause). The clause

```
p(X, Y) :- q(X), r(X, Y, Z)
```

says that if atoms `q(X)` and `r(X, Y, Z)` are true, then also atom `p(X, Y)` is true. For example, the clauses

```
reach(X, Y) :- flight(X, Y)

reach(X, Y) :- flight(X, Z), reach(Z, Y)
```

describe the 'reachability' between two cities (`X` and `Y`) via a sequence of direct flights.

Logic programming and search

Executing a logic program means asking for the truth value of a certain predicate, called the goal. For example, the goal `:- p(X, Y)` asks whether there are values for the variables `X` and `Y` such that `p(X, Y)` is true in the given logic program. The answer is found by recursively 'unifying' the current goal with the head of a clause (by finding values for the variables that make the two atoms equal). As with constraint solving, the algorithm that searches for such an answer in LP involves a backtracking search.

Constraint Logic Programming

To use constraints within LP, one just has to treat some of the predicates in a clause as constraints and to replace unification with constraint solving. The resulting programming paradigm is called 'constraint logic programming' (CLP) (Jaffar and Maher, 1994; Marriott and Stuckey, 1998). A typical example of a clause in CLP is

```
p(X, Y) :- X < Y + 1, q(X), r(X, Y, Z)
```

which states that `p(X, Y)` is true if `q(X)` and `r(X, Y, Z)` are true and the value of `X` is smaller than that of `Y + 1`. While the regular predicates are treated as in LP, constraints are manipulated using specialized constraint processing tools. The shift from LP to CLP permits the choice among several constraint domains, yielding an effective scheme that can solve many more classes of real-life problems. Some examples of CLP languages are ECLiPSe (IC-PARC, 1999), CHIP (Dincbas *et al.*, 1988) SICStus Prolog (Carlsson and Widen, 1999), CHRs (Fruhwirth, 1995), and GNU Prolog (Codognet and Diaz, 1996; Diaz, 2000).

Specialized algorithms for CLP

CLP languages are reasonably efficient, due to their use of a collection of specialized solving and propagation algorithms for frequently used constraints and for special variable domain shapes. Global constraints and bounds consistency are two aspects of such techniques that are incorporated into most current CLP languages.

Global constraints

Global constraints are constraints, usually nonbinary, for which there exist specialized and efficient solution methods. An example is the constraint `alldifferent`, which requires all the involved variables to assume different values, and which can be efficiently solved using a bipartite matching algorithm. Global constraints are used to replace a set of other constraints, usually involving fewer variables and belonging to some special class. For example, a set of binary inequality constraints seldom gives rise to useful constraint propagation and thus may require a complete search. This expensive search is avoided by replacing these constraints with a single `alldifferent` constraint that is accompanied by an efficient propogation algorithm. Most current CLP languages are equipped to handle several kinds of global constraints.

Bounds consistency

Bounds consistency is one of the major contributions of CLP to the field of constraint propagation. When the variable domains are sets of integers, they are usually represented, to save space, by intervals. In this way, one can store only their minimum and the maximum elements. However, constraint propagation techniques like arc consistency could destroy this representation by removing elements internal to the intervals. Therefore, CLP languages usually use an approximation of arc consistency, called bounds consistency, which removes an element from a domain only if the resulting domain is still an interval. This technique is used in most CLP languages, since it is both efficient (in time and space) and powerful in terms of propagation.

CONCLUSION

The study of CSPs is interdisciplinary, since it involves ideas and results from several fields, including artificial intelligence (where it began), databases, programming languages, and operations research. While it is not possible to cover all the lines of work related to CSPs, this article has covered the main ideas.

Current investigations include: identification of new tractable classes; studying the relationship

between search and propagation; extending propagation techniques to soft constraints; and developing more flexible and efficient constraint languages.

Convolution-based Memory Models

Intermediate article

Tony A Plate, Black Mesa Capital, Santa Fe, New Mexico, USA

CONTENTS

Convolution-based memory models are mathematical models of neural storage of complex data structures using distributed representations. Data structures stored range from lists of pairs, through to sequences, trees, and networks.

HOLOGRAPHIC MEMORY: THE BASIC IDEA

Convolution-based memory models (CBMMs) are mathematical models of storage for lists of paired items, and more complex data structures such as those needed to support language and reasoning capabilities. CBMMs use distributed representations in which items are represented as vectors of binary or real numbers (a *pattern*). (*See* **Distributed Representations**)

CBMMs can store information about items arranged in a great variety of relationships, such as lists of paired items, and sequences, networks, and tree structures. All CBMM storage schemes use a convolution operation to associate or *bind* two (or more) patterns together in a memory *trace*, which is also a pattern.

CBMMs are sometimes called *holographic* memory models because the properties and underlying mathematical principles of CBMMs and light holography are very similar. One of the most striking similarities is that both can reconstruct an entire pattern (in a noisy form) in response to a noisy or partial cue. This ability is a consequence of the *distributed* and *equipotential* nature of storage in both holograms and CBMMs: information about each element of an item or region of an image is distributed across the entire storage medium.

RAPIDLY BINDING TOGETHER COMPONENTS OF A MEMORY

CBMMs use two operations for composing patterns: superposition and binding. For patterns of real numbers, superposition is ordinary element-wise addition; for patterns of binary numbers, superposition is element-wise binary-OR. Superposition is useful for forming unstructured collections of items. However, associations or *bindings* between items cannot be represented using superposition alone because of the *binding problem*. (*See* **Binding Problem**; **Distributed Representations**)

CBMMs use *convolution* as a binding operation: convolution binds two patterns together into one. If $\mathbf{x}$ and $\mathbf{y}$ are n-dimensional pattern vectors (subscripted 0 to $n-1$), then the circular convolution of $\mathbf{x}$ and $\mathbf{y}$, written $\mathbf{z} = \mathbf{x} \otimes \mathbf{y}$, is also an n-dimensional pattern vector and has elements

$$z_i = \sum_{k=0}^{n-1} x_k y_{(i-k) \bmod n} \qquad (1)$$

Circular convolution can be viewed as a compression of the outer (or tensor) product of the two vectors, where compression is achieved by summing particular elements, as shown in Figure 1. (Other variants of convolution can be viewed as slightly different ways of compressing the outer product.)

A list of paired items can be represented as the superposition of pairs of items bound together by a convolution. For example, a simple way of representing the list of two pairs 'red-square and blue-circle' is as the pattern $(\mathbf{red} \otimes \mathbf{circle}) + (\mathbf{blue} \otimes \mathbf{square})$. This pattern is quite different from the one

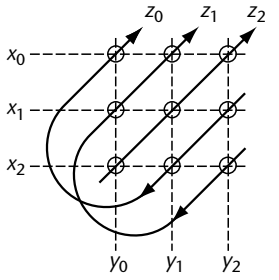

Figure 1. The *circular convolution* $\mathbf{z}$ of vectors $\mathbf{x}$ and $\mathbf{y}$ can be expressed as the sum of elements of their outer product.

that results from a different pairing of the same items such as (**blue** $\otimes$ **circle**) + (**red** $\otimes$ **square**).

In CBMMs, as in many other memory models that use vector or distributed representations, *similarity* is computed by either the *dot product* $\mathbf{x}\cdot\mathbf{y}$, or *cosine* (a scaled version of the dot product) of two pattern vectors:

$$\mathbf{x}\cdot\mathbf{y} = \sum_{i=0}^{n-1} x_i y_i \tag{2}$$

$$\text{cosine}(\mathbf{x},\mathbf{y}) = \frac{\sum_{i=0}^{n-1} x_i y_i}{|\mathbf{x}||\mathbf{y}|} = \frac{\sum_{i=0}^{n-1} x_i y_i}{\sqrt{\sum_{i=0}^{n-1} x_i^2}\sqrt{\sum_{i=0}^{n-1} y_i^2}} \tag{3}$$

One the most important properties of convolution is *similarity preservation*: if patterns **red** and **pink** are similar, then the bindings **red** $\otimes$ **square** and **pink** $\otimes$ **square** will also be similar, to approximately the same degree.

RAPID RETRIEVAL AND INTERFERENCE EFFECTS

Convolution bindings can be easily decoded using inverse convolution operations. For example, using exact inverses, $\mathbf{red}^{-1} \otimes \mathbf{red} \otimes \mathbf{circle} = \mathbf{circle}$. However, the exact inverse can be numerically unstable and is not always the best choice for decoding. For many vectors, such as those whose elements have independent Gaussian statistics with mean zero and variance $1/n$, an approximate inverse can be used. The approximate inverse of $\mathbf{x}$ is denoted by $\mathbf{x}^{\mathrm{T}}$ (this notation is chosen because the approximate inverse is closely related to the matrix transpose). It is a simple rearrangement of the elements of $\mathbf{x}$: $x_i^{\mathrm{T}} = x_{(-i) \bmod n}$. Reconstruction using the approximate inverse is noisy ($\mathbf{red}^{\mathrm{T}} \otimes \mathbf{red} \otimes \mathbf{circle}$ is only approximately equal to **circle**), but is usually more stable in the presence of noise than reconstruction using the exact inverse. If necessary, exact reconstructions can be provided by passing the noisy result through a clean-up memory, which returns the closest matching pattern among the patterns it contains.

Decoding still works when multiple associations are superimposed. For example:

$$\begin{aligned}\mathbf{blue}^{\mathrm{T}} \otimes ((\mathbf{red} \otimes \mathbf{circle}) + (\mathbf{blue} \otimes \mathbf{square})) \\ = (\mathbf{blue}^{\mathrm{T}} \otimes \mathbf{red} \otimes \mathbf{circle}) \\ + (\mathbf{blue}^{\mathrm{T}} \otimes \mathbf{blue} \otimes \mathbf{square}) \\ \approx \mathbf{square}\end{aligned} \tag{4}$$

Because of the randomizing properties of convolution, the first term on the right in the expansion ($\mathbf{blue}^{\mathrm{T}} \otimes \mathbf{red} \otimes \mathbf{circle}$) is not similar to any of **blue**, **red**, **circle**, or **square** and can be regarded as noise. The second term on the right ($\mathbf{blue}^{\mathrm{T}} \otimes \mathbf{blue} \otimes \mathbf{square}$) is a noisy version of **square**. The sum of these two terms is an even noisier, but still recognizable, version of **square**. When larger numbers of bindings are superimposed together the interference effects can become significant, though increasing the vector dimension can reduce interference effects. For further discussion and quantitative analysis, see Murdock (1982), Metcalf-Eich (1982), or Plate (1995).

TODAM

Murdock's (1982) 'theory of distributed associative memory' model (TODAM) is intended to model patterns of human performance on memorization tasks, focusing on tasks involving lists of paired associates. For example, a subject might be asked to memorize the list 'cow-horse, car-truck, dog-cat, and pen-pencil' and then answer such questions as 'Did *car* appear in the list?' (recognition), or 'What was *cat* associated with?' (cued recall). Subjects' relative abilities to perform these and other tasks under different conditions, and the types of errors they produce, give insight into the properties of human memory. Some of the conditions commonly varied are the number of pairs, the familiarity of items, the similarity of items, and the position of recall or recognition targets within the list.

The TODAM formula for sequentially constructing a memory trace for a list of pairs ($\mathbf{x}_i$, $\mathbf{y}_i$) of item patterns is as follows:

$$\mathbf{T}_j = \alpha\mathbf{T}_{j-1} + \gamma_1\mathbf{x}_j + \gamma_2\mathbf{y}_j + \gamma_3\mathbf{x}_j \otimes \mathbf{y}_j \tag{5}$$

where $\mathbf{T}_j$ is the memory trace pattern (a vector) representing pairs 1 through j (with $\mathbf{T}_0 = \mathbf{0}$). The scalars α, γ_1, γ_2, and γ_3 are adjustable parameters of the model, taking values between 0 and 1.

TODAM uses an 'unwrapped' version of convolution which expands the size of vectors each time it is applied, but TODAM could use any convolution operation.

For example, the memory trace for the list of three pairs (**a, b**), (**c, d**), and (**e, f**) is built as follows:

$$\mathbf{T}_1 = \gamma_1\mathbf{a} + \gamma_2\mathbf{b} + \gamma_3\mathbf{a} \otimes \mathbf{b} \tag{6}$$

$$\mathbf{T}_2 = \gamma_1\mathbf{c} + \gamma_2\mathbf{d} + \gamma_3\mathbf{c} \otimes \mathbf{d} + \alpha(\gamma_1\mathbf{a} + \gamma_2\mathbf{b} + \gamma_3\mathbf{a} \otimes \mathbf{b}) \tag{7}$$

$$\mathbf{T}_3 = \gamma_1\mathbf{e} + \gamma_2\mathbf{f} + \gamma_3\mathbf{e} \otimes \mathbf{f} + \alpha(\gamma_1\mathbf{c} + \gamma_2\mathbf{d} + \gamma_3\mathbf{c} \otimes \mathbf{d}) + \alpha^2(\gamma_1\mathbf{a} + \gamma_2\mathbf{b} + \gamma_3\mathbf{a} \otimes \mathbf{b}) \tag{8}$$

Item recognition is done by comparing an item with the trace: item $\mathbf{x}$ was stored in trace $\mathbf{T}$ if $\mathbf{x} \cdot \mathbf{T} > t$ (if the dot product of $\mathbf{x}$ and $\mathbf{T}$ is greater than some threshold t).

Cued recall is accomplished by decoding the trace with the cue: if item $\mathbf{x}$ was stored in trace $\mathbf{T}$, then $\mathbf{x}\#\mathbf{T}$ is a noisy reconstruction of the partner of $\mathbf{x}$ (where $\mathbf{x}\#\mathbf{T}$ is another way of writing $\mathbf{x}^{\mathrm{T}} \otimes \mathbf{T}$).

Some of the predictions of TODAM that are supported by evidence in the psychological literature are as follows:

- Performance decreases with increasing list length.
- Cued recall is symmetric: the recall of $\mathbf{x}$ given $\mathbf{y}$ from a trace containing the pair $\mathbf{x} \otimes \mathbf{y}$ is as accurate as the recall of $\mathbf{y}$ given $\mathbf{x}$ from the same trace.
- There is no primacy effect, only a recency effect, because forgetting is geometric in α.
- Cued recall for a particular item can be superior to recognition for that same item – it can be possible to recall an item that cannot be recognized. This is because weights can be defined so that associative information is stronger than item information.

CHARM

The 'composite holographic associative recall model' (CHARM) (Metcalfe-Eich, 1982) was specifically intended to address the effects of similarity among items in cued recall from lists of paired associates. CHARM uses an even simpler storage method than TODAM – it stores only associative information and no item information. The memory trace for a list of pairs ($\mathbf{x}_i$, $\mathbf{y}_i$) of item patterns is constructed as follows:

$$\mathbf{T} = \sum_{i=1}^{k} \mathbf{x}_i \otimes \mathbf{y}_i \tag{9}$$

CHARM uses a truncated version of the non-wrapped convolution used in TODAM so that the patterns for memory traces are the same size as for items.

As with TODAM, the process for performing cued recall in CHARM begins by correlating a composite memory trace with the cue; e.g., to find the item corresponding to $\mathbf{x}_1$ in $\mathbf{T}$, $\mathbf{x}_1\#\mathbf{T}$ is computed. The resulting pattern will be a noisy version of the pattern associated with $\mathbf{x}_1$ in $\mathbf{T}$, which is passed through a clean-up memory. For the purposes of Metcalfe's experiments, the clean-up memory contained patterns for items stored in the memory trace, and patterns for some other items not stored in the memory trace.

One type of retrieval phenomenon modeled with CHARM is the reduced ability to accurately recall items from a list whose members are similar, versus from a list whose members are dissimilar. For example, performance on a pair such as Napoleon–Aristotle is worse when the pair is embedded in a list of pairs of names of other famous people (a homogenous list) than when it is embedded in a list containing items conceptually unrelated to it, such as red–blue. Furthermore, with homogenous lists, incorrect recall of an item that is similar to the correct response and that was also in the list with an associated item similar to the cue is a frequent type of error in both CHARM and with human subjects.

BINDING VIA FULL TENSOR PRODUCTS

A list of paired items is a very simple set of relationships. Many cognitive tasks demand the ability to store more complicated relationships. For example, understanding language requires the ability to work with recursive structures: a phrase can have a verb, a subject and an object, but the object could be a phrase itself, which could even contain further subphrases. For example, the sentence 'I believe that politicians will say whatever will help them to get elected' contains at least three levels of recursion.

One of the first concrete descriptions of such a scheme was given by Smolensky (1990). Smolensky used tensor products to bind roles and fillers together in a recursive manner. For example, the sentence 'Politicians tell stories' could be represented as the rank-2 tensor $\mathbf{T} = \mathbf{politicians} \otimes \mathbf{tell}_{\mathrm{agent}} + \mathbf{stories} \otimes \mathbf{tell}_{\mathrm{object}}$, where **politicians** is a pattern representing politicians, $\mathbf{tell}_{\mathrm{agent}}$ is a pattern for the agent role of 'tell', etc., and $\otimes$ is the tensor product (a generalization of the outer product). Tensors can be superimposed and decoded in a manner similar to convolution traces; the role pattern $\mathbf{tell}_{\mathrm{agent}}$ can be used to decode the tensor $\mathbf{T}$ to retrieve the pattern **politicians**. What makes the use of tensors interesting is that the rank-2 tensor $\mathbf{T}$ can

be used as the filler in some higher-level role-filler binding, such as representing the meaning of the sentence 'I know politicians tell stories'. This higher-level binding is a rank-3 tensor.

HOLOGRAPHIC REDUCED REPRESENTATIONS

Holographic reduced representations (HRRs) (Plate, 1995, 2000b) use convolution-based role-filler bindings to construct patterns representing a recursive structure.

The HRR for the proposition 'Politicians tell stories' is constructed as follows:

$$\mathbf{P}_{\text{tell}} = \mathbf{tell} + \mathbf{politicians} + \mathbf{stories} + \mathbf{tell}_{\text{agt}} \otimes \mathbf{politicians} + \mathbf{tell}_{\text{obj}} \otimes \mathbf{stories} \quad (10)$$

If we have the pattern $\mathbf{P}_{\text{tell}}$ and know the role patterns, then we can reconstruct a filler pattern by convolving $\mathbf{P}_{\text{tell}}$ with the approximate inverse of a role pattern. For example, $\mathbf{tell}_{\text{agt}}^{\text{T}} \otimes \mathbf{P}_{\text{tell}}$ gives a noisy version of **politicians** which can be put through a clean-up memory to provide an accurate reconstruction.

The HRR pattern $\mathbf{P}_{\text{tell}}$ is a *reduced representation* for the proposition 'Politicians tell stories' and can be used as a filler in a higher-order proposition. For example, the HRR $\mathbf{P}_{\text{know}}$, representing 'Bill knows politicians tell stories', is constructed as follows:

$$\mathbf{P}_{\text{know}} = \mathbf{know} + \mathbf{bill} + \mathbf{P}_{\text{tell}} + \mathbf{know}_{\text{agt}} \otimes \mathbf{bill} + \mathbf{know}_{\text{obj}} \otimes \mathbf{P}_{\text{tell}} \quad (11)$$

Such higher-level HRRs can be decoded in the same way as first-order HRRs. For example, the filler of the know-object role is decoded as follows:

$$\mathbf{P}_{\text{know}} \otimes \mathbf{know}_{\text{obj}}^{\text{T}} \approx \mathbf{P}_{\text{tell}} \quad (12)$$

This reconstructed filler is a proposition. To discover its fillers it could be cleaned up and then decoded again. (*See* **Distributed Representations**)

HRRs are similar if they merely involve similar entities or predicates. Because of the similarity-preserving properties of convolution, they will be even more similar if the entities are involved in similar roles. Thus it turns out that the similarity of HRRs can reflect both superficial and structural similarity in a way that neatly corresponds to the data on human analog retrieval (Plate, 2000).

IMPLEMENTING CONVOLUTION-BASED MEMORIES IN CONNECTIONIST NETWORKS

The various operations used in convolution-based memory models – convolution, correlation, approximate inverse, dot-product, and clean-up memory – are easily implemented in connectionist networks. Convolution encoding and decoding can be implemented by suitably connected networks of 'sigma–pi' neurons. Figure 2 shows a network that computes the circular convolution of two three-element vectors.

$$z_0 = x_0\, y_0 + x_1\, y_2 + x_2\, y_1$$
$$z_1 = x_0\, y_1 + x_1\, y_0 + x_2\, y_2$$
$$z_2 = x_0\, y_2 + x_1\, y_1 + x_2\, y_0$$

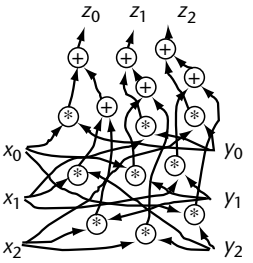

Figure 2. The *circular convolution* **z** of vectors **x** and **y** drawn as a network of three sigma–pi neurons. Each sigma–pi neuron computes the sum of three products as shown on the left.

The pattern of connections in the sigma–pi network that computes circular convolution may seem unrealistically intricate and precise for a biological circuit. However, Plate (2000a) shows that sigma–pi networks that sum random products of pairs of elements from **x** and **y** can also function as encoding and decoding networks with similar properties to convolution.

For computation of similarity, a dot product can be computed by a single sigma–pi neuron. Clean-up memory can be implemented in several ways, such as with Kanerva's (1988) sparse distributed memory, or Baum *et al*.'s (1988) various associative content-addressable memory schemes.

Cooperative and Collaborative Learning

Intermediate article

Angela M O'Donnell, Rutgers, The State University of New Jersey, New Jersey, USA

CONTENTS

Forms of cooperative or collaborative learning have been used for centuries and a variety of peer learning techniques have emerged. The underlying premise of these techniques is that learning is enhanced by peer interaction.

THEORETICAL APPROACHES TO COOPERATION AND COLLABORATION

Cooperative/collaborative learning refers to a variety of instructional arrangements that have the common characteristic of students working together to help one another learn. The term 'cooperative learning' is often used to describe particular techniques such as Slavin's *Student Teams Achievement Divisions* or the Johnsons' *Learning Together*. However, cooperative learning is also a process involving collaboration.

'Collaboration' is a term generally used to describe the process of shared learning and understanding. Because of the close relationship of the two terms, they will be used interchangeably in this article. Cooperative and collaborative learning techniques have been used for instructional purposes for centuries and constitute some of the oldest forms of instruction. The most recent meta-analysis of cooperative learning studies included five hundred studies (Johnson and Johnson, 1989) and provides strong support for the positive benefits of working with peers, including positive effects on achievement, self-confidence, peer relationships, and the inclusion of children with special needs. Although a great deal of work has been conducted since 1989, this meta-analysis remains the most comprehensive integration of the literature.

A full discussion of the various forms of instructional uses of cooperation and collaboration is beyond the scope of this chapter. These approaches to understanding the benefits or other effects of cooperative and collaborative learning differ in whether they emphasize the individual (as in peer tutoring), the group (as in distributed cognition), or the reciprocal influence of the individual and the group (as in problem-based learning). The predominant approach to understanding the effects of collaborative or cooperative learning has been in terms of a focus on individual achievement. Other approaches that emphasize learning communities and apprenticeship models emphasize the group culture and the emergence of group cognition. A number of different approaches to understanding collaborative/cooperative learning are illustrated here. Specific cooperative and collaborative learning techniques may involve elements from more than one perspective.

SOCIAL PSYCHOLOGICAL APPROACHES

A variety of theories can be used to account for the benefits associated with cooperative/collaborative learning. Most of the published research on cooperative learning is influenced by social-motivational theory originating with the work of Morton Deutsch.

According to Deutsch, cooperation is one form of interdependence in which individuals' outcomes are linked. One person cannot succeed in a cooperative group unless all participants succeed. From this perspective, group learning is expected to be more productive than individual learning as a result of interdependence among group members that increases motivation within the group. The key

mechanism by which cooperation can lead to successful outcomes is through motivation.

Interdependence can be created by providing group rewards (e.g., Slavin's *Student Teams' Achievement Divisions* (STAD)) or by developing group norms of caring and mutual helping (e.g., the Johnsons' *Learning Together*). In STAD, students work together in heterogeneous groups to help one another learn material presented by the teacher. Students' improvement scores on individual tests result in points earned for the team. Team averages are computed and the teams with the highest points are rewarded with some form of recomputed group average. The teams with the highest group points receive tangible recognition for their work in the form of certificates or other rewards valued by the group members. In contrast, cooperative learning techniques that depend on mutual care and concern as the basis for creating interdependence rarely use overt rewards. In these techniques, instructors spent a lot of time teaching students social skills and effective strategies for communicating and supporting one another.

DEVELOPMENTAL PSYCHOLOGICAL APPROACHES

Theories related to the mechanisms underlying effective collaboration can also be found in the developmental psychological literature.

Piaget described cognitive development as occurring through a process of adaptation in which a child's existing knowledge and concepts interacted with the world. Experience with the world provides the opportunity to create conflict with existing conceptual structures and the child will attempt to reduce the experience of conflict. From a Piagetian perspective, collaborative groups provide the possibility for cognitive development because group members may prompt cognitive conflict that can result in disequilibration and subsequent conceptual growth. Disequilibration occurs when the learner recognizes a conflict between new information or experience and existing conceptual structures. The effort to restore harmony to one's cognitive structures results in adaptation to the new information or experience. Conceptual growth may occur through this process, although other processes such as denial can achieve the restoration of equilibrium.

Many educators rely on the possibility that learners will bring different perspectives to a task. Difficulties can arise depending on the composition of a group. In groups in which there is a status hierarchy, students may defer to those with higher status, agreeing readily but experiencing little in the way of cognitive conflict. Without the experience of disequilibrium, conceptual growth is unlikely to occur. Piaget proposed that learning was most likely to occur when peers were mutually influential: that is a student was as likely to influence others or be influenced by them. In creating collaborative groups from a Piagetian standpoint, groups consisting of members who are relatively homogeneous are more desirable than very heterogeneous groups. Piaget did not write much about collaboration among peers and his focus was on the individual child's growth and development. Collaboration among peers provided a context for development.

Another developmental psychologist provides a contrasting perspective. Vygotsky emphasized the crucial role of society and culture in shaping the cognitive skills of children. The community is the venue in which cognitive skills are first observed and subsequently internalized by the developing learner. Learning occurs from a Vygotskian perspective when a more skilled individual supports the performance of less skilled or younger learners. The weaker partner can perform tasks with the support of the more skilled partner that he or she could not do alone. The difference between what the child can accomplish alone and with a skilled partner is called the 'zone of proximal development'. This process is one way in which learners become participants in a community of practice. In other words, this is a process in which learners come to acquire the competencies already available in the community. Unlike Piaget, who viewed mutuality in power and influence as crucial to effective collaboration, Vygotsky seems to require an imbalance in power and expertise. The more expert student or adult scaffolds the learning of the more novice individual.

Peer Tutoring as an Example of Collaborative Learning

Peer tutoring is one of the most enduring forms of instruction and typically involves a more skilled individual teaching a less skilled individual. The relationship between learners is one of inequality with respect to knowledge of the target subject. Vygotskian theory might be drawn upon to explain the benefits of this strategy. Interactions between tutor and tutee have the goal of improving the performance of the tutee and are characterized by efforts to prompt the tutee to higher levels of achievement. Tutoring works – it is a unique form

of individualized instruction that improves student achievement (Cohen *et al*., 1982). However, understanding how tutoring works is not a simple task. Empirical studies of tutoring have not been conducted under the rubric of a common theory that details the processes underlying particular this particular form of instruction.

Effects on tutees and tutors

Cohen *et al*. conducted the only available comprehensive review of the effects of tutoring in 1982. Their meta-analysis provided convincing evidence that peer tutoring is effective. Strong effects on student learning were found in studies of short duration that involved structured tutoring related to lower-level skills, often in mathematics. Very few studies examined affective outcomes from tutoring, although in those studies that did, tutored students generally had positive attitudes. Tutees are not the only beneficiaries of tutoring. In 38 studies included in the 1982 meta-analysis related to tutor achievement, the average effect size for tutor achievement was a moderate one of 0.33.

Few studies examine the joint effects on tutors and tutees. One exception to this is the work of Connie Juel (1996). In this study, underachieving student athletes spent about four hours a week preparing materials for tutorial sessions with at-risk first grade students. Both tutors and tutees made substantial progress during the course of a year. The literacy levels of both groups of students increased.

Research on tutoring in the period since 1982 has not focused on achievement *per se* but has concentrated instead on the processes by which tutors engage in their task of scaffolding the learning of their tutees. Even when tutors were naive or provided wrong answers, tutees still benefited. There was general acceptance of the utility of tutoring as an instructional strategy and a shift towards studies designed to understand the processes involved in tutoring rather than documenting outcomes from such tutors. An important strand of this research concerned comparisons of human and computer tutors.

Human and computer tutors

Human tutors allow students to do much of the work and maintain a sufficient feeling of control, provide sufficient guidance to keep the tutee from being frustrated, monitor students' reasoning and intervene to keep problem solving on track, are flexible in how they interact, and are motivating (Merrill *et al*., 1992). Naive tutors often provide indiscriminate feedback, use unsophisticated strategies, and employ politeness strategies that may interfere with tutoring effectiveness. Despite these inadequacies, even naive human tutors produce achievement gains for tutees. Many possible reasons might be offered to explain such findings. It may be that the one-to-one interaction is motivating and the tutee makes more of an effort to engage the material. Perhaps normal classroom instruction may provide such little benefit to those who end up as tutees that even a poor tutor is better than existing instruction.

Computer tutors are often designed to compare the student's problem-solving steps to those of a domain expert. In other words, the student's performance is compared to an expert model and the steps he or she uses are traced. Computer tutors attend to more of the components of recovering from error than humans and provide more diagnostic information, more accurate feedback, and provide interventions as the learner deviates from an expert model. They have limited flexibility in response to learner errors, although recent innovations in the design of computer tutors have improved this functionality. Recent innovations in the development of computer tutors use what is known about the human tutoring process and include strategies and prompts to student learning that are more typical of human tutors.

Future research

The published research on tutoring provides little analysis of how the subject matter influences the nature of the tutoring. Much of the work on tutoring is done in curricular areas that are highly constrained, such as mathematics or physics. Little is known about the effects of tutoring on more ambiguous domains such as social studies or writing. The kinds of outcome that were included in the 1982 meta-analysis were mostly low-level outcomes. The effect of tutoring on more high-level skills has not received the same kind of attention.

An additional area of potentially fruitful work is the comparison of the effectiveness of expert tutors and tutors who are subject matter experts. Tutors develop models of tutees and direct their efforts based on those models. Expert tutors are likely to have very refined models of tutee differences and have a range of tutorial strategies from which to select. Subject matter experts who are less experienced as tutors will likely bring a very different set of skills to the tutorial process.

INFORMATION-PROCESSING APPROACHES

Learning, from an information-processing perspective, occurs as a result of active processing of meaningful materials and experiences. Cooperative/collaborative learning approaches influenced by information-processing theory focus on using the group context for learning as a way for amplifying the active processing of information. Such approaches are often considered cognitive/elaborative approaches and suggest that the group interaction provides an opportunity for deeper processing of material and restructuring of ideas and understanding. Cognitive/elaborative approaches attempt to maximize the participation of each student in cognitive strategies and tasks.

Scripted Cooperation

Scripted cooperation (see O'Donnell and King, 1999) is an example of a cooperative technique that relies on elaborative processing of information by a cooperating dyad. In this strategy, pairs of students read a portion of a text. One partner then summarizes the information to his or her partner who, in turn, provides feedback on the accuracy and completion of the information summarized. Both partners work together to elaborate on the material read, generating connections to other knowledge they have and developing techniques for making the information more memorable. The students then proceed to the next section of the text in which they switch roles with the summarizer from the first section now acting as the person who detects errors and omissions. The use of this technique has been shown to be very successful. The size of the cooperating unit (pairs of students) promotes active participation by the partners, and the requirement to switch roles provides each student with practice of requisite cognitive skills.

Reciprocal Teaching

Another example of a cooperative technique that is influenced by information-processing theory, and also by Vygotskian theory, is reciprocal teaching.

Reciprocal teaching was designed for use with students who showed a significant disparity between their ability to decode and comprehend text (Palinscar and Herrenkohl, 1999). It involves guided instruction in the use of four strategies to assist text comprehension. The teacher and students take turns in leading discussions about a shared text. Before reading the text, students make predictions about what the text will be about. Second, everyone reads a segment of the text and participants then discuss the text content, asking and answering questions. The third strategy used is summarization. The fourth strategy involves clarifying difficult concepts and, finally, new predictions are made for the next segment of the text. The focus in this technique is on teaching students explicit strategies to aid comprehension that they can use with any new text. Instruction in strategy use proceeds through a dialogue between the teacher and the students. Students participate by elaborating on other students' responses or by commenting on one another's questions. Initially, the teacher is very much in charge, modeling the strategies and monitoring students' use of them. With practice, students assume a more central role in leading the discussions, with the teacher participating as a member of the group. In this role, the teacher can remind students about how to use the strategies. He or she provides a scaffold or support to the students' efforts. Finally, student leaders can conduct discussions about a segment of text without assistance from the teacher. The teacher's support has thus gradually been withdrawn from the group interaction.

The model of collaboration exemplified in reciprocal teaching is strongly influenced by Vygotskian theory. Skills are available in the social world before they can be internalized. The entire transition from the teacher-led discussions and modeling of strategies to the student-led discussions and execution of these strategies typifies the internalization of skill. Learners first observing these skills as performed and modeled by an expert practice the skills with guidance from the expert, and finally internalize them as part of their own cognitive repertoires.

Effects on student achievement

Rosenshine and Meister (1994) included 16 studies (only four were published) in their meta-analysis of studies using reciprocal teaching. Studies were selected if they included experimental and control groups and were considered high-, medium-, or low-quality studies, depending on the quality of implementation of the treatments, student assessment, and the quality of the reciprocal teaching dialogue. Across the 16 studies, the median effect size associated with reciprocal teaching was 0.32 when using standardized tests as the outcome measure, and 0.88 when using experimenter developed assessments. Reciprocal teaching was significantly better than a control comparison in only two of nine studies when standardized tests were

used. When experimenter-developed assessments were used, reciprocal teaching was significantly better in four out of five studies. Based on an analysis of the reading materials provided in a standardized test and those provided in experimenter tests, Rosenshine and Meister concluded that the experimenter-developed texts were easier because they were longer, were almost always organized in a topic-sentence-and-supporting-detail form, and answering the questions required less background and searching of text.

No conclusions could be drawn from this meta-analysis about which strategies involved in reciprocal teaching were most effective in assisting students. Many of the studies included provided explicit instruction in each of the component strategies prior to engaging in reciprocal teaching, while others embedded the instruction in cognitive strategies in the use of reciprocal teaching. Both strategies seem to work.

Although the dialogue that occurs in a reciprocal teaching group is expected to play a key role in the benefits that may be derived from reciprocal teaching, few studies analyze this dialogue or use it to detect what kinds of cognitive strategy students are learning and using. Palinscar and Herrenkohl (1999) suggest that the explicit goal of jointly making sense of text encourages an intersubjective attitude in which learners feel they are part of a community. This notion of community is further emphasized by the need for each participant to take a turn in leading the discussion and contributing to the discussion.

DISTRIBUTED-COGNITION APPROACHES

Another view of collaboration/cooperation can be found in the perspectives drawn from distributed cognition that describes a process by which cooperation or collaboration can be accomplished. The types of collaborative/cooperative learning described previously are primarily concerned with individual cognition and the effect of collaborative interactions on individual achievement. The techniques described can be viewed as examples of distributed cognition in that cognitive activity is distributed within an interactive unit. A simple version of distributed cognition and collaboration is the use of scripted cooperation described previously. In this technique, the cognitive processing of information is divided among members of a dyad. One partner engages in rehearsal (summarizing information), while the other partner provides an elaboration of the information. In this way, cognitive processing is distributed.

Some views of distributed cognition consider the distribution to be an extension of the individual's competency, a person-plus approach. Others view the distribution of cognition within a group as inseparable from the activity and functioning of the group, a social-only perspective. The focus of the 'in-the-head' or person-plus approach is on the cognitive residue that remains from group interaction. The group can serve to distribute cognitive processing (e.g., metacognition) and reduce cognitive load. The role of scribe or recorder that is specifically built into some cooperative techniques may reduce working memory demands on other participants. Other cooperative techniques in which groups of students become expert in subtopics of a major topic and are then responsible to teach this content to other members of their group involve a distribution of expertise. This person-plus approach to distributed cognition is modeled on what is known about individual cognition, and functioning within the group is described in terms of individual cognitive functions.

The social-only perspective on distributed cognition views the group members and their work as indivisible. This perspective has strong influences from cultural-historical psychology that emphasizes the role of culture and history on cognition. Thus, distributed cognition approaches that involve the social-only perspective have much in common with a Vygotskian approach to cooperation/collaboration. Interpreted from this perspective, the activity of the individual is mediated by the tools available (to include both symbols and actual artefacts), the rules of the community, and the accepted divisions of labor. Tools represent and embody the expertise of others and interaction with these tools involves interaction with the wisdom and experience of others. For example, when a doctor conducts a history and physical examination of a patient and uses a checklist of steps to guide this process, the doctor is not simply performing an act of individual cognition. The steps included in the checklist represent the embodied expertise of other doctors whose expertise and wisdom in practice has been distilled to a checklist that can be used by others. Thus, the doctor in using this tool participates in the practices of a community that extend beyond the individual interaction with a particular patient.

The notion of distributed cognition has enormous appeal. We do not wish to fly in an aircraft where the work is considered divisible. There are

products where the individual contributions to the final product should be seamless and invisible. Educational systems, however, focus on individual accomplishment, and viewing collaborative groups without concern for individual achievement is not realistic.

An Educational Example of Distributed Cognition

The examples of peer tutoring and scripted cooperation represent versions of distributed cognition and are used in many schools. There are fewer examples of the social-only perspective. One such example is the computer support for intentional learning environments (CSILE: Scardamalia *et al*., 1994). The goal of this project was to support students' intentional and autonomous learning in a community of learners. An environment was created thought the use of a networked set of computers in which students contributed to a shared database. Students could add graphical or text notes to a shared database. They could add comments to notes in the database. Only the author of a note could edit the note or delete it. Authors were notified when a comment was added to a note they contributed. Students could use CSILE for a range of tasks from very traditional schoolwork in which they rehearsed information or for more open-ended student-initiated tasks. Knowledge was public and could be added to, critiqued, revised, and reformulated by anyone in the class. The task for students was the social construction of knowledge in which individual contributions were less important than the adequacy of the emerging knowledge base. Unlike most cooperative or collaborative learning techniques, the focus was not on students improving their own skills.

In one example of students' use of CSILE, students generated notes and comments on the inheritance of characteristics or why a child might look more like one parent than another. Students developed a complicated database of information about inheritance that connected to both current uses of genetics and previous history of research on genetics. Despite the fact that the focus in CSILE classrooms is on community knowledge, students in such classes do in fact improve their individual skills and perform better on standardized tests than do students in control classrooms (Scardamalia *et al.*, 1994).

Problem-based Learning

Both person-plus and social-only aspects of distributed cognition are present in problem-based learning (PBL). PBL must be distinguished from individual problem-solving even when the problems are authentic. Problem-based learning has three key features: a rich and authentic problem that supports student inquiry, student-centered learning, and learning that is done collaboratively with group members, scaffolded by the availability of a tutor or facilitator.

In medical schools the goals of PBL are to develop clinical reasoning, integrate clinical reasoning and basic biomedical knowledge, and promote self-directed learning. The use of PBL in medical schools involves a group of five to seven students who meet with a facilitator to discuss a problem. The facilitator provides students with a small amount of information about a patient's case. One student assumes the role of scribe, recording the decisions and hypotheses of the group. This record is typically visible to all. The group evaluates and defines various aspects of the case and develops an understanding of the causes of the problem. The students do so by identifying key information, generating and evaluating hypotheses, and formulating learning issues that they deem relevant and in need of further explanation. They conduct research to find information relevant to the identified learning issues and eventually draw conclusions about the patient's problem. The process concludes with reflections upon what was learned. The role of the facilitator is crucial to this process.

Problem-based learning exemplifies a number of aspects of distributed cognition. The knowledge needed for problem solution is distributed among the members of the group, library resources, other experts in the school, and prior records of patient cases. Learning requires connecting to a community of practice and prior experience in pursuit of a solution to a particular problem. In this sense, the work of the group is an example of social-only distributed cognition in that understanding of the patient case requires joint activity. The technique also provides an example of person-plus approaches to distributed cognition in that cognitive load is reduced by the use of a single scribe. Metacognition is partially offloaded to the facilitator who adopts some of the monitoring function typical of individual cognition.

Effects on student achievement

Early evaluations of problem-based learning examined traditional learning outcomes such as performance on the medical board examinations. Students from PBL programs score below those from more traditional curricula, but there is some evidence to suggest they do better on the clinical

portions of the examinations. However, comparisons are confounded by selection problems associated with different kinds of students selecting to participate in different kinds of curricula. Hmelo (1998) compared students from a PBL program with those from a traditional curriculum on measures of problem solving. She concluded that the PBL students were more accurate, constructed better explanations, and were more likely to use hypothesis-driven reasoning strategies than students from the traditional curriculum.

Applications outside medicine

Problem-based learning is being used in contexts other than in medical training. Science departments in many universities in the United States have adopted PBL methods in basic courses at the undergraduate level as part of ongoing efforts to make science meaningful and relevant to large groups of students. Many inquiry-based programs in elementary and secondary schools include elements of PBL. In particular, anchoring knowledge acquisition in authentic problems is common and reflects a shift in theories of learning towards a view of knowledge acquisition that has social interaction as a key feature.

COMMON GROUND AMONG APPROACHES

All of the collaborative/cooperative learning techniques described here (reciprocal teaching, problem-based learning, scripted cooperation, and peer tutoring) involve some type of scaffolded instruction. Despite differences in approaches, most collaborative or cooperative techniques promote student engagement with one another or with tasks such that effective cognitive processing and productive discourse occur. Efforts to scaffold instruction are attempts to promote such processes.

Instruction can be scaffolded by setting up the initial context for learning, specifying the cognitive or other roles that students adopt during collaboration, delineating interaction rules such as taking turns, and monitoring or regulating the interactions. Task structures drive the nature and quality of interaction. Authentic tasks such as those found in problem-based learning scenarios engage student interest and provide meaningful challenges.

Instruction can also be scaffolded by the assignment of cognitive roles within a group. In problem-based learning groups, the roles of facilitator and scribe are important in assisting the group members to focus on the learning issues at hand. The scribe records the decisions of the group and this visible record of group hypotheses and decisions about needed information provides important metacognitive processing opportunities for the group. The external record of discussions allows group members to recheck their choices and monitor progress towards their goals. In many cooperative contexts (e.g., the Johnsons' *Learning Together*), specific cognitive roles are assigned (checker, recorder, question generator, etc.), and the performance of these roles provides a scaffold that moves the group towards goal completion. In some instances such as tutoring, the tutor quite deliberatively scaffolds the tutee's processing as he or she directs attention to features of the task and strategies for accomplishing the task. Depending on the content and pedagogical expertise of the tutor, the scaffolding that is provided will be more or less effective. Reciprocal teaching provides scaffolded instruction through dialogues between the teacher who models the desired cognitive strategies and the students who practice the strategies. Support is gradually removed as students become more expert in using the targeted cognitive strategies. Scaffolded instruction may include strategies for maintaining all group members' involvement in group dialogue. Examples of such strategies include requiring turn taking with specific roles or tasks such that the same individual is not always responsible for the same task. Thus, opportunity to participate is deliberately distributed.

Key features of scaffolded instruction include making the use of cognitive strategies visible and providing opportunity for modeling, practice, and feedback related to the performance of those strategies. Collaborative techniques vary depending on whose strategies are made visible (other students, experts) and how the modeling, practice, and feedback cycles occur. They share common goals of student engagement and enhancement of learning.

Distributed Representations

Intermediate article

Tony Plate, Black Mesa Capital, Santa Fe, New Mexico, USA

CONTENTS

Distributed representations are a way of representing information in a pattern of activation over a set of neurons, in which each concept is represented by activation over multiple neurons, and each neuron participates in the representation of multiple concepts.

THE IMPORTANCE OF REPRESENTATION

The way information is represented has a large impact on the type of operations that are easy or practical to perform with it. Researchers working on neural models of cognitive tasks have taken representational issues especially seriously. It is a great challenge to work out how to effectively utilize the potentially vast computational power of the human brain, in the face of the unreliability and slowness of individual neurons. It does seem clear that any neural computational scheme that performs at near-human levels must make use of neural representations that make it possible to perform relatively high-level tasks in just a few 'steps' of neural computation. There is simply not enough time for many steps of computation in the time that people take to act when having a conversation, playing sports, etc.

PROPERTIES OF DISTRIBUTED REPRESENTATIONS

In distributed representations, concepts are represented by patterns of activity over a collection of neurons. This contrasts with local representations, in which each neuron represents a single concept, and each concept is represented by a single neuron. Researchers generally accept that a neural representation with the following two properties is a distributed representation (e.g., Hinton *et al.*, 1986):

- Each concept (e.g., an entity, token, or value) is represented by more than one neuron (by a pattern of neural activity in which more than one neuron is active).
- Each neuron participates in the representation of more than one concept.

Another equivalent property is that in a distributed representation one cannot interpret the meaning of activity on a single neuron in isolation: the meaning of activity on any particular neuron is dependent on the activity in other neurons (Thorpe, 1995).

The distinction between local and distributed representations is not always as clear as it might initially seem (see van Gelder, 1991, for discussion). Is a standard eight-bit binary encoding for numbers between zero and 255 a local or a distributed code? At the level of numbers each 'concept' (number) is represented by multiple 'neurons' (bits), and each neuron participates in representing many concepts. However, this encoding can also be viewed as a local representation of powers of two: 1, 2, 4, 8, etc. This is an example of where a representation is distributed at one level of interpretation but in which individual neurons represent finer-grained features or 'micro-features' in a localist fashion.

Similarity and Generalization

The similarity of two patterns is very important in distributed representations. Similarity of two patterns is usually computed as their dot-product or cosine. The cosine is preferable when total neural activity differs significantly across patterns.

Neural networks typically respond in a similar manner to similar inputs. Distributed representations are generally designed to take advantage of this; inputs that should result in similar responses are represented by similar activation patterns, and inputs that should result in different responses are represented by quite different activation patterns. One sees the same principle at work when a

network develops distributed representations for itself, as in Hinton's (1986) family-tree learning network. Note that domain similarity can depend upon the task to be performed: two inputs that can be treated as the same for one task may need to be treated as different for another task. At the most basic level, learning is about determining which similarities and differences between inputs are and are not important for a particular task. A network that is either provided with, or that can learn, a good set of features to represent its input will often be able to generalize well from limited data.

Superposition, Multiple Concepts, Interference, and Ghosting

Using distributed representations, multiple concepts can be represented at the same time on the same set of neurons by superimposing their patterns together. Mathematically, superposition means some sort of addition, possibly followed by a thresholding or a normalizing operation.

How can we tell whether a particular pattern $\mathbf{x}$ is part of a superposition of patterns, denoted by $\mathbf{y}$? The simplest, and most commonly used way is to check whether the similarity between $\mathbf{x}$ and $\mathbf{y}$, exceeds some predetermined threshold. Another technique is discussed later in this article.

As more patterns are superimposed together, it can become difficult to tell whether or not a particular pattern is part of the superposition. When patterns appear in the result of a superposition, but were in fact not part of the superposition, this is known as interference or ghosting. The number of patterns that can be superimposed before ghosting becomes a problem depends on several aspects of the representation: the number of neurons (more neurons means less ghosting); the number of distinct patterns (more patterns means more ghosting); the degree of noise tolerance we wish the representation to have (higher noise tolerance means more ghosting); and the density of patterns.

Density and Sparse Representations

The total level of activity in a pattern is referred to as the sparseness, or alternatively, the density, of the representation. For a binary representation, this is the fraction of neurons that are active. For a continuous representation the Euclidean length of vectors is often used as the density. Patterns chosen to represent concepts in a model are often restricted to have the same density. Density of patterns in a representation can be tuned to optimize the properties of the representation, for example minimizing ghosting and maximizing capacity.

Sparse binary distributed representations have the attractive property that they can be superimposed using the binary-OR rule with little ghosting until the number of superimposed patterns becomes large. Sparse representations are also of interest because neurophysiological evidence suggests that representations used in the brain are quite sparse.

Advantages of Distributed Representations

Distributed representations are often held to have many advantages compared to symbolic (e.g., Lisp data structures) and local representations. The most common and important are as follows:

1. *Representational efficiency*. Distributed representations form a more efficient code than localist representations, provided that only a few concepts are to be represented at once. A localist representation using n neurons can represent just n different entities. A distributed representation using n binary neurons can represent up to 2^n different entities (using all possible patterns of zeros and ones).
2. *Mapping efficiency*. A microfeature-based distributed representation often allows a simple mapping (that uses few connections or weights) to solve a task. For example, suppose we wish to classify 100 different colored shapes as to whether or not they are yellow. Using a localist representation, this would require a connection from each neuron representing a yellow shape to the output neuron. Using a feature-based distributed representation, all that is required is a single connection from the neuron encoding 'yellow' to the output neuron. In general, a mapping that can be encoded in relatively few weights operating on a feature-based distributed representation can be learned from a relatively small training sample and will generalize correctly to examples not in the training set.
3. *Continuity* (in the mathematical sense). Representing concepts in continuous vector spaces allows powerful gradient-based learning techniques such as back propagation to be applied to many problems, including ones that might otherwise be seen as discrete symbolic problems.
4. *Soft capacity limits and graceful degradation*. Distributed representations typically have soft limits on how many concepts can be represented simultaneously before ghosting or interference becomes a serious problem. Also, the performance of neural networks using distributed representations tends to degrade gracefully in response to damage to the network or noise added to activations. Many researchers find these properties compellingly similar to performance observed in people.

On the other hand, local representations are far simpler to understand, implement, interpret, and work with. If distributed representations do not provide significant advantages for a particular application, it may be more appropriate to use a local representation. Page (2000) argues forcefully that this is the case in many cognitive modeling applications.

Major Areas of Research in Distributed Representations

The major areas of research in distributed representations are: (1) techniques for representing data more complex than simple tokens, such as data with compositional structure, continuous data, probability distributions; (2) properties of representational schemes, such as capacity, scaling, reconstruction accuracy; and (3) techniques for learning distributed representations.

CODING PROBLEMS AND TECHNIQUES

The Binding Problem

The problem of keeping track of which features or components belong to which objects is known as the 'binding problem'. Consider trying to represent the presence of several colored shapes. A simple local representation could have one set of features for color and another set of units for shape. A red circle would be represented by activity on the red unit and on the circle unit (Figure 1(a)). However, when we try to represent two colored objects simultaneously, we encounter a binding problem: does red + blue + circle + triangle mean red circle and blue triangle or blue circle and red triangle (Figure 1(b))? The binding problem can arise with local or distributed representations when features or components are represented independently and can belong to different objects.

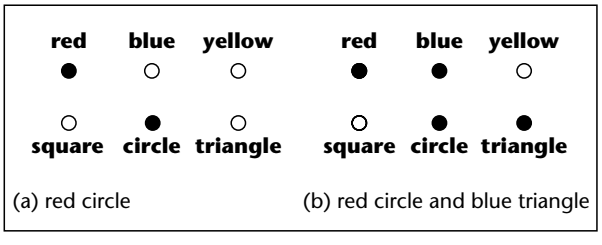

Figure 1. The binding problem: representations of multiple objects on independent feature sets can lose information about which features belong to which objects.

Conjunctive Coding

Conjunctive codes are a general approach to solving the binding problem in neural representations. A simple local conjunctive code has one neuron for every possible combination (conjunction) of a single value from each feature set. For example, to represent colored shapes with 10 possible colors and five possible shapes we would use 50 units. Figure 2 shows an example of this with just three colors and three shapes. This technique can also be used when the value on each feature dimension is encoded with a distributed representation: form the outer product of the patterns for each feature dimension. This outer-product operation underlies such well known associative memory schemes as the Willshaw net (Willshaw, 1989) and the Hopfield net (Hopfield, 1982).

This simple kind of conjunctive code is an example of how a neural code for a composite object can be computed in a systematic manner from the codes for its constituent parts or features. This is an important aspect of Hinton's influential idea of reduced representations, discussed later in this article.

There are two serious problems that occur with simple outer-product conjunctive codes. The first is inefficiency: resource requirements grow exponentially with the number of feature classes. With k feature classes (e.g., color, shape, size, etc.) each having n possible values, the total number of neurons required for a complete conjunctive code is n^k. The informational efficiency of such a code is very poor if only a handful of objects are to be represented simultaneously. Another way of looking at this is that the same set of neurons could represent far more information about each object, or about more objects, if a more efficient code were used. The second problem is that the conjunctive code can hide what makes objects

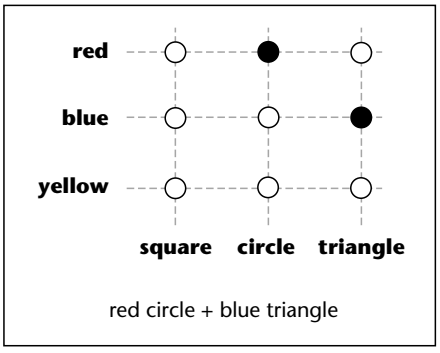

Figure 2. A conjunctive code representing two objects simultaneously.

similar, which places high resource demands on mapping and can make learning difficult. If the independent features of the input are useful for solving the problem or constructing the mapping, learning and mapping are simpler when input to a network represents each feature dimension independently rather than in a conjunctive manner.

Coarse Coding

One of the apparent paradoxes of neural codes is that a stimulus or entity can be represented more accurately by a collection of neurons with broad or coarse response functions than by a collection of neurons with more finely-tuned respone functions. This applies to the representation of both discrete and continuous stimuli or entities.

For representing continuous data, such as a position in space (with two or more dimensions), this means that one can increase the overall accuracy of coding schemes by decreasing the accuracy with which individual neurons represent a data point (i.e., by making the neurons code the data more coarsely). Consider a simple representation for a point in space, where each of n neurons has a randomly chosen centre (in input space), and responds to a data point within a radius r of its centre (its *receptive field*). A two-dimensional version of this is shown in Figure 3. Hinton *et al*. (1986) show that for neurons representing regions in a k-dimensional space, the inaccuracy of a distributed representation like this is proportional to $1/r^{k-1}$. For example, in a six-dimensional space, doubling the radius of each receptive field reduces the inaccuracy of the representation by a factor of 32 on each dimension.

When we look at the system from an information-theoretic viewpoint, it is not surprising that coarsening the receptive fields increases rather than decreases overall accuracy. With very small receptive fields, each neuron is active for only a small fraction of possible stimuli and thus each neuron carries very little information. With larger receptive fields, each neuron is active for a larger fraction of possible stimuli and thus carry more information.

Coarse coding can also be applied to representing discrete entities. The principle is the same: a single neuron is active for a moderately large proportion of possible stimuli, and different neurons cover dissimilar subsets of stimuli. For example, a distributed representation for animals based on semantic features might have one unit responding to animals that are small-to-medium in size AND moderate-to-high in ferocity; another unit might respond to animals that are medium-to-large in size AND moderate-to-high in ferocity, etc.

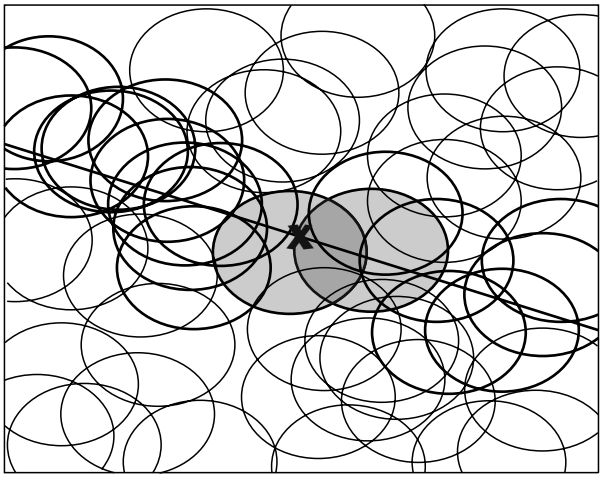

Figure 3. Coarse coding of two-dimensional positions. Each neuron is represented by an area showing its receptive field. Neurons that respond to the point X have gray receptive fields. Neurons that respond to some point along the solid line are shown with bolder receptive fields.

REPRESENTATIONS FOR INFORMATION WITH COMPLEX STRUCTURE

Many cognitive tasks involve understanding and processing information that has a very complex structure. The concepts communicated by human language almost always have a compositional nature, and quite often, the composition is hierarchical. In the sentence 'Joan watched Sam cook the eggs', there are a number of different concepts involved: 'Joan', 'watching', 'Sam', 'cooking', 'eggs'. Representing the overall concept communicated by the above sentence involves representing its components and their relationships. If the relationships are not represented we are not able to distinguish between 'Joan watched Sam cook the eggs' and 'Sam watched Joan cook the eggs'. This is another example of a binding problem; we need to bind the concepts 'Sam' and 'eggs' to the relational concept 'cooking'. One possibility is to allocate a set of neurons for each role or aspect of the relation: a relation name set containing the code for 'cooking', a subject set containing the code for 'Sam', and an object set containing the code for 'eggs'. However, there is also a hierarchical, or recursive, aspect to the

sentence 'Joan watched Sam cook the eggs'. Once we have constructed an appropriate representation for 'Sam cooking eggs' we then need to bind it and 'Joan' to the relational concept 'watching'. An approach utilizing a fixed-size set of neurons for each role prevents any neat solution for representing the recursive aspects of the whole problem because the number of neurons in the representation of a relation is larger than the number of neurons allocated to represent the filler of a role.

The compositional and recursive nature of concepts is not limited to obviously linguistic tasks, but is widespread in human cognition; visual scene understanding, and analogy recall and matching are two examples. Although representing hierarchical compositional structures in the activations and/or weights of a neural network is not easy, it is important as it could eventually allow the application of powerful neural-network learning techniques to difficult problems such as language understanding and acquisition.

Reduced Descriptions

Hinton (1990) introduced the idea of 'reduced description' as a way of representing hierarchical compositional structure in fixed-size distributed representations. The basic idea is that a relation can be represented in two different ways: (1) as an expanded representation in which the fillers of each role are represented on separate groups of neurons (e.g., a relation with two arguments and a relation name could use three groups of n neurons); and (2) as a compressed or reduced description over just n neurons. Since the reduced description for a relation occupies just n neurons, it can be used as a filler in some other relation, which in turn could have a reduced description, and so on, allowing arbitrary levels of nesting. A reduced representation behaves like a pointer in symbolic data structures in that it gives a way of referring to another structure. An important difference is that unlike a pointer, a reduced description should carry some information about its contents that can be accessed without expanding the reduced description into a full description. This allows processing to be sensitive to components nested within reduced descriptions without having to unpack multiple levels of nested relations.

In the 1990s researchers developed a number of concrete neural schemes for implementing reduced descriptions. Many use some form of conjunctive role-filler bindings in which both the roles and fillers of a relation are represented with distributed patterns. Many of these schemes differ mainly in the binding operation they use; it turns out that there are many alternatives to a straight outer-product for forming a conjunctive code of two patterns.

RAAMs

Pollack (1990) used a bottleneck auto-encoder network to learn reduced descriptions for relations, which he called 'recursive auto-associative memory' (RAAM). A full, expanded relation was represented across the input units of the network: each filler on one group of input units, and possibly the relation name on a final group of input units. The hidden layer was the same size as one of the groups of input units and was intended to contain a reduced description of the full relation. The network learned, using back propagation, to compress the full relation down to a reduced description, which could then be expanded back out to a full relation. During learning the network had to discover simultaneously how to create and how to decode reduced descriptions for relations. Pollack showed that a network like this could reliably learn to represent hierarchically structured relations that were several levels deep.

Tensor Product Representations

Smolensky (1990) proposed a tensor-product formalism for representing recursive structure. This extends the outer-product role-filler binding operation to higher dimensions. For example, suppose a role and a filler are each represented by a pattern over a line of n neurons. Then their outer-product binding is a pattern over a square of n^2 neurons. This can be bound with another role vector (again a pattern over n neurons) by forming the tensor product, which in this situation is a pattern over a cube of n^3 neurons. This can be taken to arbitrarily deep levels of nesting. However, the number of neurons required increases exponentially with the depth of conceptual nesting.

Holographic Reduced Representations

Holographic reduced representations (HRRs) (Plate, 1995), are a role-filler binding scheme for recursive compositional structure based on conjunctive coding implemented using circular convolution. In HRRs, roles, fillers, labels, and entire relations are all represented as patterns over n neurons. Circular convolution is defined as $\mathbf{z} = \mathbf{x} \otimes \mathbf{y}$, where $z_i = \sum_{k=0}^{n-1} x_k y_{(i-k) \bmod n}$ (where n is the length of the vectors). Circular convolution

is a conjunctive code that keeps dimensionality constant: given role and filler patterns over n neurons each, their circular convolution is also a pattern over n neurons. This makes it simple to build recursive structures. The encoding of a relation is the superposition of role-filler bindings (and possibly a relation label) and thus is also a pattern over n neurons and is easily used as a filler in another relation. For example, a reduced representation for the sentence 'Joan watched Sam cooking eggs' can be constructed as follows:

$$\mathbf{S_1} = \mathbf{cook} + \mathbf{cook}_{\text{agt}} \otimes \mathbf{Sam} + \mathbf{cook}_{\text{obj}} \otimes \mathbf{eggs} \tag{1}$$

$$\mathbf{S_2} = \mathbf{watch} + \mathbf{watch}_{\text{agt}} \otimes \mathbf{Joan} + \mathbf{watch}_{\text{obj}} \otimes \mathbf{S_1} \tag{2}$$

where all the variables are patterns over n neurons (**cook** and **watch** are relation labels; **Sam, eggs**, etc. are patterns representing entities; and $\mathbf{cook}_{\text{agt}}$, etc. are patterns representing the roles of the relations). (*See* **Convolution-based Memory Models**)

A filler of a role in a relation in a reduced representation may be decoded by convolving with the approximate inverse of the role pattern. The approximate inverse of $\mathbf{x}$, denoted by $\mathbf{x}^{\text{T}}$, is a simple permutation of elements: $x_i^{\text{T}} = x_{-i \bmod n}$, and has the property that $\mathbf{x}^{\text{T}} \otimes (\mathbf{x} \otimes \mathbf{y}) \approx \mathbf{y}$.

For example, to recover the filler of the cook-agent role in $\mathbf{S_1}$, we compute $\mathbf{S_1} \otimes \mathbf{cook}_{\text{agt}}^{\text{T}}$, which results in the vector $\mathbf{Sam} + \mathbf{noise}$, because

$$\begin{aligned}
\mathbf{cook}_{\text{agt}}^{\text{T}} \otimes \mathbf{S_1} &= \mathbf{cook}_{\text{agt}}^{\text{T}} \otimes (\mathbf{cook} + \mathbf{cook}_{\text{agt}} \\
&\quad \otimes \mathbf{Sam} + \mathbf{cook}_{\text{obj}} \otimes \mathbf{eggs}) \\
&= \mathbf{cook}_{\text{agt}}^{\text{T}} \otimes \mathbf{cook} + \mathbf{cook}_{\text{agt}}^{\text{T}} \\
&\quad \otimes \mathbf{cook}_{\text{agt}} \otimes \mathbf{Sam} + \mathbf{cook}_{\text{agt}}^{\text{T}} \\
&\quad \otimes \mathbf{cook}_{\text{obj}} \otimes \mathbf{eggs} \\
&= \mathbf{noise} + \mathbf{Sam} + \mathbf{noise}
\end{aligned}$$

In order to recognize $\mathbf{Sam} + \mathbf{noise}$ as the pattern **Sam**, we must pass it through an autoassociative clean-up memory that can take $\mathbf{Sam} + \mathbf{noise}$ as input and return the pattern **Sam**. All potential decoding targets, such as lower-level patterns like **cook,** $\mathbf{cook}_{\text{agt}}$, **Sam**, and higher-level patterns representing chunks, such as $\mathbf{S_1}$ and $\mathbf{S_2}$, must be stored in this long-term clean-up memory. A clean-up memory is also necessary to identify when a decoding target is not present. Without a clean-up memory it would be impossible to tell whether or not there was anything bound to $\mathbf{watch}_{\text{agt}}$ in $\mathbf{S_1}$ because $\mathbf{S_1} \otimes \mathbf{watch}_{\text{agt}}^{\text{T}}$ is a pattern with similar statistical properties to any other pattern. With a clean-up memory containing all potential decoding targets, $\mathbf{S_1} \otimes \mathbf{watch}_{\text{agt}}^{\text{T}}$ can be identified as noise because it almost certainly will not be similar to anything in the clean-up memory.

Binary Spatter Codes

Kanerva's (1996) 'binary spatter code' is a scheme for encoding complex compositional structures in binary distributed representations. Binary spatter codes use binary vectors as patterns, element-wise exclusive-OR for encoding and decoding bindings, and a thresholded sum for superposition. They have similar properties to HRRs.

Holistic Processing

A major reason for interest in distributed representations of a complex structure is the potential for performing structure-sensitive processing without having to unpack hierarchical structures.

Determining similarity is one of the simplest types of processing. Plate (2000) shows that the dot-product of HRRs reflects both superficial similarity (similarity of components) and structural similarity (similarity of structural arrangement of components). The dot-product of HRRs composed of similar entities is higher if the entities are arranged in an analogical (isomorphic) structure. This means that HRRs can be used for fast (but approximate) detection of structural similarity. HRR computations can also be used to rapidly but imperfectly identify corresponding entities in isomorphisms (Plate, 2000; Eliasmith and Thagard, 2001).

Various authors have demonstrated that a variety of structure-sensitive manipulations can be performed on distributed representations without unpacking them. Pollack (1990) trained a feedforward network to transform reduced descriptions for propositions like (LOVED X Y) to ones for (LOVED Y X) where the reduced descriptions were found by a RAAM. Chalmers (1990) trained a feedforward network to transform reduced descriptions of simple passive sentences to reduced descriptions of active sentences, where the reduced descriptions were found by a RAAM. Niklasson and van Gelder (1994) trained a feedforward network to do material conditional inference, and its reverse, on reduced descriptions found by a RAAM. Legendre *et al*. (1991) showed how tensor product representations for active sentences could be transformed to ones for passive sentences (and

vice-versa) by a pre-calculated linear transform. Neumann (2001) trained networks to perform holistic transformations on a variety of representations, including RAAMs, HRRs, and binary spatter codes.

INTERPRETATION OF DISTRIBUTED REPRESENTATIONS

It is straightforward to tell what is represented in a model that uses symbolic or local neural representations. This is not the case with models that use distributed representations. It is important to note that for the purposes of processing the information present in a distributed representation, it is usually NOT necessary to identify what is represented in terms easily understandable to people. Indeed, the whole point of having a distributed representation is that it makes further processing simpler than performing the same computations on a more easily interpretable representation. Interpretation of a distributed representation is typically necessary either when outputs need to be computed in a readily interpretable form or when a person wants to gain insight into the internal workings of a model.

There are two quite different senses in which a distributed representation can be interpreted: (1) determine which items are represented in a pattern of activation, where patterns for individual items are known; and (2) determine what features a network has learned to use to represent a set of items.

Algorithms for Determining Which Items are Represented

A simple and common algorithm for determining the items present in a distributed pattern of activation is to compute the dot-product of each item with the pattern of activation. A feedforward neural network with a localist output representation performs this computation in its final layer of weights. Often it is useful to apply a thresholding or a winner-take-all function to the outputs to cut down the noise.

It is also possible to take an inferential approach to identifying the items present in a distributed code. The idea is to find the best explanation for the observed pattern of activities, in terms of the items that could be present. Zemel *et al*. (1998) do this in analyzing the potential of sparse distributed representations for representing probability distributions. This requires three pieces of knowledge, which can be combined using Bayes' rule: (1) the set of all possible probability distributions that could be represented, and the respective prior probability of each probability distribution (prior to knowledge of current activities); (2) the currently observed pattern of activity; and (3) for each possible probability distribution, the probability that it would generate the currently observed pattern of activity. In Zemel *et al*.'s approach, the probability distribution represented by a pattern of activity is the one with the maximum a-posteriori (MAP) probability (the posterior probability of a distribution is the product of its prior probability and the probability that it would have generated the currently observed pattern of activity).

Understanding Learned Representations

Principal components analysis is often used to gain understanding into a learned distributed representation. Elman (1991) trained a network to predict the next word in sentences generated from a simple recursive English-like language. The predictions made by the network indicated that it had managed to learn something about the recursive nature of the language. Elman used principal components analysis to gain some understanding of how the network represented state (i.e., its memory of what it had seen so far); he showed that a particular phrase caused a similar shape of trajectory through the principal component space independent of its level of embedding, and that level of embedding determined the position of the trajectory.

CONCLUSION

Distributed representations offer powerful representational principles that can be used in neural network approaches to learning and to modeling human cognitive performance. Research continues on three main aspects of distributed representation: schemes for representing data; properties of representational schemes; and ways of learning distributed representations. The ability to learn and use distributed representations of concepts, and to compose complex data structures out of these representations, offers the potential of building general-purpose computers that combine the power of symbolic manipulation with the robustness, learning, and generalization ability of neural networks.

Dynamical Systems Hypothesis in Cognitive Science

Intermediate article

Robert F Port, Indiana University, Bloomington, Indiana, USA

CONTENTS

The dynamical systems hypothesis in cognitive science identifies various research paradigms applying the mathematics of dynamical systems to understanding cognitive function.

OVERVIEW

The dynamical approach to cognition is allied with and partly inspired by research in neural science since the 1950s, in which dynamical equations have been found to provide excellent models for the behavior of single neurons (Hodgkin and Huxley, 1952). It also takes inspiration from work on gross motor activity by the limbs (e.g. Bernstein, 1967; Fel'dman, 1966). In the early 1950s, Ashby made the startling proposal that all of cognition might be accounted for with dynamical system models (Ashby, 1952), but little work followed directly from his speculation because of a lack of appropriate mathematical methods and computational tools to implement practical models. More recently, the connectionist movement (Rumelhart and McClelland, 1986) has provided insights and mathematical implementations of perception and learning, for example, that have helped revive interest in dynamical modeling.

The dynamical approach to cognition is also closely related to ideas about the embodiment of mind and the environmental situatedness of human cognition, since it emphasizes connections between behavior in neural and cognitive processes, on the one hand, and physiological and environmental events, on the other. The most important such connection is the dimension of time shared by all of these domains. This permits real-time coupling between domains, whereby the dynamics of one system influence the timing of events in another. Humans often couple many systems together: for example, when dancing to music, one's auditory perception system is coupled with environmental sound, and the gross motor system with both audition and musical sounds. Because of this connection between the world, the body and cognition, the method of differential equations is applicable to events at all levels of analysis over a wide range of timescales. This approach emphasizes change over time of relevant system variables. (*See* **Embodiment**; **Dynamical Systems, Philosophical Issues about**)

MATHEMATICAL CONTEXT

The mathematical models employed in dynamical systems research derive from many sources in biology and physics. Two schemas will be discussed out here. The first is the neural network idea, partially inspired by the remarkable equations of Hodgkin and Huxley (1952) which account for many neuronal phenomena in terms of the dynamics of cell membranes. Hodgkin and Huxley proposed a set of differential equations describing the flow of sodium and potassium ions through the axonal membrane during the passage of an action potential down the axon. These equations, which apply with slight modification to all neurons, led to attempts to account for whole cells (rather than patches of membrane) in terms of their likelihood of firing given various excitatory and inhibitory inputs. Interesting circuits of neuron-like units were constructed and simulated on computers. The Hodgkin–Huxley equations inspired many psychological models, such as those of Grossberg (1982, 1986), the connectionist network models (Rumelhart and McClelland, 1986), and models of neural oscillations (Kopell, 1995). (*See* **Hodgkin–Huxley**)

In this schema, it is hypothesized that each cell or cell group in a network follows an equation like

$$\frac{dA}{dT} = -\gamma A(t) + \delta(aE(t) - bI(t) + cS(t)) + k \qquad (1)$$

indicating that the rate of change of activation (i.e., likelihood of firing) A at time t depends on the decay γ of A and a term representing inputs from other cells that are either excitatory, $E(t)$ (tending to increase the likelihood of firing), or inhibitory, $-I(t)$ (tending to decrease the likelihood of firing). For some units there may be an external physical stimulus, $S(t)$. A nonlinear function, $\delta(x)$, encourages all-or-none firing behavior, and the bias term k adjusts the value of the firing threshold. An equation of this general form can describe any neuron. Networks of units like these can exhibit a wide variety of behaviors, including many specific patterns of activity associated with animal nervous systems. (*See* **Neurons, Computation in**)

A second schema inspiring the dynamical approach to cognition is the classical equation for a simple oscillator like a pendulum. Indeed, it is obvious that arms and legs have many of the properties of pendulums. Pendular motion is a reasonable prototype for many limb motions. A similar system (lacking the complication of arc-shaped motion) is that of a mass and spring. It is described by the equation

$$m\frac{d^2x}{dt^2} + d\frac{dx}{dt} + k(x - x_0) = 0 \qquad (2)$$

which specifies simple harmonic motion in terms of the mass m, the damping d, the spring's stiffness k, and the neutral position x_0 of the mass. Fel'dman (1966) used heavily damped harmonic motion to model a simple reach with the arm. If the neutral position x_0 (the attractor position when damped) can be externally set to the intended target position (for example, by adjusting the stiffness in springs representing flexor and extensor muscles), then movements from arbitrary distances and directions towards the target can occur – simply by allowing the neuromuscular system for the arm to settle to its fixed point, x_0. A number of experimental observations – for example, reaching maximum velocity in the middle of the gesture, higher maximum velocity for longer movements, automatic correction for an external perturbation, and the naturalness and ease of oscillatory motions at various rates – can be accounted for with a model using a mass and a spring with controllable stiffness, rest length and damping. (*See* **Motor Control and Learning**)

In the most general terms, a dynamical system may be defined as a set of quantitative variables (e.g., distances, activations, rates of change) that change simultaneously in real time due to influences on each other. These mutual influences can be described by differential or difference equations (van Gelder and Port, 1995). Newton's equations of motion for physical bodies were among the earliest dynamical models. Until the 1950s, the analysis of dynamical models was restricted to linear systems (such as eqns 1 and 2) containing no more than two or three variables. Since the 1970s, mathematical developments, simulations by digital computer programs and computer graphics have revolutionized modeling possibilities, and practical methods for studying nonlinear systems with many variables are now possible (Strogatz, 1994).

PERCEPTUAL MODELS

Dynamical models seem particularly appropriate to account for motor control and for perceptual recognition. In particular, there is a large body of research on temporal aspects of perception. (*See* **Perception: Overview**; **Perceptual Learning**; **Reaction Time**)

One well-known example of a dynamical model for general perception is the adaptive resonance theory (ART) model of Grossberg (1995). This neural network is defined by a series of differential equations, similar to eqn 1 above, describing how the activation of any given node is increased or decreased by stimulus inputs, excitation and inhibition from other nodes, and intrinsic decay. This depends on weights (represented as matrices for a, b and c in eqn 1) which are modified by previous successful perceptual events (simulating learning from experience). The model can discover the low-level features that are most useful for distinguishing frequent patterns in its stimulus environment (using unsupervised learning) and identify specific high-level patterns even from noisy or incomplete inputs. It can also reassign resources whenever a new significant pattern appears in its environment, without forgetting earlier patterns. Notions like 'successful perception' and 'significant pattern' are provided with mathematical specifications that drive the system toward greater 'understanding' of its environment.

To recognize an object such as a letter of the alphabet from visual input, the signal from a spatial retina-like system excites low-level 'feature' nodes. The pattern of activated features here feeds excitation through weighted connections to a higher set of 'identification' nodes. These nodes compete through mutual inhibition to identify the pattern. The best matching unit quickly wins by suppressing all its competitors. When the match is good enough, a 'resonance loop' is established between

some sensory feature units and a particular classification unit. Only at this point is successful (and, according to Grossberg, conscious) identification achieved. This perceptual model is dynamic because it depends on differential equations that increase or decrease the activation of nodes in the network at various rates. Grossberg's research group has shown that variants of this model can account in a fairly natural way for many phenomena of visual perception, including those involving backward masking and reaction time. (*See* **Perceptual Systems: The Visual Model**)

HIGH-LEVEL MODELS

Dynamical models have also been applied to higher-level cognitive phenomena. Grossberg and colleagues have extended the ART model with mechanisms such as 'masking fields', so that, for example, the model can recognize words from temporally arriving auditory input. Several time-sensitive phenomena of speech perception can be successfully modeled in this way (Grossberg, 1986).

Models of human decision-making have traditionally applied the theory of expected utility, whereby evaluation of the relative advantages and disadvantages of each choice is made at a single point in time. But Townsend and Busemeyer (1995) have developed a 'decision field theory' that not only accounts for the likelihood of each eventual choice, but also accounts for many time-varying aspects of decision making, such as 'approach–avoidance' or vacillatory effects, and the fact that some decisions need more time than others. (*See* **Decision-making**; **Choice Selection**)

Some phenomena that at first glance seem to depend on high-level reasoning skills may in fact reflect more low-level properties of cognition. One startling result of this kind is in the 'A-not-B problem'. Infants (9 to 12 months old) will sometimes reach to grab a hidden object; yet when the object is moved to a new location, they often reach to the first location again. This puzzle was interpreted by Piaget (1954) as demonstrating a lack of the concept of 'object permanence', that is, that children have an inadequate understanding of objects, thinking that they somehow intrinsically belong to the place where they are first observed. However, Thelen *et al*. (2001) demonstrated a dynamical model for control of reaching that predicted sensitivity to a variety of temporal variables in a way that is supported by experimental tests. Thus what seems at first to be a property of abstract, high-level, static representations may turn out to result from less abstract time-sensitive processes, which are naturally modeled using dynamical equations. (*See* **Object Concept, Development of**)

RELATION TO SITUATED COGNITION AND CONNECTIONISM

From the perspective of 'situated cognition', the world, the body and the cognitive functions of the brain can all be analyzed using the same conceptual tools. This is important because it greatly simplifies our understanding of the mapping between these domains, and is readily interpreted as an illustration of the biological adaptation of the body and brain to the environment on short-term and long-term time scales. (*See* **Perception, Direct**)

Connectionist models are discrete dynamical systems, as are the learning algorithms used with them. But not all connectionist models study phenomena occurring in continuous time. Neural network models are frequently used to study time-varying phenomena, but other dynamical methods that do not employ connectionist networks are also available. The development of connectionist modeling since the 1980s has helped to move the field in the direction of the dynamical approach, but connectionist models are not always good illustrations of the dynamical hypothesis of cognition. (*See* **Language, Connectionist and Symbolic Representations of**)

CONTRAST WITH TRADITIONAL APPROACHES

The most widespread conceptualization of the mechanism of human cognition proposes that cognition resembles computational processes, like deductive reasoning or long division, by using symbolic representations (of objects and events in the world) that are manipulated by cognitive operations, modeling time only as serial order. These operations reorder or replace symbols, and draw deductions from them (Haugeland, 1985). The computational approach has been articulated as the 'physical symbol system hypothesis' (Newell and Simon, 1976). The theoretical framework of modern linguistics (Chomsky, 1963, 1965 and Chomsky and Halle, 1967) also falls squarely within this tradition since it views sentence generation and interpretation as a serially ordered process of manipulating word-like symbols (such as 'table' or 'go'), abstract syntactic symbols (such as 'noun phrase' or 'sentence') and letter-like symbols representing minimal speech sounds (such as /t/, /a/ or features like 'voiceless' or 'labial') in discrete time. The computational approach,

applied to skills like the perceptual recognition of letters of the alphabet and sounds, or recognizing a person's distinctive gait, or the motor control that produces actions like reaching, walking or pronouncing a word, hypothesizes that essentially all processes of cognition are computational operations that manipulate digital representations in discrete time. The mathematics of such systems is based on the algebra of strings and graphs of symbol tokens. Chomsky's work on the foundations of such abstract algebras (Chomsky, 1963) served as the theoretical foundation for computer science as well as modern linguistic theory. (*See* **Representation, Philosophical Issues about**; **Computation, Philosophical Issues about**; **Symbol Systems**; **Syntax**)

It should be noted that the dynamical systems hypothesis for cognition is in no way incompatible with serially ordered operations on discrete symbols. However, proponents of the dynamical systems approach typically deny that most cognition can be satisfactorily understood in computational terms. They propose that any explanation of human symbolic processing must sooner or later include an account of its implementation in continuous time. The dynamical approach points out the inadequacy of assuming that a 'symbol processing mechanism' is available to human cognition, as a computer happens to be available to a programmer. In the dynamical framework, the discrete time of computational models is replaced with continuous time; first and second time derivatives are meaningful at each instant; and critical time points are specified by the environment or the body rather than by a discrete-time device jumping from one time point to the next. (*See* **Symbol Systems**)

STRENGTHS AND WEAKNESSES OF DYNAMICAL MODELS

Dynamical modeling offers many important advantages over traditional computational cognition. First, the biological implausibility of digital, discrete-time models remains a problem. How and where in the brain might there be a device that would behave like a computer chip, clicking along infallibly performing operations on digital units? One answer that has often been put forward is 'we don't really know how the brain works, anyway, so this hypothesis is as plausible as any other' (Chomsky, 1965 and 2000). Such an answer does not seem as reasonable today as it did in the 1960s. Certainly neurophysiological function exhibits many forms of discreteness; but this fact does not justify the postulation of whatever kind of units and operations would be useful for a digital model of cognition. (*See* **Computation, Philosophical Issues about**; **Categorical Perception**)

Secondly, temporal data can, by means of dynamical models, be incorporated directly into cognitive models. Phenomena such as processing time (e.g., reaction time, recognition time, response time), and temporal structure in motor behavior (e.g., reaching, speech production, locomotion, dance), and in stimulation (e.g., speech and music perception, interpersonal coordination while watching a tennis match), can be linked together if critical, events spanning several domains can be predicted in time. (*See* **Perception: The Ecological Approach**; **Perception, Direct**)

The language of dynamical systems provides a conceptual vocabulary that permits unification of cognitive processes in the brain with physiological processes in our bodily periphery and with environmental events external to the organism. Unification of processes across these fuzzy and partly artificial boundaries makes possible a truly embodied and situated understanding of all types of human behavior. Discrete-time models are always forced to draw a boundary somewhere to separate the discrete-time, digital aspects of cognition from continuous-time physiology (as articulated in Chomsky's, 1965 distinction between 'competence' and 'performance'). (*See* **Neuropsychological Development**; **Performance and Competence**)

Thirdly, cognitive development and 'run-time' processing can now be integrated, since learning and perceptual and motor behavior are governed by similar processes even if on different timescales. Symbolic or computational models were forced to treat learning and development as separate processes unrelated to motor and perceptual activity.

Fourthly, trumping the advantages given above, dynamical models include discrete-time, digital models as a special case. The converse is not true: the sampling of continuous events permits discrete simulation of continuous functions, but the simulation itself remains discrete, and only models a continuous function to an accuracy dependent on its sampling rate (Port *et al*., 1995). Thus, any actual digital computer is also a dynamical system with real voltage values in continuous time that are discretized by an independent clock. Of course, computer scientists prefer not to regard them as continuous-valued dynamical systems (because it is much simpler to exploit their digital properties), but computer engineers have no choice. Hardware engineers have learned to constrain computer dynamics to be governed reliably by powerful

attractors for each binary cell, ensuring that each bit settles into either one of two states before the next clock tick.

These strengths of dynamical modeling are of great importance to our understanding of human and animal cognition. But there are several weaknesses of dynamical modelling. First, the mathematics of dynamical models are more inscrutable and less developed than the mathematics of digital models. It is much more difficult to construct actual models, except for carefully constrained simple cases.

Second, during some cognitive phenomena (for example, performing long division, or designing an algorithm, and possibly some processes in the use of language) humans appear to rely on ordered operations on discrete symbols. Although dynamical models are capable of exhibiting digital behavior, how a neurally plausible model could perform these tasks remains a puzzle. It seems that computational models are simpler and more direct, even if they remain inherently insufficient.

DISCRETE VERSUS CONTINUOUS REPRESENTATIONS

Intuitively one of the major strengths of the traditional computational approach to cognition has been the seeming clarity of the traditional notion of a cognitive representation. Since cognition is conceived as functioning somewhat like a program in LISP, the representations are constructed from parts that resemble LISP 'atoms' and 's-expressions'. (*See* **Symbol Systems**; **Computation, Philosophical Issues about**)

A representation is a distinct data structure that has semantic content (with respect to the world outside or inside the cognitive system). Representations can be moved around or transformed as needed. Such tokens have an undeniable resemblance to words and phrases in natural language (Fodor, 1975). Thus, if one considers making a sandwich from bread and the ham in the refrigerator, one can imagine employing cognitive tokens standing for bread, the refrigerator, and so on. Thinking about sandwich assembly might be cognitively modeled using representations of sandwich components. Similarly, constructing the past tense of 'walk' can be modeled by concatenating the representation of 'walk' with the representation of '-ed'. However, this view runs into difficulties when we try to imagine thinking about actually slicing the bread or spreading the mayonnaise. How could discrete, word-like representations be deployed to yield successful slicing of bread? If this is instead to be handled by a nonrepresentational system (such as a dynamical one), then how could we combine these two seemingly incompatible types of systems? (*See* **Representation, Philosophical Issues about**; **Language of Thought**)

In the 1980s, the development of connectionist models, employing networks of interconnected nodes, provided the first alternative to the view of representations as context-invariant, manipulable tokens. In connectionist models, the result of a process of identification (of, say, an alphabetic character or a human face) is only a temporary pattern of activations across a particular set of nodes (modeling cells or cell groups), not something resembling a context-free object. The possibility of representation in this more flexible form led to the notion of distributed representations, where no apparent 'object' can be found to do the work of representing, but only a particular pattern distributed over a set of nodes that are also used for many other patterns. Connectionists emphasized that such a representation would not seem to be a good candidate for a *symbol token*, as conceived in the formalist or computational tradition, yet can still function as a representation for many of the same purposes.

The development of dynamical models of perception and motor tasks has led to further extension of the notion of the representational function to include time-varying trajectories, limit cycles, coupled limit cycles, and attractors towards which the system state may tend. From the dynamical viewpoint, static, computational representations will play a far more limited role in cognition. Indeed, some researchers have denied that static representations are ever needed for modeling any cognitive behavior (Brooks, 1997).

Dynamical Systems: Mathematics

Intermediate article

Jerome R Busemeyer, University of Indiana, Bloomington, Indiana, USA

CONTENTS

Dynamical systems are mathematical models for describing how the state of a biological or an artificial system changes over time.

INTRODUCTION

A critical factor facilitating the 'cognitive revolution' of the early 1960s was the capability of formulating rigorous (computational or mathematical) models of how the inputs and outputs of mental processing systems change over time. The earliest approach was to view the mind as a dynamical cybernetic feedback system (Miller, Gallanter and Pribram, 1960). But this was abandoned in favour of another approach, which was to view the mind as a rule-based symbol processor (Newell and Simon, 1972). Most recently, developments in neural and connectionist networks have revived interest in a dynamical systems approach. More broadly, dynamical systems theory has been adopted by a wide range of fields in cognitive science, including the study of perceptual motor behavior, child development, speech and language, and artificial intelligence. There are excellent presentations of mathematical dynamical systems theory in Beltrami (1987), Luenberger (1979), Padulo and Arbib (1974), and Strogatz (1994).

ELEMENTS OF DYNAMICAL SYSTEMS

Generally speaking, a *dynamical system* is composed of three parts. The first part is the *state*, which is a representation of all the information about the system at a particular moment in time. As an example, the state of a computer can be summarized by a long list of the binary bits of information stored in the registers and memory banks at a given moment. The state of a brain model can be represented as a large-dimensional vector of positive real numbers, representing all the neural activations at a given moment. In general, the notation $X(t) = [x_1(t), \ldots x_n(t)]$ will be used to denote the state of a system at time t.

The second part is the *state space*. This is a set that contains all of the possible states to which a system can be assigned. The state space of a computer is the set of all of the possible configurations for the n-element binary-valued list representing its state (a set of size 2^n). The state space of a brain model is the set of points contained in the positive region of the n-dimensional Cartesian vector space IR^n. The symbol Ω is used to denote the state space of a dynamical system, and $X(t) \in \Omega$.

The third part is the *state transition function*, which is used to update and change the state from one moment to another. For example, the state transition function of a computer is defined by the production rules that change the bits of information from the state at one step $X(t)$ to the state at the next step $X(t+1)$. The state transition function for a brain model is a continuous function of time that maps the brain state $X(t)$ at time t to another state $X(t+h)$ at a later moment. The symbol $\boldsymbol{T}$ is used to denote the state transition function that maps an initial state $X(t)$ into a new state $X(t+h)$:

$$X(t+h) = \boldsymbol{T}(X(t),\, t,\, t+h) \qquad (1)$$

Whenever the state transition function is assumed to be a differentiable function of time, then we can define the *local generator* as the time derivative

$$\frac{\mathrm{d}\boldsymbol{T}}{\mathrm{d}t} = \lim_{h \to 0} \frac{X(t+h) - X(t)}{h} = \boldsymbol{f}(X(t), t) \qquad (2)$$

Given an initial starting state $X(0)$, the local generator is used to generate a *trajectory* $X(t)$ for all $t > 0$. Provided that the local generator satisfies certain

smoothness properties, a local generator is guaranteed to produce a unique trajectory from any given starting state. The objective of dynamical systems analysis is to understand all the possible trajectories produced by a local generator.

EXAMPLES OF DYNAMICAL SYSTEMS

Before describing the analysis of dynamical systems in more detail, it will be helpful to describe some well-studied examples.

Logistic Growth Model

Consider the following simple dynamical model of growth. To be concrete, suppose we wish to model a student's probability of performing a task correctly as a function of training (e.g., successfully playing a piece of classical music on the piano). Let $p(t)$ be the probability of correctly performing the task, and assume that this preference changes from one time point t to a later time point $t+h$ according to the following simple difference equation:

$$\frac{p(t+h)-p(t)}{h} = \alpha p(t) \times (1-p(t)) \tag{3}$$

This model can be understood as a product of two parts. The second part, $1-p(t)$, represents the amount that remains to be learned. The first part, $\alpha p(t)$, can be interpreted as the learning rate, which is an increasing function of the amount already learned. Note that as the probability approaches zero or one, then the change approaches zero; in effect, the probability remains bounded between zero and one.

This difference equation can be reformulated as a differential equation by allowing the time interval h to approach zero in the limit:

$$\frac{\mathrm{d}p(t)}{\mathrm{d}t} = \lim_{h\to 0}\frac{p(t+h)-p(t)}{h} = \alpha p(t)(1-p(t)) \tag{4}$$

By separating the variables and integrating, we can solve this differential equation to yield the solution (Braun, 1975)

$$p(t) = (1+c\mathrm{e}^{-\alpha t})^{-1} \tag{5}$$

where the constant c depends on the initial state, $p(0)$. Figure 1 is a time series plot that illustrates performance over time (with $c=100$ so that $p(0)$ is very close to zero). The model produces a family of smooth S-shaped curves that gradually rise from the initial level and approach the line of stable equilibrium $p=1$. The growth rate, α, determines the steepness of the curve.

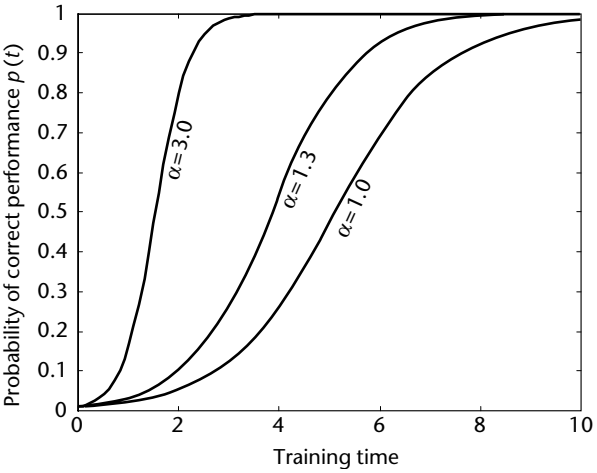

Figure 1. A time series plot showing the trajectories produced by the logistic growth model. The horizontal axis represents training time, and the vertical axis represents the probability of correct task performance.

Linear System Model

Next consider the problem of developing a simple dynamical model of motivation to perform a task (Atkinson and Birch, 1970; Townsend and Busemeyer, 1989). Suppose a student is trying to decide how much effort to invest in a task over time, for example, the amount of time to allocate towards achieving an athletic, academic, or social goal. Let $q(t)$ be the amount of effort actually expended at time t, and let $p(t)$ be the student's strength of motivation for doing the task at time t.

First we assume that the rate of change in effort is directly influenced by the motivation state at a given time. But due to fatigue, the rate of change in effort also decreases in proportion to the current effort. These assumptions are incorporated into the following model:

$$\frac{\mathrm{d}q(t)}{\mathrm{d}t} = p(t) - \alpha q(t) \tag{6}$$

Secondly, we assume that the rate of change in motivation is determined by two factors. One is the valence difference between the anticipated rewards for success and punishments for failure, denoted by $v(t)$. Another is a satiation effect, which causes the motivation to decrease in proportion to the current effort. The following model is used to represent these assumptions:

$$\frac{\mathrm{d}p(t)}{\mathrm{d}t} = v(t) - \beta q(t) \tag{7}$$

Given the initial states, $p(0)$ and $q(0)$, and given the valence differences, $v(t)$, $t \geq 0$, eqns 6 and 7 define

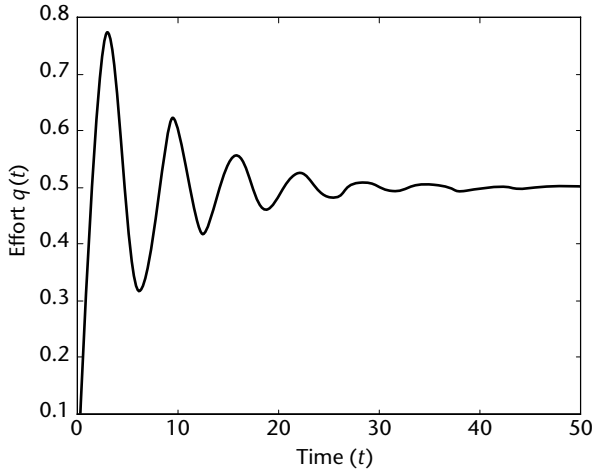

Figure 2. A time series plot showing the trajectory produced by the simple dynamic model of effort. The horizontal axis represents time elapsed on the task, and the vertical axis represents the amount of effort as a function of time.

a simple dynamical system that can be used to model the behavior of a student's effort on a task over time. The valence $v(t)$, is called the *input* or *forcing term* of the system, and the coefficients α and β are called the *parameters* of the system.

Methods for solving *coupled systems* of linear differential equations, such as eqns 6 and 7, are covered in standard texts on ordinary differential equations (see e.g. Braun, 1975). In the special case when $p(0) = q(0) = 0$ and the input valence is constant $(v(t) = v)$, the solution for effort is

$$q(t) = \frac{v}{\beta}\left(1 - e^{-\frac{1}{2}\alpha t}(\sin\theta t + \frac{\alpha}{2}\cos\theta t)\right) \quad (8)$$

where $\theta^2 = \beta - (\frac{\alpha}{2})^2$. (This can be checked by differentiating eqn 8 with respect to t and showing that it satisfies both eqns 6 and 7 and the initial conditions.)

The time series plot in figure 2 illustrates the behavior predicted by the model (with the parameters $\alpha = 0.25$, $\beta = 1.00$ and $v = 0.50$). The horizontal axis shows the time elapsed on the task, and the vertical axis shows the effort spent. The curve oscillates up and down (between zero and one), approaching the asymptotic level of effort $q = 0.50$.

Predator–Prey Model

Suppose a researcher is trying to decide how much effort to spend on generating and testing ideas. Let x_1 be the number of candidate ideas generated for testing, and let x_2 be the number of ideas tested. Note that an idea cannot be tested until it has been generated; and once it has been tested it is eliminated from the candidate pool. Consider the following simple nonlinear model of this process:

$$\frac{dx_1}{dt} = \alpha x_1 - \beta x_1 x_2 - \gamma x_1^2 \quad (9)$$

$$\frac{dx_2}{dt} = \phi x_1 x_2 - \lambda x_2 \quad (10)$$

In eqn 9, the coefficient α allows candidate ideas to grow over time, the coefficient β reflects depletion of candidate ideas that are generated and tested, and the coefficient γ represents interference between ideas. In eqn 10, the coefficient ϕ represents the increase in testing produced by a successful test and the coefficient λ provides for a fatigue effect from testing ideas. All of these coefficients are assumed to be positive.

Eqns 9 and 10 form what is called a predator–prey model. In this example, the idea-testing process is playing the role of the predator, which is preying on the idea-generating process. When dealing with nonlinear differential equations such as this, the most practical method for finding solutions is to use numerical integration routines, which are available in mathematical programming languages such as Matlab® or Mathematica®.

Figure 3 shows a time series plot for the ideas generated and tested (with $\alpha = 0.2$, $\beta = 0.3$, $\gamma = 0.1$, $\phi = 0.6$, $\lambda = 0.5$, and $x_1(0) = x_2(0) = 0.1$). As seen in the figure, generated ideas must build up first,

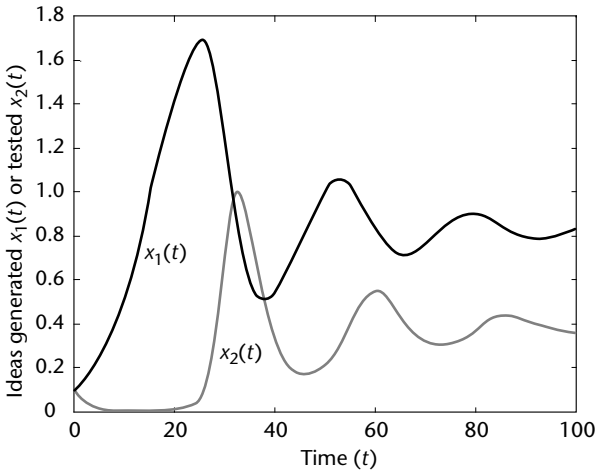

Figure 3. A time series plot showing the trajectories produced by the predator–prey model of idea generation and testing. The horizontal axis represents time elapsed on the task, and the vertical axis represents the number of ideas generated and tested, where generation leads testing.

and testing ideas dominates later. Eventually, both processes approach a steady state.

PROPERTIES OF DYNAMICAL SYSTEMS

Dynamical systems describe the general laws that systems obey. Various special cases of the general law can be derived simply by changing either the initial state $X(0)$, or the system parameters. For a given initial state and a fixed set of parameter values, a dynamical system generates a unique trajectory or path through the state space as a function of time (like that shown in figure 1). The primary goal of dynamical systems theory is to develop analytic methods for studying all the possible trajectories produced by a dynamical system, and to understand how these trajectories change as a function of the initial state and system parameters.

Phase Portraits and Attractors

Figure 4 illustrates these ideas using the simple linear system model described above. The four panels shown in the figure are called *phase portraits*. The two-dimensional plane within each portrait represents the state space of the system. The four different portraits were computed from eqns 6 and 7 by varying the parameter α in eqn 6. The remaining parameters of the model were fixed at $\beta = 1$ and $v = 1$.

Each arrow inside each phase portrait is a velocity vector representing the directional rate of change in motivation and effort that occurs at a particular state of the system. In other words, the head of an arrow indicates where the state will move in the next instant, given the current state indicated by tail of the arrow. Thus the arrows indicate the flow of the dynamical system. The smooth curve following the flow within each portrait indicates the trajectory produced by the system with initial state $p(0) = q(0) = 0$. Different trajectories would result from different choices of initial state. In fact, each initial state defines a unique trajectory, and therefore the trajectories never cross (provided that the local generator satisfies certain smoothness conditions).

The four panels illustrate how the dynamical properties of the model depend on the parameter α. The top left panel shows all of the arrows flowing

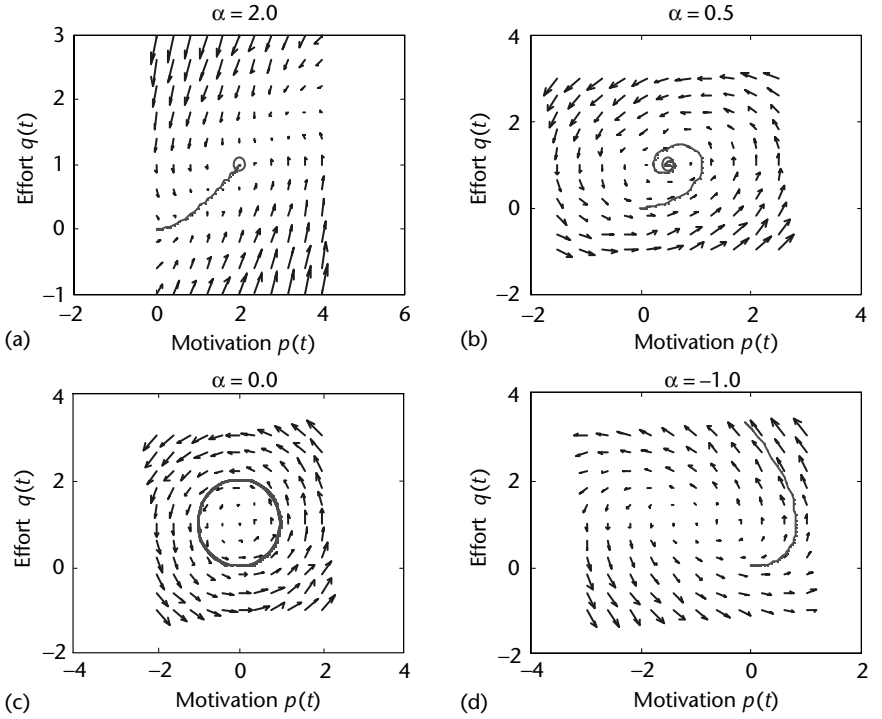

Figure 4. A display of four different phase portraits, one for each setting of the parameter α in Eqns 6 and 7. The horizontal axis within each portrait represents the preference state, and the vertical axis represents the level of effort. Each arrow is a vector indicating the direction and rate of change in the system at a particular point in the state space. The smooth curve within each portrait shows the trajectory produced by setting the initial state equal to zero for preference and effort.

towards a stable equilibrium point located at state $[p, q] = [2, 1]$. In this case, each trajectory moves steadily towards the equilibrium without any oscillation. The top right panel shows the arrows spiralling in towards a stable equilibrium point located at $[p, q] = [0.5, 1]$. The bottom left panel shows the arrows flowing in a circular manner around a central point located at $[p, q] = [0, 1]$. In this case, each trajectory oscillates indefinitely, like a clock. Finally, the bottom right panel shows the arrows spiralling away from an unstable equilibrium point located at $[p, q] = [-1, 1]$. In this case, the system shoots off towards infinity.

All four of these phase portraits contain a special state called an *equilibrium point*. But the nature of the equilibrium varies from one to another. An equilibrium point $\boldsymbol{X}^*$ has the special property that the local generator is zero at this point:

$$\boldsymbol{f}(\boldsymbol{X}^*) = 0 \tag{11}$$

Thus no change occurs when the system is in this state. The equilibrium points for the top left and top right portraits are called *stable* equilibrium points or *attractors* because the system eventually tends towards these equilibrium points whenever the state of the system starts within a close proximity of these points. The equilibrium point for the bottom right panel is an *unstable* equilibrium point or *repellor* because if the system is placed an arbitrarily small distance away from that point, it eventually drifts further away (For rigorous definitions, see any of the references cited at the end of the Introduction.)

Stability Analysis

The model defined by eqns 6 and 7 is an example of a linear system. A linear system enjoys the special property of allowing only a single equilibrium point (provided that the system is nonsingular). The stability of equilibrium points for linear systems can be easily determined by checking the eigenvalues of the linear equations (see (Braun, 1975)). Nonlinear systems, however, allow multiple equilibrium points, of which some may be stable and others unstable, and a more general method of *stability analysis* is required to determine their properties.

There are several general mathematical techniques for studying the qualitative properties of equilibrium points. One of the most powerful is based on the construction of what is called a *Liapunov function* for the dynamical system. A Liapunov function maps each state of the system to a real number

$$\boldsymbol{V}: \Omega \to \mathbb{R} \tag{12}$$

and it has the special property that its time derivative never increases:

$$\frac{\mathrm{d}\boldsymbol{V}}{\mathrm{d}t} \leq 0 \tag{13}$$

for all t. In physics, the Liapunov function can be interpreted as the potential function of a conservative system; and in engineering it can be interpreted as the objective function that a control system is designed to minimize. If there is a Liapunov function for the system, and an equilibrium point $\boldsymbol{X}^*$ is a local minimum of this function, then $\boldsymbol{X}^*$ is a stable attractor. The *basin of attraction* for $\boldsymbol{X}^*$ is the largest possible region for which $\boldsymbol{X}^*$ serves as the attractor. Thus, once the system enters the basin of attraction for $\boldsymbol{X}^*$, then it never leaves, and it converges towards the attractor. When a Liapunov function is defined over the entire state space, then the state space can be partitioned into a collection of attraction basins with a single stable attractor located within each basin (see figure 5).

To illustrate the idea of a Liapunov function, consider the predator–prey model described earlier. Figure 6(a) shows the phase portrait for this model.

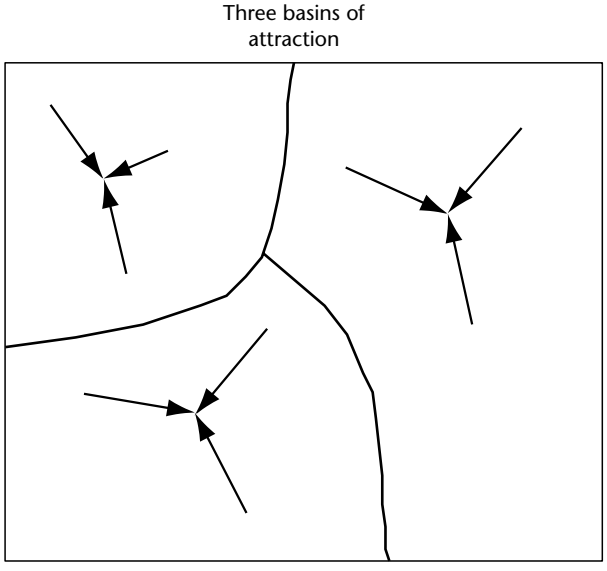

Figure 5. An illustration of a two dimensional state space that is divided into three basins of attraction. The arrows indicate the direction pointing downhill, where the Liapunov function is decreasing. The meeting point of the three arrows within each basin represents the stable attractor at the local medium. The curves indicate the boundaries that separate each basin.

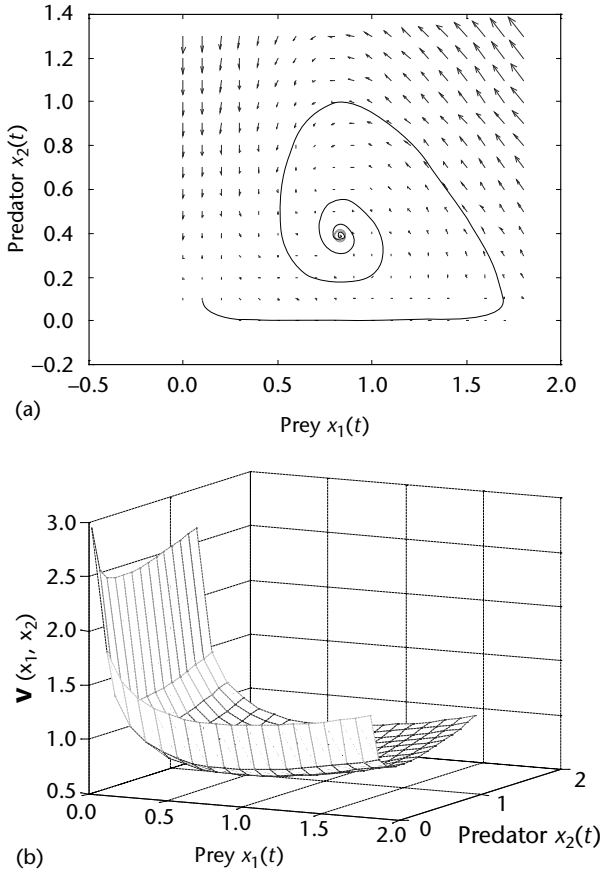

Figure 6. (a) An illustration of the phase portrait produced by the predator–prey model of effort for generating and testing ideas. (b) An illustration of the Liapunov function corresponding to this model. In (b), the plane represents the state space of the model, and the surface on the vertical axis above the plane represents the value of the Liapunov function for each point in the state space.

This nonlinear model has three equilibrium points – [0, 0], $[\frac{\alpha}{\gamma}, 0]$ and $\left[\frac{\lambda}{\phi}, \frac{\phi\alpha-\lambda\gamma}{\beta\phi}\right]$ – but only the last one is stable. For convenience, define $[x_1^*, x_2^*] = \left[\frac{\lambda}{\phi}, \frac{\phi\alpha-\lambda\gamma}{\beta\phi}\right]$. (In the case of figure 6 $[x_1^*, x_2^*] = [0.83, 0.39]$.)

It can be shown that the Liapunov function for this example is

$$\boldsymbol{V}(x_1, x_2) = \lambda\left(\frac{x_1}{x_1^*} - \ln\frac{x_1}{x_1^*}\right) + \alpha\left(\frac{x_2}{x_2^*} - \ln\frac{x_2}{x_2^*}\right) \tag{14}$$

The time derivative of this function is

$$\frac{\mathrm{d}\boldsymbol{V}(x_1, x_2)}{\mathrm{d}t} = \frac{-\lambda^2\gamma}{\phi}\left(1 - \frac{x_1}{x_1^*}\right)^2 \leq 0 \tag{15}$$

which is nonincreasing for all positive values of the state variables. The partial derivative of $\boldsymbol{V}$ with respect to the state variable is zero at $[x_1^*, x_2^*]$, so this point is a local minimum of $\boldsymbol{V}$; hence it is a stable attractor for all positive values of the state variables.

Figure 6(b) shows the surface of the Liapunov function over the state space (using the same parameters). The surface has a minimum at the equilibrium point $[x_1^*, x_2^*] = [0.83, 0.39]$. This point is the stable attractor associated with the basin of attraction inside the positive region of the state space.

Bifurcation Analysis and Catastrophe Theory

A *bifurcation* is said to occur if the equilibrium points undergo qualitative changes as a result of small continuous changes in the model parameters. The parameter values at which these bifurcations occur are called bifurcation points. To illustrate the idea of bifurcation, consider the following example of a slightly more complex version of the predator–prey model:

$$\frac{\mathrm{d}x_1}{\mathrm{d}t} = (0.4)x_1 - (0.04){x_1}^2 - (0.2)\frac{x_1x_2}{1+x_1} \tag{16}$$

$$\frac{\mathrm{d}x_2}{\mathrm{d}t} = \alpha x_2\left(1 - (0.5)\frac{x_1}{x_2}\right) \tag{17}$$

This example has only one free parameter, α, which is the focus of this bifurcation analysis. For this model, the location of the positive-valued equilibrium point $[x_1^*, x_2^*] = [2.7, 5.4]$ is independent of the parameter α (see (Beltrami, 1987)). Also, for large values of α, this equilibrium point is a stable attractor. The trajectory of the model looks very much like that shown in figure 6(a).

As the parameter α decreases, a qualitative change in the dynamics appears. The equilibrium point changes from an attractor to a repellor. A new behavior appears in which the asymptotic trajectory is attracted towards a *limit cycle* or asymptotic periodic orbit. In this case, the attractor is the set of points of the limit cycle. Figure 7 shows the phase portrait for this case, and the trajectory produced when the system is started at the initial state $[x_1(0), x_2(0)] = [0.5, 0.5]$ and $\alpha = 0.1$. This is an example of what is known as a *Hopf bifurcation*.

Catastrophe theory (Zeeman, 1977) is concerned with bifucations that result in discontinuous jumps in stable equilibrium points. Figure 8 illustrates the idea of a catastrophe. In this figure, each

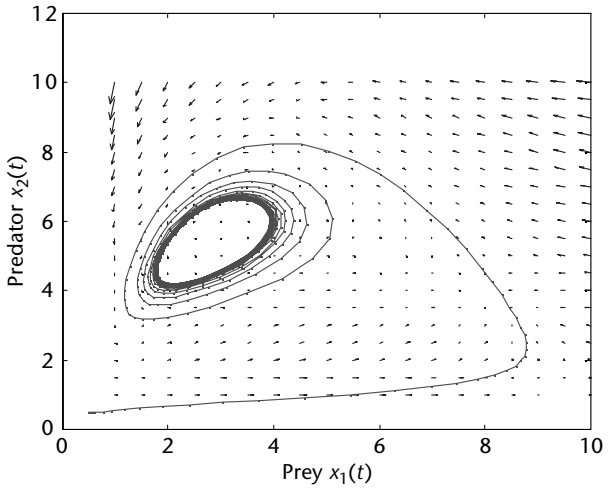

Figure 7. Phase portrait and trajectory produced by a modified predator–prey model that exhibits limit cycle behavior.

of the five curves represent a Liapunov function defined over a one-dimensional state space. The variations between the curves are produced by making small changes in a single parameter of the dynamical system. The upward-pointing arrow indicates the starting position of the system. The first curve, on the far left, exhibits an attractor on the right to which the system converges in the limit. Following a birfucation, the second, third and fourth curves exhibit two attractors, on the left and right, and a repellor in the middle. However, since the initial state lies inside the right basin, the system continues to converge to the attractor on the right. Finally, for the last curve, the change in parameter has eliminated the attractor on the right, so that the basins of attraction combine and the system converges to the attractor on the left. Exactly the opposite jump would occur if the change in parameter were reversed and the system started on the left, producing a *hysteresis* effect.

CHAOTIC SYSTEMS

So far we have encountered three types of asymptotic behavior exhibited by dynamical systems: (1) the system is attracted towards a single attracting state; (2) the system is attracted towards a limit cycle and oscillates indefinitely along some periodic orbit; or (3) the system shoots off towards infinity. However, some dynamical systems exhibit aperiodic behavior that does not fall into any of

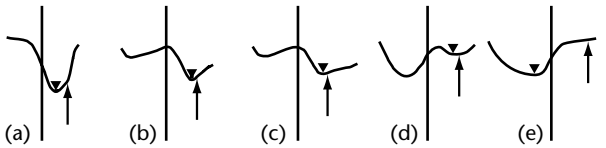

Figure 8. Five hypothetical Liapunov functions produced by small changes in a parameter of a dynamic system. The upward pointing arrow indicates the starting position. The solid triangle indicates the final equilibrium state. Note that the equilibrium makes a sudden jump into a new basin of attraction in the last case.

these three categories. This new category of *strange attractors* is exhibited by *chaotic dynamical systems*.

Chaotic behavior can arise from what appear to be very simple dynamical models. Let us reconsider the discrete-time version of the logistic growth model, given by eqn 3. (Recall that the continuous-time version produced well-behaved and easily understood trajectories for all values of the parameter α).

Setting $h = 1$ for the discrete-time model yields:

$$p(t+1) - p(t) = \alpha p(t)(1 - p(t)) \tag{18}$$

If we define $\beta = 1 + \alpha$, and $x(t) = \frac{\alpha}{1+\alpha} p(t)$, we can write the equation as.

$$x(t+1) = \beta x(t)(1 - x(t)) \tag{19}$$

When $\beta < 1$, the system described by eqn 19 decays to zero; when $1 < \beta < 3$, the system grows towards a stable equilibrium point, as in the continuous-time model. However, as β increases above 3, the system becomes periodic, and for $\beta > 3.57$ the system breaks down and becomes aperiodic or chaotic. Figure 9 shows a time series plot of the behavior of the model with $x(0) = 0.1$, and various values of β.

One of the defining features of a chaotic dynamical system is sensitive dependence on initial conditions. This means that an arbitrarily small change in the initial state is eventually magnified into a large change in future states. This is sometimes referred to as the *butterfly effect*, after the idea that the fluttering of a butterfly's wings in Brazil can eventually set off a tornado in Texas.

For example, if we set $\beta = 4$, then $x(0) = 0.100\,0$ yields $x(10\,000) = 0.209\,8$, but $x(0) = 0.100\,1$ yields $x(10\,000) = 0.981\,9$. Thus, although both of these trajectories were computed from the same equation and started from almost the same initial state, the trajectories they eventually produce are quite different.

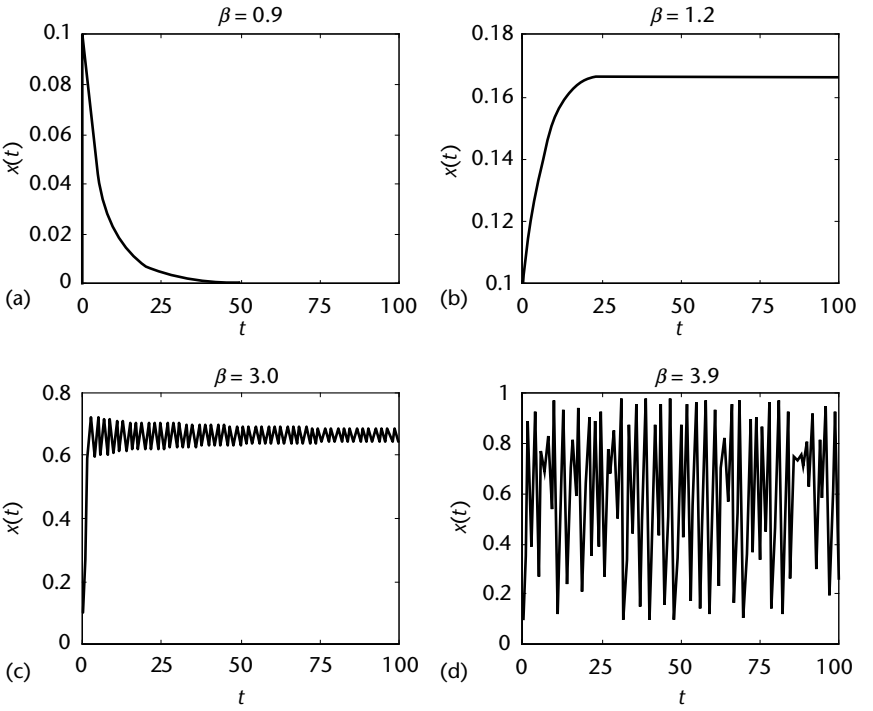

Figure 9. A display of four different time series plots produced by changing the parameter β in the discrete-time logistic growth model.

A rigorous method for identifying chaotic dynamical systems is based on an index, called the Liapunov index, λ:

$$\lambda = \lim_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} \ln|f'(x_i)| \qquad (20)$$

The function f in eqn 20 refers to the local generator for a univariate discrete dynamical system. For example, for the logistic model f is defined by the right-hand side of eqn 19, and $f'(x) = \beta(1 - 2x)$ in this case. This index provides a measurement of sensitivity to initial conditions. A dynamical system is chaotic when the Liapunov index is positive ($\lambda > 0$).

Figure 10 shows the Liapunov index plotted as a function of β for the logistic model (using $x(0) = 0.10$; however, the pattern does not depend on this starting position). Note that the index is never positive until $\beta > 3.57$, at which point the model becomes chaotic. It is also interesting to note that the system occasionally returns to periodic behavior at a few higher values of β.

The discrete-time logistic model is the simplest example of a chaotic dynamical system. However, chaotic behavior is not limited to discrete-time systems. Many (and more complex) examples of continuous-time chaotic systems have also been studied.

Chaotic behavior may seem to be an 'undesirable' property for a dynamical system. But these models do provide an alternative to stochastic dynamical models for describing the unpredictability and variability manifested by many complex biological systems.

TYPES OF DYNAMICAL SYSTEMS

Cognitive scientists have employed many different types of dynamical systems, ranging from production rule models of computers (Newell and Simon, 1972) to artificial neural network models of the brain (Grossberg, 1982; Rumelhart and McClelland, 1986). These models differ according to some basic characteristics as described below.

Discrete Versus Continuous State Spaces

A computer system has a *discrete* state space, which contains a countable number of possible states. The state space for the brain model is an example of a *continuous* vector space, which contains an uncountable number of states. The latter is also endowed with additional properties, including scalar multiplication of states ($aX \in \Omega$ for any real number a and state X), addition of states

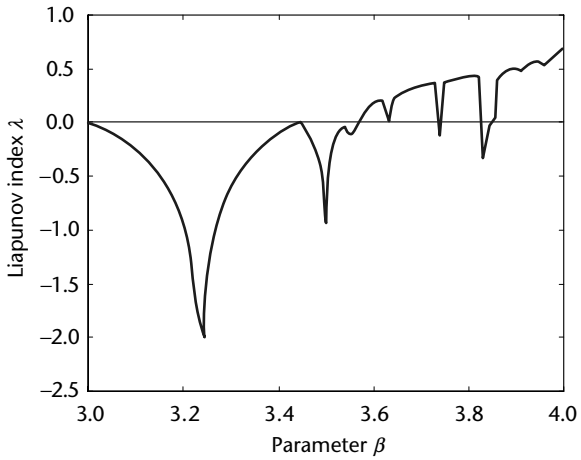

Figure 10. A plot of the Liapunov index as a function of the parameter β for the discrete-time logistic growth model.

$(X_1 + X_2 \in \Omega$ for any X_1 and $X_2 \in \Omega)$, and distances between states $(\| X_1 - X_2 \|)$. Dynamical systems theory usually assumes that state spaces are vector spaces.

Discrete Versus Continuous Time Indices

The computer model is an example of a discrete-time system, in which a countable set of time points is indexed by the set of natural numbers $\{0, 1, 2, 3, \ldots\}$. The brain model is an example of a continuous-time system, in which an uncountable set of time points is indexed by the set of nonnegative real numbers $[0, \infty]$. Originally dynamical systems theory was concerned only with continuous-time systems, but now both types are studied in parallel.

Linear Versus Nonlinear Systems

The computer model is an example of a discrete nonlinear system in which the production rules produce jumps from state to state. Some early neural models used continuous linear state transition functions, but more recent neural models use continuous nonlinear transition functions. In general, a dynamical system is linear if the local generator $\boldsymbol{f}$ satisfies the following superposition property for two arbitrary states X_1 and X_2 and scales a and b:

$$\boldsymbol{f}(aX_1 + bX_2, t) = a\boldsymbol{f}(X_1, t) + b\boldsymbol{f}(X_2, t) \tag{21}$$

In this case, the local generator can be written as a linear combination of the state variables:

$$\boldsymbol{f}_j(X(t), t) = \sum_{i=1}^{n} \alpha_i(t) x_i(t) \tag{22}$$

The coefficients used to define the linear combination are called the system parameters. The model of effort defined in eqns 6 and 7 is an example of a linear model. The logistic and predator–prey models are both examples of nonlinear models.

Time-invariant Versus Time-varying Systems

The computer model is an example of a time-invariant system, in which the state transition function does not change over time. A brain model, on the other hand, may require a time-varying system to allow for growth, development and aging. In general, the system is time-invariant if the local generator is independent of the time index:

$$\boldsymbol{f}(X, t) = \boldsymbol{f}(X) \tag{23}$$

One way to redefine a time-varying system as a time-invariant system is to add an extra state variable and set it equal to the time index. For example, the model of effort defined in eqns 6 and 7 contains a possibly time-varying input, $v(t)$. However, this two-dimensional time-varying system $[p, q]$ can be transformed into a three-dimensional time-invariant system $[p, q, x_3]$ by defining a third state variable, $x_3 = t$. The new three-dimensional system can then be described by three equations:

$$\frac{\mathrm{d}q}{\mathrm{d}t} = p - \alpha q \tag{24}$$

$$\frac{\mathrm{d}p}{\mathrm{d}t} = v(x_3) - \beta q \tag{25}$$

$$\frac{\mathrm{d}x_3}{\mathrm{d}t} = 1 \tag{26}$$

Deterministic Versus Stochastic Systems

The computer model is an example of a deterministic system: if we know the exact state of the system at time t then we can predict the state of the system at time $t + 1$. Our simple model of effort (eqns 6 and 7) was also formulated as a deterministic system. However, models of the brain must account for the inherent unpredictability of human behavior. In the past, this was usually accomplished by allowing a subset of the variables in

the state vector to be stochastic, or by allowing the initial state vector to be a random vector. Recently, deterministic but chaotic dynamical systems have been explored as alternatives to stochastic dynamical systems.

Bhattacharya and Waymire (1990) provide an introduction to stochastic dynamical systems theory.

SUMMARY

Dynamical systems theory was originally developed to solve problems arising in physics and engineering. Now cognitive scientists are making use of this approach, especially in applications of connectionist and neural models of cognition. Most applications are much more complex than the examples given in this article. Nevertheless, cognitive scientists have successfully applied these ideas to various substantive areas including pattern recognition, motor behavior, cognitive development, learning, thinking, and decision-making. There is little doubt that dynamical systems theory has much to contribute to cognitive science.

CONTENTS

Evolutionary algorithms make direct use of adaptive change in a population of computational agents in order to solve problems or model complex systems.

INTRODUCTION

So far, the only process that has produced intelligence is evolution. Consequently, the prospect of incorporating the principles underlying biological evolution into models of the development and performance of cognitive systems is attractive to many cognitive scientists. The basic principles of evolution are straightforward. Even before the mechanical details of DNA and the machinery of molecular biology were understood, it was apparent to any observer that individuals of the same species differ in minor ways. Darwin (1859) realized that these minor differences could affect the number of offspring left by an individual, particularly when there are more individuals of a species than its habitat can comfortably support. Natural selection therefore acts to reduce the genetic contribution of less fit individuals to future generations, gradually causing a population to become better adapted to its environment.

Evolution, working in a blind and directionless fashion, has produced the astonishingly orderly and robust complexity of the biosphere. It is evidently a powerful optimizer, and the idea of incorporating evolutionary principles into computer algorithms has been used since the 1940s by engineers in search of optimization tools for use in complex, nonlinear systems. Evolutionary algorithms (EAs) are also a natural choice for modeling systems to whose development biological evolution has been fundamental, such as the human cognitive architecture.

COMPUTATIONAL PARADIGMS FOR EVOLUTION

'Evolutionary algorithm' is an umbrella term, covering a family of algorithms which take inspiration from the principles of biological evolution. An EA is any algorithm that makes use of adaptive change in a population of computational agents in order to solve problems or model complex systems. There are several varieties of EA (Mitchell, 1996).

Genetic Algorithms

A genetic algorithm (GA) involves a population of individual 'chromosomes'. A chromosome may consist of a string of bits, a string of real numbers, or a more complex composition, depending on its purpose. Each chromosome can be assigned a numerical 'fitness', as defined by a fitness function, which measures how well the solution encoded in that chromosome solves the problem at hand. Chromosomes are chosen to contribute to the next generation in a fitness-dependent manner, so that fitter chromosomes have more offspring than less fit chromosomes. New chromosomes are produced by copying the parents and applying genetic operators based on biological mutation and crossover. The fitness of the new generation is then assessed, and the process iterated until a good solution is developed (Figure 1).

The term 'simple genetic algorithm' is often used to refer to an algorithm as outlined in Figure 1 using a bit-string chromosome.

There are endless variations on the basic GA. The outcome may depend on the genetic operators used, how the problem is represented, selection

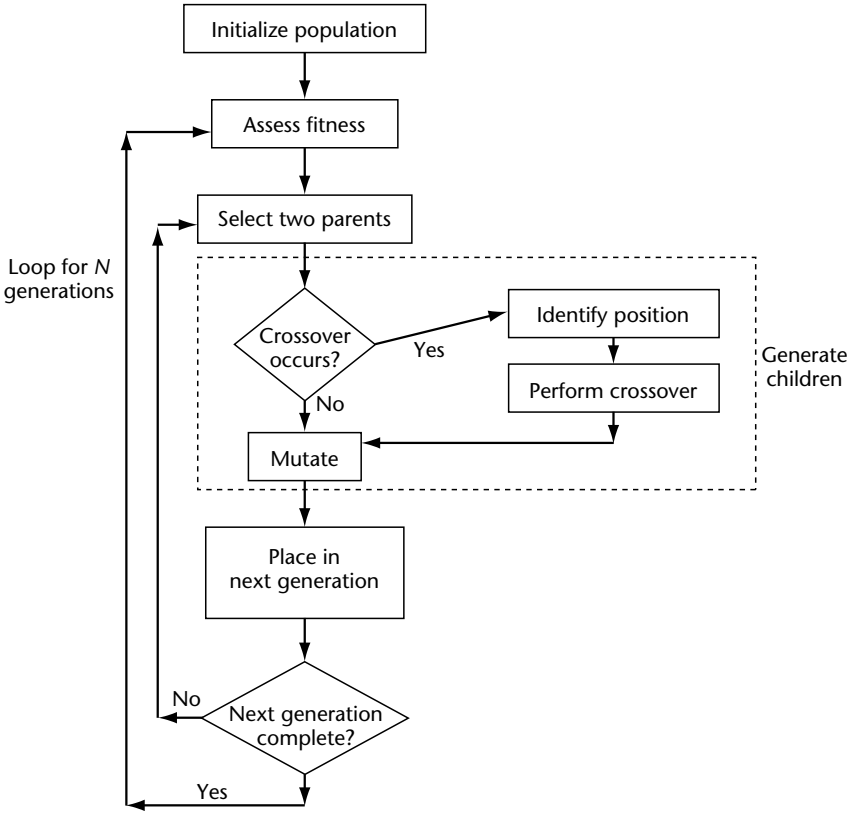

Figure 1. A simple genetic algorithm.

strategies, the order of application of the operators, and how new generations are constructed.

Other Paradigms

In addition to the simple GA, there are several other evolutionary computation paradigms. The major ones are described briefly below. Despite the differences in implementation, the various algorithms are alike in utilizing stochastic, fitness-dependent selection over random variations between individuals as a tool to develop individuals optimally adapted to their environment.

Evolutionary programming

'Evolutionary programming' (Fogel, 1999) was developed by L. J. Fogel in the early 1960s. It does not use a 'genomic' representation. Each individual in the population is an algorithm, chosen at random from an appropriate sample space. Mutation is the only genetic operator used; there is no crossover.

Evolutionary strategies

'Evolutionary strategies' (Schwefel, 1995) were developed by H. -P. Schwefel, also in the 1960s, as an optimization tool. They use a real-valued chromosome, with a population of one, and mutation as the only genetic operator. In each generation, the parent is mutated to produce a descendant; if the descendant is fitter it becomes the parent for the next generation, otherwise the original parent is retained.

Classifier systems

In a 'classifier system' (Holland, 1992), a classifier takes inputs from the environment and produces outputs indicating a classification of the input events. New classifiers are produced through the action of a genetic algorithm on the system's population of classifiers. (*See* **Classifier Systems**)

Genetic programming

The aim of 'genetic programming' (Koza, 1999), developed by J. Koza in the late 1980s, is the automatic programming of computers: allowing programs to evolve to solve a given problem. The population consists of programs expressed as parse trees; the operators used include crossover, mutation, and architecture-altering operations patterned after gene duplication and gene deletion in nature.

Evolution as a Search Process

The fundamental process underlying all evolutionary algorithms is a heuristic search through a search space, or fitness landscape, defined by the problem representation in conjunction with the fitness function.

The concept of a 'fitness landscape' was introduced by S. Wright (1932) in the context of biological evolution. He suggested that for a given set of genes, each possible combination of gene values ('alleles') could be assigned a fitness value for a particular set of conditions. The entire genotype space can then be visualized as a landscape, with genotypes of high fitness occupying peaks and those of low fitness forming troughs. Such a fitness landscape is generally very high-dimensional, but fitness landscape can be visualized in two dimensions (Figure 2).

The fitness landscape metaphor has proven to be powerful, and is applicable to computational as well as biological evolution. A population whose members have slightly differing genotypes is represented as a set of points in a fitness landscape. Mutation and natural selection will act to drive a population up to its nearest local maximum, which may or may not be the global maximum for the landscape. Under strong selection pressure, the population may become 'trapped' on a suboptimal local maximum. Because of the stochastic nature of the evolutionary process, however, the population will be spread out over the landscape to some extent, and different individuals may find themselves on the slopes of different maxima, depending on the ruggedness of the environment. The population is, in effect, performing a parallel search of the fitness landscape. (*See* **Machine Learning**)

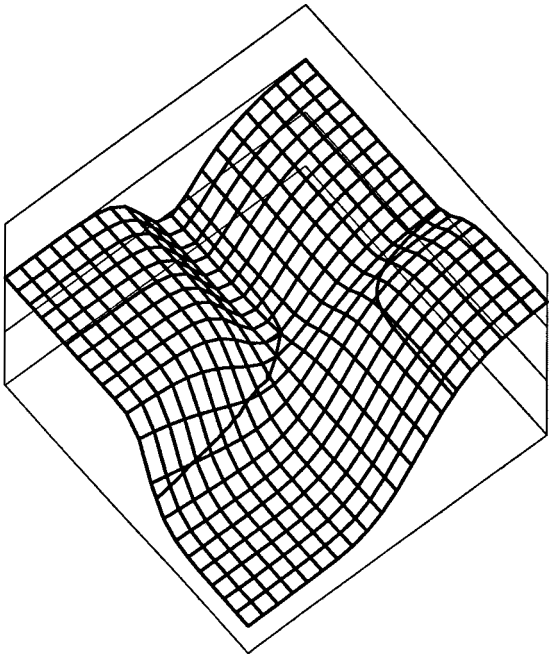

Figure 2. A two-dimensional fitness landscape. It shows the global maximum and one local maximum.

The Schema Theorem

Much of the research into evolutionary algorithms has been purely empirical, with EAs being used for optimization of problems involving multiple parameters, for which the problem domain, and hence the search space, is poorly understood. There are continuing efforts, however, to formulate a theoretical basis for evolutionary computation. One of the earliest attempts to produce such a formulation was the 'schema theorem' proposed in 1975 by Holland (Holland, 1992) and restated by Goldberg (1989) as 'short, low-order, above-average schemata receive exponentially increasing trials in subsequent generations'. Briefly, the idea is that a schema is a set of building blocks which can be described by a template comprising ones, zeros, and asterisks, with the asterisks representing 'wild cards' which can take on any value. The evolutionary algorithm proceeds by identifying schemas of high fitness and recombining them using crossover in order to produce entire individuals having high fitness. The theory is attractive because, for a given EA, schemata can be identified, and the effects of mutation and crossover on schemata in a population of a given size can be quantified, potentially providing useful insight into the way in which the EA functions.

There has been a large amount of investigation into the schema theorem, with often inconclusive and controversial results. Mitchell *et al*. (1991) designed a class of fitness landscapes which they called the 'royal road' functions. These functions produce a hierarchical fitness landscape, in which crossover between instances of fit lower-order schemata tends to produce fit higher-order schemata. However, these researchers found that the presence of relatively fit intermediate stages could in fact interfere with the production of fit higher-order solutions, since once an instance of a fit higher-order schema is discovered its high fitness allows it to spread quickly throughout the population, carrying with it 'hitchhiking' genes in positions not included in the schema. Low-order schemata are therefore discovered more or less sequentially, rather than in parallel.

The extent to which the schema theorem applies in practice remains controversial. For example, Vose (1999) places little credence in the general applicability of the schema theorem, and offers an alternative mathematical approach to analyzing the behavior of the simple genetic algorithm.

Exploration Versus Exploitation

An EA attempts to find optimal areas of its search space by discovering new solutions (exploration) as well as by maintaining fit solutions that have already been discovered (exploitation). Achieving a good balance between exploration and exploitation is important to the efficacy of the algorithm: too little exploration means that important areas of the search space may be ignored, while too little exploitation increases the risk of prematurely discarding good solutions. The trade-off between exploration and exploitation is often studied in the context of the 'n-armed bandit problem'.

The n-armed bandit is an extension of the one-armed bandit, or casino slot machine. Instead of having a single lever which can be pulled, the bandit has n levers, each of which has an expected reward. Since the expected reward associated with each lever is unknown, a strategy must be developed to balance exploitation of knowledge already gained (by playing various arms) with exploration of the behavior of untested arms. Exploitation of the best action discovered so far will maximize expected reward on a single play, but exploration may lead to a better total reward in the long run. The n-armed bandit provides a basis for a mathematical formulation of the exploration–exploitation trade-off for an EA. The optimal strategy involves exponentially increasing the probability of selecting the best solutions over time. (See Holland, 1992, chap. 5 and chap. 10 for a detailed discussion of the n-armed bandit and its application to schema theory.)

Evolution Versus Hill Climbing

The power of an EA is often assumed to lie in its 'implicit parallelization': by maintaining a population of candidate solutions that are modified by mutation or crossover, the algorithm is, in effect, exploring different regions of its search space in parallel. The simplest alternative to an EA is a 'hill climber', an algorithm which maintains a population of one individual and performs a strictly local search using mutation. There are many variations of the hill climber algorithm; most involve mutating the current best candidate and accepting the mutated individual if it is fitter than the original. A hill climber will thus typically move only to the top of the nearest peak in the fitness landscape, which may not be a global optimum.

An EA is no more efficient than multiple random restarts of a hill climber, in terms of the number of evaluations performed. An EA with a population size of 100 running for 1000 generations performs 100 000 evaluations, as does an algorithm with a single population member restarted 100 times for 1000 generations each time. The EA would, however, be expected to outperform the hill climber if the action of the genetic operators used in the EA provided advantages over local search. This would be the case if the schema theorem applied as described above, with useful partial solutions discovered by different individuals being recombined to produce fitter individuals more rapidly than could be done by mutation alone. The EA would also be expected to outperform the hill climber if the structure of the fitness landscape was such that the 'implicit memory' of a population-based algorithm (i.e., the memory encoded into the structure of the population itself as a result of evolution) allowed it to concentrate its search in areas of high fitness in a manner that would not be possible for a hill climber.

In practice, hill climbers with multiple restarts often perform at least as efficiently as population-based algorithms (Mitchell *et al.*, 1994).

COEVOLUTION

The evolutionary algorithms described so far are primarily heuristic optimizers based upon a simple model of evolution. In biological systems, however, evolution in a particular population occurs in the context of a complex mixture of endogeneous and exogenous factors. The simple EA has been extended in several directions inspired by further observations from the realm of biology.

Biological evolution does not occur in isolation. Individuals of a particular species live, breed, and die in collaboration and competition with other organisms of their own and other species, and evolutionary change in one population affects the fitness landscapes of other populations. Kauffman (1996) uses the analogy of the fitness landscape as a rubber sheet. Evolutionary change in one species deforms the sheet, not only for itself, but for all species existing in that fitness landscape.

'Coevolution' is often used in an EA as a mechanism for the prevention of premature convergence to a suboptimal fitness peak. A population of problems and a population of solutions evolving

together should, in theory, produce better solutions, since as good solutions are found the problems against which they are tested become harder, and an evolutionary 'arms race' develops (Dawkins and Krebs, 1979). For an interesting overview of the background to coevolution in evolutionary computation, see Rosin and Belew (1997).

LEARNING AND EVOLUTION

The interaction between learning and evolution has been the subject of extensive research, both by those interested in using learning as a local search operator to improve the optimization performance of the algorithm, and by those interested in understanding the evolution and utility of learning in biological systems.

The so-called Baldwin effect (Baldwin, 1896) is based upon the idea that learning on the part of individuals could guide the course of evolution in the population as a whole. A particular trait may be learned, or it may be innate (a term which can be taken, in this context, to indicate that it is genetically determined). A learned trait has the advantage of providing flexibility, but the disadvantage of being slow to acquire; an innate trait is present from birth, but inflexible. Baldwin suggested that traits that are initially learned may, over time, become encoded in the genotype of the population.

Although this suggestion appears, at first glance, to be tantamount to Lamarckism, in fact no Lamarckian phenotype-to-genotype information flow is required. For the Baldwin effect to operate, two conditions must be met. Firstly, the trait in question (which may be a behavioral or a physical trait) must be influenced by several interacting genes, so that a mutation in one of these genes will make the phenotypic expression of the trait more likely. Secondly, an individual bearing such a mutation must be able to learn to express the trait.

Under these conditions, learning acts to provide 'partial credit' for a mutation. An individual carrying a mutation that predisposes it towards an advantageous phenotype will learn the trait more easily than its less fortunately genetically endowed conspecifics, and thus will tend to survive and pass on more copies of the relevant allele to the next generation. Over time, multiple mutations for the desirable trait will accumulate in the genes, and the trait will thus become innate in the population.

Hinton and Nowlan (1987) were the first to demonstrate the feasibility of the Baldwin effect, at least in a simplified, computational model, and much research has been done in this area in the intervening years. See Turney (2001) for a comprehensive online bibliography of publications on the Baldwin effect.

Learning may also be incorporated into an EA by making a learning system, such as a neural network, the object that is evolved. When evolving a neural network, the network architecture, weights, learning rules, and input features may all be subject to evolution. Modified genetic operators may be required in order to avoid disruption of the network architecture. See Yao (1999) for a comprehensive review of recent research in the evolution of artificial neural networks. (*See* **Connectionist Architectures: Optimization**)

EVOLUTIONARY COMPUTATION AND COGNITIVE SCIENCE

Evolutionary computation plays several roles in cognitive science. It has been used both as a modeling framework for exploring ideas inspired by biological evolution, and for the optimization of computational models. (*See* **Artificial Life**)

Evolutionary algorithms have been used both to understand the development of well-known cognitive mechanisms, and to create new mechanisms with desired emergent behaviors. They are used in diverse domains, including language, memory, reasoning, motor control, and the analysis of social interactions.

Modeling contributes to cognitive science in several ways: in providing converging evidence for empirical studies, in testing the internal consistency and completeness of theories, and in investigating the functioning and emergent properties of complex systems, which are often intractable to mathematical analysis. Evolutionary models have often been shown to exhibit complex dynamics emerging from the interaction between computational agents: dynamics that are not inherent in the behavior of a single such agent.

As a modeling framework, evolutionary algorithms are most widely used within evolutionary psychology, which takes as its starting point the hypothesis that the mind contains a set of evolved systems, each one designed to solve a task that was important for survival in the human ancestral environment. (*See* **Evolutionary Psychology: Theoretical Foundations**; **Human Brain, Evolution of the**)

The Evolution of Altruism: The Prisoner's Dilemma

Many organisms exist in social groups, interacting frequently with others of their own and other

species. While an individual may benefit from cooperative interactions with others of its species, conspecifics are also any animal's fiercest competitors for food, mates, and territory. Despite this inescapable competition, altruistic behavior (i.e., behavior that benefits another at some cost to the altruist) is often observed in natural populations.

In an attempt to understand how such apparently paradoxical behavior could arise, a simple game known as the 'prisoner's dilemma' has been much studied. Suppose that two criminals have been arrested on suspicion of committing a crime. They are held incommunicado, and each offered a bargain: if the prisoner admits to the crime (defects) while the other prisoner keeps silent (cooperates), the defector will go free while the cooperator gets a long sentence. If both prisoners keep silent, they will both receive short sentences; and if they both admit to the crime they will each get an intermediate sentence. A possible pay-off matrix for the prisoner's dilemma is shown in Figure 3.

What makes the prisoner's dilemma interesting is that, while the best outcome for the prisoners as a pair is for both to cooperate, the best decision for each prisoner, in the absence of knowledge about the other prisoner's decision, is to defect. Prisoner's dilemmas arise frequently in real life – in any situation in which the action that most benefits an individual harms the group as a whole.

Analysis of the prisoner's dilemma may appear to support the conclusion that altruism cannot arise as a consequence of evolution, which requires that individuals act 'selfishly' in order to pass on their own genes to the next generation. However, Axelrod (1984) studied an iterated version of the prisoner's dilemma, in which individuals play against each other repeatedly, and have a memory of the past behavior of other individuals, with the opportunity to adjust their strategy based on this past history. In a computer tournament of strategies for the iterated prisoner's dilemma, the clear winner was 'tit for tat', which starts by cooperating, and then copies whatever its opponent did in the previous round. Once cooperation becomes established, this strategy will continue to cooperate indefinitely. This strategy has been proven to be highly robust.

	***B* cooperates**	***B* defects**
***A* cooperates**	1 year, 1 year	3 years, 0 years
***A* defects**	0 years, 3 years	2 years, 2 years

Figure 3. Pay-off matrix for the prisoner's dilemma. In each cell, the first amount is *A*'s sentence and the second amount is *B*'s sentence.

Considerable research has been conducted into the evolution of altruism, using the iterated prisoner's dilemma and other models. For an overview of the literature, see Ridley (1996). (*See* **Social Processes, Computational Models of**; **Game Theory**)

The Evolution of Language

A second area where evolutionary algorithms are being increasingly applied is the study of the evolution of language. Human language leaves no fossils, and no other animals have communication systems utilizing such extensive symbolic structures, so studying the evolution of language poses particular problems for cognitive scientists. Human languages share features (such as phonology and syntax) to such an extent that a universal grammar has been conjectured to explain the similarities, but their origins have long been controversial. (*See* **Language Learning, Computational Models of**)

Recently, questions about the evolutionary origins of language and the extent to which it is determined by the cognitive architecture of the young child have been addressed using evolutionary algorithms. Groups of simple language users, modeled as computational agents, have been programmed to evolve communication systems. The emergent behaviors of such systems provide converging evidence on the possibilities for the evolution of language.

Two levels of approach to the evolution of language phenomena have been proposed. In 'micro' evolutionary modeling, learners are modeled by computational agents; a language is a set of utterances (sequences of symbols); global properties of languages are emergent properties; and either the learners or the set of utterances evolves. By contrast, in 'macro' evolutionary modeling, learners are modeled as bundles of parameters; a language is an abstract entity; global properties are explicit parameters; and the distribution of parameters evolves. The micro and macro approaches differ in terms of model fidelity versus analytic tractability, and the role that emergence plays in explaining phenomena. (*See* **Emergence**)

EAs have been used to study language at three levels: phonology (e.g. the self-organization of sound systems); lexicon (e.g. learning concepts, relating words to meanings, and convergence of a population on common conventions for word meanings); and syntax (e.g. the emergence of compositional structure from initially unstructured

utterances). (*See* **Phonology and Phonetics, Acquisition of**; **Semantics, Acquisition of**; **Syntax, Acquisition of**)

The main conclusion that can be drawn from simulations of language evolution is that over time weak functional constraints on language use and acquisition can give the appearance of strong constraints on language structure. Interaction itself accounts for many aspects of coordinated communication of groups. See Hurford *et al*. (1998) and Wray (2002) for an introduction to the breadth of work in this area.

EVOLUTIONARY ROBOTICS

Evolutionary robotics is a rapidly expanding field based on EA techniques. Both fixed and autonomous robots have many parameters that require optimizing, for example in kinematics (topology and dimensions), dynamics, components, and control. EAs are currently being used in a wide variety of projects, as a means for optimization of many parameters in parallel, with relatively unconstrained problems. Autonomous robots are being evolved to develop their own skills via direct interaction with the environment and without human intervention. See Pfeiffer and Scheier (1999) for an introduction to this area.

CONCLUSION

Evolutionary computation draws inspiration from the study of biological evolution in order either to model the evolutionary process, or to use simplified evolutionary principles in order to solve complex, nonlinear optimization tasks. Evolutionary ideas have been used in computing since the 1940s, but it is only with the recent availability of cheap, powerful desktop computers that EAs have become a tool readily available to researchers in all fields. In the field of cognitive science, they are used both to model the development of those cognitive structures and processes that are supposed to be the product of biological evolution – such as human mental structures, language, and altruistic behavior – and to optimize the parameter settings of cognitive models in general.

Expert Systems

Introductory article

Larry R Medsker, American University, Washington, DC, USA
Theodor W Schulte, American University, Washington, DC, USA

CONTENTS

Expert systems are specialized computer programs that capture the knowledge of human experts. Problems are solved by retrieving knowledge and performing automated logical reasoning.

INTRODUCTION

An expert system is a computer program that stores the knowledge of one or more human experts concerning a limited field of expertise and is able to retrieve that knowledge as well as do automated reasoning on it. During the 1950s, computer scientists started to move computation from mere data manipulation to simulation of activities associated with human intelligence. The field of artificial intelligence (AI) encompasses a number of heterogeneous disciplines, including machine learning, robotics, machine vision, evolutionary computation, natural language processing, and knowledge-based techniques such as expert systems. After basic techniques of knowledge representation and automated reasoning were developed in the 1960s and 1970s, functional expert systems were developed in the late 1970s and commercial applications appeared in the early 1980s. Starting in the late 1980s and early 1990s, expert systems have been combined with other intelligence technologies to form hybrid systems, and from the late 1990s computer networks and the internet have allowed existing software to be further integrated to increase its functionality.

The interest in expert systems derives from the importance and value of human expertise. During a long process of training and experience, a human expert gains special knowledge in a limited field (usually called a 'domain' in computer science). Human expertise typically includes rules of thumb, or heuristics. Heuristics allow human experts to solve complex tasks that cannot be solved by strict mathematical formulas or algorithms. Experts are generally rare and expensive, and their expertise is important in many areas of science, business, engineering, medicine, and so on. Expert systems have been successfully implemented in all of these areas even though they have not been able to abolish or significantly reduce the need for human experts. Often, the role of an expert system is to cover a large proportion of routine situations so that the expert can concentrate on more unusual and interesting cases.

THE COMPONENTS OF EXPERT SYSTEMS

A central component of an expert system is its knowledge base. In rule-based systems, the knowledge base consists of facts and rules (Figure 1). Facts are simple statements that are believed to be true. Rules are complex statements of the form 'if premise then conclusion'. The logic of the domain knowledge is separated from the logic of the general program. The user of the expert system interacts via a user interface, which formats the questions of the user and passes them on to an inference engine. The inference engine uses its programmed algorithms for automated reasoning to find an answer or adequate response to the question or input. It uses a scheduling mechanism to handle multiple inputs, facts, and rules that are active. The interpreter executes the item chosen by the scheduler by applying the rules and facts in the knowledge base. The final result of the reasoning is passed on to the user interface, which formats the output for the user. An expert system may also have an explanation component that can tell the user how the conclusion was derived.

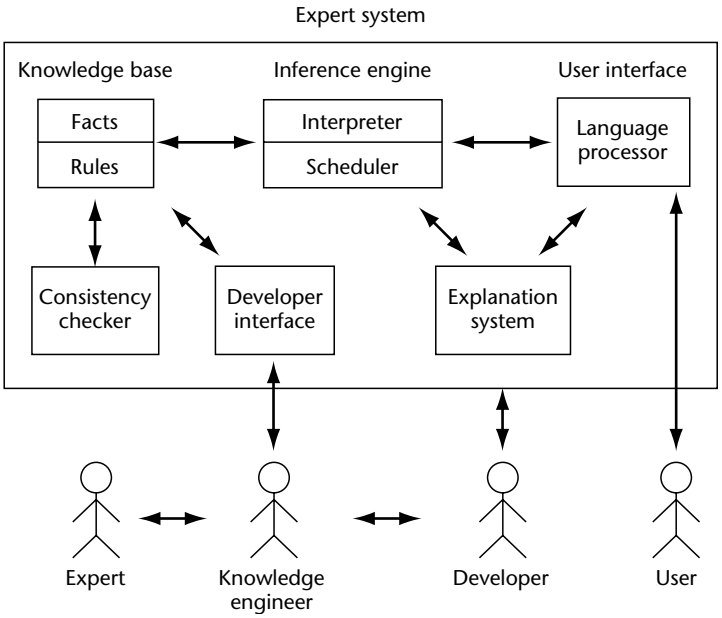

Figure 1. Components of a rule-based expert system.

The development of an expert system consists of two separate tasks: the development of the expert system tool (often called an expert system shell), and the definition of the expert knowledge (rules and facts), a process called 'knowledge engineering'. Expert system shells can be implemented in general-purpose computer languages, such as C or C++, which allow very fast computation, or in computer languages developed for AI programming, such as LISP or PROLOG, which often allow faster development or prototyping.

KNOWLEDGE REPRESENTATION AND AUTOMATED REASONING

A data structure commonly used to represent knowledge is the 'frame', which represents an entity that is being described by a number of attributes ('slots'). Frames can have procedures attached to them that determine how to process certain data. Also, frames can be linked by relationships, such as 'is a' or 'is a part of'. The special case of a supertype–subtype relationship between two frames is called 'inheritance' because the more specific subtype inherits components from the more general supertype. Frames are somewhat similar to 'objects' in object-oriented programming, which is a popular paradigm in the design and development of computer programs. Objects are parts of computer programs that facilitate modularity of large programs, reuse of code, and representation of real-life objects in software. Objects are formed from classes, patterns which determine the attributes (data stored in variables), the behavior (procedures, usually called 'methods'), and inheritance of the objects.

Frames are also somewhat similar to semantic nets. The nodes of the net represent the entities that are being described and the links between the nodes represent the relationships between these entities. Semantic nets have been used to model rich semantic relationships between entities such as 'agent', 'object', 'instrument' and 'recipient'.

In addition to facts, knowledge is often represented as if–then rules that allow reasoning based on the facts. The premises of a rule are called its left-hand side and the conclusions its right-hand side. If the pattern of the left-hand side of a rule can be matched with the facts in the knowledge base, the rule is activated ('fired'). The conclusions of the rule can establish new facts and activate new rules, thus cascading through a line of reasoning to a final conclusion.

Rule systems can be used in two different ways, which are called 'forward chaining' and 'backward chaining'. In forward chaining, the input consists of a set of facts describing a specific problem or situation that demands a solution or response. These facts activate rules, which again activate new rules, until the solution is found (a 'data-driven' approach). In backward chaining, the user first establishes a hypothesis or goal. The system tries to find a fact that matches the goal, and if no fact is found, it looks for a right-hand side of a rule. If a

right-hand side of a rule is found that matches the question, the system tries to match the left-hand side of this rule, and so on until finally all hypotheses are matched by facts (a 'goal-driven' approach). If a required fact cannot be found in the knowledge base, the interface may be used to query the user for the fact.

Often, expert systems have to use rules or facts that are not certain but can be stated only with a certain likelihood. One mathematical technique to handle uncertain information is probability theory. The probability of an event can be any number between 0, for an impossible event, and 1, for a certain event. Probabilities of facts and rules can be combined. Although probabilities can be based on calculations of the likelihood of random events, statistics, or even subjective judgments of experts, it often proves difficult to find good estimates of probabilities.

The most important alternative approach to the calculation of probabilities is the use of certainty factors. Certainty factors describe how confident human experts feel about facts and rules. This approach reflects the point that human experts often use rules of thumb and experience-based intuition rather than exact probabilities. Certainty factors can range between -1, for impossible events, and 1, for certain events. The mathematical formulas used to combine conclusions of rules that have certainty factors are simpler than methods using probabilities.

Finally, fuzzy logic, a mathematical theory developed by Lotfi Zadeh, provides a means of describing inexact knowledge and semantic terms such as 'very certain', 'tall', 'medium', or 'close to 18 years'. Exact values and fuzzy terms can be related to each other using membership functions. Systems based on fuzzy rules use procedures to combine fuzzy terms, define inexact rules, and perform reasoning based on these concepts.

KNOWLEDGE ENGINEERING

The development of a new expert system starts with a number of questions. The need for a particular kind of expert system needs to be established. Is human expertise scarce in a particular field, justifying the efforts of development? Is there a market for a new expert system; or will it help to save money and justify the investment in its production? Next, the feasibility of the expert system needs to be established. Can the task to be solved be limited in such a way that it will be not too large, not too difficult, and well enough understood? Do enough human experts exist, and are these experts willing to collaborate on the project? One problem is a possible need for common sense, which has never been successfully implemented in expert systems so far.

Once the need for and feasibility of the new expert system have been established, the knowledge engineer has to define the project's goal and the main problems and sub-problems. At least one human expert has to be found to be part of the team. Usually, an expert system is not built from scratch, but a tool, often called an expert system shell, is used. The right tool for the task at hand has to be chosen. The knowledge engineer interviews the human expert and turns the information gleaned into facts and rules that are appropriate for the expert system tool. Once a significant part of the expert system has been implemented, it needs to be tested to see if it produces the expected output. Usually, the human expert has to validate the answers produced by the new expert system.

It is important to have an experienced knowledge engineer on the team who knows the strengths and weaknesses of the various expert system tools and is able to avoid pitfalls. A clear separation of the roles of the knowledge engineer and the human expert is also important. Competent domain experts often find it difficult to describe their knowledge, especially the exact ways by which they solve problems. The knowledge engineer helps the domain expert to formalize the problem-solving methods and to separate the domain-specific knowledge from the system-specific reasoning strategies.

Expert systems are expensive and their development is time-consuming. Some expert systems have taken more than 30 person-years to build. As with other kinds of software, the total development time of a new expert system is reduced by rapid prototyping and early testing of the system, followed by further cycles of planning, knowledge acquisition, coding, and system evaluation.

EARLY EXPERT SYSTEMS AND DEVELOPMENT ENVIRONMENTS

The development of expert systems was pioneered in the 1960s at Stanford University (by Edward Feigenbaum) and at Carnegie-Mellon University (by Allen Newell and Herbert Simon). Among the first successful systems was MYCIN, which was developed at Stanford in the 1970s to diagnose serious bacterial infections in hospitalized patients and help to find the right antibiotic treatment. MYCIN used information about patient history, symptoms, and laboratory results, suggested a diagnosis, and recommended a drug treatment.

MYCIN was implemented in LISP, and used if–then rules and backward chaining. Uncertainty was handled using certainty factors. MYCIN reached the stage of a research prototype and proved the viability and usefulness of the concept of expert systems in narrow knowledge domains.

Subsequently, the domain knowledge of MYCIN was removed in order to create an expert system shell called EMYCIN. Since the inference engine used backward chaining, it was especially appropriate for diagnosis and classification tasks. EMYCIN has been used to develop several expert systems, including PUFF, which diagnosed lung diseases on the basis of pulmonary function data. PUFF was developed at Stanford and reached the stage of a production prototype. The development of PUFF required only 5 person-years, compared with 20 person-years for MYCIN, because of its use of an existing expert system shell.

TEIRESIAS was developed at Stanford as a research system. It was implemented in a LISP dialect. In order to integrate domain knowledge into an EMYCIN expert system, the knowledge had to be coded in an EMYCIN-specific, LISP-like code. TEIRESIAS helped with this process by analyzing rules, checking their completeness and consistency, and making suggestions for how to improve and troubleshoot them. It facilitated research in knowledge acquisition and expert system development and maintenance.

XCON was a commercial expert system developed as a collaboration between Carnegie-Mellon University and Digital Equipment Corporation (DEC). Configuring the DEC VAX family of computer systems was a difficult task that often led to costly mistakes. The expert system tool OPS5, developed at Carnegie-Mellon, was a rule-based system that used forward chaining and was based on the efficient Rete pattern-matching algorithm developed by Charles Forgy. XCON was developed using OPS5, and reached a production stage in the late 1970s. It grew over the following years to a size of over 3000 rules. It reached a performance level of 90 to 95 percent, while demonstrating that commercial viability was consistent with a limited rate of mistakes. Development and maintenance required four person-years per year, but the system saved DEC a significant amount of money by enabling faster and more accurate processing of new orders.

Following the success of the early expert systems, a number of expert system tools were developed by various commercial companies. These include ART, a rule-based knowledge engineering language developed by Inference Corporation. ART was written in LISP and supported forward and backward chaining and certainty factors. It featured a debugging aid and a graphical monitor. S.1, which was developed in a LISP dialect by Teknowledge, supported not only rule-based representations, but also frame-based and procedure-oriented methods. It supported certainty factors and graphical debugging tools. KEE, developed by Intellicorp in a LISP dialect, supported frames and both rule-based and procedure-based knowledge representations. It featured a modular knowledge base, forward and backward chaining, and a graphical debugging tool. These and other tools were used to develop a large number of expert systems in a variety of areas including agriculture, chemistry, computer systems, engineering, geology, law, financial analysis, mathematics, medicine, and physics.

Besides these commercial tools, free or inexpensive tools have been developed, many of which can be downloaded from the internet. The most important one is CLIPS, an OPS-like tool developed by NASA. CLIPS is implemented in C, it runs on many platforms, and its rules are coded in a LISP-like language. CLIPS supports only forward chaining and does not handle uncertainty. Extensions such as FuzzyCLIPS and AgentCLIPS have been developed, as well as an implementation in Java called JESS.

HYBRID SYSTEMS

Progress in other fields of AI suggested the combination of expert systems with other intelligent systems to create hybrid systems. The most common hybrid systems combine expert systems with artificial neural networks. Other useful hybrid systems are systems based on fuzzy rules and combinations of expert systems with genetic algorithms.

While much progress has been made in the areas of knowledge representation and automated reasoning, knowledge acquisition remains a bottleneck in the development of expert systems. Machine learning techniques can be used to generate knowledge from data with less involvement of a human expert. Induced decision trees are a machine learning technique pioneered by J. Ross Quinlan, who developed the ID3 and the C4.5 algorithms. Decision-tree systems form a hierarchical structure by dividing a data set according to the values of the most informative attribute. This process is repeated, and leads to a predictive rule-based model.

Artificial neural networks are another machine learning technology that was inspired by biological

brains. Neural networks are used for pattern extraction, classification, and prediction of quantitative data. Although they do not produce rules, neural networks equivalent to rule-based systems can be developed. Also, neural networks can be used in combination with knowledge-based systems. Because these two types of system have complementary characteristics, the use of human knowledge and symbolic reasoning of expert systems can fruitfully be combined with the pattern-oriented, data-based nature of neural networks and statistical techniques.

Case-based reasoning is an alternative technique, related to expert systems. Instead of creating rules based on expert knowledge, cases are stored using feature descriptors. Case-based reasoning resembles learning by analogy. The computer system searches through its store of cases and develops a solution based upon the most similar case in the case base. The main difficulties are in defining correct criteria for retrieving, matching, and applying similar cases.

Intelligent natural language processing systems are being used to improve the user interface of expert systems. The goal is to develop an interface that allows questions to be asked in English without the knowledge of a special syntax. The system should also be able to formulate answers in English. Teaching computers to understand natural languages is a difficult problem, which has only partially been solved. The various efforts in natural language processing and computational linguistics are beyond the scope of this article.

USE OF KNOWLEDGE-BASED SYSTEMS FOR DECISION SUPPORT AND ENTERPRISE SOFTWARE

Changes in computer system architecture have influenced the way corporate data are handled and how expert systems are integrated into enterprise software. While in the past a mainframe or minicomputer was connected to a number of dumb terminals, the dominant architecture now is a network system in which client computers have significant computing capabilities of their own, and can use programs and data stored on larger server machines for more complex tasks. In a distributed system, various database and application servers are connected on a network and can cooperate on tasks and share resources. The size and power of networks have been greatly increased by the advent of the internet and the subsequent development of intranets (networks restricted to one organization) and extranets (networks open to partner organizations but not the general public), and intelligence technologies have been a growing part of network operations and applications.

Decision support systems manage corporate data and knowledge to facilitate management decisions. The functionality of these systems has substantially increased over time. Transaction processing and other organizational functions create raw data that are stored in databases. These data can be queried, aggregated, analyzed, and visualized using spreadsheets, reports, graphs, and more sophisticated tools such as online analytical processing. Besides using databases, decision support tools usually contain modules for data modeling, visualization, simulation, and forecasting. Corporate knowledge derived from these large databases is stored in text-based systems and expert systems.

In recent years, decision support systems have tended to include data warehouses, where raw data from various sources are stored permanently, after cleaning, integration, and transformation of the data in order to support 'knowledge discovery'. Statistical and machine learning tools have been adapted to glean knowledge from these large amounts of data ('data mining'). Results take the form of classifications and rules with predictive power or clusters and patterns that are useful for analyzing and understanding the data. Rules derived from knowledge discovery in databases can be integrated into expert systems once they have been validated.

Knowledge has become one of the most important assets of business enterprises as well as of other large organizations. This has led to the concept of knowledge management, which includes the identification and analysis of knowledge and knowledge-related processes as well as the development of new knowledge strategies. In large organizations a common knowledge vocabulary needs to be developed and different knowledge sources and knowledge models need to be harmonized and integrated. A culture of knowledge sharing supported by software tools is essential in a context of rapid fluctuations of personnel, massive amounts of raw data, and organizations that are spread out over locations that are far apart.

Other examples of how expert systems can be integrated into mission-critical enterprise software are systems that monitor and control production processes. Data are typically collected through sensors connected to production machinery, then stored in databases and automatically analyzed, often using rule-based expert systems. Output can include diagnostic messages and alarms as well as feedback signals for tuning the production

machinery through motors. Often changes have to be made in a small time frame, which requires specialized real-time computer systems. An example is Gensym's G2 software, which offers a graphical, object-oriented environment that supports rule-based expert systems as well as real-time systems. It has visual programming and debugging tools, and other intelligent applications such as neural networks and genetic algorithms. G2 can be connected to other software and hardware and is typically used to monitor, diagnose, and control dynamic production environments or to perform simulations.

Distributed computer systems and the internet have created interest in an intelligent software technology called the 'intelligent agent'. An agent is a program that can take action on behalf of its user. It is mobile, and can travel through the network, perceiving its environment using sensors. It communicates with other agents by sending and receiving messages; it stores information; and it performs reasoning and takes action using 'effectors'. Expert systems are often a component of intelligent agents: the technologies developed for expert systems can support knowledge representation, reasoning, and communication in intelligent agents. The rapid development of the internet and its associated computer languages and standards (especially the 'extensible markup language' XML) will facilitate the development of agent systems. In business applications agents can collect information, compare offers, and even negotiate with other software agents.

STRENGTHS, WEAKNESSES, AND APPLICATIONS OF MODERN EXPERT SYSTEMS

Modern expert systems are different in certain ways from the systems in the late 1970s and 1980s. While many of the early expert systems were written in LISP and required special hardware, current expert systems are adapted to UNIX and Windows environments and are often implemented in general-purpose computer languages such as C or C++. Modern expert systems have several features that simplify development, such as graphical support, debugging and explanatory devices, and rule integrity checking. Systems that use the Rete algorithm for efficient pattern matching or PROLOG for backward chaining are still in use. Handling of uncertainty, and the use of fuzzy logic, are often supported. While most expert systems are rule-based, other paradigms exist. An example is the commercial Hugin software, which develops expert systems based on probabilistic networks, an extension of Bayesian mathematics due to Steffen Lauritzen and David Spiegelhalter. Integration with and embedding in other software are important features in today's internet-oriented client–server architectures.

A large number of vendors offer expert systems and products, ranging from small inexpensive systems to large systems for mission-critical enterprise software. The internet and recent publications are a good resource for further information in the rapidly changing field of computer software. Because of the importance of internet commerce, specialized expert systems in this area are popular. For example, a financial institution can use expert system technology for applications such as credit evaluation and fraud detection, as well as for web-based helpdesk applications and support for employees in call centers. Software support for customer relations management is one of the most important areas in electronic commerce today.

The strengths of expert systems lie in their ability to store and use human knowledge. Knowledge plays an important role in many fields, and is of a practical, heuristic nature, often based on many years of human experience. Expert systems have been shown to be efficient and reliable when used in well-described problem areas. The abundance of data in large organizational systems can be used only if the data are transformed into information and the information organized as knowledge and summarized as meta-knowledge. In this knowledge management enterprise, machine learning and automated knowledge discovery in databases can be combined effectively with expert systems. Concepts and techniques for knowledge representation and automated reasoning have been developed over many years. Modern rule-based systems are modular, allow efficient explanations of their results, and provide debugging tools.

Still, a number of problems with expert systems have not been solved, and weaknesses remain. One problem is the knowledge acquisition bottleneck. Building expert systems is still time- and personnel-intensive, although improvements have been achieved with more powerful expert system development tools. A second major problem (sometimes called 'brittleness') is that towards the boundaries of the expert knowledge, expert systems, rather than showing a gradual decline in performance, often show a sudden drop from good function to no function. Missing information and unexpected values cannot be handled well. Expert systems can work only in well-defined and limited areas. Unlike human experts, expert systems cannot fall

back on general principles and common sense, or create or evaluate new solutions. Expert systems do not learn by themselves but have to be updated by knowledge engineers. The handling of numeric data is often more efficiently managed by statistical or neural network techniques, although these can possibly be combined with expert systems.

AI techniques including expert systems were a major focus of research and development in the 1970s and 1980s, but the focus in the 1990s shifted to database and data-mining strategies, machine learning, internet-based technologies including internet commerce, and the integration of computer systems. The internet has made expert systems available to many users worldwide, and has created a need for automated helpdesk and information systems in the growing number of knowledge-based organizations. In the future, well-focused, quickly-developed expert systems will be needed, and expert systems will play a growing role in knowledge management and knowledge discovery in databases.

Frame Problem, The

Intermediate article

Murray Shanahan, Imperial College, London, UK

CONTENTS

The frame problem is a difficulty that arises when formal logic is used to represent the effects of actions. The challenge is to avoid having to represent explicitly large numbers of common-sense facts about what does not change when an action occurs.

INTRODUCTION

The frame problem, in the strictly technical sense of the term coined by McCarthy and Hayes (1969), is a difficulty that arises when we attempt to formalize the effects of actions in mathematical logic. Put briefly, the problem is this. How is it possible to represent the changes brought about by an action without having to explicitly enumerate all the non-changes? For example, suppose I tell you that taking certain medication cures a given ailment. Then common sense licenses the conclusion that taking that medication doesn't cause the color of the walls to change, that it doesn't cause it to rain, doesn't cause the government to collapse, doesn't cause your neighbor to turn into a frog, and so on. Unfortunately, formal logic does not inherently license any of these perfectly reasonable implications. Somehow, our logical formalization of the effects of taking the medication has to have the apparatus for drawing such common-sense conclusions deliberately built into it.

This article will discuss the variety of ways by which this difficulty may be overcome. Some of these will employ non-monotonic forms of inference, while others will adhere to classical, monotonic logic. In either case, a viable solution will have to be robust in the presence of certain phenomena, such as concurrent actions, actions with nondeterministic effects, actions with indirect effects, and continuous change. This article will not address the question of the desirability or otherwise of using logic as a representational formalism in the first place; nor will it discuss the frame problem in the wider sense of the term that has become current among philosophers (Pylyshin, 1987).

HOW THE FRAME PROBLEM ARISES

Let us take a closer look at how the frame problem arises. We first need to settle on a formalism for representing the effects of actions. Since the most prevalent formalism in the literature is the 'situation calculus' (McCarthy and Hayes, 1969), this will be our initial choice. The choice of formalism has only a minor bearing on the way the problem manifests itself and the possible methods for addressing it. It is important to see through the details of the presentation to the underlying issue. On the other hand, without a precise description of the problem as our starting point, it would be easy to misunderstand the underlying issue altogether.

The language of the situation calculus includes actions, fluents, and situations. A fluent is any property whose value is subject to change, such as the color of a block, the location of a robot, or the height of a ball. The most basic kind of formula in the situation calculus expresses the fact that, in a situation that results from performing a given type of action, a given fluent holds. Consider the following example:

$$\forall s\ [\mathrm{Holds}(\texttt{Cured},\mathrm{Result}(\texttt{TakeDrug},s)) \leftarrow \neg\mathrm{Holds}(\texttt{Anemic},s)] \quad (1)$$

This formula says that, in a situation that results from performing the action `TakeDrug`, the fluent `Cured` will be true, provided the fluent `Anemic` does not hold beforehand. (Universal quantifiers that range over an entire formula will be dropped from now on.) In general, Result(e,s) denotes the situation that results from carrying out action e in situation s, while Holds(f,s) says that fluent f is true in situation s. Now suppose we include the following three formulae representing the fluents that hold in the initial situation S_0:

$$\neg\mathrm{Holds}(\texttt{Cured},S_0) \quad (2)$$

$$\neg\mathrm{Holds}(\texttt{Anemic},S_0) \quad (3)$$

$$\mathrm{Holds}(\texttt{Alive},S_0) \quad (4)$$

Naturally, it follows from the conjunction of formulae 1 to 4 that

$$\text{Holds}(\texttt{Cured},\text{Result}(\texttt{TakeDrug},S_0)) \quad (5)$$

However, it does not follow from these formulae that

$$\text{Holds}(\texttt{Alive},\text{Result}(\texttt{TakeDrug},S_0)) \quad (6)$$

To obtain this conclusion, we could augment our attempted formalization with the following formula:

$$\text{Holds}(\texttt{Alive},\text{Result}(\texttt{TakeDrug},s)) \leftarrow \text{Holds}(\texttt{Alive},s) \quad (7)$$

In other words, the fluent `Alive` is unchanged by the action `TakeDrug`.

This kind of formula, describing a non-effect of an action, is known as a *frame axiom*. The strategy of adding frame axioms will allow us to make the desired inferences. But clearly, to formalize any domain of reasonable size, a very large number of frame axioms will be required. Even to formalize this simple domain properly requires four further frame axioms:

$$\text{Holds}(\texttt{Cured},\text{Result}(\texttt{TakeDrug},s)) \leftarrow \text{Holds}(\texttt{Cured},s) \quad (8)$$

$$\text{Holds}(\texttt{Anemic},\text{Result}(\texttt{TakeDrug},s)) \leftarrow \text{Holds}(\texttt{Anemic},s) \quad (9)$$

$$\neg\text{Holds}(\texttt{Alive},\text{Result}(\texttt{TakeDrug},s)) \leftarrow \neg\text{Holds}(\texttt{Alive},s) \quad (10)$$

$$\neg\text{Holds}(\texttt{Anemic},\text{Result}(\texttt{TakeDrug},s)) \leftarrow \neg\text{Holds}(\texttt{Anemic},s) \quad (11)$$

In general, since most fluents are unaffected by most actions, the number of frame axioms required will be around $2 \times N \times M$, if there are N actions and M fluents in the domain. This is the frame problem, as it arises in the situation calculus. The challenge is to find a way to capture the non-effects of actions without having to use a large number of explicit frame axioms.

A natural reaction to the frame problem is to attribute it to the monotonicity of classical logic. A form of inference is 'monotonic' if the set of conclusions that follow from a collection of premises can only ever increase with the addition of new premises: once a conclusion has been drawn, it can never be retracted on the basis of new information. Classical logic is monotonic in this sense. So perhaps the frame problem arises because the monotonicity of classical logic makes it impossible to say: 'assume an action doesn't affect a fluent unless the contrary is stated explicitly'. With a non-monotonic inference method, the addition of a premise describing some new effect of an action may cause a previous default conclusion about its non-effects to be revised. So if we want to express the assumption above, a non-monotonic form of inference is required.

NON-MONOTONIC SOLUTIONS

Circumscription (McCarthy, 1986) is one form of non-monotonic inference. Formally, if Σ is a set of formulae, the formula CIRC[Σ ; P] denotes the 'circumscription' of Σ, minimizing the set P of predicates. The effect of 'minimizing a predicate' is to keep its extension – the set of things of which it is true – as small as possible. So the formulae that follow from CIRC[Σ ; P] are those that follow from Σ alone, together with a number of extra default conclusions that follow only if the extensions of the predicates in P are constrained in this way.

For example, suppose Σ comprises the formulae `Happy(Fred)` and `Happy(Jill)`. Then, although ¬`Happy(Albert)` does not follow from Σ alone, it does follow from CIRC[Σ ; `Happy`], since the circumscription constrains the extension of `Happy` to exclude `Albert`. Note that ¬`Happy(Albert)` no longer follows if we add `Happy(Albert)` to Σ. In other words, ¬`Happy(Albert)` does not follow from CIRC[$\Sigma \cup$ {`Happy(Albert)`} ; `Happy`]. So the set of consequences of the circumscription has diminished, although the set of premises has increased. This is the sense in which circumscription is a non-monotonic form of inference.

Let us now consider the application of circumscription to the frame problem. Can we use it to formalize the default assumption that the only effects of actions are the explicitly enumerated effects? One way to do this is to formalize the so-called 'common-sense law of inertia' (McCarthy, 1986), according to which change is abnormal, and persistence is to be expected in the absence of information to the contrary. A natural way to formalize this law in the context of the situation calculus is as follows:

$$[\text{Holds}(f,\text{Result}(e,s)) \leftrightarrow \text{Holds}(f,s)] \leftarrow \neg\text{Ab}(e,f,s) \quad (12)$$

Intuitively, Ab(e,f,s) means that action e is abnormal with respect to fluent f in situation s, in the sense that the value of f is subject to change when e is performed in s. Now, for this 'universal frame axiom' to have its desired effect, we must conjoin it to a description of the effects of actions in the

problem domain, and then circumscribe minimizing the predicate Ab. So, for the drugs example above, if we let Σ consist of formulae 1 to 4 and formula 12, we are interested in what follows from the circumscription CIRC[Σ ; Ab]. In this case, we have

$$\begin{aligned}&\mathrm{Ab}(e,f,s) \leftrightarrow \\ &\quad [e = \mathtt{TakeDrug} \wedge f = \mathtt{Cured} \\ &\quad \wedge \neg \mathrm{Holds}(\mathtt{Cured},s) \\ &\quad \wedge \neg \mathrm{Holds}(\mathtt{Anemic},s)]\end{aligned} \tag{13}$$

from which, by formula 12, it follows that

$$\mathrm{Holds}(\mathtt{Alive},\mathrm{Result}(\mathtt{TakeDrug},S_0)). \tag{14}$$

Unfortunately, the naive application of circumscription can lead to a difficulty known as the Hanks–McDermott problem, in which the circumscription yields two alternative ways of minimizing change, only one of which is intuitively correct (Hanks and McDermott, 1987). The problem is traditionally presented by means of a benchmark known as the Yale shooting scenario. In this scenario, there are three actions: `Load`, `Shoot`, and `Sneeze`. The `Load` action causes a gun to be loaded; the `Shoot` action causes the gun to be fired; and the `Sneeze` action makes no change. Formally, these actions affect two fluents: `Alive` and `Loaded`. In the initial situation, `Alive` holds. The initial situation and the effects of subsequent actions can be represented as follows:

$$\mathrm{Holds}(\mathtt{Alive},S_0) \tag{15}$$

$$\mathrm{Holds}(\mathtt{Loaded},\mathrm{Result}(\mathtt{Load},s)) \tag{16}$$

$$\begin{aligned}&\neg \mathrm{Holds}(\mathtt{Alive},\mathrm{Result}(\mathtt{Shoot},s)) \\ &\quad \leftarrow \mathrm{Holds}(\mathtt{Loaded},s)\end{aligned} \tag{17}$$

Now, let Σ consist of the formulae 12, 15, 16, and 17, and consider what follows from CIRC[Σ ; Ab]. In particular, consider the sequence of actions: `Load`, `Sneeze`, `Shoot`. Clearly `Loaded` follows immediately after the `Load` action, from axiom 16. And since we have incorporated the common-sense law of inertia, we might expect `Loaded` to continue to hold through the `Sneeze` action, thus ensuring that the `Shoot` action causes `Alive` to stop holding, by axiom 17. But this intuitive conclusion does not follow, because the minimization of the Ab predicate is ambiguous. In addition to the intuitive minimization, in which the only effects of actions are that `Load` modifies `Loaded` and `Shoot` modifies `Alive`, there is another equally valid minimization in which the `Sneeze` action miraculously unloads the gun, thus preventing the `Shoot` action from affecting the `Alive` fluent.

This scenerio is interesting because it is exemplary. The lesson is that the common-sense law of inertia, if formalized incorrectly, fails to rule out unintended effects of actions, whether in the context of circumscription or of other forms of default reasoning. Moreover, the Hanks–McDermott problem arises not only with the situation calculus, but also with other formalisms for representing actions, such as the event calculus (Shanahan, 1999b). In the late 1980s, many researchers devised techniques for overcoming the Hanks–McDermott problem, including chronological minimization (Shoham, 1988), which works by imposing temporal directionality on the minimization process, and causal minimization (Lifschitz, 1987), in which special causal predicates are introduced. Other researchers have produced effective solutions by modifying the original circumscriptive formalization (Baker, 1991). (In our description above, we have, for the sake of simplicity, ignored certain formal details, such as 'uniqueness of names' axioms and the question of which predicates are allowed to vary in circumscription.) All this work is surveyed in detail in Shanahan (1997).

FILTERING

With hindsight, two related approaches stand out for being both simple and robust in the presence of diverse phenomena such as nondeterminism and actions with indirect effects. These two approaches are called 'filtering' (Sandewall, 1994) and 'explanation closure' (Haas, 1987).

Although filtering can be successfully applied to the situation calculus (Kartha and Lifschitz, 1995), it is easiest to explain in the context of a formalism that employs explicit predicates for encapsulating the effects of actions, such as the event calculus (Kowalski and Sergot, 1986; Shanahan, 1999b). The idea of filtering is to isolate formulae describing the effects of actions, and apply default reasoning to them, separately from their application to a given scenario.

We will see how this works below, after briefly introducing the event calculus. An event calculus theory comprises two parts, a description of the effects of actions using the predicates 'Initiates' and 'Terminates', and a description of a narrative of events using the predicates 'Initially' and 'Happens'. These two sets of formulae are conjoined with some generic axioms to yield, as logical consequences, formulae describing the values of fluents at different time points. The formula Initiates(e,f,t) means that immediately following the occurrence of an action of type e at time t, the fluent

f starts to hold. Similarly, Terminates(e,f,t) means that immediately following an action of type e at t, the fluent f ceases to hold. The formula HoldsAt(f,t) means that fluent f holds at time t. So the effects of the actions in the Yale shooting scenario are represented as follows:

$$\text{Initiates}(\texttt{Load},\texttt{Loaded},t) \tag{18}$$

$$\text{Terminates}(\texttt{Shoot},\texttt{Alive},t) \leftarrow \text{HoldsAt}(\texttt{Loaded},t) \tag{19}$$

The narrative of events in the Yale shooting scenario can be given the following representation. The formula Initially(f) means that the fluent f is true in the initial situation, and the formula Happens(e,t) means that an action of type e occurs at time t.

$$\text{Initially}(\texttt{Alive}) \tag{20}$$

$$\text{Happens}(\texttt{Load},1) \tag{21}$$

$$\text{Happens}(\texttt{Sneeze},2) \tag{22}$$

$$\text{Happens}(\texttt{Shoot},3) \tag{23}$$

Now, to get results, we need some domain-independent axioms:

$$\text{HoldsAt}(f,t_2) \leftarrow \text{Initially}(f) \wedge \neg\exists\, e,t_1\ [\text{Happens}(e,t) \wedge t_1 < t_2 \wedge \text{Terminates}(e,f,t_1)] \tag{24}$$

$$\text{HoldsAt}(f,t_3) \leftarrow \text{Happens}(e_1,t_1) \wedge \text{Initiates}(e_1,f,t_1) \wedge t_1 < t_3 \wedge \neg\exists e_2,t_2[\text{Happens}(e_2,t_2) \wedge t_1 < t_2 < t_3 \wedge \text{Terminates}(e_2,f,t_2)] \tag{25}$$

$$\neg\text{HoldsAt}(f,t_3) \leftarrow \text{Happens}(e_1,t_1) \wedge \text{Terminates}(e_1,f,t_1) \wedge t_1 < t_3 \wedge \neg\exists\, e_2,t_2[\text{Happens}(e_2,t_2) \wedge t_1 < t_2 < t_3 \wedge \text{Initiates}(e_2,f,t_2)] \tag{26}$$

In the context of the situation calculus, we tried to tackle the frame problem by minimizing the Ab predicate. The analogous thing to do with the event calculus is to minimize the Initiates and Terminates predicates – this corresponds to the default assumption that there are no unknown effects of actions. In addition, the Happens predicate must be minimized – this corresponds to the default assumption that there are no unknown action occurrences. But if we naively conjoin all the relevant formulae (18 to 26), and circumscribe them minimizing these predicates, the Hanks–McDermott problem arises. We get just the same unintended possibilities as we did with the Yale shooting scenario in the situation calculus.

Fortunately, a straightforward technique will overcome this problem. We just need to isolate the various components of the formalization, and circumscribe them separately. This technique is known as filtering (Sandewall, 1994), since the idea is to filter out those parts of the formalization that should not be subject to default reasoning. This ensures that the assignment of fluents to actual time points cannot interfere with the process of minimizing the effects of actions. In the case of the Yale shooting scenario, this means that the `Shoot` action has the effect of terminating `Alive` if `Loaded` holds – and this conditional effect is retained in the minimization of the Terminates predicate, irrespective of which fluents actually hold at what times. This effect cannot be replaced by a miraculous unloading by the `Sneeze` action. Formally, if we let EC be the conjunction of formulae 24, 25, and 26, Σ consist of formulae 18 and 19, and Δ consist of formulae 20 to 23, then we are interested in

$$\text{CIRC}[\Delta\ ;\ \text{Happens}] \wedge \text{CIRC}[\Sigma\ ;\ \text{Initiates},\ \text{Terminates}] \wedge \text{EC} \tag{27}$$

This, at last, yields the desired results, and among the logical consequences of this theory we have HoldsAt(`Loaded`,3) and ¬HoldsAt(`Alive`,4). This technique works for any simple theory describing the effects of actions with preconditions. Moreover, it can be used for theories involving concurrent actions, actions with nondeterministic effects, and actions with indirect effects (Shanahan, 1997). Solving the frame problem in the context of actions with indirect effects is the most challenging of these tasks, and is known as the ramification problem. We will return to the ramification problem below.

EXPLANATION CLOSURE

A crucial property of the circumscription CIRC[Σ ; Initiates, Terminates] is that it reduces, in the case of the Yale shooting scenerio, to the predicate completions of Initiates and Terminates (Clark, 1978), because of the simple form of Σ (Lifschitz, 1994). That is:

$$\text{Initiates}(e,f,t) \leftrightarrow [e = \texttt{Load} \wedge f = \texttt{Loaded}] \tag{28}$$

$$\text{Terminates}(e,f,t) \leftrightarrow [e = \texttt{Shoot} \wedge f = \texttt{Alive} \wedge \text{HoldsAt}(\texttt{Loaded},t)] \tag{29}$$

The above formulae, which are in biconditional ('if and only if') form, directly encode the assumption that the only effects of actions are the known effects. So it is natural to ask whether we can use this style of formula directly. Instead of writing a

set of formulae describing the effects of actions and then circumscribing them, why not omit the circumscription process altogether and proceed directly to a set of biconditional formulae? One of the main attractions of this approach to the frame problem is that it altogether avoids the use of non-monotonic formalisms, with their attendant mathematical difficulties.

A similar maneuver is possible for the situation calculus, as was first noted by Haas (1987). Instead of using a form of non-monotonic reasoning, we can simply rewrite the frame axioms in a more parsimonious form, known as *explanation closure axioms*. Consider a slightly extended version of the Yale shooting scenario, in which the `Shoot` action unloads the gun, and in which there is also an `Unload` action with the same effect. We then have the following effect axioms in addition to formulae 16 and 17:

$$\neg\text{Holds}(\texttt{Loaded},\text{Result}(\texttt{Shoot},s)) \tag{30}$$

$$\neg\text{Holds}(\texttt{Loaded},\text{Result}(\texttt{Unload},s)) \tag{31}$$

The following two explanation closure axioms say, respectively, that the only way to terminate the `Alive` fluent is by a `Shoot` action while `Loaded` holds, and that the only way to terminate the `Loaded` fluent is by either a `Shoot` action or an `Unload` action:

$$[\text{Holds}(\texttt{Alive},s) \wedge \neg\text{Holds}(\texttt{Alive}, \text{Result}(e,s))] \rightarrow [e = \texttt{Shoot} \wedge \text{Holds}(\text{Loaded},s)] \tag{32}$$

$$[\text{Holds}(\texttt{Loaded},s) \wedge \neg\text{Holds}(\texttt{Loaded}, \text{Result}(e,s))] \rightarrow [e = \texttt{Shoot} \vee e = \texttt{Unload}] \tag{33}$$

Two further explanation closure axioms concern the conditions under which the fluents are initiated. Clearly, explanation closure axioms subsume frame axioms: taken together with formulae 15, 16, and 17, the above axioms yield the expected conclusions for the Yale shooting scenario. However, since only two explanation closure axioms are required per fluent, the total number required for a domain of N actions and M fluents is around $2 \times M$. The length of an individual explanation closure axiom will typically increase with the size and complexity of the domain. But this increase will reflect the amount of change being captured, not the amount of non-change. This is why explanation closure axioms, though strictly monotonic, offer a parsimonious alternative to frame axioms.

An effect axiom and an explanation closure axiom can be combined into a single formula, known as a *successor state axiom* (Reiter, 1991). One such formula is required for each fluent, defining exactly the circumstances under which that fluent does and does not hold. Here, for example, are the successor state axioms for the Yale shooting scenario with an `Unload` action:

$$\text{Holds}(\texttt{Alive},\text{Result}(e,s)) \leftrightarrow [\text{Holds}(\texttt{Alive},s) \wedge \neg[e = \texttt{Shoot} \wedge \text{Holds}(\texttt{Loaded},s)]] \tag{34}$$

$$\text{Holds}(\texttt{Loaded},\text{Result}(e,s)) \leftrightarrow [e = \texttt{Load} \vee [\text{Holds}(\texttt{Loaded},s) \wedge e \neq \texttt{Unload} \wedge e \neq \texttt{Shoot}]] \tag{35}$$

One possible criticism of monotonic solutions to the frame problem is that they lack elaboration-tolerance. A formalism is elaboration-tolerant to the extent that it can easily accommodate the addition of new information (McCarthy, 1988). In the case of a formalism for reasoning about action, we would expect it to smoothly absorb new facts about the effects of actions – both previously unknown effects of known actions and effects of previously unknown actions. Using a non-monotonic formalism, such as circumscription, the assimilation of new information is simply a matter of conjoining it to the old theory and recircumscribing. By contrast, adding new information to a set of successor state axioms requires the dismantling and reconstruction of the whole theory. It is possible, however, to introduce elaboration tolerance by formally defining operators that take a set of standard situation calculus effect axioms and return the corresponding successor state axioms (Reiter, 1991). Such an operator is itself non-monotonic in the same sense as the circumscription operator.

THE SCOPE AND LIMITS OF A SOLUTION

One of the lessons of the Hanks–McDermott problem is that no formalization can be assumed to yield the expected results without a proper investigation of its properties. The Hanks–McDermott problem arises when the process of projecting fluents along a narrative line is permitted to interfere with the process of non-monotonically minimizing the effects of actions. We can be confident that the Hanks–McDermott problem has been solved when these two processes are separated, as they are in filtering and (implicitly) in explanation closure. But how can we establish rigorous criteria for the class of problem scenarios to which a proposed solution to the frame problem can be applied?

Two approaches to this question are 'action description languages' (Gelfond and Lifschitz, 1993) and the 'features and fluents' framework (Sandewall, 1994).

An action description language is a formal language for describing the effects of actions, together with a corresponding entailment relation. The idea is that the action description language should be used as a standard against which other formalisms couched in general-purpose logic are measured. Many such languages have been designed, to handle various phenomena.

Similarly, in the features and fluents framework, a hierarchical class of domains is defined, together with formal criteria for demonstrating that an action formalism correctly captures the expected logical consequences in that domain. Sandewall's classes range from domains that are restricted to deterministic actions with no concurrency or indirect effects, to domains allowing concurrent actions, continuous change, and actions with nondeterministic effects.

Many of these phenomena can be handled by existing formalisms, including the situation calculus, the event calculus, and others (Sandewall, 1994; Shanahan, 1997). But the issue that has proved most difficult is the ramification problem, which is the challenge of supplying a solution to the frame problem that works in the presence of actions with indirect effects. One way to represent the indirect effects of actions is through state constraints. A state constraint, in effect, rules out certain simultaneous combinations of fluents. For example, in the situation calculus, we might write the following state constraint:

$$\mathrm{Holds}(\texttt{Walking},s) \rightarrow \mathrm{Holds}(\texttt{Alive},s) \quad (36)$$

This formula rules out the possibility of the `Walking` fluent holding while the `Alive` fluent does not hold. So if an action has the direct effect of terminating `Alive`, it has the indirect effect of terminating `Walking`. The explanation closure approach to the frame problem can be extended to handle state constraints. The above formula, for example, in combination with the effect axiom 17, can be incorporated into a successor state axiom for the `Walking` fluent as follows (McIlraith, 2000):

$$\begin{aligned}&\mathrm{Holds}(\texttt{Walking},\mathrm{Result}(e,s)) \leftrightarrow \\ &\quad [\mathrm{Holds}(\texttt{Walking},s) \wedge \neg[e = \texttt{Shoot} \\ &\quad \wedge \mathrm{Holds}(\texttt{Loaded},s]] \end{aligned} \quad (37)$$

However, state constraints can lead to unexpected conclusions. For example, if we include a `Walk` action that initiates the `Walking` fluent, then we cannot avoid the conclusion that after the sequence of actions '`Load`, `Shoot`, `Walk`', the `Alive` fluent holds. In other words, the `Walk` action will bring about the unexpected resurrection of the victim of the `Shoot` action. The reason for this anomaly is that the relationship between `Alive` and `Walking` has a causal dimension – any action that terminates `Alive` indirectly causes `Walking` to be terminated – and state constraints cannot capture the directionality of the cause–effect relation. The issue is made more complicated by the possibility of concurrent actions with multiple, interacting indirect effects (Lin, 1995; Thielscher, 1997). However, many researchers have supplied formalisms that successfully address both the frame problem and the ramification problem, even in such extreme scenarios, by capturing the causal character of the effects of actions (e.g., McCain and Turner, 1997; Shanahan, 1999a).

Fuzzy Logic

Intermediate article

Ronald R Yager, Machine Intelligence Institute, Iona College, New Rochelle, New York, USA

CONTENTS

Fuzzy logic provides a methodology that enables the modeling of human reasoning.

INTRODUCTION

Humans have a remarkable capability to perform a wide variety of physical and mental tasks without precise measurements. Examples of such tasks are driving a car, deciding what to wear, and playing many types of sport. In performing such tasks, humans mainly use imprecise information, perceptions, rather than precise readings. Some statements involving this kind of perception-based information are: the weather will turn cold in the early afternoon; he appears intent on attacking; and the vehicle is moving rapidly. The use of perceptions, in addition to being necessitated by the finite ability of humans to resolve detail, facilitates the acquisition, expression, and manipulation of knowledge. A fundamental aspect of many types of perceptions is their granularization and fuzziness (gradularization). In considering an attribute such as temperature, a perception would be it is *cold* rather than a precise measurement such as 20°F. One clearly sees the granular nature of cold in that it involves a collection or clump of temperatures. The fuzzy nature of perceptions is reflected in the fact that the common use of the word *cold* does not entail a crisp boundary distinguishing cold from not cold but more naturally reflects a gradual decay at its boundaries. The modeling of human cognition requires the manipulation of perceptions of many different kinds of variables. Physical variables such as time, direction, speed, and shape as well as intellectual constructs such as probability, causality, and stability are but a few examples. Fuzzy logic and the related idea of approximate reasoning is a technology expressly developed to help in this task. The idea of a fuzzy subset was originally introduced by L. A. Zadeh in 1965 (Zadeh, 1965). In Yager *et al*. (1987) the editors provide a selection of seminal papers by Zadeh. A collection of the pioneering papers on fuzzy logic by various authors can be found in Dubois *et al*. (1993). Recent works have focused on the development of a computational theory for reasoning with perceptions, and a framework for computing with words (Zadeh, 1999, 2001). A number of books provide good introductions to this subject (see Further Reading).

BASIC IDEAS AND CONCEPTS

The concept of a fuzzy subset was originally introduced by Zadeh as a generalization of the idea of an ordinary set. A fuzzy subset A on the universe X is defined by a function called the membership function. For each x the membership function A (x) can assume any value in $[0, 1]$, the unit interval, indicating the degree of membership of x in A. This extension from the classic binary/crisp case, in which the membership grade is restricted to be either zero or one, allows for the description of concepts in which the boundary between satisfying and not satisfying the concept is not sharp. Here we shall define some of the fundamental operations and concepts of fuzzy set theory and fuzzy logic.

Basic Operations on Fuzzy Sets

Here we begin with some of the basic operations. We shall assume A and B are two fuzzy subsets of X and use them to describe these basic fuzzy set operations:

- A is said to be a subset of B, denoted $A \subset B$, if $B(x) \geq A(x)$ for all $x \in X$
- The union A and B is a fuzzy subset $C = A \cup B$ such that $C(x) = \text{Max}[A(x), B(x)]$
- The intersection A and B is a fuzzy subset $D = A \cap B$ such that $D(x) = \text{Min}[A(x), B(x)]$
- The negation of A is a fuzzy subset $\bar{A}$ such that $\bar{A}(x) = 1 - A(x)$

It is easily seen that these operations reduce to the ordinary set operations when we restrict the membership grades to be one or zero. The operations we have introduced are the standard definitions of these operations. A lively literature exists in this field describing alternative ways of extending the set operations to the fuzzy domain.

Measuring Fuzziness

Since the concept of a fuzzy set was first introduced, various authors have attempted to define a measure of fuzziness of a fuzzy subset A, **FUZ**(A). DeLuca and Termini (1972) stated conditions which a measure of fuzziness should satisfy. Among these conditions are that $\mathbf{FUZ}(\mathrm{A}) = 0$ if A is a crisp set and **FUZ**(A) is maximum for a fuzzy subset where $\mathrm{A}(x) = 0.5$ for all x. Yager (1979) suggested that fuzziness is related to the lack of distinction between a set and its negation. Based on this he suggested

$$\mathbf{FUZ}(\mathrm{A}) = \frac{1}{n^{1/2}} \left(\sum_{i=1}^{n} |\mathrm{A}(x_i) - \overline{\mathrm{A}(x_i)}|^2 \right)^{1/2}.$$

Other measures for fuzziness have been suggested in the literature; among these is one suggested by Kosko (1986).

Linguistic Values and Computing with Words

A concept which plays a crucial role in many applications of fuzzy logic is the idea of a linguistic value. Consider the statement: Mary is *young*. This statement involves the assignment of a value to a variable. The variable is *the Age of Mary* which we shall denote as V. Associated with V is a set X, called its universe of discourse, consisting of the set of allowable values for the variable, $\mathrm{X} = \{1, 2...., 100\}$. The value assigned to V is *young*. In our case, rather than knowing that Mary's age is precisely one particular element in the set X, we are presented with the imprecise information, perception, that her age is *young*. Young in this framework is what is called a linguistic value. The concept of *young* can in turn be defined as a fuzzy subset A. In this fuzzy subset, the membership grade $\mathrm{A}(x)$ is the compatibility of the age x with the concept of *young*. The fuzzy subset A can be viewed as a constraint on the allowable value of the variable. Here we are viewing information as constraints on the allowable values of variables. A common notational convention is to use the form V *is* A to express this association of a value with a variable.

Approximate reasoning, sometimes called fuzzy logic or computing with words, provides a unified structure in which human reasoning can be modeled. This reasoning system uses the idea of a linguistic value and its representation as a fuzzy subset as a central knowledge representation tool. The theory of approximate reasoning has two fundamental components, 'translation rules' and 'inference rules'. The translation rules provide a mechanism for the translation of natural language statements into fuzzy subsets. This translation step can be seen as a bridge between human expression of information and the formal representation required for computerized manipulation of this information. The inference component of approximate reasoning provides rules for the manipulation of knowledge, which allow us to make inferences and in other ways process information.

Possibility and Certainty

Our representation of this type of linguistic information using fuzzy sets allows us to process this information formally. One type of processing involves answering questions. When one has information such as V *is* x^* and is asked if some other statement V *is* B is true, one can calculate 'the degree of truth' as the membership grade of x^* in B, $\mathrm{B}(x^*)$. In situations in which our knowledge involves a linguistic value, a fuzzy subset, the question of determining the truth is not as straightforward. Consider the knowledge *John is in his twenties*. If we are asked is John 33, we can easily answer no. If we are asked is John over fifteen, we can easily answer yes. But if we are asked is John 25, the best we can say is that it is possible but we are not certain. In order to handle this situation, where our information has a granular nature, two measures are introduced. We shall assume that A and B are fuzzy subsets of the set X corresponding to some linguistic concepts. Assume we have the knowledge that V *is* A and we are interested in confirmation of the statement V *is* B. One measure of this confirmation is called the *possibility* of B given A. It is denoted as Poss[B/A] and defined as $\mathrm{Poss}[\mathrm{B/A}] = \mathrm{Max}_x[\mathrm{D}(x)]$ where $\mathrm{D} = \mathrm{A} \cap \mathrm{B}$. A second measure of this confirmation is called the *certainty* of B given A. It is denoted as Cert[B/A] and defined as $\mathrm{Cert}[\mathrm{B/A}] = 1 - \mathrm{Poss}[\bar{\mathrm{B}}/\mathrm{A}]$. We can view the possibility and certainty measures as providing optimistic and pessimistic measures on the confirmation of B given A. The possibility and certainty measures can also be viewed as providing upper and lower bounds on the truth of B given A.

Information in a Fuzzy Set

When using linguistic values one becomes concerned with the issue of measuring the amount of information contained in the associated possibility distribution. For example, knowing that Rachel is 27 is more informative than knowing that she is in her twenties. In the framework of probability theory, the Shannon entropy is commonly used to measure the amount of information contained in a probability distribution. In fuzzy logic the measure of specificity can be used in an analogous manner. Assume A is a fuzzy subset corresponding to a linguistic value, the specificity of A, denoted Sp(A), can be defined as the difference between the maximal membership in A minus the average membership grade in A, $\mathrm{Sp(A)} = \mathrm{Max}_x(\mathrm{A}) - \mathrm{Ave}_x(\mathrm{A})$. A fundamental feature of this measure is that it attains its biggest value when A just contains one element with membership grade one and all other elements have membership zero. Another feature is that it decreases in value as membership grades increase.

PROTOTYPICAL APPLICATIONS OF FUZZY LOGIC

While fuzzy logic has found numerous applications, many of these involve two prototypical methodologies. The first of these is fuzzy systems modeling and the second is criteria satisfaction. In the following we describe these prototypical applications.

Fuzzy Systems Modeling

Fuzzy systems modeling is a technique for modeling complex nonlinear relationships using a rule-based methodology. Central to this approach is a partitioning of the model into fuzzy subregions in which we have knowledge of the model's performance. Consider a relationship $\mathrm{U} = f(\mathrm{V}, \mathrm{W})$. Here V and W are the input variables and U is called the output variable. Typically we are interested in obtaining the value of U for a given value of V and W. In fuzzy systems modeling we represent this relationship by a collection of fuzzy if–then rules of the form:

If V is *Large* and W is *About 25* then U is *Medium*

At a formal level we have a collection of rules expressed as:

If V is A_i and W is B_i then U is D_i

where the A_is, B_is and D_is are fuzzy subsets over the universes X, Y and Z. In using fuzzy systems modeling we are essentially partitioning the input space $\mathrm{X} \times \mathrm{Y}$ into fuzzy regions $\mathrm{A}_i \times \mathrm{B}_i$ in which we know the output value, $\mathrm{D_i}$.

Given values for the input variables, $\mathrm{V} = a$ and $\mathrm{W} = b$, we calculate the value of U as a fuzzy subset E by using a process called fuzzy inference:

1. For each rule we find the firing level $\lambda_i = \mathrm{Min}[\mathrm{A}_i(a), \mathrm{B}_i(b)]$.
2. We calculate the effective output of each rule $\mathrm{E_i}$.
3. Combine individual effective rule outputs to get overall system output E.

Two different paradigms have been typically used for implementing steps two and three in the above procedure. The first paradigm, called the Min-Max inference procedure, uses $\mathrm{E}_i(z) = \mathrm{Min}[\lambda_i, \mathrm{D}_i(z)]$ for the effective rule outputs. It then uses a union of these outputs to get the overall output $\mathrm{E} = \cup_{i=1}^{n} \mathrm{E}_i$, hence $\mathrm{E}(z) = \mathrm{Max}_i[\mathrm{E}_i(z)]$. The second paradigm uses arithmetic operations instead of the Min-Max operation. In this approach $\mathrm{E}_i(z) = \lambda_i * \mathrm{D}_i(z)$ and $\mathrm{E}(z) = \frac{1}{\mathrm{T}} \sum_{i=1}^{n} \mathrm{E}_i(z)$ where $\mathrm{T} = \sum_{i=1}^{n} \lambda_i$. As a simplified expression of this we have $\mathrm{E}(z) = \sum_{i=1}^{n} \mathrm{E}_i(z)$ where $\mathrm{E}_i(z) = w_i * \mathrm{D}_i(z)$ with $w_i = \frac{\lambda_i}{\mathrm{T}}$. We shall call this the arithmetic inference procedure.

When we desire a crisp output value z* rather than a fuzzy one we use a defuzzification step such as the center of area (COA) method where we calculate

$$z^* = \frac{\sum_z z\mathrm{E}(z)}{\sum_z \mathrm{E}(z)}$$

The most commonly used approach to fuzzy systems modeling, due to Takagi and Sugeno (1985) and called the TSK method, involves the use of the arithmetic method with a further simplification in the model. In this approach the outputs of the rules rather than being fuzzy sets are assumed to be specific values. In this case a rule becomes *If V is A_i and W is B_i then U is d_i*. Here d_i is a specific value from the space Z. This assumption leads to a simplification of the process of obtaining the output so that the output is obtained directly as

$$z^* = \sum_{i=1}^{n} w_i * d_i.$$

Criteria Satisfaction

The second major fuzzy technology focuses on criteria satisfaction problems. This technology has found applications in areas such as decision-

making, database-querying, and internet search and information retrieval.

Assume we have a collection of criteria which we desire to satisfy by selecting an action from a set of alternative actions X. The starting point of this approach is the representation of each of the criteria by a fuzzy subset. Specifically, a criterion can be represented by a fuzzy subset C_i in which the membership grade $C_i(x)$ indicates the degree to which alternative x satisfies the criterion. In this environment we let $D(x) = \text{Agg}(C_1(x), C_2(x), \ldots, C_n(x))$ be the fuzzy subset representing the overall satisfaction of alternative x to the collection of criteria. In some applications, such as decision-making, we select the alternative with the largest membership in D. In other applications, such as information retrieval, we provide an ordered listing of the objects based on their membership in D.

A central problem here is the formulation of the function D. The structure of the function Agg is a reflection of the desired relationship between the criteria. In many cases the relationship between the criteria can be most conveniently expressed by the decision maker in terms of natural language. In these environments we are able to take advantage of the strong connection between fuzzy logic and natural language to obtain formal representations of the decision function. If we desire to satisfy *all* the criteria, the decision function can be linguistically expressed as requiring C_1 *and* C_2 *and* C_3 *and*… *and* C_n. Using the definition for the *anding* (intersection) of fuzzy subsets we obtain $D(x) = \text{Min}_i[C_i(x)]$. In some situations, rather than requiring that all the criteria be satisfied an agent may only require that some portion of the criteria be satisfied. For example, one may find a solution acceptable if it satisfies *most* of the criteria. We can express this as $D = \textit{Most}[C_1, C_2, \ldots, C_n]$. The introduction of a quantifier such as *most* provides a softening of the decision function by allowing for a relaxation to the satisfaction of some of the criteria while still obtaining a good solution. More complex quantifiers-based decision rules can be envisioned, for example All of $[C_1, \ldots, C_k]$ and some of $[C_{k+1}, \ldots, C_n]$. A considerable body of literature has focused on the modeling of complex relationships between criteria. The Ordered Weighted Averaging (OWA) operator (Yager, 1988) has played a major role in this task.

SUMMARY

Human cognition uses information that is often imprecise. Fuzzy logic provides a formal framework for the modeling and manipulation of this kind of information. A fundamental idea in the use of fuzzy logic is the idea of the linguistic value and its representation as a fuzzy set.

Game-playing Programs

Intermediate article

Susan L Epstein, Hunter College and The Graduate Center of The City University of New York, New York, USA

CONTENTS

Game-playing programs rely on fast, deep search and knowledge to defeat human champions. For more difficult games, simulation and machine learning have been employed, and human cognition is under consideration.

GAME TREES

Board games are not only entertaining – they also provide us with challenging, well-defined problems, and force us to confront fundamental issues in artificial intelligence: knowledge representation, search, learning, and planning. Computer game playing has thus far relied on fast, deep search and vast stores of knowledge. To date, some programs have defeated human champions, but other challenging games remain to be won.

A *game* is a noise-free, discrete space in which two or more agents (*contestants*) manipulate a finite set of objects (*playing pieces*) among a finite set of locations (the *board*). A *position* is a world state in a game; it specifies the whereabouts of each playing piece and identifies the contestant whose turn it is to act (the *mover*). Examples appear in Figure 1. Each game has its own finite, static set of rules that specify legal locations on the board, and when and how contestants may *move* (transform one state into another). The rules also specify an *initial state* (the starting position for play), a set of *terminal states* where play must halt, and assign to each terminal state a *game-theoretic value*, which can be thought of as a numerical score for each contestant.

As in Figure 1, the search space for a game is typically represented by a *game tree*, where each node represents a position and each link represents one move by one contestant (called a *ply*). A *contest* is a finite path in a game tree from an initial state to a terminal state. A contest ends at the first terminal state it reaches; it may also be terminated by the rules because a time limit has been exceeded or because a position has repeatedly occurred.

The goal of each contestant is to reach a terminal state that optimizes the game-theoretic value from its perspective. An *optimal move* from position p is a move that creates a position with maximal value for the mover in p. In a terminal state, that value is determined by the rules; in a non-terminal state, it is the best result the mover can achieve if subsequent play to the end of the contest is always optimal. The game-theoretic value of a non-terminal position is the best the mover can achieve from it during error-free play. If a subtree stops at states all of which are labeled with values, a *minimax algorithm* backs those values up, one ply at a time, selecting the optimal move for the mover at each

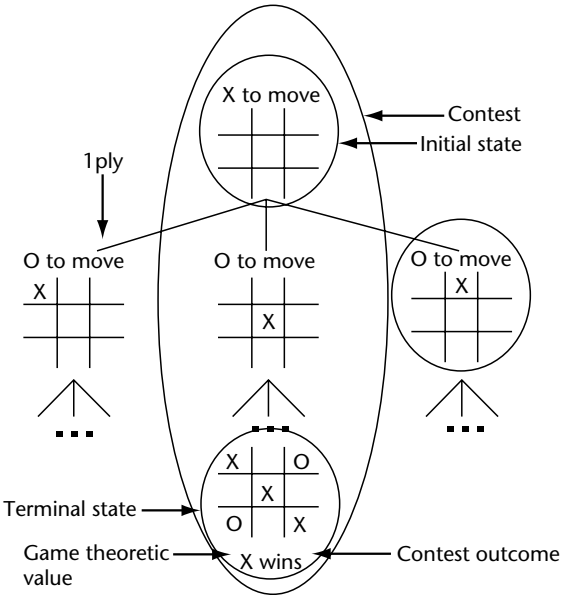

Figure 1. A game tree and basic game-playing terminology.

node. In Figure 2, for example, each possible next state in tic-tac-toe is shown with its game-theoretic value; minimax selects the move on the left.

Retrograde analysis backs up the rule-determined values of all terminal nodes in a subtree to compute the game-theoretic value of the initial state. It minimaxes from all the terminal nodes to compute the game-theoretic value of every node in the game tree, as shown in Figure 3. The number of nodes visited during retrograde analysis is dependent both on a game's *branching factor* (average number of legal moves from each position) and the depth of the subtree under consideration. For any challenging game, such as checkers (draughts) or chess, retrograde analysis to the initial state is computationally intractable. Therefore, move selection requires a way to compare alternatives.

An *evaluation function* maps positions to values, from the perspective of a single contestant. A *perfect* evaluation function preserves order among all positions' game-theoretic values. For games with relatively small game trees, one can generate a perfect evaluation function by caching the values from retrograde analysis along with the optimal moves. Alternatively, one might devise a way to compute a perfect evaluation function from a description of the position alone, given enough knowledge about the nature of the game. In this approach, a position is described as a set of *features*, descriptive properties such as piece advantage or control of the center. It is possible, for example, to construct, and then program, a perfect, feature-based evaluation function for tic-tac-toe. Given a perfect evaluation function, a game-playing program searches only one ply – it evaluates all possible next states and makes the move to the next state with the highest value. For a challenging game, however, the identity of the features and their relative importance may be unknown, even to human experts.

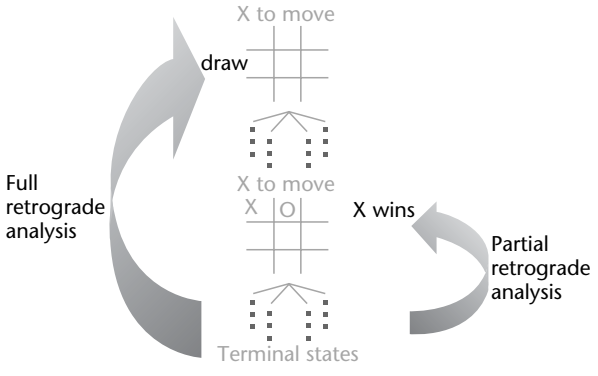

Figure 3. Retrograde analysis backs up rule-determined values.

SEARCH AND KNOWLEDGE

Confronted with a large game tree and without a perfect evaluation function, the typical game-playing program relies instead on heuristic search in the game tree. The program searches several ply down from the current state, labels each game state it reaches with an estimate of its game-theoretic value as computed by a heuristic evaluation function, and then backs those values up to select the best move. Most classic game-playing programs devote extensive time and space to such heuristic search. The most successful variations preserve exhaustive search's correctness: a *transposition table* to save previously evaluated positions, the α-β algorithm to *prune* (not search) irrelevant segments of the game tree, extensions along promising lines of play, and extensions that include forced moves. Other search algorithms take conservative risks; they prune unpromising lines early or seek *quiescence*, a relatively stable heuristic evaluation in a small search tree. Whatever its search mechanisms, however, a powerful game-playing program typically plays only a single game, because it also relies on knowledge.

Knowledge is traditionally incorporated into a game-playing program in three ways. First, formulaic behavior early in play (*openings*) is prerecorded in an *opening book*. Early in a contest, the program identifies the current opening and continues it. Second, knowledge about features and their relative importance is embedded in a heuristic evaluation function. Finally, prior to competition, the program calculates the true game-theoretic values of certain nodes with exhaustive search and stores them with their optimal moves (*endgame database*). Because a heuristic evaluation function always returns any available endgame values, the larger that database, the more accurate the evaluation and the better the search is likely to perform.

EARLY ATTEMPTS AT MECHANIZED GAME PLAYING

Chess has long been the focus of automated game playing. The first known mechanical game player was for a chess endgame (king and rook against king), constructed about 1890 by Torrès y Quevedo. In the 1940s many researchers began to consider how a computer might play chess well, and constructed specialized hardware and algorithms for chess. Work by Shannon, Turing, and de Groot was particularly influential. By 1958 a program capable of playing the entire game was reported, and by the mid-1960s computers had begun to compete against each other in tournaments (Marsland, 1990).

At about the same time, Samuel was laying the foundation for today's ambitious game-playing programs, and much of machine learning, with his checkers player (Samuel, 1959, 1967). A game state was summarized by his program in a vector of 38 feature values. The program searched at least three ply, with deeper searches for positions associated with piece capture and substantial differences in material. The checker player stored as many evaluated positions as possible, reusing them to make subsequent decisions. Samuel tested a variety of evaluation functions, beginning with a prespecified linear combination of the features. He created a compact representation for game states, as well as a routine to learn weighted combinations of 16 of the features at a time. Samuel's work pioneered rote learning, generalization, and coevolution. His program employed α-β search, tuned its evaluation function to book games played by checker masters, constructed a library of moves learned by rote, and experimented with nonlinear terms through a signature table. After playing 28 contests against itself, the checker program had learned to play tournament-level checkers, but it remained weaker than the best human players.

For many years it was the chess programs that held the spotlight. The first match between two computer programs was played by telegraph in 1967, when a Russian program defeated an American one 3–1. Although they initially explored a variety of techniques, the most successful chess programs went on to demonstrate the power of fast, deep game-tree search. These included versions of Kaissa, MacHack 6, Chess 4.6, Belle, Cray Blitz, Bebe, Hitech, and a program named Deep Thought, the precursor of Deep Blue. As computers grew more powerful, so did chess-playing programs, moving from Chess 3.0's 1400 rating in 1970 to Deep Blue's championship play in 1997.

BRUTE FORCE WINS THE DAY

Brute force is fast, deep search plus enormous memory directed to the solution of a problem. In checkers and in chess, brute force has triumphed over acknowledged human champions. Both programs had search engines that rapidly explored enormous subtrees, and supported that search with extensive, efficient opening books and endgame databases. Each also had a carefully tuned, human-constructed, heuristic evaluation function, with features whose relative importance were well understood in the human expert community.

In 1994, Chinook became the world's champion checker player, defeating Marion Tinsley (Schaeffer, 1997). Its opening book included 80,000 positions. Its 10-gigabyte endgame database, constructed by exhaustive forward search, included about 443 billion positions, every position in which no more than 8 pieces (checkers or kings) remain on the board. The frequency with which Chinook's search reached these game-theoretic values was in large measure responsible for the program's success.

In 1997 Deep Blue defeated Garry Kasparov, the human chess champion. Deep Blue's custom chess-searching hardware enabled it to evaluate 200 million moves per second, sometimes to depths over 30 ply. In the year immediately before its victory, the program benefited from a substantial infusion of grandmaster-level knowledge, particularly in its evaluation function and its opening book. Deep Blue's endgame database included all chess positions with five or fewer pieces, but it was rarely reached.

SIMULATION AND MACHINE LEARNING, THE ALTERNATIVES

There are, however, games more difficult than chess, games where programs require more than brute force to win. Consider, for example, Shogi and Go, played on the boards in Figures 4(a) and 4(b), respectively. Although the branching factor for chess is 35, for Shogi it is 80–150, and for Go it is 250. Such a large branching factor makes deep search intractable. Games with very long contests also reduce the opportunity for search to reach an endgame database, where the evaluation function would be perfect. For example, the typical checkers contest averages about 100 moves, but the typical Go contest averages more than 300. In games that include imperfect information (e.g. a concealed hand of cards) or nondeterminism (e.g. dice), the

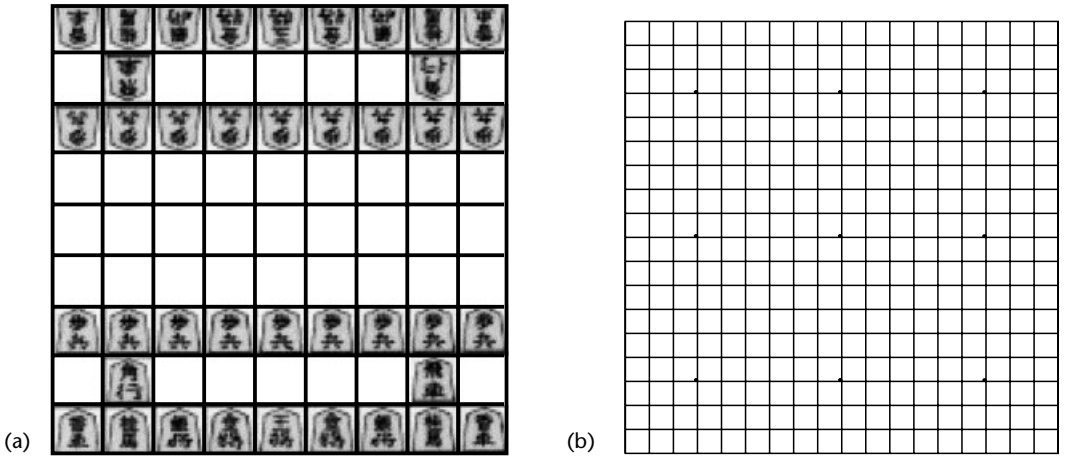

Figure 4. (a) The starting position in Shogi. (b) The Go board.

brute force approach represents each possibility as a separate state. Once again, the branching factor makes deep search intractable. In bridge, for example, after bidding the declarer can see 26 cards, but there are more than 20 million ways the other 26 cards may be distributed between the opponents' hands.

In a game with a very large branching factor, rather than search all possibilities exhaustively, a program can sample the game tree by simulation. Simulation generates the unknown information (e.g. the opponents' hands) at random and evaluates game states based on that assumption. Since a single random guess is unlikely to be correct, simulation is repeated, typically thousands of times. The evaluation function is applied to each state resulting from the same move in the simulated trees, and averaged across them to approximate the goodness of a particular move. Simulation can be extended as many ply as desired. Maven, for example, plays Scrabble®, a game in which contestants place one-letter tiles into a crossword format. Scrabble® is nondeterministic because tiles are selected at random, and it involves imperfect information because unplayed tiles are concealed. Nonetheless, Maven is considered the best player of the game, human or machine (Sheppard, 1999). Instead of deep search, Maven uses a standard, game-specific move generator (Appel and Jacobson, 1988), a probabilistic simulation of tile selection with three-ply search, and the B* search algorithm in the endgame.

When people lack the requisite expert knowledge, a game-playing program can learn. A program that learns, executes code that enables it to process information and reuse it appropriately. Rather than rely upon the programmer's knowledge, such a program instead acquires knowledge that it needs to play expertly, either during competition (*on-line*) or in advance (*off-line*). A variety of learning methods have been directed toward game playing: rote memorization of expert moves, deduction from the rules of a game, and a variety of inductive methods. An approach that succeeds for one game does not necessarily do well on another. Thus a game-learning program must be carefully engineered.

A game-playing program can learn openings, endgame play, or portions of its evaluation function. Openings are relatively accessible from human experts' play. For example, Samuel's checkers player acquired a database of common moves on-line, and Deep Blue learned about grandmasters' openings off-line. Endgame database computations are costly but relatively straightforward; Chinook's endgame database, learned off-line, was essential to its success. In a game whose large branching factor or lengthy contests preclude deep search, however, an endgame database is rarely reached during lookahead.

Machine learning for game playing often focuses on the evaluation function. TD-gammon is one of the world's strongest backgammon players. The mover in backgammon rolls a pair of dice on every turn; as a result, the branching factor is 400, precluding extensive search. TD-gammon models decision-making with a neural network whose weights are acquired with temporal difference learning in millions of contests between two copies of the program. Given a description of the position with human-supplied features, the neural net serves as an evaluation function; during competition, TD-gammon uses it to select a move after a two- to three-ply search (Tesauro, 1995).

Ideally, a program could learn not only weights for its evaluation function, but also the features it references. Logistello plays Othello (Reversi); in 1997 it defeated Takeshi Murakami, the human world champion, winning all 6 contests in the match (Buro, 1998). Logistello's heuristic evaluation function is primarily a weighted combination of simple patterns that appear on the board, such as horizontal or diagonal lines. (Which player has the last move and how far a contest has progressed are also included.) To produce this evaluation function, 1.5 million weights for elaborate conjunctions of these features were calculated with gradient descent during off-line training, from analysis of 11 million positions. Although it uses a sophisticated search algorithm and a large opening book, Logistello's evaluation function is the key to its prowess. Its creator supplied the raw material for Logistello's evaluation function, but the program learned features produced from them, and learned weights for those features as well.

COGNITION AND GAME-PLAYING PROGRAMS

Although no person could search as quickly or recall as accurately as a champion program, there are some aspects of these programs that simulate human experts. A good human player remembers previous significant experiences, as if the person had a knowledge base. A good human player expands the same portion of a game tree only once in a contest, as if the person had a transposition table. A good human player has a smaller, but equally significant, opening book and recognizes and employs endgame knowledge.

There are also features of human expertise that programs generally lack. People plan, but planning in game playing has not performed as well as heuristic search. People narrow their choices, but simulation or exhaustive search, at least for the first few ply, have proved more reliable for programs. People construct a model of the opposition and use it to guide decision-making, but most programs are oblivious of their opposition. People have a variety of rationales for decisions, and are able to offer explanations for them, but most programs have opaque representations. Skilled people remember *chunks* (unordered static spatial patterns) that could arise during play (Chase and Simon, 1973), but, at least for chess programs, heuristic search ultimately proved more powerful. Finally, many people play more than one game very well, but the programs described here can each only play a single game. (One program, Hoyle, learns to play multiple games, but their game trees are substantially smaller than that for chess.)

The cognitive differences between people and programs become of interest in the face of games, such as shogi and Go, games that programs do not yet play well at all. These games do not yield readily to search. Moreover, the construction of a powerful evaluation function for these games is problematic, since even the appropriate features are unknown. In shogi, unlike chess, there is no human consensus on the relative strength of the individual pieces (Beal and Smith, 1998). In Go there are thousands of plausible features (often couched in proverbs) whose interactions are not well understood. Finally, because the endgame is likely to have at least as large a branching factor as earlier positions, the construction of a useful endgame database for either game is intractable. Although both games have attracted many talented researchers and have their own annual computer tournaments, no entry has yet played either game as well as a strong amateur human.

Timed photographs of a chess player's brain demonstrate that perception is interleaved with cognition (Nichelli *et al.*, 1994). Although Go masters do not appear to have chunks as originally predicated (Reitman, 1976), there is recent evidence that these people do see dynamic patterns and readily annotate them with plans. Moreover, Go players' memories now appear to be cued to sequences of visual perceptions. As a result, despite their inferiority for chess programs, work in Go continues to focus on patterns and plans. Another promising technique, foreshadowed by the way human experts look at the Go board, is decomposition search, which replaces a single full search with a set of locally restricted ones (Muller, 1999).

The challenges presented by popular card games, such as bridge and poker, have also received attention recently. Both involve more than two contestants and include imperfect information. Bridge offers the challenge of pairs of collaborating opponents, while poker permits tacit alliances among the contestants. At least one bridge program has won masters' points in play against people, relying on simulation of the concealed card hands. Poker pits a single contestant simultaneously against many others, each with an individual style of play. Poki plays strong Texas Hold'em poker, although not as well as the best humans (Billings *et al.*, 1999). The program bases its bets on probabilities, uses simulation as a search device, and has begun to model its opponents.

Finally, a synergy can develop between game-playing programs and the human experts they

simulate. Scrabble® and backgammon both provide examples. Maven has hundreds of human-supplied features in its evaluation function. The program learned weights for those features from several thousand contests played against itself. Since their 1992 announcement, Maven's weights have become the accepted standard for both human and machine players. Meanwhile, TD-gammon's simulations, known as *rollouts*, have become the authority on the appropriateness of certain play. In particular, human professionals have changed their opening style based on data from TD-gammon's rollouts.

SUMMARY

Game-playing programs are powerfully engineered expert systems. They often have special-purpose hardware, and they employ concise representations designed for efficiency. Where the branching factor permits, a game-playing program relies on fast, deep, algorithmic search, guided by heuristics that estimate the value of alternative moves. If that is not possible, simulation is used to determine a decision. Champion programs play a single game, and benefit from vast stores of knowledge, knowledge either provided by people or learned by the programs from their experience. Nonetheless, challenging games remain, games that humans still play best.

Hill-climbing Search

Intermediate article

CONTENTS

Many computational and cognitive tasks involve a search through a large space of possible solutions. Hill-climbing, or local search, is one strategy for searching such a solution space.

LOCAL VERSUS GLOBAL SEARCH

There are many problems that require a search of a large number of possible solutions to find one that satisfies all the constraints. As a basic example consider the problem of composing a classroom schedule given a set of constraints on the availability of classrooms, and various time constraints involving students and lecturers. Even with a relatively simple set of constraints, one may be forced to search through many possible schedules in order to find one that satisfies all constraints. In certain cases, computer scientists have found clever algorithms to solve such computational problems without having to search through the space of all potential solutions. However, in many other cases, such a search cannot be avoided. We refer to the search space as a *combinatorial* search space. A key question is what is the best way of searching a combinatorial space. The answer often depends on the underlying problem to be solved. In order to illustrate the two main techniques for searching a combinatorial space, we consider the N-queens problem as an example. (*See* **Search**; **Constraint Satisfaction**; **Problem Solving**)

The N-queens problem is that of placing N queens on an N by N chess board, so that no two queens can attack each other. Carl Friedrich Gauss considered this problem in its original form on an 8 by 8 chess board (Campbell, 1977). Given that a queen can move horizontally in its row, it follows that we can have at most one queen in each row. In fact, because we need to place N queens, a solution will require us to place exactly one queen in each row. Similarly, because of the movement of a queen in its column, the placement of queens is such that there is exactly one queen in each column. What makes the problem difficult is the fact that queens can also move diagonally. Therefore, we have to find a placement with exactly one queen per row and column where no two queens share a diagonal.

To search for a solution to the N-queens problem, there are two fundamentally different techniques. Both techniques search through the space of placements of N queens on a chess board, but in dramatically different ways.

One strategy is referred to as a *global* (or *systematic*) search strategy. In this strategy, a solution is constructed incrementally. That is, we place one queen at a time, starting with one in the first row, then one in the second row etc. For each placement, we look for a position in the row that is not under attack from any of the previously placed queens. One difficulty is that after placing several queens, we may be unable find such an 'open' position in a row (i.e. one that is not being attacked). When we encounter such a situation, say in row i, we need to go back to row $i-1$, and shift the queen in that row to another open position in the row. We may find that even with the queen in the new position in row $i-1$, we still cannot place a queen in row i. We then again shift the queen in the $(i-1)^{\text{th}}$ row to another open position. We may, of course, run out of open positions to move to in row $i-1$, in which case we have to revisit the placement of the queen in row $i-2$, etc. The process of shifting previously placed queens is called *backtracking*. We literally revise or 'backtrack' on our earlier placement choices. Such a search technique will eventually search the full space of all possible placements of queens. So, if a solution exists, it will eventually be found. Unfortunately, the search space is exponentially large and a backtrack technique can therefore be quite inefficient. Using sophisticated heuristics to try the 'most promising' available positions first, one can solve the N-queens problem for up to around 100 queens using backtrack search (Stone and Stone, 1987).

Hill-climbing or *local search* provides a very different search strategy for this problem. In a local

search approach, we first start with a 'random' guess at a solution, for example by placing a queen in each row, where the position within a row is chosen randomly. Because of the random placements, it is quite likely that we have one or more pairs of queens that can attack each other either because they share a column or a diagonal. This means that our initial placement does not yet give us a valid solution to the N-queens problem. We now select one of the queens on the board that is under attack from one or more other queens. We move this queen to another location in its row, giving preference to the positions that are not attacked by any other queen. If all positions in a row are under attack, we select a position that is under attack from the least number of queens. If after shifting a queen, which is referred to as a 'local move' or 'local modification', we still have queens under attack, we again select a queen randomly from the ones that are under attack and move that queen, each time trying to further minimize the number of conflicts on the board. This basic strategy is surprisingly effective. It can solve the N-queens problem for over a million queens in less than a minute on a standard PC (Sosic and Gu, 1991; Minton *et al*., 1992).

In general, the key benefits of hill-climbing search are that it requires only a limited amount of memory (only the current state is stored), it is easy to implement efficiently, and, if one or more solutions exists in the search space, hill-climbing search can be surprisingly effective at finding it. Perhaps the first successful use of a hill-climbing strategy was that of Lin and Kernighan (1973; Lin, 1965) for finding good solutions for the traveling salesperson problem. In this problem, the goal is to find the shortest route for a salesperson to take to visit a given set of cities. Starting with an arbitrary tour that visits the cities, Lin and Kernighan showed how one can quickly reduce the length of the tour by making a series of local changes to the route. Since the work by Lin and Kernighan, local search has become one of the main practical techniques for tackling combinatorial optimization problems (Papadimitriou and Steiglitz, 1982).

An important drawback of local search is its inability to detect the unsolvability of a problem instance. That is, if no solution exists, a local search method will simply continue to make local modifications indefinitely. (When dealing with an optimization problem, such as the traveling salesperson problem, the difficulty is that local search cannot be used to determine whether the solution found is globally optimal.) In principle, one could memorize all previously visited problem states and force the local search method to never explore states it has explored before. Provided the local modifications are general enough, such a search would eventually explore the full search space underlying the problem. However, given the combinatorial nature of these problems, this is not feasible on instances of practical interest. Interestingly, for global search techniques, there are memory-efficient ways of keeping track of the space explored so far. Therefore, global search techniques, in contrast to local search methods, can tell us that no solution exists after the method has explored the full search space and no solution has been found.

LOCAL SEARCH STRATEGIES

In hill-climbing search, we are optimizing a certain objective function. For example, in our N-queens problem, our objective function is $O(board) = (N^2/2) - L$, where L is the number of pairs of queens that attack each other on the current board. ($N^2/2$ is the number of pairs of queens.) A solution corresponds to finding a board with the largest possible value for the objective function, i.e. $N^2/2$.

In hill-climbing search, we select any local change that improves the current value of the objective function. *Greedy local search* is a form of hill-climbing search where we select the local move that leads to the largest improvement of the objective function. Traditionally, one would terminate hill-climbing and greedy search methods when no local move could further improve the objective function. Upon termination, the search would have reached a local, but not necessarily global, optimum of the objective function. For many optimization problems, such as the traveling salesperson problem, such a local optimum is quite acceptable, since it often is a reasonable approximation of the global optimum value. However, when a globally optimal solution is required – such as in our N-queens example – local optima present a serious problem for local search methods.

In recent years, it has been found, perhaps somewhat surprisingly, that simply allowing the local search to continue, by accepting 'sideway' or even 'downhill' moves, i.e. local moves to states with, respectively, the same or worse objective values, one can often eventually still reach a global optimum. For example, such 'non-improving' moves are a key component of local search methods for the Boolean satisfiability (SAT) problems, such as GSAT and Walksat (Selman *et al*., 1992, 1994; Gu, 1992). These local search methods for SAT

outperform the more traditional backtrack search strategies for a number of SAT problem classes. Many combinatorial problems can be encoded effectively as Boolean SAT problems, so these local search algorithms provide a general mechanism for solving combinatorial problems.

The local search framework allows for a large number of different realizations, and literally hundreds of variants have been explored over the years. The main variants are tabu search, simulated annealing, and genetic algorithms.

Simulated annealing (Kirkpatrick *et al*., 1983) is another example of a local search technique that incorporates sideway and downhill moves. In simulated annealing, downhill moves are accepted with a probability based on the size of the change in the objective function, with the 'worst' moves becoming the least likely. The fraction of accepted local changes is also controlled by a formal parameter, called the 'temperature'. At a high temperature, almost any possible local move is accepted. When lowering the temperature parameter, fewer moves are accepted that worsen the objective value, and the search starts to resemble a purely greedy strategy. In simulated annealing, inspired by the physical process of annealing, the temperature starts high and is slowly lowered during the search process. Simulated annealing has been successfully applied in a wide range of applications.

In tabu search (Glover, 1989), a 'tabu' list is added to the local search method. The tabu list contains the most recent local moves; the local search method is prevented from undoing those modifications. The tabu list is of limited length, and is updated after each local move. Therefore, any particular change is only prevented for a limited period of time. A tabu list provides a powerful way of forcing a local search method to explore a larger part of the search space.

Another form of local search can be found in so-called genetic algorithms (Holland, 1992). Genetic algorithms are inspired by the natural selection process encountered in evolution. A genetic algorithm can be viewed as a strategy for running a large number of local searches in parallel. Aside from local modifications, the states are also modified through a process called 'crossover', in which states from different local searches are combined to provide a (hopefully) better starting point for a new local search.

Hill-climbing search also has a long tradition in the area of continuous optimization. In continuous search spaces, one generally uses the gradient of the objective function to take local steps in the direction of the greatest possible improvement. There are many refinements on the basic gradient search techniques, such as dynamically varying the local step size during the search (Miller, 2000).

In conclusion, hill-climbing search provides a powerful strategy for exploring combinatorial search spaces. In many applications, hill-climbing outperforms global search. In recent work on randomizing backtrack search methods (Gomes *et al*., 2000), we see how some of the ideas from local search are being used to boost the performance of global search methods.

History of Cognitive Science and Computational Modeling

Introductory article

Whit Schonbein, Washington University, St Louis, Missouri, USA
William Bechtel, University of California, San Diego, California, USA

CONTENTS

The various strands of computational modeling in cognitive science are simultaneously grounded in foundational work in the theory of computation and in recent developments in computational neuroscience and dynamical systems theory. All these approaches face important challenges, and to some degree they stand opposed in their treatment of role of computation in modeling.

COMPUTATION

In 1936 – the birth year of the theory of computation – various strands of mathematical logic had all converged on a common set of questions. Which problems can be solved through a finite number of applications of a finite number of rules? For example, is there a general procedure – an algorithm – for multiplying two integers? Is there an algorithm for deciding whether a given well-formed formula is a theorem of a particular set of axioms? Are there problems that cannot be solved by applying a finite set of rules a finite number of times?

In that year, Alan Turing, Alonzo Church and Emil Post independently proposed equivalent answers. They argued that in fact the power of algorithms is limited. There are problems that cannot be solved in this way. Turing's proof has come to play a central role in current accounts of computation, and therefore deserves special emphasis.

Turing focused on what it was that humans do when they solve calculation problems (such as multiplication or division) using pencil and paper. Turing constructed a formal 'machine' with three parts. The first, corresponding to the paper used by the human, is a 'tape'. The tape is unbounded, or as long as it needs to be (as if the human had as much paper as he or she needed), and divided into discrete squares arranged linearly. Each square can contain a single 'symbol' (e.g. an 'x', a '1', or a squiggle).

The second part of Turing's machine is a 'controller', corresponding to the brain of the human. It is responsible for keeping track of where in a given calculation the machine is at any moment. For example, when multiplying large numbers, one must sometimes carry a digit. In this case, a person would write a numeral on the paper, and make a 'mental note' to add it to the result of the next multiplication. The paper is the tape, and the 'mental note' is a state of the controller. So a Turing machine (TM) would write a symbol (or symbols) to the tape and change the state of the controller to one representing the need to carry.

Finally, corresponding to the eyes and hands of the human, a TM has a read–write head that can read and write symbols from and to the tape. At each moment, the head is over one square of the tape, can read the symbol written on that square, can write a symbol to the square, and can move to another square.

For the TM to actually do anything, we need to specify how it behaves in various circumstances. This is done by means of a 'transition table'. This is a finite collection of rules, each of which is of the form: 'If the current symbol is W_1, and the current controller state is Q_1, then write symbol W_2 to the tape, change to state Q_2, and move the tape head one square to the left or right.'

So a TM is a tape, a controller, a read–write head, and a set of rules describing its behavior. To run a TM, one simply provides it with an input and starts it. The machine continues to follow the rules

contained in its table, until it halts, leaving the result printed on the tape. Thus, after a finite number of applications of a finite number of rules, the TM provides an answer.

Using this formalism, Turing proved a number of interesting results. First, in some cases the TM will not halt – it may continue forever. Second, there are limits to what a TM can do. There are more functions than there are TMs, so there are functions that lack algorithms to compute them; some functions are uncomputable. Finally, Turing demonstrated that it is possible to define a TM that takes as an input the specification of any other TM. This 'universal' TM then simulates the behavior of that other TM. In other words, Turing discovered the possibility of a machine that could be programmed to compute arbitrary Turing-computable functions.

Turing's machines constitute one attempt at formalizing the intuitive notion of an algorithm. Assuming they are adequate, important consequences follow for what can be accomplished using algorithms, for example, not all functions can be calculated using algorithms. Thus the TM constitutes Turing's simple, elegant, and fruitful contribution to mathematical logic. (Other attempts include those of Emile Post and Alonzo Church, both from 1936. Post's formalization has been demonstrated to be equivalent to Turing's; Church's has not.) In addition, however, TMs embody a particular conception of computation: they compute by manipulating symbols stored on a tape according to a set of rules as indicated in the transition table. This conception of computation, as we shall see, is adopted in traditional models in cognitive science.

TURING AND HUMAN INTELLIGENCE

During the Second World War Turing was part of a team at Bletchley Park attempting to break the increasingly complex codes employed in German communications. Turing and his colleagues built a series of machines to aid in the tedious (and otherwise practically impossible) job of considering possible solutions to these cryptographic puzzles. Some of these machines were purely mechanical, but others were composed of electronic components. This experience indicated to Turing the possibility of actually building a general computing device, designed along the lines of the universal TM.

Immediately after the war, Turing was involved in the design and implementation of such a device (the ACE), but he soon lost control of the project to other interested parties. (Similar projects were underway in the United States, leading to the construction of ENIAC and EDVAC. Turing's role in the conception and design of these devices is a matter of some dispute.) However, unlike many of his contemporaries (who saw a general-purpose computer as a way of solving mathematical problems), Turing had a vision of the role the computer could play in the science of human behavior. Turing viewed the human problem-solving capacity – presumed by many to be uniquely human – as nothing more than what TMs do. That is, Turing believed that humans solve problems – they act intelligently – by manipulating symbols according to rules. In a personal letter from 1947, he wrote: 'In working on the ACE I am more interested in the possibility of producing models of the action of the brain than on the practical applications to computing.'

Indeed, the idea that the logical formalization of the notion of an algorithm could be fundamental to the study of human intelligence was in place as early as 1936, when Emil Post proposed a mechanism for computation equivalent to Turing's machines, and possessing the same basic features. Post explicitly considers the relevance of his account for 'psychological fidelity', or the accuracy of its relation to human psychological mechanisms. He proposes that his system captures 'wider and wider formulations', in that extensions will be logically reducible to it. This suggests that his system puts an 'upper limit' on how to conceive of problem-solving, and if this is the case, then the hypothesis is not just a definition or an axiom but a 'natural law'. In other words, Post hypothesizes that no physical device – including human beings – can fail to be describable in terms of one of his systems. By equivalence, this holds for TMs as well. (The thesis that no physical device can compute a function not computable by a TM or Post system is only a hypothesis, and has not been proven.) So the capacity of humans to act intelligently can be accounted for in terms of a system such as those proposed by Turing or Post, i.e., in terms of the manipulation of symbols according to rules.

THE TURING TEST FOR INTELLIGENCE

In 1950, Turing published a provocative paper on the capacity for computers to exhibit human intelligence in which he proposed a 'test' for machine intelligence. Passing this test, he argued, is sufficient for the possession of genuine intelligence.

The test is an imitation game. A human 'examiner' sits in front of a keyboard and screen. By typing questions and reading responses, the examiner can interact with two other entities. One of these entities is a computer programmed to mimic human

responses. The other is an actual human being. The goal of the examiner is to distinguish the human from the computer by their responses to questions the examiner poses. If a computer can fool the examiner into believing it is the human, the computer has passed the 'test', and, according to Turing, is intelligent. Turing predicted that computers would pass the test by the year 2000.

Much can be (and has been) said about the Turing test. Some have objected that the test measures only verbal behavior and ignores other possible indicators of intelligence, such as a capacity to construct tools, navigate in messy environments, engage in long-term planning, or interact in social groups. Furthermore, it neglects the actual processes by which humans manifest the intelligent behaviors they do.

The distinction here is between systems that behave intelligently because they execute the same processes by which humans achieve that behavior, and systems that 'merely' behave intelligently. John Searle has called this the distinction between 'strong' and 'weak' artificial intelligence (AI). Suppose, for example, that we have a computer that can pass the Turing test in the restricted domain of reading a story and answering questions about it. According to Searle, if the program mimics the relevant human behavior (i.e., answers the questions as a human would), then it is a successful instance of weak AI. In contrast, strong AI requires that the computer actually be intelligent in the way we are. Thus, it would have to understand the story and employ that understanding in answering the questions.

In strong AI, the computer program is a model of the psychological processes underlying the production of intelligent behavior in human beings. The program explains how humans behave by making explicit the symbols (and collections of symbols) that humans think with, and the rules they use to manipulate them. Indeed, this was the goal of a summer workshop held at Dartmouth University in the summer of 1956, which gave birth to the discipline of artificial intelligence. According to the original proposal, the workshop's aim was to pursue the hypothesis that 'every aspect of learning or any other feature of intelligence can in principle be so precisely described that a machine can be made to simulate it'. This is essentially Turing's prophecy of 1950.

THE 'GENERAL PROBLEM SOLVER'

At the 1956 Dartmouth workshop, Alan Newell and Herbert Simon demonstrated their 'logic theorist', which constructed its own proof of a theorem from Whitehead and Russell's *Principia Mathematica*. It was the first AI system actually implemented in a physical machine. Newell and Simon's goal was not merely to have the program construct proofs, but to generate them in the same way that humans do, thereby realizing strong AI.

In 1963, Newell and Simon extended their endeavor beyond logic to reasoning in general with their 'general problem solver' (GPS). This employs a set of symbols that designates a solution to a problem (e.g. a theorem in sentential calculus) and a set of symbols that constitutes the current knowledge possessed by the system (e.g. a set of axioms). Its goal is to generate the solution by applying a finite number of rules to the initial knowledge base. For example, to make a move in chess, it would begin with a symbolic representation of the initial board configuration and apply various operations to it that would correspond to legal moves, and other rules that evaluated the positions they generated (with the ultimate goal of checkmate). In this way, intelligent behavior is conceived of as a search through a problem space. Newell and Simon recognized that 'blind' search is too costly, and proposed that intelligence does not result from considering all possible operations, but rather in choosing the best rules to apply in a given situation. Thus GPS uses a heuristic, or 'rule of thumb', for selecting a rule to apply. GPS compares representations of its goal state and current state, determines the differences, and identifies which of its stored rules would be most likely to minimize these differences. This process is repeated until the solution is reached. Such 'means–ends analysis' is only one of a number of possible ways to make a search through a problem space more efficient and more 'clever'.

Protocol Analysis

To support their claim that GPS is a model of human problem-solving, Newell and Simon compared its behavior with how humans solve the same problems, using a process called protocol analysis. A subject is given a problem, such as transforming one logical expression into another using a finite set of valid rules, and asked to report aloud their thoughts as they solve the problem. A 'protocol' is then a verbatim record of all that the subject or the experimenter said during the experiment. The protocol is compared to a 'trace' of GPS's performance (i.e. a report of the rules it applied in order to generate the solution). Newell and Simon held that if the trace were close enough to the

protocol then the program would constitute a good theory of the subject's problem-solving. Although 'logic theorist' did not fit the behavioral data, GPS exhibited some interesting correspondences.

Physical Symbol Systems

In their 1976 address to the Association for Computing Machinery, Newell and Simon characterized GPS and computational systems like it as 'physical symbol systems', which they define as follows:

> A physical symbol system consists of a set of entities, called symbols, which are physical patterns that can occur as components of another type of entity called an expression (or symbol structure). Thus a symbol structure is composed of a number of instances (or tokens) of symbols related in some physical way (such as one token being next to another). At any instant of time the system will contain a collection of processes that operate on expressions to produce other expressions: processes of creation, modification, reproduction, and destruction. A physical symbol system is a machine that produces through time an evolving collection of symbol structures.

Several points in this passage need clarification.

First, the distinction Newell and Simon make between symbols and symbol strings has been left implicit in the above accounts, but the basic idea can be illustrated through a simple example. Suppose we have the symbols 'A', '&', and 'B'. These symbols can be arranged in different ways – one way is to concatenate them: 'A & B'. Newell and Simon note that operations transform complexes of symbols. For example, a rule might transform 'A & B' to 'A'. This is in contrast to the basic definition of a TM, which defines rules over single symbols. However, as Turing pointed out in his 1936 article, the definition of a TM allows one to use finite sequences of rules to simulate the operation of a single rule defined over symbol strings. For example, if a system has a rule that transforms 'A & B' to 'A', a TM might use four rules: three to erase the individual symbols 'A', 'B', and '&', and one to write 'A'. It is this capacity that allows one to abstract symbols away from whatever primitives a particular machine might use (just as we treat the ones and zeros in a computer as characters, numbers, addresses, and so on, rather than just as strings of ones and zeros.)

Secondly, the definition of a physical symbol system says nothing about what a set of symbols means. For example, the collection of words 'There's gold in them than hills' is a collection of symbols (words) related to one another (through concatenation) in a structure (a sentence). And it clearly means something – in English. But there is nothing about its being part of a physical symbol system that makes it have the meaning it does: the meaning of that collection of symbols is open. Therefore, transformations over expressions do not depend on the meanings of the symbols but simply on their form. That is, transforming 'A & B' into 'A' depends on the fact 'A' is next to '& B', not on anything these symbols might mean.

Finally, the definition is silent on the question of how to choose the appropriate rule. Newell and Simon address this question in a separate hypothesis, the 'heuristic search hypothesis':

> The solutions to problems are represented as symbol structures. A physical symbol system exercises intelligence in problem-solving by search – that is, by generating and progressively modifying symbol structures until it produces a solution structure.

Having characterized physical symbol systems, Newell and Simon make the following strong claim: 'A physical symbol system has the necessary and sufficient means for general intelligent action'. In other words, physical symbol systems provide resources sufficient for manifesting intelligent behavior, and furthermore, all intelligent behaviors are necessarily the product of a physical symbol system. The first claim is consistent with weak AI. The second, however, is a clear declaration of strong AI. Returning to the GPS as a theory of human problem-solving, the claim becomes that the reason human subjects exhibit behavior that corresponds with the trace of GPS solving the same problem is that those individuals realize a physical symbol system like the one implemented in GPS. GPS is not merely a way to mimic human behavior, it is a way of explaining the mechanisms underlying that behavior.

COMPUTATIONAL MODELS OF LANGUAGE PROCESSING

Since language use is a quintessentially intelligent human activity, it provides a natural target of computational modeling. One goal has been to devise computational systems that can understand sentences presented in a natural language such as English, and one measure of understanding is the ability of the system to generate reasonable responses to such sentences.

Language processing programs developed in the 1960s used relatively simple template matching. For example, Bert Green's BASEBALL program answers questions about one season of American League games by transforming simple queries into

a canonical form, and using this form to search a prespecified database. Bertram Raphael's SIR program matches English inputs to templates (e.g., * IS PART OF *, HOW MANY * DOES * HAVE?). If the input is declarative, it extracts the symbol string for later use in answering queries; if the input is a question, it searches stored strings for an appropriate response. Daniel Bobrow applied the same approach in his program STUDENT, designed to solve high school algebra story problems. The most famous of the template matching language processing systems is Joseph Weizenbaum's ELIZA, which simulates a (Rogerian) therapist by extracting pre-identified terms from the user's inputs and using these to formulate questions to continue the 'dialogue'. The system includes a number of 'tricks' that allow the substitution of one term for another (e.g. 'mother' for 'family'), yielding a modicum of unpredictability in its responses.

These relatively simple systems were followed in the 1970s by more substantial programs, three of which are described here.

SHRDLU

Terry Winograd objected to the exclusive emphasis on syntax in the programs described above. He proposed that to really understand language, a program also must have access to the meanings of words. He designed SHRDLU with this in mind. SHRDLU both answered questions and could 'manipulate' a simulated world made of blocks. For example, SHRDLU could answer the question whether there was a blue box under a green pyramid, or could stack a blue pyramid on a yellow box.

Winograd used procedural representations to capture aspects of the meaning of terms or phrases in English. Roughly speaking, he attached actions to words. For example, the concept CLEARTOP (associated with commands to move a block, or to determine whether a block has anything on top of it) can be used to describe a situation (i.e., as a predicate), but, if false, can also be 'run' so as to generate a sequence of actions that result in the desired block being clear on top.

Although SHRDLU is limited to 'toy problems', by linking words to actions and thereby incorporating information beyond that contained in the syntax of the natural language it represented a clear advance over template-matching approaches. Subsequent language understanding programs have followed the approach of supplementing syntactic information with rich internal representations so as to expand their behavioral repertoires.

MARGIE

In his book *Conceptual Information Processing*, Roger Schank expressed the view that the basis of human thought is 'a representation of meaning of natural language that does not involve any of the words of the language'. This language-free representation is an 'interlingua' – so named because of its possible role as an intermediary in translating between natural languages. Thus it 'should be extractable from any language and be capable of being generated into any other language'. In a later work, Schank and his colleague Robert Abelson express this view in their 'basic axiom' of conceptual dependency: 'For any two sentences that are identical in meaning, regardless of language, there should be only one representation'. MARGIE was an attempt to put this principle into practice.

When presented with a sentence in English, MARGIE extracts a conceptual dependency representation: a symbol structure that captures the meaning of the sentence, rather than its syntactic profile. This involves, for example, representing the roles of agent and patient. Furthermore, as Schank and Abelson note, MARGIE operates on the principle that 'any information in a sentence that is implicit must be made explicit in the representation of the meaning of that sentence'. Thus, if MARGIE is presented with the sentence 'Bob smokes a cigarette', the system constructs a representation that includes implicit information such as the fact that MOUTH is the recipient of the cigarette smoke.

SAM

Semantics is attached not only to words or sentences, but also to larger units such as paragraphs or pages. To deal with these, Schank and Abelson developed SAM, a program designed to read and understand stories. They proposed that stories are organized around 'scripts', or prototypical scenarios. When one hears about a person going to a restaurant, one expects the person to be seated, to be given a menu, to have his or her order taken by a waiter or waitress, to have food delivered, to eat the food, to be presented with a bill, and to pay the bill before leaving. All of these are stereotypical components of a visit to a restaurant.

Schank and Abelson proposed that scripts could be realized as abstract data structures that included representations of the components, with slots and default fillers for the various ways these components might be filled. When SAM reads a story, it encodes the events in such a script. Using the default slot fillers, it is able to make inferences from

partial accounts of actions in a given setting. For example, if a story states that Dabney entered a restaurant, ordered a hamburger, and caught the 6 o'clock bus, SAM can infer that Dabney ate the hamburger, since this is part of the script. In addition to scripts, Schank and Abelson found that other conceptual dependency data structures were also useful. For example, 'plans' were used to help SAM to identify the goals of the main actors and to propose actions required to fulfill them. By using plan structures, SAM could guess what an agent would do next.

Both MARGIE and SAM are exercises in strong AI. As accounts of human cognition, they propose that conceptual dependency representations are what humans think with and that understanding the meaning of a sentence involves forming such a representation.

Like GPS, these programs all work by manipulating symbols and collections of symbols according to sets of rules. What was innovative was the kind and extent of the information that the programmers encoded in these symbols, structures, and rules. This observation brings us to two important challenges to strong AI: the frame problem, and Searle's Chinese room argument.

THE FRAME PROBLEM

In essence, the frame problem is the problem of determining what information is relevant to a given task. This difficulty is apparent in MARGIE: by following conceptual dependencies between internal representations, the system is designed to make information implicit in a sentence explicit. But this process could go on indefinitely: with the sentence 'Bob smokes a cigarette', MOUTH is the recipient of the smoke, so TEETH come in contact with the smoke, so they turn more BROWN, and so on. One solution is simply to place an arbitrary limit on the length of inferential chains. But given a large knowledge base, even series of limited length may result in an infeasibly large number of inferences being explored – so large, indeed, that effective action may be blocked. This is especially important in real-world contexts, which usually have built-in time constraints.

The frame problem runs even deeper than this. Not only must an intelligent system determine which of the facts it possesses are relevant to a given task; it must also decide which changes in the world are relevant. For example, when SHRDLU clears the top of one block, its actions may cover the top of another. If this other block is relevant to the task, SHRDLU must detect this; otherwise the change should be ignored. But how do we determine whether a fact should be ignored? We might add a rule (a 'frame axiom') to the effect that, if the task is of a certain sort, and the fact has a certain feature, then it is not relevant. But adding more rules to cover judgments of relevance is tantamount to adding more inferences that must be explored: so, instead of simply inferring that Bob's teeth turn brown, MARGIE might expend resources inferring that the fact that their brownness is irrelevant to the current task (or not). In general, the problem is successfully keeping track of relevant changes while discarding irrelevant ones, without a rampant proliferation of frame axioms.

In some ways the frame problem is a practical problem for which the solution is to design more effective abstract representations of knowledge and heuristics for the manipulation of those representations, and a wide variety of solutions have been proposed. Some theorists, however, have suggested that the frame problem is intrinsic to – and unsolvable by – traditional computational approaches to cognitive modeling: that it is the reliance on the rule-based manipulation of representations that generates the frame problem, and therefore an alternative approach must be adopted. A second challenge to traditional strong AI – the Chinese room argument – can be interpreted as leading to a similar conclusion.

THE CHINESE ROOM ARGUMENT

In 1980, John Searle proposed a criticism of strong AI in an argument as simple and as elegant as Turing's machine. Searle offered the following simple thought experiment. You are a native English speaker, and have no knowledge of Chinese. You sit in an empty room, where there is a slot in one wall. Three batches of cards are passed through the slot. The first is a set of Chinese characters. By hypothesis, they are meaningless to you. The second is another collection of Chinese characters, together with some rules in English (which you understand, of course), instructing you how to correlate the new batch of Chinese characters with those of the first. Finally, more Chinese characters are fed through the slot, along with some further instructions in English. These instructions tell you how to correlate the newly arriving symbols with those of the first two batches and sometimes to feed cards containing Chinese characters back through the slot.

Unbeknown to you, the first batch of Chinese characters was a *script*, the second batch was a story, and the third batch was a set of questions.

By virtue of the rules you followed, the characters you fed back out through the slot were cogent answers to these questions. However, you did not know what any of the Chinese characters meant, so you did not understand the story.

Searle concludes that strong AI is effectively refuted. First, neither you in the Chinese room nor SAM understands the stories you have read. Since you can realize SAM without understanding the story, realizing SAM is not sufficient for understanding. Secondly, since there is no relation between realizing SAM and understanding the story, there is no reason to think that running a program like SAM is necessary for understanding.

Searle thus rejects the fundamental idea, evinced by Turing, Post, Newell, Simon, Schank and others, that human cognitive processes can be captured by appeals to the manipulation of symbols according to rules. When you manipulate Chinese characters according to the rules given in English, you cannot identify those characters in terms of what they mean since, by hypothesis, you do not understand Chinese. The same holds for TMs as well. A rule in a TM transition table operates over controller states and symbols. Symbols are not distinguished on the basis of what they might mean, but rather on their formal properties. Likewise, physical symbol systems are defined in terms of purely formal symbols, and so are the language processing systems considered above. Searle's claim is therefore that human psychological states such as understanding cannot be accounted for by rules that transform symbols.

If not symbol manipulation, then what does explain the understanding achieved by cognitive agents? Searle suggests that we need to stop thinking in terms of computation and consider the physical properties of the brain. But there is another possibility: to examine the computational capacities of the brain. One approach to this task is to design and study the capacities of artificial brains.

EARLY NEURAL NETWORKS

In 1943, inspired by the work of Turing, the neurophysiologist Warren McCulloch and the logician Walter Pitts formulated a model for computing using networks of artificial neurons. An artificial neuron could receive input from others, and when the sum of the inputs to it exceeded a specified threshold, it would 'fire' and pass input to other neurons to which it was connected. McCulloch and Pitts proved that networks of these elements were equivalent to finite state automata (essentially, TMs without a tape), and suggested that, with the addition of a tape, they would be the same as Turing machines.

Although McCulloch and Pitts were initially interested in instantiating logic operations in a network, they and others soon began to explore the capacities of networks more broadly. In particular, researchers began to think of networks as devices that could 'learn' to perform desired mappings between inputs and outputs by modifying the strengths of connections between units. In 1949, Donald Hebb proposed what has turned out to be a powerful rule for adjusting weights. In essence, it allows for the strengthening of connections between units whenever they are both active together ('units that fire together wire together').

In 1962, Frank Rosenblatt introduced the formal notion of a 'perceptron', a network of linear-threshold artificial neurons (similar to those of McCulloch and Pitts) in which some constituted an input layer, others an output layer, with connections between input and output units. Rosenblatt introduced a learning algorithm that he proved would allow these networks to learn any mapping for which there was a possible set of weights. In particular, Rosenblatt trained perceptrons to classify various characters presented on a two-dimensional array.

Initially perceptrons seemed to offer great potential as tools for modeling cognitive operations; but in 1969 Marvin Minsky and Seymour Papert demonstrated that there was a large class of problems that could not be solved by (two-layer) perceptrons. An example is the logical 'exclusive or' operation, whose value is true when one proposition is true and the other false. The values of weights required to determine the proper output for some instances (both true) is incompatible with those required for other instances (both false). Technically, these are known as problems that are not linearly separable.

Minsky and Papert's objections focused not only on nonlinear problems. In some cases, perceptrons were able to learn a problem at a small scale, but unable to learn the problem at a larger scale. The reason, they argued, is that the learning procedure used by perceptrons suffers from exponential growth. That is, as the size n of the problem (e.g. the size of the image to be classified) increases, the amount of processing required of the perceptrons increases exponentially (as x^n where x is some constant): thus, the amount of processing required quickly becomes infeasible. Partly as a result of Minsky and Papert's analysis, interest in artificial neural networks waned for over a decade.

CONNECTIONISM

Rosenblatt (as well as Minsky and Papert) recognized that by inserting an additional layer of units (known as hidden units) between input and output units, one could overcome the problem of linear separability. But he failed to discover a learning rule that could determine the appropriate weights feeding into the hidden units. In 1986 three researchers independently discovered such a learning rule (back propagation). In the same year, a two-volume compilation of articles edited by David Rumelhart and James McClelland entitled *Parallel Distribution Processing: Explorations in the Microstructure of Cognition* heralded the revival of interest in artificial neural networks. Such 'connectionist' networks have since been employed to model a great variety of cognitive activities, including simple pattern matching or pattern detection, but also including cognitive tasks like problem-solving and reasoning that had been the preserve of symbolic models. However, one of the problems noted by Minsky and Papert is still unresolved: how to scale from 'toy' problems to the sorts of problems that real cognitive agents confront.

The rapid expansion of connectionist modeling in the cognitive sciences raises a basic theoretical question: do these models count as computational? Since, prima facie, they do not operate by manipulating symbols according to rules, they do not compute in the same manner as Turing machines or symbolic models. But they are frequently employed for similar problems (including problems of cognitive modeling). Moreover, under appropriate constraints, they can perform the same input–output mappings as symbolic systems, and indeed they can be configured to literally implement a Turing machine. Some theorists argue that it is only at a high level that they are characterizable in terms of symbol processing, proposing that instead they should be viewed as performing subsymbolic computation.

In part, the question of whether connectionist networks are computational is a semantic issue that depends on how 'computation' is defined. But one idea that has been proposed by some theorists is that by construing neural networks as computational devices, we increase the range of computable functions. If we follow Turing and Post in thinking of human cognition in terms of computing function, this raises the possibility that their hypothesis that Turing- or Post-computable functions set an upper bound on what humans could do may be false: neural networks may be able to do things – realize and explain behaviors – that traditional computational automata cannot.

Expanding the notion of computation, however, is not without cost. If whatever any physical device does is construed as computation, then characterizing an activity as computation becomes vacuous. This concern is illustrated by a recent challenge to both symbolic and connectionist models of cognition.

THE DYNAMICAL APPROACH

A number of theorists have recently argued that computational approaches to modeling cognition are misguided. They propose instead that cognitive science should follow the model of physics, where explanation consists of putting forward a set of equations describing a system's behavior. In 1995, Timothy van Gelder illustrated the contrast between the computational and dynamical approaches by describing two ways in which James Watt could have designed a governor to control the steam flow in a steam engine. Had Watt been a computer programmer, he could have written a symbolic program that would have regularly calculated the difference between the target speed of the engine and the actual speed and determined how much to open or close the value in order to reduce the difference to zero. In fact, Watt designed a physical device in which a spindle with arms was attached to the flywheel of the engine. Centrifugal force caused the arms to open or close in proportion to the engine's speed. All Watt then needed to do was add a mechanical linkage so that when the arms opened too far, the opening of the steam valve was reduced, and when they closed too far, it was increased. Van Gelder argued that Watt's solution was not merely a necessity given inadequate computational devices, but in fact was a superior solution.

Van Gelder's argument raises two questions. The first is whether a mechanical solution such as Watt's can be extended to human cognition, where reasoning and planning are the objects of interest: recall that Turing and Post developed their conception of computation by reflecting on these sorts of human activities. The second is whether the Watt governor and the various dynamical systems that have been proposed to account for cognition really are noncomputational. One common strategy to account for why these devices achieve their purposes is to try to understand their intermediate states in terms of what information

they carry (the angle of the arms carries information about the speed of the flywheel) and how the system then utilizes the information to generate behavior. Giving such accounts seems to require us to construe the devices as computational. This response, however, seems almost to imply that every physical system is computational. Thus, the problem remains of specifying just what constitutes computation.

Implicit Learning Models

Intermediate article

Axel Cleeremans, Université Libre de Bruxelles, Brussels, Belgium

CONTENTS

Implicit learning is the process through which we become sensitive to certain regularities in the environment (1) in the absence of intention to learn about those regularities, (2) in the absence of awareness that one is learning, and (3) in such a way that the resulting knowledge is difficult to express.

INTRODUCTION

Implicit learning – broadly construed, learning without awareness – is a complex, multifaceted phenomenon that defies easy definition. Frensch (1998) lists as many as eleven definitions in a recent overview – a diversity that is undoubtedly symptomatic of the conceptual and methodological challenges that continue to pervade the field 35 years after the term first appeared in the literature (Reber, 1967). According to Berry and Dienes (1993), learning is implicit when we acquire new information without intending to do so, and in such a way that the resulting knowledge is difficult to express. In this, implicit learning thus contrasts strongly with explicit learning (e.g. as when learning how to solve a problem or learning a concept), which is typically hypothesis-driven and fully conscious.

Since the early 1990s, the field of implicit learning has come to embody ongoing questioning about three fundamental issues in the cognitive sciences, namely (1) consciousness (how we should conceptualize and measure the relationships between conscious and unconscious cognition); (2) mental representation (in particular the complex issue of abstraction); and (3) modularity and the architecture of the cognitive system (whether one should think of implicit and explicit learning as being subtended by separable systems of the brain or not). Computational modeling plays a central role in addressing these issues, most importantly by offering principled ways of deconstructing early characterizations of implicit learning as involving the unconscious acquisition of abstract knowledge.

IMPLICIT COGNITION: THE PHENOMENA

Everyday experience suggests that implicit learning is a ubiquitous phenomenon. For instance, we often seem to know more than we can tell. Riding a bicycle, playing tennis or driving a car all involve mastering complex sets of motor skills that we find very difficult to describe verbally. These dissociations between our ability to report on cognitive processes and the behaviors that involve these processes are not limited to action but also extend to high-level cognition. Most native speakers of a language are unable to articulate the grammatical rules they nevertheless follow when uttering expressions of the language. Likewise, expertise in domains such as medical diagnosis or chess, as well as social or esthetic judgments, all involve intuitive knowledge that one seems to have little introspective access to.

We also often seem to tell more than we can know. In a classic article, social psychologists Nisbett and Wilson (1977) reported on many experimental demonstrations that verbal reports on our own behavior often reflect reconstructive and interpretative processes rather than genuine introspection. While it is generally agreed that cognitive *processes* are not in and of themselves open to any sort of introspection, Nisbett and Wilson (1977) further claimed that we can sometimes be '(a) unaware of the existence of a stimulus that importantly influenced a response, (b) unaware of the existence of the response, and (c) unaware that the stimulus has affected the response' (p. 231).

Demonstrations of dissociations between subjective experience and various cognitive processes have now been reported in many domains of cognitive science. For instance, dissociations have been reported between conscious awareness and memory. Memory for previous events can be expressed explicitly, as a conscious recollection, or implicitly, as automatic, unconscious influences on behavior. Numerous studies have demonstrated dissociations between implicit and explicit memory, both in normal participants (see Schacter, 1987) as well as in special populations. Amnesic patients, for instance, who exhibit severe or total loss in their ability to explicitly recall previous experiences (conscious recollection) nevertheless retain the ability to learn novel procedural skills or to exhibit sensitivity to past experiences of which they are not conscious.

Findings of 'learning without awareness' have also been reported with normal subjects (Cleeremans *et al*., 1998). It is Arthur Reber, in a classic series of studies conducted in 1965 (Reber, 1967), who first suggested that learning might be 'implicit' to the extent that people appear to be able to learn new information without intending to do so and in such a way that the resulting knowledge is difficult to express. Implicit learning contrasts with implicit memory in that it typically involves sensitivity to relationships between events rather than sensitivity to single events, and with subliminal perception in that it typically involves supra-liminal stimuli.

Implicit learning research has essentially been focused on three experimental paradigms: artificial grammar learning, dynamic system control, and sequence learning. Additional paradigms that will not be discussed further include probability learning, hidden covariation detection, acquisition of invariant characteristics, or visual search in complex stimulus environments.

In Reber's seminal study of artificial grammar learning (Reber, 1967), subjects were asked to memorize meaningless letter strings generated by a simple set of rules embodied in a finite-state grammar (Figure 1). After this memorization phase, subjects were told that the strings followed the rules of a grammar, and were asked to classify novel strings as grammatical or not. In this experiment and in many subsequent replications, subjects were able to perform this classification task better than chance despite remaining unable to describe the rules of the grammar in verbal reports. This dissociation between classification performance and verbal report is the finding that prompted Reber to describe learning as implicit, for subjects appeared sensitive to and could apply knowledge that they remained unable to describe and had had no intention to learn.

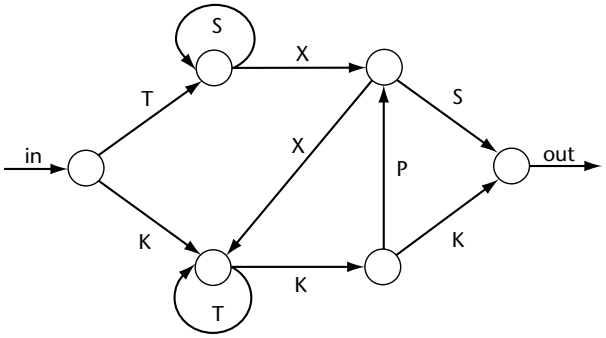

Figure 1. A finite-state grammar is a simple directed graph consisting of nodes connected by labeled arcs. Sequences of symbols can be generated by entering the grammar through an 'in' node, and by moving from node to node until an 'out' node is reached. Each transition between a node and the next produces the label associated with the arc linking the two nodes. Concatenating the symbols together produces strings of symbols, in this case letters of the alphabet.

In a series of studies that attracted renewed interest in implicit learning, Berry and Broadbent (1984) showed that success in learning how to control a simulated system (e.g. a 'sugar factory') so as to make it reach certain goal states was independent from ability to answer questions about the principles governing subjects' inputs and the system's output. Practice selectively influenced ability to control the system, whereas verbal explanations about how the system works selectively influenced ability to answer questions.

Today, in 2002, another paradigm – sequence learning – has become dominant in the study of implicit learning. In sequence learning situations (Clegg *et al*., 1998), participants are asked to react to each element of a sequentially structured visual sequence of events in the context of a serial reaction time task. On each trial, subjects see a stimulus that appears at one of several locations on a computer screen and are asked to press as fast and as accurately as possible on the key corresponding to its current location. Nissen and Bullemer (1987) first demonstrated that subjects progressively learned about the sequential structure of the stimulus sequence in spite of showing little evidence of being aware that the material contained structure. Numerous subsequent studies have indicated that subjects can learn about complex sequential relationships despite remaining unable to fully deploy this knowledge in corresponding direct tasks.

DEMONSTRATING IMPLICIT COGNITION

These findings all suggest that unconscious influences on behavior are pervasive. This raises the question of how to best characterize the relationships between conscious and unconscious processes, and in particular whether one should consider that mental representations can be unconscious. Because there is no accepted operational definition of what it means for an agent to be conscious of something, three challenges need to be overcome when attempting to contrast conscious and unconscious cognition: a definitional challenge (what is it that we want to measure?), a methodological challenge (which measure offers an appropriate index of awareness?), and a conceptual challenge (what are the implications of dissociation findings?).

The Definitional Challenge

Addressing this first challenge involves delineating which aspects of consciousness 'count' when assessing whether a subject is aware or not of a particular piece of information: awareness of the presence or absence of a stimulus, conscious memory for a specific previous processing episode, awareness of one's intention to use some information, or awareness that one's behavior is influenced by some previous processing episode. Consciousness is not a single process or phenomenon, but rather encompasses many dimensions of experience. Different aspects of conscious processing are thus engaged by different paradigms. In subliminal perception studies, for instance, one is concerned with determining whether stimuli that have not been consciously encoded can influence subsequent responses. In contrast, implicit memory research has been more focused on retrieval processes, that is, on the unintentional, automatic effects that previously consciously perceived stimuli may exert on subsequent decisions. In studies of implicit learning, it is the relationships between ensembles of consciously processed stimuli that remain purportedly unconscious.

These subtle differences in which specific aspects of the situation are available to awareness emphasize the need to distinguish carefully between awareness during encoding and awareness during retrieval of information. Further, both encoding and retrieval can concern either individual stimuli or relationships between sets of stimuli, and both can either be intentional or not. Even so, there is continuing disagreement about exactly which criteria for conscious awareness should be used. In a recent review for instance, Butler and Berry (2001) found little evidence for implicit memory if one takes 'implicit' to imply that performance (1) results from an unintentional retrieval strategy, and (2) is not accompanied by conscious recollection. Likewise, in a landmark review article dedicated to implicit learning, Shanks and St. John (1994) failed to identify convincing evidence for learning without awareness and therefore concluded that 'Human learning is almost invariably accompanied by conscious awareness' (p. 394).

The Methodological Challenge

This second challenge consists of devising an appropriate measure of awareness. Most experimental paradigms dedicated to exploring the relationships between conscious and unconscious processing have relied on a simple quantitative dissociation logic aimed at comparing the sensitivity of two different measures to some relevant information: a measure *C* of subjects' awareness of the information, and a measure *P* of behavioral sensitivity to the same information in the context of some task. Unconscious processing, according to the quantitative dissociation logic, is demonstrated whenever *P* exhibits sensitivity to some information in the absence of correlated sensitivity in *C*. There are several important pitfalls with this reasoning, however.

First, the measures *C* and *P* cannot typically be obtained concurrently. This 'retrospective assessment' problem (Shanks and St. John, 1994) means that finding that *C* fails to be sensitive to the relevant information need not necessarily imply that information was processed unconsciously during encoding, but that, for instance, it might have been forgotten or otherwise distorted before retrieval. It is therefore important, but often impossible – short of resorting to on-line measures of awareness such as are made possible through brain imaging techniques – to obtain concurrent measures of learning and awareness, partly because measuring awareness concurrently to processing entails a form of 'observer paradox' in which what is measured comes to be influenced by the measurement itself.

A second issue is to ensure that the information revealed through *C* is in fact relevant to perform the task. As Shanks and St. John (1994) suggested, many studies of implicit learning have failed to respect this 'information' criterion. For instance, successful classification in an artificial grammar learning task need not necessarily be based on

knowledge of the rules of the grammar, but can instead involve knowledge of the similarity relationships between training and test items. Subjects asked about the rules of the grammar would then understandably fail to offer relevant explicit knowledge, not because they have no awareness of the relevant rules, but simply because these rules are not necessary to perform the classification task successfully.

A third issue is to ensure that *C* and *P* are both equally sensitive to the relevant information (the 'sensitivity' criterion; Shanks and St. John, 1994). At first sight, verbal reports and other *subjective measures* such as confidence ratings would appear to offer the most direct way through which to assess the contents of subjective experience. The use of subjective measures to assess awareness was first advocated by Cheesman and Merikle (1984), who also introduced the notions of subjective and objective thresholds. Performance on a given task (i.e. identification) is said to be below the subjective threshold if one can show that performance is better than chance while subjects indicate they are guessing through subjective measures such as confidence judgments. Performance is said to be below the objective threshold if it fails to differ from chance on *objective measures* of awareness such as forced-choice tests (e.g. recognition, presence-absence decisions, or identification). Unconscious perception, for instance, would thus be demonstrated whenever performance is below the subjective threshold and above the objective threshold. This logic can also be applied to the domain of implicit learning, and several studies have now applied these ideas in the domains of artificial grammar learning and sequence learning. Overall, these studies indicate that the knowledge acquired by participants in these empirical situations can indeed be implicit to the extent that it is 'below the subjective threshold'.

Even if the different criteria briefly overviewed above are fulfilled, however, it might be optimistic to hope to be able to obtain measures of awareness that are simultaneously *exclusive* and *exhaustive* with respect to knowledge held consciously. In other words, finding null sensitivity in *C*, as required by the dissociation paradigms for unconscious processing to be demonstrated, might simply be impossible because no such absolute measure exists. A significant implication of this conclusion is that, at least with normal participants, it makes little sense to assume that conditions exist where awareness can simply be 'turned off'.

It might therefore instead be more plausible to assume that any task is always sensitive to both conscious and unconscious influences. In other words, no task is *process-pure*. Hence, according to this logic, even performance on forced-choice, objective tests such as recognition might be influenced by unconscious influences. These tests could therefore overestimate explicit knowledge. This is the *contamination* problem. Two methodological approaches that specifically attempt to overcome the conceptual limitations of the dissociation logic have been developed.

The first approach was introduced by Reingold and Merikle (1988), who suggested that the search for absolute measures of awareness should simply be abandoned in favor of approaches that seek to compare the sensitivity of *direct* measures and *indirect* measures of some discrimination. Direct measures involve tasks in which the instructions make explicit reference to the relevant discrimination, and include objective measures such a recognition or recall. In contrast, indirect measures, such as stem completion in memory tasks, make no reference to the relevant discrimination. By assumption, direct measures should exhibit greater or equal sensitivity than indirect measures to consciously held task-relevant information, for subjects should be expected to be more successful in using conscious information when instructed to do so than when not. Hence, demonstrating that an indirect task is more sensitive to some information than a comparable direct task can only be interpreted as indicating unconscious influences on performance. This 'relative sensitivity approach' has been successfully applied in the study of subliminal perception and implicit memory. Jiménez *et al*. (1996) first applied this logic to the study of implicit learning by comparing direct and indirect measures of the knowledge acquired by participants trained on an SL (sequence learning) task. Using detailed correlational analyses, Jiménez *et al*. were able to show that some sequence knowledge tended to be expressed exclusively through choice reaction decisions.

The second approach – Larry Jacoby's 'Process Dissociation Procedure' (Jacoby, 1991) – is based on the argument that, just as direct measures can be contaminated by unconscious influences, indirect measures can likewise be contaminated by conscious influences: particular tasks cannot simply be identified with particular underlying processes. The process dissociation procedure thus aims to tease apart the relative contributions of conscious and unconscious influences on performance. To do so, two conditions are compared in which conscious and unconscious influences either both contribute to performance improvement, or act

against each other. For instance, subjects might be asked to memorize a list of words and then, after some delay, to perform a stem completion task in which word stems are to be completed either so as to form one of the words memorized earlier (the *inclusion* condition) or so as to form a different word (the *exclusion* condition). If the stems nevertheless tend to be completed by memorized words under exclusion instructions, then one can only conclude that memory for these words was implicit, since if subjects had been able to consciously recollect them, they would have avoided using them to complete the stems. Numerous experiments have now been designed using the process dissociation procedure. They collectively offer convincing evidence that performance can be influenced by unconscious information in the absence of conscious awareness. In the context of implicit learning research, Destrebecqz and Cleeremans (2001) adapted the process dissociation procedure to sequence learning, asking trained participants to either generate a sequence that resembled the training sequence (inclusion) or a sequence that was as different as possible from the training sequence (exclusion). Results indicated that under certain conditions, participants were unable to exclude familiar sequence fragments, thus suggesting that they had no control over the knowledge acquired during training. Destrebecqz and Cleeremans (2001) concluded that this knowledge was best described as implicit, for its expression is not under conscious control.

Despite the considerable methodological advances achieved over the past decade or so, assessing awareness in implicit learning and related fields remains particularly challenging. The central issue of the extent to which information processing can occur in the absence of conscious awareness remains as controversial today as it was in 1967.

The Conceptual Challenge

The third conceptual challenge is to determine how best to interpret existing dissociation results. Dunn and Kirsner (1988) pointed out that even crossed double dissociations between two tasks do not necessarily indicate the involvement of separable, independent processes. Other authors have appealed to theoretical and simulation work to call the dissociation logic into question. Many authors have described non-modular architectures that can nevertheless produce double dissociations. Plaut (1995) explored these issues in the context of cognitive neuropsychology. In a compelling series of simulation studies, Plaut not only showed that lesioning a single connectionist network in various ways could account for the double dissociations between concrete and abstract word reading exhibited by deep dyslexic patients, but also that lesions in a single site produced *both* patterns of dissociations observed with patients. In other words, the observed dissociations can clearly not be attributed to architectural specialization, but can instead be a consequence of *functional specialization* (functional modularity) in the representational system of the network. These issues are also debated in the context of implicit learning research.

THE ROLE OF COMPUTATIONAL MODELING

Computational modeling has played a central role in deconstructing early verbal theories of implicit learning (1) by offering 'proof of existence' demonstrations that elementary, associative learning processes (as opposed to rule-based learning) are in fact often sufficient to account for the data, (2) by making it possible to cast specific predictions that can then be contrasted with those of competing models, and (3) by making it possible to explore how specific computational principles can offer novel, unitary accounts of the data.

Detailed computational models have now been proposed for all three main paradigms of implicit learning. Two families of models are currently most influential: neural network models and fragment-based models. Neural network models typically consist of simple auto-associator models (Dienes, 1992) or of networks capable of processing sequences of events, such as the simple recurrent network (SRN, see Figure 2) introduced by Elman

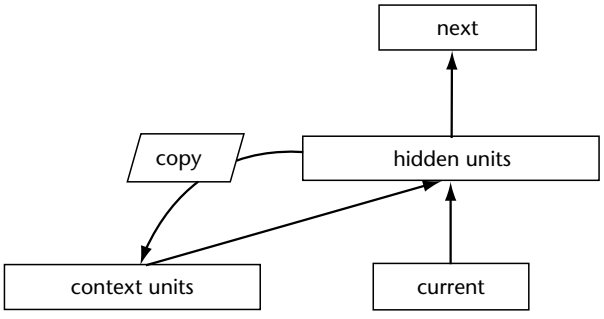

Figure 2. The simple recurrent network (SRN) introduced by Elman (1990). The network takes the current element of a sequence as input, and is trained to predict the next element using back propagation. Context units, which on timestep contain a copy of the activation pattern that existed over the network's hidden units on the previous timestep, enable previous information to influence current predictions.

(1990) and applied to sequence learning by Cleeremans and McClelland (1991). Such models assume that over the course of training, information about the statistical structure of the stimulus material is stored in the connection weights between the model's processing units. This information is thus subsymbolic to the extent that it is embedded in the same structures that are used to support processing itself. Fragment-based models (e.g. Perruchet and Vinter, 1998), in contrast, are variants of exemplar-based models which assume that learning results in the acquisition of memory structures such as whole exemplars or fragments thereof.

While no type of model can currently claim generality, both approaches share a number of central assumptions: (1) learning involves elementary association or recoding processes that are highly sensitive to the statistical features of the training set, (2) learning is viewed essentially as a mandatory by-product of ongoing processing, (3) learning is based on the processing of *exemplars* and produces *distributed* knowledge, and (4) learning is *unsupervised* and *self-organizing*.

More recently, hybrid models that specifically attempt to capture the relationships between symbolic and subsymbolic processes in learning have also been proposed. Sun (2001), for instance, has introduced models that specifically attempt to link the subsymbolic, associative, statistics-based processes characteristic of implicit learning with the symbolic, declarative, rule-based processes characteristic of explicit learning.

All these models have been essentially directed at addressing two questions: (1) What knowledge do people acquire in implicit learning situations? and (2) To what extent should demonstrated dissociations be interpreted as reflecting the involvement of separable learning systems?

Rules vs. Statistics

Early characterizations of implicit knowledge have tended to describe it as abstract based essentially on findings that subjects exhibit better-than-chance transfer performance, as when asked to make grammaticality judgments on novel strings in the context of artificial grammar learning situations (Reber, 1989). Likewise, it has often been assumed that the reaction time savings observed in sequence learning tasks reflect the acquisition of 'deep' knowledge about the rules used to generate the stimulus material (Lewicki *et al.*, 1987). These abstractionist accounts have generally left unspecified what the exact form of the acquired knowledge may be, short of noting that it must somehow represent the structure of the stimuli and their relationships, and be independent of the surface features of the material. The latter claim was further substantiated by findings that artificial grammar learning knowledge transfers to strings based on the same grammar but instantiated with a different letter set, or even across modalities, as when training involves letter strings but transfer involves tone sequences.

However, there now is considerable evidence that non-abstractionist mechanisms are largely sufficient to account for the data. Brooks (1978) first suggested that subjects in artificial grammar learning experiments were classifying novel strings based not on abstract knowledge of the rules, but simply on the extent to which novel grammatical or ungrammatical strings are similar to *whole exemplars* memorized during training. Perruchet and colleagues (Perruchet and Pacteau, 1990) showed that the knowledge acquired in both artificial grammar learning and sequence learning tasks might consist of little more than explicitly memorized short fragments or chunks of the training material such as bigrams or trigrams, or simple frequency counts. Both learning and transfer performance can then be accounted for by the extent to which novel material contains memorized chunks. Figure 3 illustrates some of the computational possibilities that have been suggested in the context of artificial grammar learning tasks, ranging from purely exemplar-based approaches to neural network models.

More recently, accounts that assume separate memory systems for representing general or specific knowledge in artificial grammar learning tasks have been proposed based on evidence that significant sensitivity to grammaticality remains even when similarity and fragment overlap is carefully controlled.

Overall, while it is clear that the knowledge acquired in typical implicit learning situations need not be based on the unconscious acquisition of symbolic rules, significant areas of debate remain about the extent to which unitary, fragment-based mechanisms are sufficient to account for sensitivity to both the general and specific features of the training material. Simulation models have generally been suggestive that such mechanisms are in fact sufficient to account simultaneously for both grammaticality and similarity effects.

Based on these properties of successful models of implicit learning, it is appealing to consider it as a complex form of priming whereby experience continuously shapes memory, and through which stored traces in turn continuously influence further

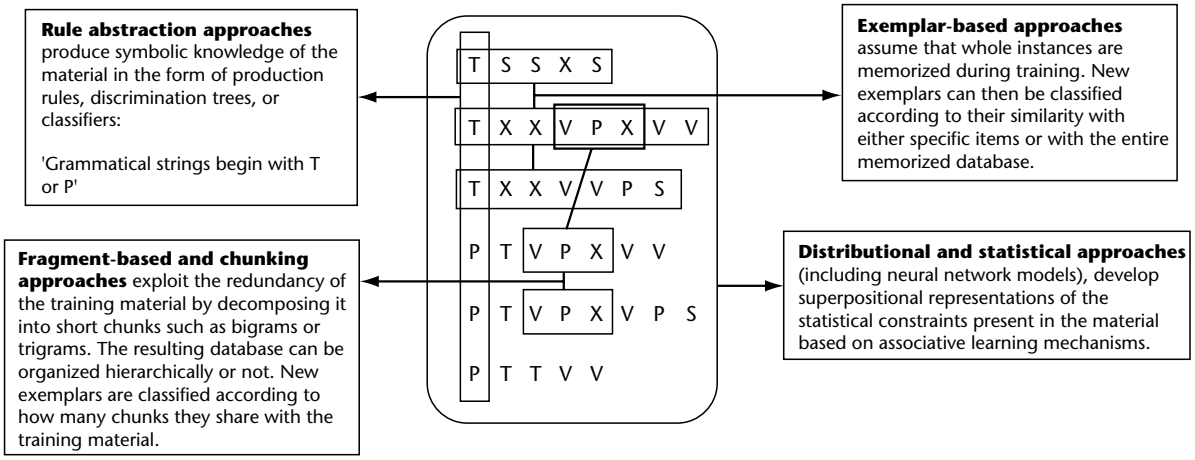

Figure 3. A representation of different computational approaches to artificial grammar learning.

processing. Such priming, far from involving the sort of passive and automatic acquisition of abstract structure that were previously assumed to lie at the heart of implicit learning, is in fact highly dependent on task demands and attentional processing during acquisition, as well as on the congruence between learning and transfer conditions (Whittlesea and Dorken, 1993).

Finally, while both fragment-based and neural network models make it clear how sensitivity to the distributional properties of an ensemble of stimuli can emerge out of the processing of exemplars, they differ in whether they assume that the shared features of the training materials are represented as such or merely computed when needed. This *locus of abstraction* issue is a difficult one that is unlikely to be resolved by modeling alone. Thus overall, it appears that the knowledge acquired through implicit learning is best described as lying somewhere on a continuum between purely exemplar-based representations and more general, abstract representations – a characteristic that neural network models are particularly apt at capturing.

Separable Systems?

Dissociations between implicit and explicit learning or processing have often been interpreted as suggesting the existence of separable memory systems. For instance, Squire and collaborators have shown that artificial grammar learning is largely preserved in amnesia (e.g. Knowlton *et al*., 1992), to the extent that amnesic patients perform at the same level as normal controls when asked to classify strings as grammatical or not, but are severely impaired when asked to discriminate between familiar and novel instances (or fragments) of the strings. These results suggest that the processes that subtend declarative and non-declarative memory depend on separable brain systems respectively dedicated to representing either information about the specific features of each encountered exemplar on the one hand (the hippocampus and related structures), and information about the features shared by many exemplars on the other hand (the neocortex).

In this case also, however, computational modeling often casts the empirical findings in a different light. For instance, Kinder and Shanks (2001) were able to simulate the observed dissociations by tuning a single parameter (the learning rate) in a simple recurrent network trained on the same material as used in the behavioral studies, and therefore concluded that a single-system account is in fact sufficient to account for the data.

CONCLUSIONS

The study of differences between implicit and explicit processing is a major endeavor for the cognitive neurosciences. Indeed, as our knowledge of how the brain works accumulates, our knowledge about how the mind works is changing rapidly. In particular, many existing distinctions previously described in purely functional, binary terms, such as the implicit–explicit distinction, the controlled–automatic distinction, or the declarative–procedural distinction, are now being explained anew in terms of graded characterizations of the computational problems that corresponding

brain systems have been evolved to solve. In this respect, the study of implicit learning, from the perspective of computational cognitive neuroscience, has a bright future, for it is through the development of sensitive paradigms through which to explore the differences between conscious and unconscious cognition that one can best contribute to the search for the neural, behavioral, and computational correlates of consciousness.

Inference using Formal Logics

Intermediate article

David McAllester, AT&T Labs-Research, Florham Park, New Jersey, USA

CONTENTS

Formal logics are used fundamentally in mathematics, natural language syntax and semantics, computer programming languages, and artificial intelligence.

INTRODUCTION

Logic is fundamental to a variety of disciplines. Logic provides insight into the nature of mathematics and human mathematical reasoning. Logic provides insight into the syntax and semantics of human language. Logic is an important tool in the design and implementation of computer programming languages. Logic also holds the promise of playing an important role in the development of artificial intelligence (AI). We will briefly consider each of these motivations in more detail.

Metamathematics

The idea that human thought is governed by linguistic rules started with the development of syllogisms by Aristotle. A syllogism is a pattern of inference. For example, if all men are mortal, and Socrates is a man, then Socrates is mortal. The general pattern is, of course, if all X are Y and Z is an X, then Z is a Y. In modern terminology, such a pattern is called a 'rule of inference'. The study of inference rules, begun by Aristotle, led to the development in the 1920s of the system of rules and axioms known as ZFC – Zermelo–Fränkel set theory with the axiom of choice. It is now generally accepted by mathematicians that all the provable truths of mathematics can be formally derived from the nine axioms of ZFC using the inference rules of first-order logic. Gödel's incompleteness theorem, proved in 1930, implies that if ZFC is sound then there are true statements not provable in ZFC. Gödel's theorem is consistent with the idea that the theorems provable by human mathematicians are precisely those provable in ZFC: true statements unprovable in ZFC are presumably also unprovable by human mathematicians. Gödel's theorem is itself provable in ZFC. A general treatment of logic as metamathematics can be found in Bell and Machover (1977).

Metaprogramming

A compiler is a computer program that takes as input another computer program and compiles that input into low-level instructions executable by computer hardware. A compiler is a metaprogram – a program that manipulates and analyzes other programs. Logic plays an important role in metaprogramming. Computer programs are composed of symbolic expressions, which have well-defined meanings (which may be determined by the meaning of their subsidiary expressions). (*See* **Symbol Systems**; **Computation, Philosophical Issues about**)

Compilers often analyze (reason about) the programs being compiled. For example, many compilers can determine that a pointer variable must be non-null (not equal to zero) at a certain place in the program. Logic is fundamental to such software analysis. A survey of the theory and practice of compilers can be found in Appel (1997).

Human Language

All human languages have sentences which form 'complete thoughts'. Furthermore, in all languages sentences have phrase structure, e.g. a sentence may be composed of a noun phrase and a verb phrase each of which in turn can be composed of subsidiary phrases. It seems that the meaning of a sentence is constructed from the meanings of its phrases and the meaning of a phrase is constructed from the meaning of its subsidiary phrases. The phrase 'book on the table' has a meaning that is determined by the meaning of the word 'book' and

the meaning of the phrase 'on the table'. The ability to combine meanings by putting words together into phrases, and phrases together into larger phrases, allows for a very large number of different ideas to be expressed – the number of ideas expressible in a fixed number of words grows exponentially in the number of words allowed. Logic provides a clear (though approximate) mathematical model of the way meanings are assigned to phrases and the way the meaning of a phrase is determined by the meanings of its subphrases. A detailed study of the logical treatment of human language can be found in Carpenter (1997). (*See* **Categorial Grammar and Formal Semantics**; **Generalized Quantifiers**)

Knowledge Representation

Since the early days of AI, logic has been proposed as a foundation for the representation of knowledge about the world (Lifschitz, 1998). Logic-based mechanical deduction has not produced human-level intelligence in machines. But alternatives such as neural networks, genetic algorithms, and reinforcement learning have also failed to produce human-level intelligence (e.g. machines that that can have sustained intelligent conversations in human language). Because of the fundamental importance of logic to metamathematics, metaprogramming, human language, and knowledge representation, logic remains relevant to the study of intelligence. (*See* **Computation, Formal Models of**; **Knowledge Representation**; **Knowledge Representation, Psychology of**)

WHAT IS LOGIC?

Logic is the study of the manipulation of symbolic expressions. A symbolic expression is a concise representation of a much larger (often infinite) set of behaviors or responses. For example, the symbolic expression 'x^2+2x+1' is a concise representation of an infinite input–output relation: the relation mapping input x to output x^2+2x+1. Algebraic rules of inference allow one to deduce that if $2y+4=4x+6$ then $y=2x+1$. The symbolic expression '$2y+4=4x+6$' is a proposition – an expression that, given values for its variables, is either true or false. To say that a proposition Φ 'entails' a proposition Ψ means that in any situation where Φ is true, Ψ must also be true. For example, $2y+4=4x+6$ entails $y=2x+1$.

Formally, a symbolic expression can be defined as a tree where each node is labeled by a character string. For example, the expression '$2y+4=4x+6$' is a tree whose root is labeled with '$=$' and has two children, one representing '$2y+4$' and one representing '$4x+6$'. An expression whose root is labeled with the string f and with children trees $t_1, \ldots, t_n$ is often written as $f(t_1, \ldots, t_n)$. For example, the expression $2y+4=4x+6$ can be written as '$=(+(*(2,y),4),+(*(4,x),6))$'. The leaves of this tree are labeled with the numerals '6', '4' and '2' and the variables 'x' and 'y'. The internal nodes are labeled with '$=$', '$+$' and '$*$'.

An expression is usually used to represent a function whose inputs are the variables occurring in the expression and whose output is the value of the expression. There are many different ways of assigning values to expressions. Different ways of evaluating expressions correspond to different logics. There are logics of time, modal logics, logics of knowledge, logics of communicating systems, logics of imperative computer programs, and many more. Historically, however, the best-known logic is first-order logic.

FIRST-ORDER LOGIC

In first-order logic, one assumes a set of variables, a set of constants, a set of function symbols, and a set of predicate symbols where each function and predicate symbol is associated with a specified 'arity' (number of arguments). There are two types of expressions: terms and formulas. The terms t and formulas Φ can be defined by the following grammar:

$$\begin{aligned} t &:= x|c|f(t_1, \ldots, t_n) \\ \Phi &:= P(t_1, \ldots, t_n)|t_1 = t_2|\Phi_1 \vee \Phi_2|\Phi_1 \wedge \Phi_2| \\ &\quad \Phi_1 \rightarrow \Phi_2|\neg\Phi|\forall x\Phi|\exists x\Phi \end{aligned} \tag{1}$$

In the grammar for terms, x ranges over variables, c ranges over constants, and f ranges over function symbols. (We assume some unspecified way of classifying character strings into variables, constants and function symbols with specified arities.) For example, if f is a function symbol of two arguments, g is a function symbol of one argument, x and y are variables, and b and c are constants, then $f(b,f(g(x),f(c,y)))$ is a term. In the grammar for formulas, P ranges over predicate symbols.

The defining feature of most logics is the 'semantics' assigned to the expressions, i.e. the way in which values are assigned to expressions. In the case of first-order logic, the semantics is defined relative to a 'structure'. A structure $\mathcal{M}$ consists of: a set $D_{\mathcal{M}}$ called the domain of $\mathcal{M}$; a meaning $\mathcal{M}(c) \in D_{\mathcal{M}}$ for each constant c; a meaning $\mathcal{M}(f)$ for each function symbol f, such that if f has arity n then $\mathcal{M}(f)$ is a function taking n arguments in

$D_{\mathcal{M}}$ and returning an element of $D_{\mathcal{M}}$; and finally a meaning $\mathcal{M}(P)$ for each predicate symbol P, such that if P has arity n then $\mathcal{M}(P)$ is a function taking n arguments in $D_{\mathcal{M}}$ and returning a truth value (either T or F). Meaning can be assigned to terms and formulas if, in addition to the meanings provided by the model, one is also given a meaning for each variable. A variable interpretation ρ relative to a structure $\mathcal{M}$ is a mapping from variables to elements of $D_{\mathcal{M}}$. For any structure $\mathcal{M}$ and variable interpretation ρ relative to $\mathcal{M}$, and any term t, we can define the value of the term t under $\mathcal{M}$ and ρ, $V(t, M, \rho)$, by the following equations:

$$\begin{aligned} &V(c, \mathcal{M}, \rho) = \mathcal{M}(c) \\ &V(x, \mathcal{M}, \rho) = \rho(x) \\ &V(f(t_1, \ldots, t_n), \mathcal{M}, \rho) = \mathcal{M}(f)(V(t_1, \mathcal{M}, \rho), \ldots, \\ &\quad V(t_n, \mathcal{M}, \rho)) \end{aligned} \tag{2}$$

As an example, let $\mathcal{N}$ be a structure whose domain $D_{\mathcal{N}}$ is the integers, that interprets the binary function symbols '$+$' and '$*$' as addition and multiplication respectively, and that interprets numerical constants such as '2' and '7' as the appropriate integers in $D_{\mathcal{N}}$. For any variable interpretation ρ and domain element d we write $\rho\ [x{:=}d]$ for the variable interpretation identical to ρ except that it maps the variable x to the value d. As an example of the semantic evaluation of terms, we have:

$$V(+(*(2, x), 3), \mathcal{N}, \rho[x := d]) = 2d + 3 \tag{3}$$

While the value of a term is a domain element, the value of a formula is a truth value. For a given structure $\mathcal{M}$, and variable interpretation ρ relative to $\mathcal{M}$, the values of formulas are defined by the following equations:

$$\begin{aligned} &V(P(t_1, \ldots, t_n), \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ \mathcal{M}(P) \\ &\quad (V(t_1, \mathcal{M}, \rho), \ldots, V(t_n, \mathcal{M}, \rho)) = \mathrm{T} \\ &V(t_1 = t_2, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ V(t_1, \mathcal{M}, \rho) = \\ &\quad V(t_2, \mathcal{M}, \rho) \\ &V(\Phi_1 \vee \Phi_2, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ V(\Phi_1, \mathcal{M}, \rho) = \mathrm{T} \\ &\quad \text{or } V(\Phi_2, \mathcal{M}, \rho) = \mathrm{T} \\ &V(\Phi_1 \wedge \Phi_2, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ V(\Phi_1, \mathcal{M}, \rho) = \mathrm{T} \\ &\quad \text{and } V(\Phi_2, \mathcal{M}, \rho) = \mathrm{T} \\ &V(\Phi_1 \rightarrow \Phi_2, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ V(\Phi_1, \mathcal{M}, \rho) = \mathrm{F} \\ &\quad \text{or } V(\Phi_2, \mathcal{M}, \rho) = \mathrm{T} \\ &V(\neg\Phi, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ V(\Phi, \mathcal{M}, \rho) = \mathrm{F} \\ &V(\forall x\Phi, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ \text{for all } d \in D_{\mathcal{M}}, \\ &\quad V(\Phi, \mathcal{M}, \rho[x := \mathrm{d}]) = \mathrm{T} \\ &V(\exists x\Phi, \mathcal{M}, \rho) = \mathrm{T} \ \text{ iff } \ \text{there exists } d \in D_{\mathcal{M}} \\ &\quad \text{such that } V(\Phi, \mathcal{M}, \rho[x := d]) = \mathrm{T} \end{aligned} \tag{4}$$

Inference is a computational process for determining symbolic consequences of symbolic assertions. For example, consider the following formula:

$$\forall x, y, z(x \leq y \wedge y \leq z) \rightarrow x \leq z \tag{5}$$

Here $\forall x, y, z\ \Phi$ is being used as an abbreviation for nested universal quantification and $x \leq y$ is being used as a more legible notation for the formula $\leq(x, y)$ where $\leq$ is a binary predicate symbol. Since $\leq$ is a binary predicate symbol, in any structure $\mathcal{M}$, $\mathcal{M}(\leq)$ must be a binary relation on the set $D_{\mathcal{M}}$. Formula 5 is true in structure $\mathcal{M}$ provided that $\mathcal{M}(\leq)$ is transitive. Note that all variables in formula 5 are quantified – we say that all variable occurrences are 'bound'. A variable occurrence not bound by a quantifier is called a 'free occurrence'. A formula with no free occurrences of variables is called 'closed'.

The truth value of a closed formula (such as formula 5) is determined by the structure and is independent of the variable interpretation. Formula 5 is true in a structure whose domain is the natural numbers and that interprets the predicate symbol $\leq$ as the standard ordering predicate on natural numbers. However, formula 5 can be false in other structures.

We say that formula Φ 'entails' formula Ψ (written $\Phi \models \Psi$) if, for any pair $\langle\, \mathcal{M}, \rho \,\rangle$ such that $V(\Phi, \mathcal{M}, \rho) = \mathrm{T}$ we have $V(\Psi, \mathcal{M}, \rho) = \mathrm{T}$. If Σ is a set of formulas then we say that a pair $\langle\, \mathcal{M}, \rho \,\rangle$ satisfies Σ if $V(\Phi, \mathcal{M}, \rho)) = \mathrm{T}$ for every Φ in Σ. We say that Σ entails Ψ (written $\Sigma \models \Phi$) if for every pair $\langle\, \mathcal{M}, \rho \,\rangle$ satisfying Σ we have $V(\Psi, \mathcal{M}, \rho) = \mathrm{T}$. As we shall see below, for a given set Σ of formulas representing 'knowledge' of some sort, and given a question formula Φ, symbolic processing (theorem proving) can, in many cases, determine whether $\Sigma \models \Phi$. Now we turn to the significance of this symbolic processing in early logicist models of AI.

THE SITUATION CALCULUS

In logicist models of artificial intelligence, human world knowledge is modeled by a large set of first-order formulas (Lifschitz, 1998). These formulas are taken to express 'commonsense knowledge'. A fundamental concept in early AI models is the notion of a situation. Intuitively, a situation is a certain place at a certain time: for example, the coffee room in the mathematics department at about 4 p.m. on a certain day. In addition to variables that range over situations, early AI models often used variables and terms intended to denote actions. An action is something that an agent can choose to do. The formula CAN (x, a, s) can be used to represent the statement that in situation s agent x can choose to take action a. The term RESULT (x, a, s) can be used to represent the situation that results from agent x performing action a in

situation s. The formula $\mathrm{ON}(x,y,s)$ can be used to represent the assertion that object x is on object y in situation s. An example of a formula expressing world knowledge might be the following:

$$\forall x, y, z, s\ \mathrm{CAN}(x, \mathrm{PUTON}(y, z), s) \rightarrow \mathrm{ON}(y, z, \mathrm{RESULT}(x, \mathrm{PUTON}(y, z), s)) \quad (6)$$

In the early logicist models, symbolic inference from world knowledge is presumed to be the computational method by which people 'understand' the world, i.e. the way they make predictions, answer questions, and plan actions. (*See* **Learning Rules and Productions**; **Deductive Reasoning**)

RESOLUTION THEOREM PROVING

We have defined semantic entailment for first-order formulas, but we have not defined any corresponding computational process. Early AI research focused on the resolution principle as a means of mechanizing general-purpose symbolic inference. Resolution is based on the notion of a clause. Formula 5, expressing the transitivity of the predicate $\leq$, is equivalent to the following:

$$\forall x, y, z\ \neg(x \leq y) \vee \neg(y \leq z) \vee x \leq z \quad (7)$$

To see the equivalence, one should try to verify that in any model where formula 5 is true, formula 7 is true, and vice versa. Formula 7 is in a special form, called a clause. Formally, an atom is defined to be a formula of the form $P(t_1, \ldots, t_n)$ and a literal is defined to be either an atom or the negation of an atom. The formula $x \leq z$ is an atom (which is a special case of a literal) and the formula $\neg(x \leq y)$ is a literal. A clause is defined to be a closed formula of the following form, where each Φ_k is a literal:

$$\forall x_1, \ldots, x_n\ \Phi_1 \vee \Phi_2 \vee \ldots \vee \Phi_k \quad (8)$$

It turns out that, in a technical sense, clauses suffice for arbitrary first-order knowledge representation and reasoning. To state the technical sense in which this is true, we will introduce some notation. For closed formulas Φ and Ψ we have $\Phi \models \Psi$ if and only if there is no model $\mathcal{M}$ such that $V(\Phi, \mathcal{M}) = \mathrm{T}$ but $V(\Psi, \mathcal{M}) = \mathrm{F}$, or equivalently, the formula $\Phi \wedge \neg\Psi$ is unsatisfiable (is not true in any model). This means that any question of entailment can be reduced to a question of satisfiability. The following lemma implies that any question of entailment can be reduced to a question about clauses.

Lemma 1. Any closed first-order formula Φ can be converted, in time linear in the size of Φ, into a finite set Σ of clauses such that Φ is satisfiable if and only if Σ is satisfiable (there is a model satisfying all of the clauses in Σ).

We will not prove this lemma here, but the basic idea is to introduce predicates representing subformulas of Φ. For example, if $\Psi[x, y]$ is a subformula of Φ involving the variables x and y then one introduces a predicate P_Ψ and adds clauses to Σ ensuring that in any model of the clauses we have that $P_\Psi(x, y)$ is true if and only if $\Psi[x, y]$ is true. The clauses defining the predicate for $\Psi_1 \wedge \Psi_2$ can be stated in terms of the predicates for Ψ_1 and Ψ_2. A similar construction applies to other formula types.

When a clause representation is desired, world knowledge is often written directly as clauses and no mechanical translation is used. The existence of a mechanical translation shows, however, that clauses suffice as a representation language.

'Resolution' is a mechanical inference procedure for deriving new clauses from a given set of clauses. It can be viewed as composed of two inference rules: factoring and binary resolution (these two rules can be combined into a single rule, with some loss of clarity). In discussing these rules, we will omit the universal quantifier in front of clauses, but it should be understood that the variables in a clause are universally quantified as in formula 8. (*See* **Resolution Theorem Proving**)

The factoring rule can be applied to clauses where two of the literals in the clause can be interpreted as the same literal. For example, consider the clause $P(x, y) \vee P(y, x)$. By considering the case where $x = y$ we can derive the clause $P(x, x)$. To formally state the general factoring rule we first need to define some terminology. A substitution is a mapping from variables to terms. For any substitution σ and literal Φ we define $\sigma[\Phi]$ to be the result of replacing each variable x in Φ by $\sigma(x)$. Two literals Φ_1 and Φ_2 are unifiable if they can be interpreted as the same literal, i.e. if there exists a substitution σ such that $\sigma[\Phi_1]$ is the same literal as $\sigma[\Phi_2]$. In this case σ is called a 'unifier' of Φ_1 and Φ_2. If Φ_1 and Φ_2 are unifiable, then a 'most general unifier' of Φ_1 and Φ_2 is a unifier γ such that any other unifier σ is a specialization of γ, i.e. there exists a substitution δ such that for any variable x we have that $\delta[\gamma(x)] = \sigma(x)$. The most general unifier of two literals is unique up to an arbitrary renaming of variables in the range of the substitution, and can be computed in time linear in the size of the two given literals. The general form of the factoring rule states that, given a clause $\Phi_1 \vee \ldots \vee \Phi_n$ containing two unifiable literals Φ_i and Φ_j, one can derive the clause $\gamma[\Phi_1] \vee \ldots \vee \gamma[\Phi_n]$ where γ is the most general unifier of Φ_i and Φ_j. The resulting clause always has fewer literals.

The other fundamental inference rule of resolution theorem proving is binary resolution. Here

we will assume that the literals in a clause can be reordered arbitrarily (a clause is viewed as a set of literals), and that the variables in a clause can be renamed arbitrarily at any time (they are universally quantified). The binary resolution rule states that given two clauses

$$\begin{array}{l}\Phi_1 \vee \ldots \Phi_{n-1} \vee \Phi_n \\ \neg\Psi_1 \vee \Psi_2 \ldots \vee \Psi_k\end{array} \tag{9}$$

where no variable occurs in both clauses (the second clause can be renamed to make this true) and where Φ_n and $\neg\Psi_1$ are unifiable, one can derive the following, where γ is the most general unifier of Φ_n and $\neg\Psi_1$:

$$\gamma[\Phi_1] \vee \ldots \vee \gamma[\Phi_{n-1}] \vee \gamma[\Psi_2] \vee \ldots \vee \gamma[\Psi_k] \tag{10}$$

As an example, consider the simple statement of transitivity in formula 5. Converting this formula to the clause 7 and applying binary resolution between this clause and a renamed version of itself results in the following:

$$\neg(x \leq y) \vee \neg(y \leq z) \vee \neg(z \leq w) \vee x \leq w \tag{11}$$

This clause is equivalent to the following implication:

$$x \leq y \wedge y \leq z \wedge z \leq w \rightarrow x \leq w \tag{12}$$

So the resolution rule can be used to compose the transitivity clause with itself to yield a three-step transitivity statement.

As another very simple example, suppose we want to show that $P \wedge (P \rightarrow Q) \models Q$. Here P and Q are predicate symbols of no arguments, i.e. they are formula constants. This can be formulated as the problem of showing that the set of formulas $\{P, P \rightarrow Q, \neg Q\}$ is unsatisfiable. The formula $P \rightarrow Q$ can be replaced by the clause $\neg P \vee Q$. The binary resolution rule can be applied to the clause P and the clause $\neg P \vee Q$ to yield the clause Q. The binary resolution rule can then be applied to the clause Q and the clause $\neg Q$ to yield the empty clause. A derivation of the empty clause shows that the given clause set is unsatisfiable; hence the original entailment holds.

The resolution rules are complete in the following sense.

Theorem 2. If Σ is an unsatisfiable set of clauses then the rules of factoring and binary resolution can be used to derive the empty clause.

The proof of this theorem is somewhat involved, and will not be given here – a complete proof can be found in Leitsch, (1997). Lemma 1 and theorem 2 show that resolution theorem proving is, in a technical sense, sufficient for first-order inference.

Researchers soon discovered that mechanical resolution theorem proving was in many cases impractical: while the empty clause was derivable in principle, the system might take the age of the universe to derive it. Over the years there has been much research into methods for implementing more efficient variants of resolution theorem proving. Today, resolution theorem provers are very good at solving certain kinds of problems particularly amenable to first-order reasoning Leitsch (1997). However, first-order logic itself seems to be of limited value in most important applications of logic. Other logics seem more relevant.

THE BOYER–MOORE LOGIC

As mentioned above, logics differ in the way they associate values with expressions. One way of assigning values to expressions is inspired by computer programming. Most programming languages allow expressions that include procedure calls. For example, if f is a defined procedure then the expression '$x + f(y)$' computes to the sum of the value of x and the value returned by the procedure f when applied to the argument y. As in programming languages, the Boyer–Moore logic requires function and predicate symbols (procedure names) to be defined: the precise input–output relation of each function and predicate symbol must be completely specified. This is not true of first-order logic, where, for example, formula 5 can be assumed and used without stating any definition of the meaning of the predicate $\leq$. In the Boyer–Moore logic, the specification of the meaning of a function symbol is directly analogous to the definition of a procedure in a programming language. In fact, the Boyer–Moore logic is a kind of programming language together with inference rules for proving general assertions, such as $\forall x \quad f(f(x)) = f(x)$ where f is a defined procedure. Note that no amount of testing formally establishes a desired property on all of the (infinitely many) possible inputs to a procedure. Establishing the truth of a statement for all inputs requires logical inference.

The Boyer–Moore logic, and its descendent ACL2 (Kaufmann *et al*., 2000) are complex languages with many features that have been used for a large number of mathematical proofs and hardware and software verifications. Here we will explain the essential ideas of this logic by presenting a simpler but similar logic, the 'simplified Boyer–Moore logic' (SBM). The terms of SBM are defined by the following grammar, where "s"

ranges over character string constants, `if`, `pair`, Π_1, Π_2, `stringp`, and `equal` are special function symbols (primitives of the language), and f ranges over procedure names.

$$t ::= \text{“}s\text{”} \mid x \mid \texttt{if}(t_1,t_2,t_3) \mid \texttt{pair}(t_1,t_1) \mid \Pi_1(t) \mid \Pi_2(t) \mid \texttt{stringp}(t) \mid \texttt{equal}(t_1,t_2) \mid f(t_1,\ldots,t_n) \quad (13)$$

The method of assigning values to terms differs from that of first-order logic in that here the evaluation process must be given a definition for each procedure name. A definition is an expression of the form '$f(x_1,\ldots,x_n) \equiv t$' where t is a term not containing variables other than $x_1,\ldots,x_n$. A set D of definitions will be called self-contained if every procedure symbol appearing on the right-hand side (the body) of a definition is itself defined in D. Note that a self-contained set of definitions allows recursive definitions. For example, under the standard way of representing sequences with pairs, we can define a procedure `append` for concatenating two sequences as follows:

$$\texttt{append}(x,y) \equiv \texttt{if}(\texttt{stringp}(x), y, \texttt{pair}(\Pi_1(x), \texttt{append}(\Pi_2(x), y))) \quad (14)$$

For the remainder of this discussion we assume a given self-contained set of definitions. A term all of whose procedure names have definitions (in the given definition set) will be called 'fully-defined'. Values are themselves taken to be terms defined by the following grammar:

$$v ::= \text{“}s\text{”} \mid \texttt{pair}(v_1, v_2) \quad (15)$$

In other words, a value is either a string constant or a pair of values. If t is a fully-defined closed term (one not containing variables), we say that t has value v (written $t \Rightarrow v$) if a certain evaluation process generates value v for t. The value relation $\Rightarrow$ should not be confused with the logical implication relation $\rightarrow$ – evaluation maps an expression to a value (e.g. a number), while implication is a logical relationship between two statements.

The value relation can be made more precise by giving specific inference rules for deriving values. For any string constant “s” we have “s” $\Rightarrow$ “s”. If $t_1 \Rightarrow v_1$ and $t_2 \Rightarrow v_2$ then `pair` $(t_1, t_2) \Rightarrow$ `pair` (v_1, v_2). Note that these two rules together imply $v \Rightarrow v$ for any value v. If $t \Rightarrow$ `pair` (v_1, v_2) then $\prod_1(t) \Rightarrow v_1$ and $\prod_2(t) \Rightarrow v_2$. If $t \Rightarrow$ “s” then `stringp` $(t) \Rightarrow$ “`true`” and if $t \Rightarrow$ `pair` (v_1, v_2) then `stringp` $(t) \Rightarrow$ “`false`”. If $t_1 \Rightarrow$ “`true`” and $t_2 \Rightarrow v$ then `if` $(t_1, t_2, t_3) \Rightarrow v$. If $t_1 \Rightarrow$ “`false`” and $t_3 \Rightarrow v$ then `if` $(t_1, t_2, t_3) \Rightarrow v$. If $t_1 \Rightarrow v$ and $t_2 \Rightarrow v$ then `equal` $(t_1, t_2) \Rightarrow$ “`true`”. If $t_1 \Rightarrow v_1$ and $t_2 \Rightarrow v_2$ with v_1 different from v_2 then `equal` $(t_1, t_2) \Rightarrow$ “`false`”. Finally, if '$f(x_1, \ldots, x_n) \equiv s$' is one of the given definitions, and v_1, v_n are values, we write $s[v_1/x_1, \ldots, v_n/x_n]$ for the result of replacing each variable x_i with the value v_i in s. If $t_1 \Rightarrow v_1, \ldots, t_n \Rightarrow v_n$, the procedure f is defined by $f(x_1, \ldots, x_n) \equiv s$ and $s\,[v_1/x_1, \ldots, v_n/x_n] \Rightarrow \omega$ then $f(t_1, \ldots, t_n) \Rightarrow \omega$. These inference principles do not always allow a value to be derived. For example, if f is defined by $f(x) \equiv$ `pair` $(x, f(x))$ then no value can be derived for f (“a”). However, if a value can be derived for a term then that value is unique.

The given system of definitions is called 'terminating' provided that a value can be derived for every fully-defined closed term. The Boyer–Moore logic enforces the constraint that the given system of definitions must be terminating – a definition is only accepted after termination has been proved. The methods for proving termination in the Boyer–Moore logic involve well-founded orders on values (Kaufmann *et al.*, 2000).

SBM can express mathematical facts as universally quantified terms. For example, given the above definition of `append`, the following universally quantified statement holds:

$$\forall x,y,z\ \texttt{equal}(\texttt{append}(x, \texttt{append}(y,z)), \texttt{append}(\texttt{append}(x,y), z)) \quad (16)$$

In general, a formula of the form $\forall x_1, \ldots, x_n\, t$ is true if, for all values $v_1, \ldots, v_n$, we have $t[v_1/x_1, \ldots, v_n/x_n] \Rightarrow$ “`true`”. It is easy to give SBM definitions of the Boolean operators `and`, `or`, `not` and `implies`. It is also easy to define natural arithmetic operations on positive integers, so that, for example, Fermat's last theorem can be formulated as follows, where `and5` is a five-argument conjunction operator:

$$\forall\, n,x,y,z\ \texttt{implies}(\texttt{and5}(\texttt{nat}(n), \texttt{nat}(x), \texttt{nat}(y), \texttt{nat}(z), \texttt{greater}(n, \texttt{two}())), \texttt{not}(\texttt{equal}(\texttt{sum}(\texttt{exp}(x,n), \texttt{exp}(y,n)), \texttt{exp}(z,n)))) \quad (17)$$

It turns out that a wide variety of statements can be formulated as universally quantified terms of SBM. The Boyer–Moore logic and its descendent ACL2 have been used to state and prove many theorems of number theory and to formulate and verify specifications for microprocessors, machine-language assemblers and compilers. All of these theorems and specifications can be easily formulated (though not easily verified) in SBM.

DEFINITIONS, COMPLETENESS, AND GÖDEL'S THEOREM

Gödel's incompleteness theorem states that for any sufficiently expressive logic there cannot exist any sound and complete system of inference. Intuitively, 'sufficiently expressive' means that the language is expressive enough to make simple statements about the integers, such as the statement that a certain polynomial does not equal zero for any integer values of its variables. The logic SBM is clearly expressive enough to make these kinds of statements. It follows that no sound and complete inference system exists for SBM. Here, 'sound' means that every provable statement is true, and 'complete' means that every true statement is provable. In practice one works with inference rules that are sound but incomplete. Although no precise characterization has been given of the statements that are provable using the inference rules provided by the Boyer–Moore system, it is clear that these inference rules are powerful enough to prove much of number theory and most specifications for hardware and software systems.

Resolution theorem proving provides a sound and complete system of inference for first-order logic. It follows immediately from Gödel's incompleteness theorem that first-order logic is not sufficiently expressive. In particular, first-order logic is not expressive enough to define addition and multiplication on the natural numbers – the natural numbers themselves cannot be defined in first-order logic. More specifically, for any set of first-order statements about the natural numbers there exist 'nonstandard' models of those statements: models different from (not isomorphic to) the natural numbers in which those statements are also true.

It is possible to introduce a notion of 'nonstandard model' for the Boyer–Moore logic and replace the notion of truth with the notion of being true in all possible (nonstandard) models. This reduces the expressive power of the logic: one can no longer define the set of natural numbers and the standard arithmetic operations on them. However, it allows a complete system of inference to be given: all statements that are true in all the (nonstandard) interpretations can be proven. On the other hand, the natural semantics seems easier to understand, and allows, in principle, the construction of ever more powerful proof systems. In practice the construction of ever more powerful proof systems is limited by the fact that all human proofs can be expressed in ZFC, so that no proof system more powerful than ZFC can be proven sound by human mathematicians.

HIGHER-ORDER LOGIC

Second-order logic allows quantification over predicates on individuals. Third-order logic allows quantification over predicates that take predicates as arguments. Higher-order logic allows n^{th}-order quantification for any n. Higher-order logic is of central importance in the theory of computer programming languages and in the study of the syntax and semantics of human language.

To formally define higher-order logic, one must first define types. The type of an expression determines its order. For example, a predicate P of one argument has type $D \to B$. This means that it takes an individual (a first-order object) as its input and returns a truth-value as its output. One writes $P{:}D \to B$ to indicate that P has type $D \to B$. One can also write $x{:}D$ to indicate that x is a first-order value, or $f{:}(D \to B) \to B$ to indicate that f takes a predicate as an argument and returns a truth-value. More generally, one writes $f{:}\tau$ to indicate that f has type τ where τ is a type expression as defined by the following grammar:

$$\tau ::= D|B|\tau_1 \to \tau_2 \tag{18}$$

Here D is the type of individuals (first-order values), B is the type of truth values, and $\tau_1 \to \tau_2$ is the type of functions that take as input values of type τ_1 and produce as output values of type τ_2. For each type expression we assume an infinite number of variables and constants of that type. We will write x^τ and c^τ to signify variables and constants of type τ. The terms of higher-order logic are defined by the following grammar:

$$t ::= x^\tau|c^\tau|\texttt{apply}(t_1, t_2)|\lambda(x^\tau, t) \tag{19}$$

The term $\texttt{apply}\ (t_1, t_2)$ represents the application of the operator t_1 to the argument t_2. The term $\lambda\ (x^\tau, t)$ represents the function that takes an input of type τ and produces as output the value of t when x^τ is assigned the input value. We write $t{:}\tau$ to indicate that the term t is a well-typed term of type τ. This well-typedness relation is defined by certain simple rules. First, we have $x^\tau{:}\tau$ and $c^\tau{:}\tau$. Next, if $t_1{:}\sigma \to \tau$ and $t_2{:}\sigma$ then $\texttt{apply}\ (t_1, t_2){:}\tau$. Finally, if $t{:}\tau$ then $\lambda\ (x^\sigma, t){:}\sigma \to \tau$. A term t is called well-typed if there exists a type τ such that these rules derive $t{:}\tau$. Note that if t is well-typed then there is only one type τ such that $t{:}\tau$.

Just as there are many different logics, so there are many different higher-order type systems. The system presented above is called the simply-typed lambda calculus with explicit types. In other systems, the same variable might be assigned different types and the single term $\lambda(x,\ x)$ can be assigned any type of the form $\tau \rightarrow \tau$. Still other systems allow type schemes and quantified types.

Several abbreviations are standard in treatments of higher-order logic. The term `apply` $(t_1,\ t_2)$ is usually abbreviated to $(t_1\ t_2)$. Types are usually left implicit on variables and constants, so that x denotes a typed variable. The term $\lambda(x^\tau,\ t)$ is often written as $\lambda x.t$. It turns out that functions of more than one argument can be represented by functions of one argument. The term $\lambda x,y.t$ is used as an abbreviation for $\lambda x.\lambda y.t$. The notation $\sigma_1 \times \sigma_2 \rightarrow \tau$ is an alternative notation for $\sigma_1 \rightarrow (\sigma_2 \rightarrow \tau)$; and the two-argument application $(f\ x\ y)$ is an abbreviation for $((f\ x)\ y)$.

In higher-order logic we assume the standard logical Boolean constants: $\wedge{:}B \times B \rightarrow B$, $\wedge{:}B \times B \rightarrow B$, $\neg{:}B \rightarrow B$, and $\rightarrow{:}B \times B \rightarrow B$ (we rely on context to distinguish Boolean implication from the type-theoretic function constructor). These constants are assigned their standard logical meaning. In higher-order logic we also assume constants representing existential and universal quantification. Thus, $\forall x^\tau\ \Phi$ (where $\Phi{:}B$) is an abbreviation for $\forall^\tau(\lambda x^\tau \Phi)$ where $\forall_\tau$ is a constant with the appropriate standard meaning of type $(\tau \rightarrow B) \rightarrow B$. Similarly, $\exists\ x^\tau\ \Phi$ is an abbreviation for $\exists_\tau\ (\lambda x^\tau \Phi)$ where $\exists_\tau$ is an appropriate logical constant.

As in first-order logic, the value of a well-typed higher-order term is defined relative to a model, where the model specifies a domain – a set of first-order values – and a meaning for each non-logical constant. Given a domain of first-order values, each type expression is associated with a well-defined set: D denotes the set of first-order values; B denotes the set {T, F}; and $\tau_1 \rightarrow \tau_2$ denotes the set of (all semantic) functions that take as input an element of the set denoted by τ_1 and produce as output an element of the set denoted by τ_2. The value for each non-logical constant c^τ must be an element of the set denoted by τ. A variable environment ρ assigns a value to each variable, in such a way that the value assigned to x^τ is in the set denoted by τ. Given a model $\mathcal{M}$, a variable environment ρ, and a well-typed term t, the value $V\ (t,\ \mathcal{M},\ \rho)$ can be defined in a manner similar to that used for first-order logic. If we have $t{:}\tau$ then $V\ (t,\ \mathcal{M},\ \rho)$ is an element of the set denoted by τ.

The formalism of higher-order logic, and its uses in the study of the syntax and semantics of human language, are described in more detail in Carpenter (1997).

HIGHER-ORDER LOGIC AND GÖDEL'S THEOREM

Although higher-order logic does not explicitly support recursive definitions, it is sufficiently expressive for Gödel's theorem to apply. In higher-order logic one can write the following induction principle for the natural numbers:

$$\forall P \quad [P(0) \wedge (\forall x\ P(x) \rightarrow P(x+1))] \rightarrow \forall x\ P(x) \tag{20}$$

Combined with a few more simple axioms, this formula yields a set of formulas (the second-order Peano axioms) whose only model (up to isomorphism) is the natural numbers. So no sound system of inference for higher-order logic can be complete. As with the Boyer–Moore logic, it is possible to give an 'unnatural' semantics, making sound and complete inference possible. However, the natural semantics seems easier to understand and in principle allows for the construction of ever more powerful inference systems.

It is possible to approximate higher-order logic using first-order schemata. For example, the induction principle for natural numbers can be expressed by the infinite set of all first-order formulas of the following form, where $\Phi\ [x]$ represents an arbitrary first-order formula with a single free variable x:

$$[\Phi[0] \wedge (\forall x\ \Phi[x] \rightarrow \Phi[x+1])] \rightarrow \forall x\ \Phi[x] \tag{21}$$

This, however, is only an approximation to the second-order statement given in formula 20: there are subsets of the integers that are nameable in richer (higher-order) languages but not nameable by a first-order formula $\Phi[x]$. Hence there are uses of the true second-order induction principle that are not covered by the first-order schema. There are natural statements of number theory that are known to be true (they are provable in ZFC) but are not provable from the first-order version of Peano's axioms. The completeness theorem for first-order logic implies that if Φ is not provable in first-order Peano arithmetic then there must be nonstandard models of these axioms where Φ is false, even if Φ is true of the actual natural numbers. In the case of Peano arithmetic it seems reasonable to work with the higher-order formulation even though it is sufficiently expressive for Gödel's theorem to apply.

SUMMARY

Logic is fundamental to our understanding of mathematics, computer programming, human language, and knowledge representation. It has been proposed as a foundation for artificial intelligence. Although no theoretical framework has led to the construction of machines matching human thought, it seems clear that logic remains relevant to the study of intelligence. The relationship between logic and statistics is currently an active area of research (Getoor *et al*., 2001).

Intelligent Tutoring Systems

Introductory article

Alan Lesgold, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

CONTENTS

Intelligent tutoring systems are computer programs that use artificial intelligence techniques to interact with students and to provide experiences tailored to students' immediate needs. Originally, the term included only systems that modeled the student's developing knowledge, but today the term often includes systems that adapt to the pattern of a student's activity and to estimates of what the student knows.

INTRODUCTION

Learning involves intelligent interactions – with teachers, with fellow students, and with environments like laboratories. When researchers began to consider the possibilities of machine intelligence, they soon realized that instruction was an area in which an intelligent computer could play a useful role. Today, there are a number of intelligent computer systems, which help people learn a variety of things, from basic skills like reading and mathematics to specific technical jobs like maintaining complex equipment in a factory.

Intelligent tutoring systems vary in the details of how they work, but they all do some of the things that human teachers do. For example, one system tracks students as they solve algebraic word problems. It tries to infer from a student's performance whether he or she is on the right track towards solving a problem, and uses accumulated knowledge about the student's past performance to decide what advice to offer if not. Another system listens to young children as they try to read aloud and offers corrective feedback if they have trouble pronouncing particular words. A third system provides a simulation of a complex machine and assigns trainees tough problems, like determining what is wrong when the machine fails to work properly. If the trainees get stuck, the system offers advice based upon what actions have already been taken in trying to solve the problem. (*See* **Learning from Advice**)

These systems take advantage of several important advances in the world of computer science. They use realistic multimedia presentation, both to motivate the student and to provide realistic scenarios for learning. They promote 'learning by doing', providing feedback as students try to apply what they already know and to learn from experience. And a major part of their intelligence is based upon representations or models of the environment or task on which the student is working, what the student knows that is relevant to the problem, and what an expert would be thinking about the problem.

MULTIMEDIA PRESENTATION FOR EDUCATION

Intelligent tutoring systems try to achieve cognitive realism. That is, they present information in ways that support thought processes relevant to the desired learning and that highlight features of an environment that merit special notice by the learner. For example, an intelligent system helping teachers to improve their skills might present video clips of classroom activity. To maximize the efficiency of learning, the video might skip uninteresting moments, and it might not be high-fidelity, but it would make relevant parts of a situation clear. To facilitate attending to the important aspects of discussion, the system might simultaneously include a running transcript of classroom talk – similar to closed captioning on television. (*See* **Instructional Design**)

Sometimes sketches and diagrams can be more useful than complete realism. For example, one system built for industrial training lets trainees click on various parts of schematic diagrams to

access menus of actions they can ask a simulated machine to perform. Another system presents intelligent diagrams that can have different segments emphasized or shown in more detail, depending on where the system wants to focus student attention.

A few intelligent systems need very high fidelity to be effective. For example, a system that trains captains to steer submarines into port has full 'surround sound' capability, since expert steering sometimes responds to the direction and loudness of harbor bell buoys. Virtual-reality components, whereby scenes change in response to student movement, are also used by some intelligent training systems. For example, in one system being developed, teachers can use a mouse to move around a classroom and look for interesting activity, and then zoom in on areas of interest. Here, the system intelligence lies in how the rough sketch of the classroom from which interactions start calls attention to important information. Such systems can also adapt to the pattern of where students look.

Some intelligent instructional systems have substantial ability to understand student activity that involves movement or speech. For example, although computers are not yet perfect at understanding arbitrary speech, they are quite able to decide whether or not specific words have been spoken. One system listens to children reading aloud, decides what they are saying, and offers corrective feedback when the student misses a word. Another system, used to train special military forces, tracks the movements of trainees and modifies the behavior of simulated environments according to where they move and in which direction they look.

FORMS OF FEEDBACK

As mentioned above, the source of learning is interaction. Teachers, in particular, work by interacting with students, offering various forms of feedback. The simplest feedback is an evaluation of a performance. Just as teachers mark problems as correct or incorrect or give grades on short essays, some intelligent instructional systems offer this kind of feedback. In the simplest case, instructional computer systems may have the correct answer to every problem stored in memory, but intelligent instructional systems can do much more. By comparing the actions taken by a student in solving a problem to those modeled by an expert system, they can determine whether the student was expert-like in his or her performance. (*See* **Expert Systems**)

Of course, many tasks have multiple correct answers, so an expert system may not be able to 'score' a student's performance if the student displayed originality that the expert system did not have. There are a number of intelligent actions a computer system might take even when the range of possible answers is less constrained. First, it is possible in some cases to infer logically that an answer is correct. In this case, an intelligent system uses a combination of inference techniques and knowledge it has about the problem domain. For example, in courses where students must prove theorems, alternative proof strategies can be evaluated this way. Another possibility is to evaluate the solution, if some dimension of value exists. For example, a training system that asks people to work in a simulated environment to repair or reconfigure machinery might have a knowledge base that allows it to determine the cost of a student's proposed solution. If there is also an expert model that can solve the problem in a different way, then the cost of the student's solution can be compared with that of the expert model, and the system can give feedback accordingly (e.g. 'your solution is correct, but doing it that way would cost about $500, and there is a way to solve the problem for $75').

For written essays, a technique called latent semantic analysis can be used. Actual essays that are considered to be of high quality are used to develop a statistical profile of which words are mentioned in close proximity to which others. This profile can then be compared to that derived from a student's essay, and a score computed. Since essays can be compared to each of a number of partial responses, a system can get a reasonably good sense of where the student's weaknesses are. If each of the standard partial essays is associated with a knowledge base, that knowledge base can then be used to generate further advice to the student.

A good teacher can do more than just evaluate a student's performance. The best teachers explain why one approach is better than another and how complex systems work. They tailor explanations and advice to the particular needs of students. They adapt the complexity and extent of their advice to the student's current capabilities. We will now explore how this can be done.

MODELING AND ADAPTING TO THE MIND OF THE STUDENT

Overlay Models

In order for a computer system to be able to adapt to a student's current knowledge level, it must

somehow construct a model or representation of the student's knowledge. Such representations can take a number of different forms. The simplest approach is to list everything an expert ought to know about a domain (the expert model) and then check which items of knowledge on the list the student appears to know (the student model). Finally, the system must decide what to say to the student to help him or her learn more. (*See* **Knowledge Representation**; **Knowledge Representation, Psychology of**)

This method will work if the form in which pieces of knowledge are listed is both standardized enough to fit available computational tools and sufficient to support the needed coaching. We call this approach an 'overlay' model, since the model of the student's knowledge is some subset of the expert model.

The expert model must be stated in terms that capture everything the tutor wishes to teach, and the individual elements of the expert model must be identifiable with aspects of student performance. That is, there must be a way of determining which of the knowledge elements the student knows. One approach to this is called model tracing. The basic idea is that each performance by the student is simulated by the intelligent tutoring system, using the expert model. For this to work, the expert model needs to be expressed as a production system. A production system is a set of contingent action rules, or productions, stated in the form of 'if–then' statements (if a condition is satisfied, then carry out an action). (*See* **Learning Rules and Productions**)

Production systems can easily produce a trace of how an expert would tackle a given task. The system alternately determines which productions have a match between the current situation and their 'if' conditions and carries out the actions associated with those conditions. (*See* **Production Systems and Rule-based Inference**)

Production systems used as expert models in intelligent tutors tend to involve explicitly stated goals. Most productions in such a system have among their conditions that a particular goal be present. Many productions have among their actions the changing of a goal. For example, a production to dial a phone number might set as goals dialing the area code and then dialing the local number. The productions that dial the area code would have among their conditions that the goal be to dial the area code and among their actions to set the goal to now dial the local number.

Modeling a student's performance with such an expert system amounts to going through the student's actions step by step and asking, for each action, whether a sequence of one or more expert productions would have led to that action. If so, this constitutes prima facie evidence that the student knows those productions. If not, then this suggests that the student does not yet know the productions an expert would have used.

Once it is known which productions the student still needs to learn, it is possible to provide appropriate feedback aimed at teaching the student to apply the missing production (note that being able to state the 'if–then' relationship is not the same as knowing to apply it whenever it is relevant). Generally, such feedback is generated through a combination of text prepared in advance, sentence frames, and inferred explanations. This method is often effective, since it can take account of the specific rule the student did not apply. It can be made more effective by tailoring feedback to the specifics of the situation in which it is offered. This is straightforward when productions contain variables that are matched to specific characteristics of the current situation. The values matched by those variables can then be used to make an explanation more specific.

Here is a simple example. Suppose that a geometry expert system has a rule that has as a condition that two angles be complementary; for example: 'if angle α is complementary to angle β, then compute $\alpha = 90^\circ - \beta$'. (That is, if two angles are complementary, then the measure of one is equal to 90° minus the measure of the other.) Suppose that a student fails to apply this rule when it is appropriate. It would be more effective if the intelligent tutor could refer to the specific angles that are complementary in the specific problem the student is working on, rather than just to the rule as an abstraction. Since the specific angles must be identified anyway in order for the expert production to apply, it is quite straightforward to substitute references to the angles of the problem situation into a coaching frame that helps the student understand the rule. For example:

> You need to determine the measure of $\angle\mathbf{ABC}$. You know that $\angle\mathbf{ABC}$ and $\angle\mathbf{CBD}$ are complementary, and you know that $\angle\mathbf{CBD} = \mathbf{37}^\circ$. So, since two complementary angles sum to 90°, $\angle\mathbf{ABC}$ must equal $90^\circ - \mathbf{37}^\circ = \mathbf{53}^\circ$. (All of the substitutions for variables in the expert rule are shown in bold face.)

Bayesian Models

An alternative to symbolic inference of student knowledge using ordinary logical reasoning is to infer the knowledge of various rules or concepts

from student actions via a web of conditional probabilities. This approach allows for student modeling that captures both understanding (sometimes called declarative knowledge) and performance capability (sometimes called procedural knowledge). The basic idea is to develop a set of estimates of the conditional probability of knowing one piece of knowledge given evidence that the student knows a second piece. For example, if a student knows the definition of complementary angles, then it is likely that he or she knows the rule mentioned above.

Ideally, an intelligent tutor would possess complete knowledge of all the conditional probabilities that interrelate all the knowledge segments. This represents a lot of information (if there are n knowledge pieces, then there could be $(n-1) \times n$ conditional probabilities interconnecting them). Actually, the scheme will work as long as there are at least a few interconnections between any one piece and the rest of the knowledge base.

But there is another, potentially more severe, problem. This is the computational complexity of updating a student model of this kind as new information comes in. Once there are a number of conditional probabilities specified among knowledge elements, the exact probabilities that the student knows all the different pieces of knowledge must match the conditional probability constraints. Getting all the numbers perfect is beyond the reach of any computer if the number of knowledge pieces is large.

However, efficient schemes have been developed for approximating the student model given a network of conditional probabilities and information about which pieces of knowledge have been demonstrated. Today, there are intelligent tutoring systems (e.g. for the mechanics portion of introductory physics courses) that use Bayesian technology to improve their student modeling. These systems can make good guesses not only about procedural capabilities of students (what they can do) but also about conceptual capabilities (what they understand).

Other Schemes

There are other student modeling schemes that focus only on the context of a particular task. They do not maintain a detailed model of what the student knows, but rather maintain a model of the task given to the student and of the implications of actions the student has already taken. For example, systems have been built that track the actions of a student trying to solve a problem (medical diagnosis, or repairing a piece of equipment) in a simulated environment, and attempt to determine what an expert would do next given what the student has done already. When advice is needed, such systems tend to offer the student a choice of different kinds of advice, depending on the situation.

A related approach is to observe the actions of the student and, when they fit a known pattern, offer general advice relating to the kind of situation that usually produces that pattern. Sometimes this kind of advice is in the form of anecdotes, from which the student might infer some new knowledge or new procedural options. This approach can be very effective, especially in situations where the task is only partly specified or where many very different approaches might all be reasonable.

ENCOURAGING EXPLORATION, EXPERIMENTATION AND ACTIVE LEARNING

Intelligent tutoring systems can encourage active learning. Many researchers now believe that all personal knowledge is constructed by the student, and that drill can sometimes interfere with the student constructing rich knowledge and understanding that will be useful outside the context of tightly specified examinations and schoolwork. Even those who do not accept the more radical forms of constructivism (e.g. that nothing can be learned just by being told) still believe that active engagement of the student with a body of knowledge and its applications is essential to the achievement of significant levels of learning. (*See* **Learning, Psychology of**; **Learning Aids and Strategies**)

The earliest computer-based instruction schemes provided limited active learning possibilities, but since they worked by simple scoring of students' 'answers' rather than by assessing the patterns of their ongoing work, those possibilities were limited. By modeling the knowledge needed to solve a problem, and possibly even the knowledge apparently possessed by the student, intelligent tutors are able to go further, providing more specific advice and hence allowing students to tackle more substantial problems. Thus schooling can proceed rather like sports learning, where much of the activity consists in engaging the whole body of knowledge at once (one learns to play tennis mostly by playing tennis, not by doing tiny exercises that can be scored as right or wrong).

Active learning means more than just doing large tasks. Sometimes one has to test one's knowledge

by experimenting with the environment. Just as scientists test their theories through experiments, so, according to constructivist theory, each of us tests our new knowledge through combinations of experiments and interactions with others. We may hope that intelligent systems will, over time, become better able to support such broader knowledge gathering. Some preliminary efforts already seem productive. For example, one system, developed for limited laboratory use, helps students to access web pages with various hypotheses and data on them, store these in an 'intelligent notebook', and then annotate the connections between these different sources of information. An intelligent coach observes the patterns of annotation and makes a few broad suggestions about further research that might be useful. For example, a student might access both a collection of data relevant to a question (e.g. 'why are there mountains?') and discussions of alternative theories. If the student then draws a diagram showing the ways in which various data support different hypotheses, then the student's reasoning may be sufficiently examinable that inferences can be made about what coaching is needed.

ASSESSMENT OF TUTORING SYSTEMS

However sensible the ideas behind intelligent instructional systems may seem, it is important to test the systems to see if they really work – particularly given the high cost of producing them. Generally, those systems developed by researchers with sound understanding of how learning happens have been shown to be substantially more effective than extant forms of group instruction, but substantially less effective than the best human one-to-one tutoring (assessment based upon quizzes given before and after tutoring).

In the business world, evaluations of tutors tend to be most useful if they translate into measures of the cost of a worker's performance and the savings produced by the changes in work performance after tutoring. For example, one intelligent tutor was built for a technical job in which the biggest concern was the time it takes to repair a piece of equipment that was vital to a production line. It was possible to assign a time cost to every action that might be taken in trying to diagnose and repair this equipment. Then, the tutor could be evaluated by estimating the total time that each trainee's solution to each of several realistic problems might have taken in real life, where some actions take hours to complete. The tutor was shown to produce an average decrease in the time required to repair the equipment of about ten hours for difficult problems. The business managers knew how often such difficult problems occur, and they were able to determine that the approach was cost-effective.

For educational applications, assessment poses a special problem. Since intelligent tutors focus on more complex performances, it is likely that their main effect will be on the ability to apply complex bodies of knowledge successfully in novel situations. However, for a variety of reasons, routine measures of student educational achievement tend not to tap this high level of knowledge. Standardized tests need to take account of the many different curricula used in different schools. They also need to be fair to students coming from different backgrounds. In subtle ways, these requirements force much of standardized testing to focus on ability to use knowledge in the simplest situations (for example, complex situations are hard to standardize, so they tend to favor students with certain life experiences over those with others). Thus, the general pattern of evaluation results on intelligent tutors for use in schools has been a modest positive effect on standardized tests and a very positive effect on more demanding tasks, including some of those appearing in recently-published standards for mathematics and science.

INTELLIGENT TUTORING SYSTEMS AS PSYCHOLOGICAL RESEARCH TOOLS

Since intelligent tutoring systems carefully track the performance of students engaged in well-specified but rich problem solving, the technology behind these tutors has become useful in cognitive research. Given a hypothesis concerning how people solve certain kinds of problems or acquire certain knowledge, it is possible to specify the hypothesis as the expert system for an intelligent tutor. The tutor can then be operated in a mode where it does not provide feedback, providing a means of automatically scoring participants' performances and matching them against the hypothesized performance model. Essentially, instead of giving advice, the system tells the experimenter about when and how the student deviates from the hypothesized performance model. Such studies can be very helpful in establishing how people address complex tasks and the specific circumstances in which the tasks are addressed in a given way. (*See* **Computation, Formal Models of**; **Computer Modeling of Cognition: Levels of Analysis**)

INTELLIGENT TUTORING SYSTEMS AND OTHER FORMS OF INSTRUCTION

Intelligent tutoring systems are an important tool for education and training. They are especially effective in promoting 'learning by doing', since they permit students to tackle larger tasks while still having the support of an intelligent coach. In many respects, they follow a 'sink or swim' approach in which sinking (i.e. being overwhelmed by a large real-life task) is prevented by intelligent coaching. On the other hand, the intelligent tutors developed so far cannot effectively replace the learning that comes from critical interactions among people. We still learn much of what we know by discussing our ideas with teachers and peers in a respectful but critical way. We challenge each other's thinking and thereby make our own thinking stronger. Intelligent tools to help with this kind of learning are still at an early stage of development.

Knowledge Representation

Introductory article

Stuart C Shapiro, State University of New York, University at Buffalo, USA

CONTENTS

Knowledge representation is a subarea of artificial intelligence concerned with understanding, designing, and implementing ways of representing information in computers so that programs can use this information to: derive information that is implied by it; to converse with people in natural languages; to plan future activities; and solve problems in areas that normally require human expertise.

INTRODUCTION

Knowledge representation is a subarea of Artificial Intelligence concerned with understanding, designing, and implementing ways of representing information in computers so that programs can use it:

- to derive information that is implied by it,
- to converse with people in natural languages,
- to plan future activities,
- to solve problems in areas that normally require human expertise.

Deriving information that is implied by the information already present is a form of reasoning. Because knowledge representation schemes are useless without the ability to reason with them, the field is usually known as 'knowledge representation and reasoning'. (*See* **Language of Thought**; **Artificial Intelligence, Philosophy of**; **Representation, Philosophical Issues about**; **Implicit and Explicit Representation**; **Deductive Reasoning**; **Knowledge Representation, Psychology of**; **Reasoning**)

Many philosophers consider knowledge to be justified true belief. Thus, if John believes that the world is flat, we would not say that John knows that the world is flat, because he is wrong—'the world is flat' is not true. Also, it may be that Sally believes that the first player in chess can always win, Betty believes that the second player can always win, and Mary believes that, with optimal play on both sides, chess will always end in a tie. One of them is correct, but we would still not say that any of them knows the answer, because their belief cannot have been justified by a complete analysis of the game. A computer system could not limit its information to knowledge in this strict sense, so it would be more accurate to say that the topic being discussed is belief representation rather than knowledge representation. Nevertheless, we will continue to use 'knowledge representation', because that has become accepted as the name of this subject. (*See* **Epistemology**)

REPRESENTING COMMON-SENSE KNOWLEDGE

The field of knowledge representation began, around 1958, with an investigation of how a computer might be able to represent and use the kind of common-sense knowledge we have when we decide that to get from our house to the airport, we should walk to our car and drive to the airport rather than, for example, drive to our car and then walk to the airport.

In the 1960s and 1970s, much knowledge representation research was concerned with representing and using the kind of information we get from reading and talking to other people; that is, the information that is often expressed in natural languages, and that underlies our ability to understand and use natural languages. For example, we probably understand each of the sentences in the first column of Table 1 as shown in the second column, by adding our 'background knowledge'

Table 1. Some sentences and how we understand them

Sentence	*How we understand it*
John likes ice cream.	John likes to eat ice cream.
Mary likes Asimov.	Mary likes to read books by Isaac Asimov.
Bill flicked the switch. The room was flooded with light.	Bill moved the switch to the 'on' position, which caused a light to come on, which lit up the room Bill was in.
Betty opened the blinds. The courtyard was flooded with light.	Betty adjusted the blinds so that she could see through the window they were in front of, after which she could see that the courtyard on the other side of the window was bright.

to what the sentences explicitly say. Moreover, our understanding of English includes our being able to make the following inferences. (*See* **Natural Language Processing**; **Meaning**; **Semantic Memory: Computational Models**)

Every student studies hard. Therefore every smart student studies.

On Tuesday evening, Jack either went to the movies, played bridge, or studied. On Tuesday evening, Jack played bridge. Therefore, Jack neither went to the movies nor studied on Tuesday evening. (1)

In the 1970s and 1980s, researchers became increasingly concerned with knowledge about specific domains in which human experts operate, such as medical diagnosis and the identification of chemical compounds from mass spectrometry data, and also with the other extreme – knowledge about the everyday world that everyone knows, such as the fact that when you tip over a glass of water, the water will spill on the floor. (*See* **Expert Systems**; **Expertise**)

In the 1980s and 1990s, these concerns focused on the details of specific subdomains of everyday knowledge, such as theories of time and space, and also on the general structure of our knowledge of everyday terms, leading to the construction of large and general purpose 'ontologies'. For example, the Cyc Project has devoted many staff-years to the organization of a computer-usable representation of all the knowledge that is *not* contained in encyclopedias (thus the name 'Cyc,' from 'encyclopedia') but is assumed to be already known by people who read them, and Lycos is using such an ontology to organize searches of the World Wide Web. (*See* **Spatial Representation and Reasoning**)

All these threads continue into the 2000s.

PREDICATE CALCULUS AND OTHER LOGICAL REPRESENTATION SCHEMES

In the late 1800s and early 1900s, various formal systems were developed by people who hoped to turn human reasoning into a kind of calculation. From our perspective, we can now see that what these people were engaged in was research in knowledge representation. The formal systems they developed were systems of logic, a topic which has been studied since the days of Plato and Aristotle. We may consider logic to be the study of correct reasoning. The systems of logic developed in the late 1800s and early 1900s consist of three basic components:

- syntax: the specification of a set of atomic symbols, and the grammatical rules for combining them into well-formed expressions;
- semantics: the specification of the meaning of the atomic symbols, and the rules for determining the meanings of well-formed expressions from the meanings of their parts;
- proof theory: the specification of a set of rules, called 'rules of inference', which, given an initial collection, called a 'proof', of well-formed expressions, called 'axioms', specify what other well-formed expressions can be added to the proof. (*See* **Inference using Formal Logics**)

There are two kinds of 'meaning' determined by the semantics of a system of logic. In one, we might say that the meaning of G is the claim made by the sentence, 'The moon is made of green cheese.' For this notion of meaning, the meaning of $\neg G$, as shown in Table 2, would be the same as 'It is not the case that the moon is made of green cheese' or 'The moon is not made of green cheese.' The other sense of 'meaning' is a truth value. Different systems of logic have different truth values, and

Table 2. A set of propositional connectives and their meaning

Propositional connective	*Sample use*	*Meaning*
$\neg$	$\neg P$	It is not the case that P
$\wedge$	$P \wedge Q$	P and Q
$\vee$	$P \vee Q$	P or Q, or both
$\Rightarrow$	$P \Rightarrow Q$	If P then Q

Table 3. The quantifiers and their meanings

Quantifier	*Sample use*	*Meaning*
$\forall$	$\forall x\ P\ (x)$	Every x is a P
$\exists$	$\exists x\ P\ (x)$	Some x is a P

even different numbers of truth values. There are two-valued logics, three-valued logics, four-valued logics, and even logics with an infinite number of truth values. Two-valued logics usually call their truth values 'True' and 'False'. Some logicians would say that in such a two-valued logic any sentence either means True or False. Less strictly, one might say that in such a logic, the semantics assigns a truth value of True or False to every sentence. In this notion of meaning, if some sentence P happened to be (or be assigned the truth value of) True, then $\neg P$ would be (or be assigned the truth value of) False, and if P were False, then $\neg P$ would be True. So, if G meant (by the first sense of meaning) 'The moon is made of green cheese,' then G would be (or mean, in the second sense of meaning) False, so $\neg G$ would be (or mean, or have the truth value of) True.

Although the proof theory considers only the syntax of the expressions, not their semantics, it is usually the case that if the semantics assigns a truth value of True to the axioms, all expressions that the rules of inference add to the proof will also be True. Logics that have this property are called *sound*. Soundness seems to capture the notion of correct reasoning, which is what the study of logic is all about.

Many different logics have been described and investigated. Propositional (or 'sentential') logics do not analyze information below the level of the proposition (or sentence), but use 'propositional connectives,' such as are shown in Table 2 to build more complex sentences from simpler sentences. For example, the sentence '*Students who study hard get good grades*' could not be represented in more detail than $P \Rightarrow Q$, where P represents '*Students study hard*' and Q represents '*Students get good grades*'. First-order logics (predicate logics) continue the analysis down to objects, classes, properties, and relations, with the aid of the quantifiers shown in Table 3. So in some first-order logic, '*Students who study hard get good grades*' might be represented as $\forall x\ (Student(x) \wedge study\ (x, hard) \Rightarrow get\ (x, good\ (grades))$. Some first-order logics allow functions. In one of them, this sentence might be represented as $\forall x\ (Student(x) \wedge study\ (x, hard) \Rightarrow get\ (x, good\ (grades)))$. Second-order logics allow functions, classes, properties, and relations, themselves, to be the arguments of other functions, classes, properties, and relations. In one of them, this sentence might be represented as $\forall x\ (Student\ (x) \wedge hard\ (study)\ (x) \Rightarrow get(x, good\ (grades)))$. (*See* **Representations Using Formal Logics**)

A logical sentence that always evaluates to True regardless of the meanings of its atomic parts is called *valid*. In most standard logics, the sentence $P \wedge \neg P \Rightarrow Q$ is valid, meaning that a contradiction implies anything whatsoever, but in some logics, called 'paraconsistent' logics, that sentence is not valid. In most standard logics the sentence $P \vee \neg P$ is valid, meaning that any sentence is either True or False, but in some logics, called 'intuitionistic' logics, that sentence is not valid.

Someone who uses a propositional logic to formalize some domain of interest chooses the proposition symbols to be used to represent the sentences of the domain, and their semantics – what sentence each symbol will represent. Someone who uses a predicate logic to formalize some domain of interest chooses the syntax and semantics of the individual constants that represent objects in the domain, the function symbols that represent functions in the domain, and the predicate symbols that represent classes, properties, and relations in the domain. The logic itself determines the propositional connectives and the quantifiers, and how they are to be used, along with function and predicate application, to determine the nonatomic expressions, and their meaning. The rules of inference also operate only on nonatomic expressions, and pay attention only to the logical constants. This is the sense in which people consider these logics to be 'formal' logics that pay attention only to the form, and not to the content, of the logical expressions. When selecting a logic to use, one is choosing the formal apparatus supplied by that logic.

Any knowledge representation and reasoning system consists of two parts – a knowledge representation language and a reasoning component.

If the knowledge representation language is well-defined, it will have a well-defined syntax to describe the atomic symbols and how well-defined symbol structures may be constructed from them, and a well-defined semantics to describe what the atomic symbols and the symbol structures are supposed to mean. The reasoning component is a program, often called an 'inference engine', that, given a 'knowledge base' of symbol structures, adds additional symbol structures to that knowledge base according to the rules implemented in the program. Clearly these components – syntax, semantics, inference engine, knowledge base – correspond to the components of logics – syntax, semantics, proof theory, proof. So we may view any knowledge representation and reasoning system as a logic, and ask what kind of logic it is, what formal apparatus it supplies, and whether or not it is sound. The user of a knowledge representation and reasoning system, like the user of a logic, must choose a system, and then design the representations that are not at the level of knowledge representation constructs that the system deals with. In the knowledge representation world, this person is called a 'knowledge engineer'.

PROCEDURAL REPRESENTATIONS

In the mid-1970s, knowledge representation researchers were embroiled in what was called the 'declarative/procedural controversy'. Although this controversy has largely been resolved (in a sort of compromise), it is worthwhile understanding these two approaches to knowledge representation.

Firstly, we must recognize that there are several kinds of knowing, among which are *knowing that*, *knowing who*, and *knowing how*. *Knowing that* is the kind of knowledge we have of propositions. For example, we may know that Seattle is north of San Francisco. *Knowing who* is acquaintance with a person, animal, object, etc. We may say that we know a person even though we might not know some important facts about that person, for example their birthdate. On the other hand, we may know many facts about a person without being able to say we know that person. For example, many of us know many facts about Bill Clinton, but how many of us can truly say, 'I know Bill Clinton'? *Knowing how* is knowledge of how to do things, for example how to swim or ride a bicycle.

There has not been much work in knowledge representation on *knowing who*, and everyone would agree that a procedural representation is appropriate for *knowing how*, though more on this later. The declarative/procedural controversy was about how to represent *knowing that*. The declarativists were in favor of representing propositions that are known (believed) by some agent as a symbol structure with declarative semantics, for example a well-formed expression of propositional or predicate logic, stored in the agent's knowledge base. The proceduralists were in favor of representing such propositions as small programs. For example, when the early (simulated) robot SHRDLU was told, 'I own blocks which are not red, but I don't own anything which supports a pyramid', it represented that information as two small procedures in the PLANNER programming language. When, later, SHRDLU was asked 'Do I own anything in the box?', it ran those two procedures to determine the answer. The problem with maintaining this distinction between declarative and procedural representations of *knowing that* is the well-known equivalence of data and program. A procedure can be written in a declarative programming language such as Lisp or Prolog, and can thereby be viewed as a symbol structure with declarative semantics. On the other hand, when a declarative representation is used by the inference engine to draw some inference, the declarative representation may be viewed as a program in the programming language interpreted by the inference engine. In this sense, whether a representation is declarative or procedural depends on how one views it. (*See* **SHRDLU**)

We might resurrect the declarative/procedural distinction by considering our own knowledge of how to do things. Many of us know how to ride a bicycle. However, few of us can describe how to ride a bicycle, for example in order to instruct someone else. We might consider this knowledge procedural *only*. In this view, all knowledge may be viewed as procedural knowledge, but only knowledge that can be expressed in a declarative language by the knower may be viewed as declarative knowledge. As another example, the restaurant script (see below) is a representation of what typically happens in a restaurant. There have been programs that, supplied with the restaurant script, could fill in details about what happened in restaurant stories. For example, given the story, 'John went to a restaurant and ordered a steak', such a program could infer that John was seated and given a menu between entering and ordering. However, most of these programs could not answer questions about the restaurant script itself, such as 'What typically happens in a restaurant after the patron is seated?' It is, therefore,

reasonable to say that for these programs the restaurant script is not represented declaratively, but only procedurally. (*See* **Story Understanding**)

PRODUCTION SYSTEMS

Production systems are a subclass of knowledge representation and reasoning systems. The knowledge base of a production system is divided into two parts, a working memory and a rule memory. The working memory consists of a set of symbol structures not containing variables. The rule memory consists of a set of pattern-action rules. Each pattern-action rule has a 'left-hand side', which is a set of patterns, and a 'right-hand side', which is a set, or sequence, of actions. The patterns and actions may contain variables as long as every variable in the right-hand side of a rule is also in the left-hand side of the same rule. If every pattern in a rule matches some symbol structure in working memory, with a consistent substitution of constants for the variables in the patterns, then the rule is said to be 'triggered'. A triggered rule may 'fire', in which case every action in the right-hand side is performed after replacing the variables with the constants they were matched to in the left-hand side. The actions allowed in the right-hand sides of rules vary among different production systems, but they generally include adding structures to working memory and removing structures from working memory. They may also include adding and removing rules, and interacting with a user. (*See* **Production Systems and Rule-based Inference**; **Working Memory, Computational Models of**; **Rule-based Thought**)

Since the firing of a rule may change the structures in working memory, it may also change which other rules are triggered. So if several rules are triggered at the same time, the ultimate behavior of the production system may depend on which triggered rule fires first. This is determined by a conflict resolution strategy. Typical strategies are: don't fire any rule more than once on the same variable substitutions; fire the rule that was triggered most (or least) recently; fire a more specific rule before a less specific rule.

Production systems were first designed to be a model of the human mind. For this purpose, the size of working memory and the allowed actions were restricted. However, they have been a popular architecture for expert systems, for which purpose those restrictions were lifted.

It should be noted that the symbol structures in working memory and the patterns and actions in rule memory must be formulated in some knowledge representation language. What the production system architecture provides is a particular style of reasoning and acting using that language.

SEMANTIC NETWORKS

Semantic networks are a variety of labeled, directed acyclic graph in which the nodes denote entities and labeled directed arcs denote relations between the nodes they connect. Two kinds of semantic networks have been developed, inheritance networks and propositional semantic networks. Figure 1 illustrates an inheritance network which is intended to represent the following information:

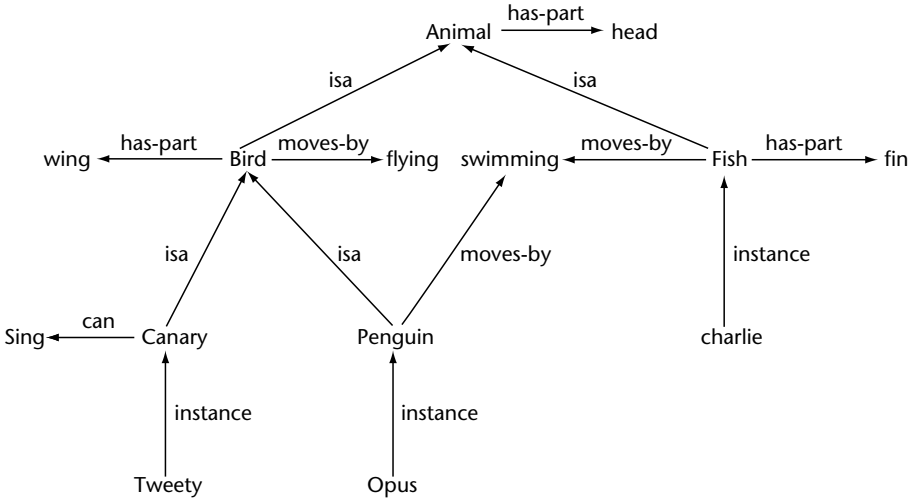

Figure 1. An inheritance-style semantic network.

Birds and fish are animals. Canaries and penguins are birds. Animals have heads. Birds have wings. Fish have fins. Birds move by flying. Fish and penguins move swimming. Canaries can sing. Tweety is a canary. Opus is a penguin. Charlie is a fish. (2)

Notice that some of the nodes represent categories (Animal, Bird, Fish, Canary, and Penguin), and others represent individuals (Tweety, Opus, and Charlie). The relation between an individual and the categories it is a member of (instance) is different from the relation between a category and its supercategories (isa). (*See* **Semantic Networks**)

Early presenters of inheritance networks did not make the semantics of the relations very clear. For example, it is not clear in Figure 1 what it means when arcs with the same label emanate from a category and one of its supercategories. Surely, birds have both wings and heads, but penguins swim and do not fly. Moreover, although the 'has-part' relation seems simple, the 'has-part' relation from 'Animal' to 'head' must mean *Every instance of Animal has a part which is an instance of head*. These semantic confusions were clarified in the successors to simple inheritance networks, the most prominent of which are called *description logics*.

Description logics are a variety of inheritance networks in which categories (called 'concepts') and relations (called 'roles') between them can be defined without the semantic confusions of earlier inheritance networks. For example, using a formalism called $\mathcal{KL}$, which was designed to reflect many of the features common to different description logics, a parent can be defined as a person with at least one child who is also a person, as follows.

```
(cdef PARENT (and PERSON (c-some
  Child PERSON)))                    (3)
```

Here, PARENT is the concept being defined, PERSON is a concept which, presumably, has already been defined, and Child is a role. This is also an example of a concept defined with necessary and sufficient conditions. That is, if Ken is said to be a PARENT, it is *necessary* that Ken be a PERSON with at least one Child who is a PERSON. So the description logic system can infer that Ken is a person, has at least one child, and that child is a person. On the other hand this same definition says that if Judi is a PERSON with at least one Child who is a PERSON, that is *sufficient* information to conclude that Judi is a Parent. Natural kinds, such as birds, fish, and animals, cannot be given necessary and sufficient conditions, so *primitive concepts* can be defined with only necessary conditions. The $\mathcal{KL}$ definitions of ANIMAL and FISH from Figure 1 are:

```
(cprim ANIMAL (and top
  (c-some Part HEAD)
  (c-atmost 1 Part HEAD)))
(cprim FISH (and ANIMAL
  (c-some Part FIN)
  (c-some Moves-by SWIMMING)))       (4)
```

This says that every FISH has one head, by inheritance from ANIMAL, and, in addition, has one or more FINs. Since description logic roles accumulate in this way, the only way to say that birds fly, but penguins are birds that swim instead, is to separate flying birds from swimming birds:

```
(cprim BIRD (and ANIMAL
  (c-atleast 2 Part WING)
  (c-atmost 2 Part WING)))
(cdef FLYING-BIRD (and BIRD
  (c-some Moves-by FLYING)))
(cprim PENGUIN (and BIRD
  (c-some Moves-by SWIMMING)))
(cprim CANARY (and FLYING-BIRD
  (c-some Can SING)))                (5)
```

(*See* **Concepts, Philosophical Issues about**; **Conceptual Representations in Psychology**; **Natural Kinds and Artifacts**)

All these $\mathcal{KL}$ constructs define concepts, and are considered part of the description logic *terminological component*. To actually make assertions about individuals, most description logics also have an *assertional component*. Assertions in the assertional component are usually written in a syntax that looks like normal first-order predicate logic in which defined concepts can be used as unary predicates and defined relations can be used as binary relations. For example, we might have:

CANARY(Tweety) WING(Tweety-left-wing)
PENGUIN(Opus)
SWIMMING(Opus-swimming-style) (6)

Part(Tweety, Tweety-left-wing)
Moves-by(Opus, Opus-swimming-style) (7)

Besides the confused semantics of their relations, another deficiency of inheritance networks is that since information can only be represented about nodes, one cannot represent information about relations, such as that the 'isa' relation is transitive. Nor can one represent information about beliefs, such as that the encyclopedia is the source of the belief that canaries are birds. Description logics

do represent information about relations, but they do not represent information about beliefs. This deficiency is solved by propositional semantic networks, in which nodes are used to represent beliefs (propositions) as well as the individuals, categories, and properties represented by nodes in inheritence networks. Figure 2 illustrates a propositional semantic net in which 'M1!' represents the proposition that canaries are birds, 'M2!' represents the proposition that 'isa' is a transitive relation, and 'M3!' represents the proposition that the source of 'M1!' is the encyclopedia.

SCHEMAS, FRAMES, AND SCRIPTS

Some researchers felt that semantic networks used a representation that was too fine-grained and too passive. Instead, they argued for representational structures that contain more information about the entities being represented, and also incorporate active processes. They adapted the notion of schemas (or 'schemata') from psychological literature. The two most widely used schema representation systems are frames and scripts. (*See* **Schemas in Psychology**)

Frames were originally proposed as a representation of structured visual information about complex objects. For example, if you open a door to an office, you expect to see certain things, such as a desk, chairs, etc. You would be surprised to see a tennis court, a beach, and a swimming pool in the office. On the other hand, if you opened a door to a bedroom, you would expect to see a bed, a chest of drawers, etc. The proposal was that the 'office frame' would contain pointers to the representations of objects you would expect to be in an office, the 'bedroom frame' would contain pointers to the representation of objects you would expect to be in a bedroom, etc. As frame representation systems were implemented, they became more similar to semantic networks, but with the labelled arcs, now called 'slots', pushed into the nodes, now called 'frames', and the nodes pointed to by the arcs, now called 'slot fillers'. For example, Figure 3 shows the information of Figure 1 as a frame system.

One feature frame systems tend to have that semantic networks do not is *procedural attachment*. Instead of a slot being filled by a pointer to a frame or a set of such pointers, the slot could be filled by an *if-needed* or an *if-added* procedure. If a slot containing an if-needed procedure is accessed, the procedure is executed and is expected to compute and return the slot filler. If a slot containing an if-added procedure is filled, the procedure is executed and is expected to fill other slots that depend on the new information being added to this slot. If-needed and if-added procedures are procedural versions of inference by backward chaining and forward chaining, respectively.

Scripts, like frame systems, were designed to be structured representations, but of activities rather than objects. For example, the restaurant script contains a representation of all the activities that typically occur when one visits a restaurant. If you read a story about someone going to a restaurant and ordering a steak, you fill in the information about being seated and being given a menu from your restaurant script. (*See* **Natural Language Processing: Models of Roger Schank and his Students**)

PICTORIAL REPRESENTATIONS

Some people think mostly linguistically; others think mostly in pictures. Everyone can probably do both, even though they usually do one or the other. Try this: Think of an elephant. Which way is it facing? If, when you thought of an elephant, you pictured one in your mind, you should have a definite answer to that question.

Just as people can represent entities in their minds either linguistically or pictorially, we can

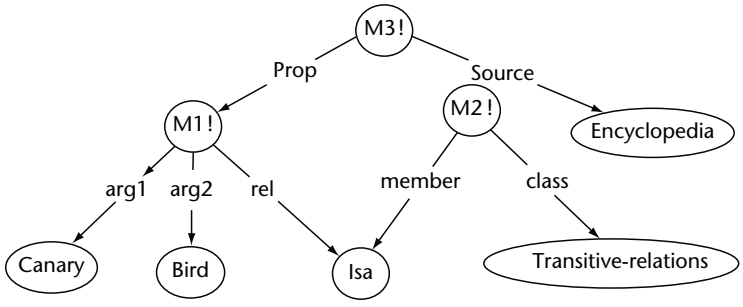

Figure 2. A propositional semantic network.

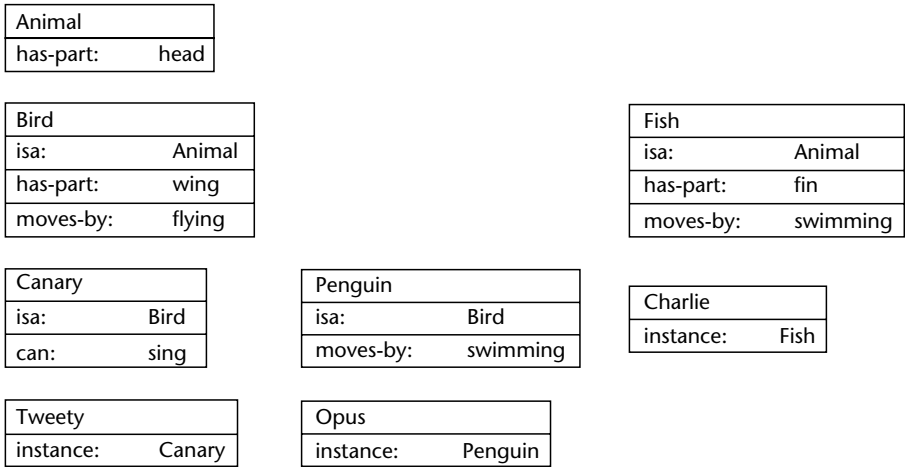

Figure 3. Figure 1 as a frame system.

use linguistic and pictorial representations in other media, including computers. The distinction is also often termed digital vs. analog, as in digital clocks vs. analog clocks. (*See* **Mental Imagery, Philosophical Issues about**)

The best way to distinguish analog from digital representations is to compare the domain of the representation (syntax) to the domain of what is represented (semantics). An analog representation has a syntactic operation that is a direct analogue of a semantic representation. Consider clocks. What is represented is time. On an analog clock, the representation is the rotation of the clock hands around the circle of the clock face. The difference between the representation of 10.15 a.m. and that of 10.30 a.m. is a 90 degree rotation of the minute hand, which is one quarter of the complete 360 degree rotation. The complete 360 degree rotation represents one hour, and one quarter of a rotation represents one quarter of an hour. On a digital clock, however, the times 10.15 a.m. and 10.30 a.m. are represented with different numerals. Nothing about the difference between the two sets of numerals indicates what the difference in the represented times is, unless one moves to the separate semantic domain of numbers, and subtracts 15 from 30.

Analogue representations can be constructed in computers by using a data structure whose operations are analogues of the relations being represented. For example, consider a predicate logic representation of items arranged in a row: *Left (desk, chair), Left(sofa, desk), Left (chair, stool)*, where *Left (x, y)* means that *x* is to the left of *y*. To decide the left-to-right arrangement of the stool and the sofa requires a certain amount of search and inference. However if, instead, the Left relation were represented by order in a list, the four relations would be captured by the list *(sofa, desk, chair, stool)*, and the left-to-right arrangement of the stool and the sofa could be decided by a linear search. Some researchers have created systems that can reason about diagrams or visual scenes by representing them in two-dimensional data structures where it is easy to rotate or otherwise manipulate the figures. (*See* **Analogical Reasoning, Psychology of**)

CONNECTIONIST REPRESENTATIONS: LOCAL AND DISTRIBUTED

Connectionist representations are designed to model the brain by using a large collection of intercommunicating units, each of which is a model of a neuron. These units are organized in layers: an input layer, an output layer, and one or more 'hidden' layers. Each unit maintains an activation level and connections to other units, which may be on the same layer (in some versions) or on layers closer to the output layer. Each connection is also given some weight, which might be negative or positive. The network as a whole makes some decision or characterizes its input. Input is achieved by adjusting the activation level of the units in the input layer. When the activation of a unit exceeds some threshold (which may be different for different units), an activation is passed to all outgoing connections, where it is adjusted by the connection weights, and passed to the connected units, etc. The final decision or characterization is read off the units in the output layer. Networks are trained by adjusting the weights on the connections by one of several possible feedback mechanisms. (*See* **Connectionism**; A00068; A00163)

Local connectionist representations are distinguished by the requirement that each decision or characterization is represented by a single unit, and each input unit also represents some concept of the input. For example, in a lexical decision task, each input unit might represent a particular letter in a particular position, and each output unit might represent a particular word.

In a distributed connectionist representation, each represented decision or characterization is represented, not by a single unit, but by a pattern of unit activations. Distributed representations have been found to generalize what they have learned better than local representations do.

Connectionist representations are considered subsymbolic rather than symbolic representations. As such, they are not as capable of representing and reasoning about beliefs as the other representation techniques discussed in this article. (*See* **Symbolic versus Subsymbolic**; **Bayesian Belief Networks**; **Language, Connectionist and Symbolic Representations of**)

MANAGING CHANGE

Consider again some of the information in Figures 1 and 3, namely that birds fly, but penguins do not. If you learn that Opus is a bird, you are justified in concluding that Opus can fly. However, if you then learn that Opus is a penguin, you must reject your conclusion that Opus can fly. This is an example of an interesting phenomenon where a new piece of information causes the rejection of a previous conclusion. It is sometimes said that, in this case, the new piece of information *defeats* the old conclusion. This phenomenon often occurs in the presence of general information to which there are exceptions. The general information is sometimes referred to as *default* knowledge, and conclusions drawn from the general information are sometimes said to be *defeasible*. From the point of view of classical propositional and predicate logic, this situation is most unusual, since these logics are *monotonic*, meaning that if a conclusion can be drawn from some set of beliefs, it can also be drawn from any superset of those beliefs. (Just ignore the extra beliefs.) Attempts to formalize defeasible reasoning have been made by knowledge representation researchers, and this remains an active area of research. (*See* **Non-monotonic Logic**)

Removing default conclusions that have been defeated by more specific information is just one possible reason that information might have to be removed from a knowledge base. If the knowledge base is a model of the world, or a model of some agent's beliefs about the world, it may be that the world changes because of the action of the agent or some other agent. If the knowledge base is a model of some agent, or a collection of beliefs input by some agent or agents, it may be that the agent or agents have changed their beliefs. If the knowledge base is a collection of facts and 'laws' of some developing theory, it might be found that some of the facts and laws are contradictory, and the theory must be revised. Removing information from a knowledge base seldom involves merely removing a single proposition (fact, rule, law). If additional propositions have been derived from the one to be removed, they might need to be found and removed also. If the proposition to be removed was derived from other propositions in the knowledge base, or could be rederived from them, they must be found, and at least one of them must be removed or else the removed proposition could be reintroduced. The first systems that knowledge representation researchers implemented to handle these complications of removing information from knowledge bases were called 'truth maintenance systems'. More formal studies, carried out by computer scientists, logicians, and philosophers go under the name 'belief revision'.

Using belief revision or truth maintenance to deal with a changing world is appropriate if the knowledge base always represents the *current* time, and should be changed as time moves. However, this eliminates the possibility of representing what was the case at past times. To do that, time must be represented explicitly, and propositions that hold only for some specific time must indicate so explicitly. To do this, specialized logics including temporal logics and modal logics have been used. Another logic for this purpose, popular among knowledge representation researchers, is situation calculus, in which predicates that can change are given an extra argument that ranges over situations. For example, if a particular book is on a particular table in a particular situation, this might be represented as *On(book 1, table3, S5)*. In situation calculus, an action is considered to be a function from the situation before the action is performed to the situation afterward. (Some versions of situation calculus use slight variations of this.) For example, the action *pickup*(*book1, S5*) might represent the situation that exists after picking up *book1* in situation *S*5. We would then have ¬*On* (*book1, table3, pickup*(*book1, S5*)). Stating the effects of actions is fairly straightforward. However, stating what is *not* changed by an action is more involved. For example, if it is the case that *In*(*table3, room2, S5*), is it the case that *In*(*table3, room2, pickup*

(*book1*, *S5*))? The problem of specifying what is not changed by an action has been called the 'frame problem', not to be confused with the frames used as schema representations. (*See* **Frame Problem, The**)

Language Learning, Computational Models of

Intermediate article

Michael Gasser, Indiana University, Bloomington, Indiana, USA

CONTENTS

Computational models of language acquisition range from symbolic approaches based on linguistic theory and relying on built-in (innate) constraints to statistical and connectionist approaches relying only on general-purpose learning mechanisms.

INTRODUCTION

Probably no single issue had more influence on the development of cognitive science in the second half of the twentieth century than the question of how natural languages are learned. As in other areas of cognitive science, much progress has been made through attempts to build formal models of the processes and to implement these as computer programs. Language acquisition is also of practical interest within computational linguistics: even fragments of natural languages are complex enough to make hand-coding of grammars and lexicons cumbersome or impossible. Thus systems that learn, at least in part, may be the only usable language processing systems. This article examines formal models of language acquisition, focusing on models that have actually been implemented. (*See* **Language Acquisition**)

Computational models of language acquisition vary in at least the following ways: the nature of the task (what theory of language and language behavior is assumed, what the learner is learning to do, and what characterizes the input to learning); and the nature of the model (what is built in ('innate'), and what sort of learning architecture and algorithm are used).

THE TASK

Theories of Language and Language Behavior

In most linguistic theories, language, and each level of linguistic inquiry, is treated as a module, something that can be studied without consideration of other domains. This view corresponds to learning models in which the modeled behavior is purely linguistic. In cognitive linguistics, on the other hand, as well as in some work on natural language within artificial intelligence, it is felt that language can be understood only in terms of its place in cognition. The corresponding goal in models of processing and learning is the grounding of linguistic behavior in psychological processes or robotics. (*See* **Cognitive Linguistics**)

More fundamentally, theories of language differ in what they take language to be, what it means to know a language. Everyone accepts the general view that a language is a set of patterns, associating features of linguistic form (phonetic, phonological, syntactic) with each other and with features of linguistic function (semantic and pragmatic). The simplest view, then, would be that language is just associations, of varying complexity and generality, and that it is these associations that are learned. This idea lends itself to particular kinds of learning algorithms, especially connectionist and memory-based algorithms, which are discussed below.

The idea of knowledge as associations and learning as rote memorization or statistical correlation makes sense to most researchers when applied to certain aspects of language: the relationship between acoustic or articulatory parameters and phonetic categories, the arbitrary forms that morphemes take in a given language, morphological irregularities, and the details of lexical semantics. More controversial are aspects of language that are thought to be systematic, those aspects that make up grammar: the mapping between underlying and surface phonological forms, the formation of regular morphological inflections, the assignment of words to syntactic categories, the grouping of words into syntactic constituents, the mapping between syntax and sentence-level semantics, grammatical relationships between constituents within

sentences, and relationships between sentences. Nearly all accounts of these aspects of language treat them as rule-governed. In general, these accounts assume structured representations, built up from atomic symbols, including both constants and variables. (*See* **Symbol Systems**)

Knowledge in these symbolic theories of language often takes the form of formal grammars; thus, learning is often grammatical induction, in which the learner attempts to arrive at a grammar characterizing the target language on the basis of examples provided by the environment. An important concern in computational linguistics has been which type of grammar, or equivalently which type of automaton, in the Chomsky hierarchy is adequate for natural language. Interest has centered on context-free grammars and, to a lesser extent, regular (finite-state) grammars, which may be adequate for morphology and phonology. Some symbolic models also make use of transformations that can move elements within the tree structures generated by context-free grammars. There has been considerable interest in what would be necessary in order for a learning model to learn these different classes of grammars. (*See* **Syntax**)

To capture the commonalities among languages and deal with some of the learnability issues discussed below, some modern theories within generative linguistics express the possible range of variation within natural language grammars in terms of a finite set of parameters. In learning models that rely on these theories, it is the parameter settings, rather than explicit grammatical rules, that are learned (Roeper and Williams, 1987). One symbolic theory, optimality theory, posits a set of universal constraints which apply to abstract, underlying forms to yield surface forms. Languages differ in the priority that these constraints have, and it is this priority that an optimality-theoretic learner learns (Tesar and Smolensky, 1998). (*See* **Optimality Theory**; **Learnability Theory**)

Thus, to some researchers, learning a language means learning patterns of associations. To others, learning a language means learning both rote associations and the regularities that make up grammar (explicit rules, parameter settings, or constraint rankings). As described below, there are correspondingly two sorts of views on what the learner needs to know beforehand and what sort of learning algorithms are needed: the 'symbolic' and the 'subsymbolic' (or 'connectionist') views. Language grounding models are usually of the subsymbolic type, because the extralinguistic domains they take into consideration are often best handled by such models. To the extent that symbolic and subsymbolic models have been applied to similar phenomena, they have often been seen as competitors. (*See* **Symbolic versus Subsymbolic**; **Language, Connectionist and Symbolic Representations of**)

What the Learner Learns to Do

Language behavior includes both analysis (parsing, recognition, comprehension) and production. A 'performance-oriented' model is designed to learn one or other or both of these behaviors directly. For example, given an input form produced by a speaker, an analysis model attempts to assign a category, a structure, or a meaning representation to it. A 'competence-oriented' model is designed to learn the knowledge (usually some form of grammar) which, together with analysis and production algorithms, permits language behavior. For these models, the overt task of the model may be to determine whether an input is grammatical or not. (*See* **Language Comprehension**; **Performance and Competence**)

For grammatical induction, there is also the question of what would constitute success. The process would have to converge on the adult grammar. Gold (1967) formalized this notion: if, in the learning of a target language, the learner's hypothesized grammar never changes beyond some point, and that grammar correctly generates the target language, then the learner is said to have 'identified the language in the limit'.

Obviously no model, whether of the competence or the performance type, can be expected to learn phenomena across the full range of linguistic enquiry. Specific areas that have been addressed include word recognition, segmentation, phonemes, stress, regular and irregular inflectional morphology, word meaning, syntactic categories, formal grammars, grammatical parameter settings, verb subcategorization frames, and long-distance dependencies. Several ambitious projects have addressed both syntactic and semantic phenomena. An early symbolic example is Anderson's (1977) 'language acquisition system', which learns a procedural grammar in the form of an augmented transition network. A subsymbolic example is Miikkulainen's (1993) model, which learns distributed syntactic and semantic representations for lexical items.

The Input to Learning

In theories of human language acquisition, the character of the input that the learner receives is a

crucial issue, one that computational models must address. One way in which tasks vary with respect to the available input is in the degree of supervision that is available. Does the environment provide the learner with feedback concerning the correctness of the learner's response? (*See* **Bayesian and Computational Learning Theory**)

Purely phonetic or phonological acquisition is usually treated as unsupervised, as it is for human learners. Inputs are not labeled with their phonological categories, and word boundaries are not provided. Word recognition, on the other hand, is usually treated as a supervised task. Given a form, the learner responds with a word, and the environment provides feedback on whether the response is correct. The acquisition of word meaning may be treated as supervised or unsupervised, depending on what 'meaning' is taken to be. If the meaning of a noun is taken to be its referent noun, for example, a model may provide the meaning along with the word being learned. If word meaning is seen as a property to be extracted on the basis of the interrelationships among words, on the other hand, then the learning may be unsupervised. (*See* **Word Recognition**; **Lexical Semantics**)

For grammatical induction, both approaches have been considered. The unsupervised approach simply presents grammatical forms. The supervised approach presents both grammatical and ungrammatical forms with their grammaticality labeled; or, in the case of optimality theory, pairs of underlying forms and corresponding surface forms. When ungrammatical forms are labeled as such, the learner has access to a form of negative evidence. As noted below, negative evidence can greatly constrain the space of possible grammars hypothesized by the learner. On the other hand, it has been argued that children do not normally have access to negative evidence, and that when they do, they ignore it. For this reason, most grammatical induction models make use of positive evidence only.

In connectionist models, grammatical learning is sometimes a side effect of exposure of a network to an unsupervised task. One such task is prediction. A network is presented with one element in a sequence (for example, a phonetic segment or a word) and trained to predict the next element in the sequence. Networks trained on prediction can learn about the structure of the input as a side effect of the overt prediction task (Elman, 1991).

Models also vary in the extent to which they make use of real data. While most models still use artificial training sets, statistical models, especially those acquiring phonetic categories, segmentation strategies, syntactic categories, probabilistic grammars, and lexical semantics, often learn on the basis of real data.

TYPES OF MODELS

Innateness

The negative evidence problem

Probably the most contentious question within the study of language acquisition concerns what knowledge or mechanisms are assumed to be in place before learning takes place – that is, to be innate. Early work on language identification in the limit by Gold (1967) has been very influential in this regard. Gold proved that, even with a very powerful learning algorithm which tries each of the possible grammars until it hits on the right one, negative evidence is required to learn the sorts of grammars that characterize natural language.

Consider the acquisition of the passive in English. The learner hears several examples: *the dog got caught*, *he'll get hurt*, *it got eaten*. The hypothesis might be that a verb phrase can consist of a form of the verb *get* followed by the past participle form of another verb. But in the absence of negative evidence, how would the learner know what restrictions there are on the possible verbs that can take this pattern? For example, would *they got died* and *I get seemed* be grammatical?

Similar arguments, going back at least to the influential work of Quine (1960), have been made regarding the learning of word meaning. The problem is that too many meanings are apparently compatible with words when they are presented to children. Without being told explicitly what a word does not mean, it again appears impossible to settle on the correct meaning.

Within the field of computational language acquisition, there have been two sorts of responses to the apparent insufficiency of the input. One is to treat these idealizations of the learning task as missing essential information, specifically semantics and pragmatics in the case of the learning of grammar. This is the view taken by Anderson (1977) in his model mentioned above. Another is to constrain the learner to particular sorts of hypotheses on the basis of innate mechanisms or knowledge. This innate help may be specific to language, or it may be applicable to cognitive processes more generally. (*See* **Innateness and Universal Grammar**)

Innate constraints specific to language

One well-known proposal for constraining the set of possible hypothesized grammars is the 'subset principle' (Berwick, 1985). By this principle, when there are two grammars that accommodate the input examples, and one is a proper subset of the other, the smaller grammar is to be preferred. For example, if the learner, for other reasons, had already divided verbs into transitive and intransitive verbs and had then been presented with the passive sentences given above, the hypothesis could be that only transitive verbs could take part in the passive rule. This would obviate the need for negative examples such as **they got died*.

Most other proposals for innate linguistic knowledge constrain the set of possible languages more directly, limiting them to what is compatible with 'universal grammar', the purported system of properties that all natural languages share. Universal grammar is supposed to be built into the language learner, overcoming the limitations found by Gold because the size of the search space is much smaller. The best-known current proposals of this type are the parameter-setting models mentioned above. The learner starts with an innate finite set of parameters, each with a finite set of possible values, normally including a default initial value for each.

Innate general cognitive constraints

Other models are based on the hypothesis that language acquisition is possible because of more general constraints: cognitive mechanisms, regularities in the world, and properties of the input. Most such models are subsymbolic.

Regier (1996) provides an example from the domain of word meaning. In his connectionist model of the acquisition of spatial terms such as *in* and *through*, most of the constraints come from a built-in visual processing module. This module extracts information such as the relative positions of the centers of mass of the objects in the input. This processing is compatible with what is known about the human visual system, and this constrains what can be learned by the linguistic part of the system.

Some connectionist models are best described in terms of what is *not* innate in them. In the acquisition of word meaning, it has been proposed that the learner is guided by possibly innate biases: for example, the 'shape' bias whereby nouns referring to solid objects are generalized on the basis of shape. There has been much connectionist research designed to show that such biases emerge from general learning mechanisms in combination with the properties of the input itself. (*See* **Word Learning**)

Learning Architectures and Algorithms

Symbolic models

Symbolic models are designed to learn grammar, whether in the form of phonological rules, syntactic rules, parameter settings, or constraint rankings. These models work by maintaining an explicit candidate grammar and modifying it when it fails to handle an input form.

The model must have a way of determining whether the grammar fails to handle an input. Many models have a parser as a separate module for this purpose. The parser may also provide structural information that is relevant to the change that would take place when the grammar fails. For example, if the model is learning how to set the 'pro-drop' parameter, which reflects whether the language permits zero subjects, it must be able to identify the subject noun phrase and the verb in sentences. (*See* **Learnability Theory**)

Models vary in how they respond to input forms. There are two major issues. Firstly, which aspect of the grammar is changed when the grammar fails to handle the input? Some parameter-setting models select a parameter randomly, change its current value to some other value, attempt to parse the form again, and if they succeed, change the parameter setting in the evolving grammar. Others, such as Dresher and Kaye's (1990) model, select a parameter according to the type of input that is presented: thus, there is further innate knowledge specifying which sorts of forms convey information about which parameters.

Secondly, how much information is taken into account when a parameter is changed? In the simplest treatment, the learner takes only a single input into account each time (e.g. Gibson and Wexler, 1994). The danger in this approach is that the learner may jump to a conclusion and make an inappropriate change to the grammar. This is possible when there is more than one parameter change that can make the form parsable, when the form is an exception to the rules, or when the form contains an error. One solution is to give the learning model some form of memory: then, rather than responding to a single item, it responds to an accumulated set of items. In the most complex treatment, the learner has access to all of the relevant data (e.g. Dresher and Kaye, 1990). A model may also maintain a count of different categories of relevant data, and use a statistical algorithm to make adjustments in its grammar.

Connectionist models

Connectionist (neural) networks consist of simple processing units joined by weighted connections. Short-term memory is represented by the patterns of activation across the units, long-term memory is represented by the pattern of weights on the connections, and learning consists in adjusting the weights in response to inputs, and output targets if these are available. Connectionist models are most appropriate for cognitive tasks that involve parallel constraint satisfaction, the solving of best-match problems, and similarity-based generalization, and for which robustness is desirable. They have been applied to a wide range of language acquisition tasks, from word recognition to syntax. (*See* **Connectionism**)

Connectionist networks have two apparent limitations. Firstly, internal representations in neural networks consist simply of patterns of activation across units; they have no overt internal structure. Secondly, a connectionist network responds to a novel pattern entirely on the basis of its similarity to familiar patterns. This means that variables, which should match any item within a domain regardless of its similarity to familiar items, are excluded from connectionist models. As noted above, however, structured representations, variables, and the formal rules they make possible, have long been thought to be characteristic of human language. (*See* **Language, Connectionist and Symbolic Representations of**)

Connectionist modelers have argued that the connectionist alternative to structured representations and variables may be better able to model human linguistic behavior and learning. In numerous studies, they have shown that networks, especially simple recurrent networks, that have been trained on inputs that embody internal structure, can generalize to novel patterns that are similarly structured (e.g. Morris *et al*., 2000). The internal representations that are learned by such a network, rather than being general-purpose structures, as in a symbolic model, are optimized for the training set. Thus, these models make predictions about human performance that are different from those of the more powerful symbolic models.

Similarly, connectionist modellers have attempted to show that networks can learn to approach variable-like behavior, though the nature of the training set will always influence the network's performance. They have argued that the connectionist account may more closely resemble the performance of humans. Beginning with the well-known model of Rumelhart and McClelland (1986), connectionists have attempted to demonstrate that a connectionist network could learn both regular and irregular morphology in a manner that resembles the behavior of human language learners. The idea is that the rule or rules embodied in the regular patterns are implicit in the weights of the trained network, rather than being explicit as in a symbolic model. (*See* **Morphology**)

This research has led to a debate between proponents of purely associationist models and proponents of dual-mechanism models embodying both associationist and rule-based components for the learning of morphology (and of grammar generally). The debate has inspired new behavioral experiments, as well as refinements to connectionist architectures and modes of representation. It is still not clear whether connectionist networks are adequate for handling apparently rule-governed linguistic behavior. For recent positions on either side of the debate, see Marcus (2000) and Nakisa *et al*. (2000).

Hidden Markov models

Hidden Markov models (HMMs) are applicable to problems in which there are sequences of input elements ('observations') selected from a finite set. An HMM is an abstract characterization of such a sequence in terms of a set of 'hidden states'. Each hidden state has an 'output probability' associated with each of the possible input elements, a 'transition probability' associating it with each other hidden state, and an 'initial probability' representing its likelihood of beginning a sequence. An HMM learning algorithm assigns these three types of probabilities to the states in a set of HMMs in such a way that the regularities in the available observation sequences are captured. (*See* **Markov Decision Processes, Learning of**)

A set of HMMs can be used to classify input sequences. For example, each HMM may represent a particular word that is input in the form of a sequence of phonemes. Alternately, an HMM can be used to estimate the probability that each element in a sequence belongs to a particular category. For example, each hidden state in an HMM could represent a particular syntactic category; a path through the HMM would then represent a sequence of syntactic categories associated with an observation sequence in the form of an input sentence.

HMMs have been applied to the acquisition of phonetic categories, word forms, syntactic categories, and probabilistic grammars. Since they are a finite-state formalism, they are limited in terms of the sorts of regularities in sequences that they can handle. They have not been proposed as a

general-purpose model of natural language processing and acquisition.

Other models

Other statistical learning techniques, especially those involving 'dimensionality reduction' or some information-theoretic construct such as relative entropy (Resnik, 1996), have been applied to the problem of learning lexical semantics. One view of lexical semantics is that words get their meanings in part from their pattern of co-occurrences with other words. 'Latent semantic analysis' (Landauer and Dumais, 1997) is one well-known example of a model that learns about word meaning by accumulating co-occurrences in corpora. It maintains a table of co-occurrences of words with contexts (for example, encyclopedia articles). For each word in the corpus this yields a vector representing its co-occurrences with the various contexts. This vector is subjected to singular value decomposition, a technique for reducing dimensionality. The vector for each word is a point in a high-dimensional space which is taken to represent its semantics. (*See* **Information Theory**; **Latent Semantic Analysis**)

There has been some recent interest in memory-based learning models for language acquisition (Daelemans, 1999). These models, borrowed from machine learning, base generalization on stored exemplars, rather than on abstractions over exemplars, as in a symbolic model (which induces rules) or a connectionist model (which combines the exemplars in its weights).

FUTURE PROSPECTS

There is deep disagreement over some of the most basic issues in computational language acquisition. Yet the ideas that have been generated by the modeling of human language acquisition from such diverse perspectives represent real progress. We can expect the debate over whether language requires an explicit rule-learning mechanism and innate linguistic constraints to continue, with increasingly specific predictions coming from the different models. In addition, future work should address the following outstanding issues.

Firstly, how could a single model learn to handle a wide range of linguistic behaviors? Because of the different sorts of mechanisms that are required, and the potential for interference when a single device is presented with more than one task, some modularity will presumably be needed in any large-scale model, whether it be symbolic or connectionist. (*See* **Modularity**)

Secondly, how well do the models handle real data? Symbolic models will need to adopt statistical learning components to overcome their brittleness, and connectionist models will need to address the problem of how later learning can interfere with earlier learning. (*See* **Language Acquisition and Language Change**)

Finally, how do language acquisition, historical language change, and the evolution of human language interact? Modelers have begun to build computational models of aspects of language evolution (e.g. Cangelosi and Parisi, 2001) and of historical language change (e.g. Niyogi and Berwick, 1997). An integrated computational picture of change at all three timescales may help to solve some remaining problems concerning language acquisition.

Learning from Advice

Intermediate article

David C Noelle, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

Computer models of how humans learn from direct instruction by a knowledgeable teacher have demonstrated how language processing mechanisms may be leveraged to rapidly acquire and apply new knowledge, as well as how such explicit knowledge may be refined through experience.

INTRODUCTION

There is a wide variety of learning strategies that appear to be shared by humans and non-human animals. The advent of language, however, has given rise to a distinctly human form of learning. Through language, new knowledge may be directly transfered from one individual to another in the form of instructions or advice. Learning from advice (also called learning from direct instruction, instructed learning, or learning by being told) has a number of advantages over other learning strategies. Compared with learning from induction over many example experiences, new knowledge can be acquired very rapidly when presented via direct instruction. Furthermore, fairly abstract knowledge can be communicated using language. Instructors can explicitly specify the situations in which their advice might be fruitfully deployed, helping the learner determine the generality of the instructions. This ability to make advice conditional on hypothetical situations also allows learners to gain knowledge about useful courses of action in rare or dangerous situations, in which personal experience is difficult or risky to obtain (for example, what to do if your parachute fails to open). Also, the speed with which abstract knowledge may be acquired is conducive to very flexible learning. Knowledge may be modified with the same rapidity as its initial acquisition, given appropriate instructions. Lastly, making knowledge explicit through advice facilitates uniformity and coordination of behavior between individuals. Learning from advice is a critical component of the transmission of cultural knowledge to each member of a society.

Researchers interested in the computational structure of human cognition recognized the importance of advice taking very early. In his most widely cited paper on artificial intelligence, Alan Turing discussed the benefits of instructed learning over learning from rewards and punishments (Turing, 1950); and within a decade of Turing's paper John McCarthy began laying the foundations for an 'advice taker' computer program (McCarthy, 1958). Despite this early interest, however, relatively little work has been done on computational models of learning from advice. This article describes some approaches that have been taken to the modeling of instructed learning.

OPERATIONALIZATION

The central problem of learning from advice is the translation of statements in a human language into internal representations that can influence behavior in beneficial ways. This process is analogous to compiling a computer program into executable machine code. Learning from direct instruction can be more difficult than program compilation, however, because commonly offered advice is rarely as precise and complete as the instructions of a computer program. The cognitive mechanisms underlying instructed learning must be able to use established knowledge to infer appropriate behaviour from vague advice (e.g. being told that 'to win at this card game, you should generally avoid taking points' does not specify exactly which card to play at each step of the game – this must be inferred), and these mechanisms must be able to determine the range of situations in which the given advice is applicable (e.g. there could be specific situations in which it is good to take points). This process of transforming instructions into behaviorally efficacious internal representations – into conditionalized plans of action – is called operationalization. In humans, operationalization is accomplished quickly and produces knowledge

representations that can be flexibly refined by experience.

TRANSFORMING ADVICE INTO RULES

Some theories of cognition posit internal mental representations encoded in a 'language of thought'. From this perspective, the process of operationalization initially involves translating advice provided in a natural language into this internal language of logical propositions and rules. If the format of these sentential representations is similar to that of natural language, this initial translation process may be simple. Once this process is complete, standard rule-based reasoning mechanisms may be used to transform the given advice into action. Also, rule refinement techniques may be used to generalize from provided instructions and to adapt the agent's knowledge in response to experience.

One of the earliest investigations of this approach involved a computer program called FOO (First Operational Operationalizer) (Mostow, 1983). FOO was designed to learn to play a card game called 'hearts'. The focus of this work was on the operationalization of abstract and incomplete forms of advice, such as 'avoid taking points'. Statements of this kind were encoded as propositional goals, and a heuristic backward chaining search was conducted over a knowledge base of rules to find chains of actions that, when applied, resulted in the attainment of the given goals. The knowledge base was then augmented with rules that performed these action plans under the appropriate conditions. One of the main lessons drawn from the work on FOO was how computationally difficult it is to translate general preferences and constraints into plans of action. The system required long chains of inference in order to generate such plans, suggesting that human learners, who appear to cogitate less on such instructions, may postpone the burden of operationalizing such advice until times when action is required.

The suggestion that learning mostly occurs in the context of actually performing a task became the focus of a subsequent computer model of instructed learning called Instructo-SOAR (Huffman, 1994). While executing a 'blocks world' construction task, this program could solicit and receive natural language instructions related to the current task context. A natural language understanding system translated instructions into production rules, which could directly influence behavior. As in FOO, advice invoked an effort to fabricate general rules of action, but this effort was limited in Instructo-SOAR. Given an instruction to take a particular action in a particular situation, Instructo-SOAR would use a form of explanation-based learning to find a chain of rules that related the advised action to the current goals. If found, this chain would be abstracted into new general knowledge. If such an explanation was not easily found, however, the program would abandon its attempt to generalize the given advice and would record the instructions as pertinent only within the current context. One result of this approach was speedy response to instructions, with the effort to generalize knowledge distributed over multiple practice sessions. Instructions also became integrated with other sources of knowledge through SOAR's chunking mechanism, a technique for abstracting rules based on experience. In brief, work on Instructo-SOAR showed that the computational problem of translating instructions into an operational form is greatly simplified when such instructions appear in the context of a specific situation.

TRANSFORMING ADVICE INTO WEIGHTS

Artificial neural networks have been successfully used to model various forms of inductive learning in humans and non-human animals, but learning from advice poses a particular challenge to this computational modeling framework. Connectionist theories of cognition present behaviour as arising from the parallel and distributed flow of activity between very simple processing units, with knowledge encoded in the strengths of connections between units. The internal representations used by connectionist networks are profoundly different in structure from natural language utterances, and it is difficult to imagine how direct instruction might be translated into knowledge encoded as connection weights.

Techniques have been developed, however, for encoding a collection of propositional rules in a connectionist network in a manner which allows inference to be performed through the propagation of activity between units. For example, if the system is told that a particular action should be taken in a particular situation, separate processing units may be used to represent the features of the situation and the features of the prescribed action, and strongly weighted connections may be placed between the situation units and the action units, causing the perception of the given situation to activate a representation of the appropriate action. Logical operators, such as 'and' and 'or', may be

implemented by selecting appropriate weights for hidden units, and such hidden units may be used to group situations and actions according to provided rules.

These techniques suggest a hybrid approach to modeling learning from advice. Instructions may be translated into propositional rules, and these rules may, in turn, be used to construct a connectionist network which performs the given task. The connection weights may then be further refined based on experience, using standard connectionist methods for inductive learning. This approach naturally supports generalization of knowledge provided via instruction, since similar situations will tend to activate similar candidate actions through the normal process of activation propagation.

Such a hybrid model of instructed learning, incorporating a neural network construction module along with the resulting connectionist network, was developed in RATLE (Reinforcement and Advice-taking Learning Environment) (Maclin, 1995). This system was given the task of successfully playing a computer game called 'Pengo'. Advice was provided using an artificial rule-based language, and instructions were compiled into networks which could then be refined using a connectionist reinforcement learning algorithm. RATLE was able to operationalize instructions involving plans and iterative procedures as well as condition–action rules, and the system handled incomplete instructions robustly, learning from experience what was not explicitly provided by the teacher. This system demonstrated how the inductive learning strengths of connectionist networks could be augmented with the ability to learn from explicit advice.

TRANSFORMING ADVICE INTO ACTIVATION PATTERNS

Some connectionist modelers view processing elements as an abstraction of neural tissue in the brain. From this perspective, responding to instructions by rapidly constructing networks whose weights encode the given advice seems like an implausible account of human learning. Although neurogenesis (i.e., the appearance of new neural cells) is thought to occur in the adult cortex, there is little evidence for mechanisms that would be capable of promptly recruiting these cells and wiring them together appropriately. There are also problems with a perspective in which instruction quickly sets weight values in an established network architecture. Such rapid weight changes can introduce performance difficulties, such as catastrophic forgetting of previously acquired knowledge.

An alternative connectionist approach to learning from advice avoids these problems by encoding explicitly provided knowledge in the activation states of units rather than in weight values. The insight behind this approach is that the behaviour of a recurrently connected connectionist network is determined not only by connection weights but also by the activation levels of its units. These activation levels can be substantially influenced by previous inputs to the network, such as verbal instructions. An input activation pattern that encodes advice may be actively maintained over time, through the use of attractor networks, and the actively maintained internal representation of the given instructions can immediately influence how the network performs some task.

Early work on parallel distributed processing models suggested this segregation of implicit knowledge encoded in weight values and more explicit knowledge encoded in activation levels (Rumelhart *et al*., 1986). More recently, an 'activation space' model of instructed learning (Noelle, 1997) was proposed and simulated in the context of a category learning task. This model inductively learned to form internal representations of advice which was provided as input to the network, and these internal representations could be actively maintained over time. On receiving input instructions, these internal representations could immediately guide behaviour by propagating activity to units involved in the selection of actions. Also, the knowledge provided via advice could be refined through the continued modification of weights based on experience and feedback. While these simulations involved only very restricted types of instruction, they do suggest that connectionism might provide a biologically plausible account of learning from advice.

SUMMARY

Learning from advice is unlike other learning strategies in that it allows for the very rapid acquisition of abstract knowledge. The central problem faced by a computational account of instructed learning is that of operationalization: of transforming explicit advice into internal knowledge representations that can directly influence behavior. Computational models of learning by being told have been proposed in which instructions are translated into symbolic rules, connectionist weight values, and patterns of activity in a parallel distributed

processing network. Research continues on this topic, focusing on the biological foundations of instruction following and on integrating learning from advice with other learning strategies.

Learning Rules and Productions

Intermediate article

Niels A Taatgen, University of Groningen, Groningen, Netherlands

CONTENTS

Learning rules and productions involves creating new rules through inference, induction and compilation and is used in both machine learning and cognitive modeling.

INTRODUCTION

Rules are a popular means of knowledge representation used in several different domains of cognitive science. Not only are they a powerful form of representation, they differ from many other types of representation in the sense that they incorporate both the knowledge itself, and the way to use this knowledge. (*See* **Knowledge Representation, Psychology of**)

Different Types of Rules

Rules are small units of knowledge that, although they work in concert with other rules, are relatively independent, as opposed to a line of code in an arbitrary programming language. The attractive property of this independence is that knowledge can be built up incrementally. The focus of this article will be on two types of rules, logical rules and production rules.

Logical rules are a subclass of first-order logic expressions, often Horn clauses. A Horn clause is an expression of the form:

$$(L_1 \text{ and } L_2 \text{ and} \ldots \text{and } L_n) \rightarrow H \qquad (1)$$

In this expression, L_1 to L_n and H are all literals. Horn clauses closely resemble production rules, which have the following form:

IF condition_1 and condition_2 and ... and condition_n THEN action_1, action_2 ... action_m

For the present discussion, we will largely ignore the difference between the two, but the reader must be aware that they have different properties. As an example, production rules are generally used left-to-right: once the conditions of the rule are satisfied, the action can be carried out. Horn clauses on the other hand, when used in a Prolog context, are used the other way around: in order to satisfy some predicate, a rule is selected that has the predicate as a conclusion.

Goals of Learning Rules

Before examining mechanisms for rule learning, it is useful to characterize the context in which rules are learned, and the goals of rule learning. Two broad fields can be distinguished: machine learning and cognitive modeling. (*See* **Machine Learning**; **Computational Models: Why Build Them?**)

Machine learning

The main focus in this field is to learn rules that characterize concepts. The goal is to find a set of rules that can decide whether or not a particular example is an instance of a certain concept. A concept can correspond to a natural category like a bird, a dog or a chair, or concepts like 'paper accepted at the cognitive science conference'. Suppose we want to characterize this latter category, papers accepted at a certain conference. The final part of the decision process is whether or not to accept a paper given the judgments of the reviewers. Table 1 gives an example of judgments. (*See* **Concept Learning**; **Concept Learning and Categorization: Models**)

The goal here is to find a rule or set of rules that characterizes the concept of 'accepted paper'. Given the five examples we may come up with the following rules:

$$(\text{Overall A} = \text{Good}) \wedge (\text{Overall B} \neq \text{Poor}) \rightarrow \text{Accept} = \text{yes} \qquad (2)$$

$$(\text{Overall B} = \text{Good}) \wedge (\text{Overall A} \neq \text{Poor}) \rightarrow \text{Accept} = \text{yes} \qquad (3)$$

Table 1. Five judgments in the conference example

	Relevance A	*Technical A*	*Overall A*	*Relevance B*	*Technical B*	*Overall B*	*Accept?*
1	Good	Fair	Good	Fair	Fair	Good	Yes
2	Good	Good	Good	Fair	Poor	Poor	No
3	Good	Good	Good	Fair	Poor	Fair	Yes
4	Fair	Poor	Fair	Good	Good	Good	Yes
5	Good	Fair	Poor	Good	Good	Fair	No

The assumption in this and later examples will be that if Accept is not set to 'yes' by some rule, Accept will be 'no'. Although this may look like a very plausible characterization of the five examples, it is by no means the only one. It may be too general, as it does not take into account attributes other than Overall A and Overall B.

The following three rules also characterize the five examples:

$$\begin{aligned}&(\text{Relevance A} = \text{Good}) \wedge (\text{Technical A} = \text{Fair})\\&\quad\wedge(\text{Overall A} = \text{Good})\wedge\\&(\text{Relevance B} = \text{Fair}) \wedge (\text{Technical B} = \text{Fair})\\&\quad\wedge(\text{Overall B} = \text{Good}) \rightarrow \text{Accept} = \text{yes}\end{aligned} \quad (4)$$

$$\begin{aligned}&(\text{Relevance A} = \text{Good}) \wedge (\text{Technical A} = \text{Good})\\&\quad\wedge(\text{Overall A} = \text{Good})\wedge\\&(\text{Relevance B} = \text{Fair}) \wedge (\text{Technical B} = \text{Poor})\\&\quad\wedge(\text{Overall B} = \text{Fair}) \rightarrow \text{Accept} = \text{yes}\end{aligned} \quad (5)$$

$$\begin{aligned}&(\text{Relevance A} = \text{Fair}) \wedge (\text{Technical A} = \text{Poor})\\&\quad\wedge(\text{Overall A} = \text{Fair})\wedge\\&(\text{Relevance B} = \text{Good}) \wedge (\text{Technical B} = \text{Good})\\&\quad\wedge(\text{Overall B} = \text{Good}) \rightarrow \text{Accept} = \text{yes}\end{aligned} \quad (6)$$

This set of rules, though technically correct, is much less satisfactory, because it just lists examples 1, 3 and 4, and is therefore too specific. The goal of a good rule learning algorithm is to find the right set of rules for a certain set of positive and negative examples.

The general procedure in machine learning is that the learning algorithm is trained on a set of examples for which the answers are provided. After learning, the rule set that has been developed is tested on a new set of examples, the test set. The quality of the algorithm is judged by its efficiency, and the score on the test set.

Cognitive modeling

If rules are considered not merely as convenient representations, but as atomic components of human knowledge (Anderson and Lebiere, 1998) then such a theory of human knowledge has to include mechanisms to learn these rules. Whereas the goal of machine learning is to find a rule set that characterizes some concept, the focus in cognitive modeling is more on the learning process than the learning outcome. A cognitive modeler tries to produce a computer simulation that mimics human learning as closely as possible. Cognitive modeling approaches that use rules have to answer the question of how these rules are learned, and what the effects of rule learning are on performance. (*See* **Unified Theories of Cognition**; **Production Systems and Rule-based Inference**; **Learning, Psychology of**)

An issue in cognitive modeling is how task-specific rules can be learned on the basis of general rule knowledge on the one hand and instruction and experience on the other. Anderson (1987) uses the example of learning to program in Lisp. When novices have to learn a new skill like programming, they rely not only on general instruction but also on examples that can be used as templates. (*See* **Skill Learning**; **Learning, Psychology of**)

In an experiment, participants were given a template on how to define Lisp functions, and an example:

```
(DEFUN <function name>
  (<parameter 1><parameter 2>...
  <parameter n>)
  <process description>)
(DEFUN F-TO-C (TEMP)
  (QUOTIENT (DIFFERENCE TEMP 32)
  1.8))
```

They were then given the assignment to write a Lisp definition of a new function FIRST that returns the first element of a list. Many participants came up with the following definition:

```
(DEFUN FIRST (LIST1)
  (CAR (LIST1)))
```

They had produced this definition by using both the general template and the example, but had wrongly generalized the (DIFFERENCE TEMP 32) part to produce (LIST1) in the answer. The paren-

theses are present because DIFFERENCE is itself a function call. No parentheses are needed in the case of LIST1 as this is one of the parameters. The correct solution is:

```
(DEFUN FIRST (LIST1)
  (CAR LIST1))
```

Anderson's rule learning system, which we will examine in detail later on, produced the following two rules in a simulation of the knowledge acquisition in this task:

```
IF   the goal is to write a function
     of one variable
THEN write (DEFUN function (vari-
     able) and set as a subgoal to
     code the relations calculated
     by this function and then
     write)
IF   the goal is to code an argument
     and that argument corresponds
     to a variable of the function
THEN write the variable name
```

Note that these functions are generalizations of both examples, but that the first rule is a specialization of the general template, as it only applies to functions of one variable.

In the Lisp example, general knowledge and a single example are used to find the solution to a new example. Except for the template and the example, general strategies like analogy are assumed in the model. Almost as a by-product, rules are learned. Although this setting is different from the machine learning perspective, there is a strong resemblance: rules are learned on the basis of examples, in this case with some domain knowledge. In cognitive modeling the focus is also on errors and speed, so the cognitive model also has to make the same errors people do, and show the same increase in performance due to practice.

ALGORITHMS FOR CONCEPT LEARNING

Single Hypothesis Learning

An early rule learning algorithm was developed by Winston (1970). Many variants have been produced, but the basic idea is very simple. A single rule or rule set is maintained, and this rule is adjusted as new examples arrive.

When a new example is presented, it is first checked to see if the rule is already consistent with the example. When the example is inconsistent, we have to update the rule. If the example is a positive example, we have to generalize the rule, so that it will include the new example. In the case of a negative example, the rule has to be specialized to exclude the new example.

Table 2. Simplification of the conference example

	Reviewer A	*Reviewer B*	*Accept?*
1	Good	Good	Yes
2	Good	Poor	No
3	Good	Fair	Yes
4	Fair	Good	Yes
5	Poor	Fair	No

Consider a simplification of the conference acceptance problem in Table 2.

A possible rule based on the first example is:

$$\text{A} = \text{Good} \rightarrow \text{Accept} = \text{yes} \ (1) \tag{7}$$

The second, negative example is inconsistent with this rule, so specialization is needed, for example by adding a condition:

$$\text{A} = \text{Good} \wedge \text{B} \neq \text{Poor} \rightarrow \text{Accept} = \text{yes} \ (2) \tag{8}$$

The third example is consistent with this rule, so no further modification is necessary. The fourth example, however, again requires a generalization of the rule. This may be achieved by dropping a condition, resulting in:

$$\text{B} \neq \text{Poor} \rightarrow \text{Accept} = \text{yes} \ (3) \tag{9}$$

Example five is again inconsistent with the rule, requiring a final specialization:

$$\text{B} \neq \text{Poor} \ \wedge \text{A} \neq \text{Poor} \rightarrow \text{Accept} = \text{yes} \ (4) \tag{10}$$

A problem with this approach is that with each generalization or specialization we have to make sure all the previous examples are still consistent with the current rule. Also, finding a new hypothesis can become very hard, as there are many possible generalizations and specializations, and they are not all as easy to derive from the current rule.

Version Space

In the example two methods were used to update the rule: generalization and specialization. Rules can be ordered with respect to generality: rule p is said to be more general than rule q when all instances that are included in the concept by rule q are also included by rule p. This ordering is a partial order. The most general rule is the rule that includes all instances of the concept, and the most specific rule is the rule that includes no instances at all. All other rules are in between these extremes.

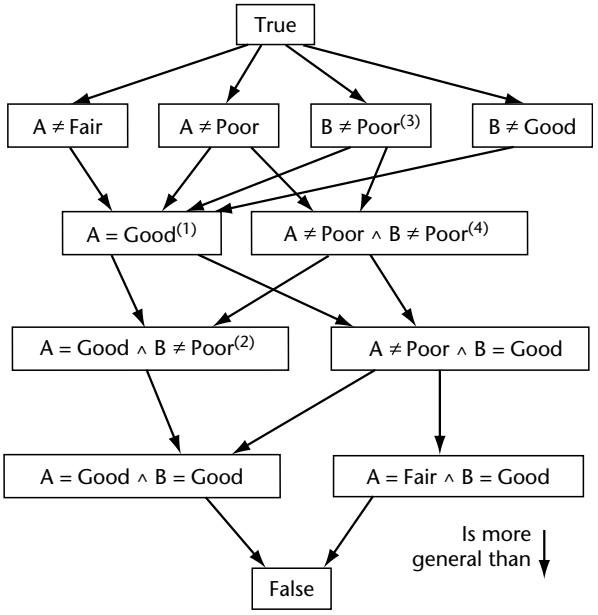

Figure 1. Part of the hypothesis space of the conference problem.

This view on hypotheses offers a handle for a more systematic approach than the one offered by single hypothesis learning. Figure 1 shows part of the hypothesis space for the conference problem.

The most general hypothesis is that all papers are accepted (True), and the most specialized hypothesis is that none are accepted (False). All other hypotheses are ordered in between. The numbers in Figure 1 refer to the four hypotheses we had in the previous example: each time a positive example is not included in the current hypothesis, we have to generalize and move up in hypothesis space, and each time a negative example is not excluded we have to move down. The version space, the space of all plausible versions of the concept, is the subset of all possible hypotheses that are still consistent with the examples we have seen up to now.

Version Space Learning

Instead of maintaining a single hypothesis about the target concept, an alternative is to represent all hypotheses that are still consistent with the present set of examples. The naive version would be to list all the hypotheses, but fortunately this is not necessary. Due to the fact that hypotheses are partially ordered by the more-general-than relation, it is only necessary to represent the set of the most general hypotheses that are still consistent with all examples, and the set of the most specific hypotheses that are still consistent with all examples. These two sets, usually designated *G* and *S* respectively, are often called boundary sets, as everything more general than *G* or more specialized than *S* is not consistent with the examples, but everything in between is. The algorithm that maintains these boundary sets is known as version space learning (Mitchell, 1977). *G* is initialized to (True), and *S* to (False). For each example, *G* and *S* are updated along the following lines.

For positive examples:

- Remove all members of *G* that do not include the example.
- For each member of *S* that does not include the example, replace it by all immediate generalizations of that member that do include the example, and are specializations of some member of *G*.

For negative examples:

- Remove all members of *S* that do not exclude the example.
- For each member of *G* that does include the example, replace it by all immediate specializations of that member that do not include the example, and are generalizations of some member of *S*.

Figure 2 shows how version space learning would handle the conference acceptance example. The algorithm starts out with *G* set to (True) and *S* set to (False). The first example is a positive example: `A=Good ∧ B=Good`. This means that False is no longer the most specific hypothesis, so it is generalized to `A=Good ∧ B=Good`. The second example is a negative example, which means that the True hypothesis needs specialization. Although there are two specializations of True consistent with the second example `(A≠Good, B≠Poor)`, only

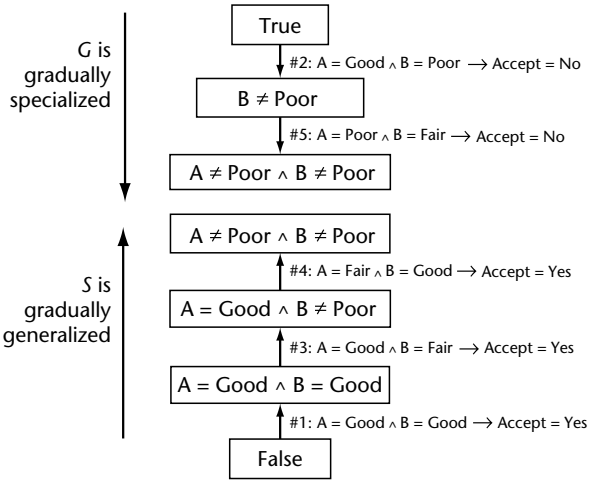

Figure 2. Version space learning operating on the conference example.

B ≠ Poor is also a generalization of a member of *S*. The process continues until, after example 5, both *G* and *S* have converged to the hypothesis A ≠ Poor ∧ B ≠ Poor. Note that in this example both *G* and *S* only contain one hypothesis at a time; this is not true in general.

A disadvantage of version space learning is that it cannot handle noise: it relies on the fact that all examples are correct. Another problem is that it cannot handle disjunction very well. In our example we have only used a limited form of disjunction (in the sense that B ≠ Poor means B = Good ∨ B = Fair). The case A = Fair ∧ B = Fair is classified as a positive example, although it has never been presented as an example, and it would be perfectly plausible for it to have been a negative example (in the case the criterion is 'At least one Good and no Poors').

Other Concept Learning Algorithms

Besides single hypothesis learning and version space learning, many other algorithms have been developed for concept learning. Decision tree learning, for example, learns a decision tree for a concept. Learning is, however, not incremental, because the algorithm learns the whole tree on the basis of a set of examples. As a decision tree is not really a rule-based representation, it is beyond the scope of this article. Another family of algorithms, often shared under the heading of inductive logic programming, infers sets of rules to characterize concepts instead of single rules. The advantage of using a set of rules is that single rules only cover part of the concept, so there is no problem of overly specific rules. Inductive logic programming algorithms also operate on the set of examples as a whole.

LEARNING WITH DOMAIN KNOWLEDGE

A property of the algorithms discussed in the previous paragraph is that they operate on the basis of examples only. In addition to examples there may be other knowledge that may guide the learning process, for example common sense knowledge, or a complete set of domain knowledge. An algorithm that includes the use of domain knowledge is explanation-based learning (EBL) (DeJong, 1981).

Explanation-Based Learning

The assumption of explanation-based learning (EBL) is that we have a complete set of knowledge, the domain knowledge, that is in principle enough to make decisions, but may be computationally intractable. The goal of EBL is, given a proof for a single example, to derive new rules of intermediate computational complexity that are generalizations of the example, but specializations of the domain theory. Suppose we have the following rule set to make conference decisions:

$$\text{reviewer}(X) \wedge \text{review}(X, \text{poor}) \rightarrow \text{negative} \tag{11}$$

$$\text{reviewer}(Y) \wedge \text{review}(Y, \text{good}) \rightarrow \text{positive} \tag{12}$$

$$\text{negative} \rightarrow \text{decide}(\text{no}) \tag{13}$$

$$\text{positive} \wedge \neg\text{negative} \rightarrow \text{decide}(\text{yes}) \tag{14}$$

Given a specific example, for instance reviewer(a) ∧ reviewer(b) ∧ review(a, good) ∧ review(b, good) a general problem solver like Prolog can derive decide(yes). EBL now uses the proof (or explanation, hence the name) of decide(yes) to generate a new rule that is a generalization of the example but a specialization of the domain theory:

$$\neg\text{review}(a, \text{poor}) \wedge \text{review}(b, \text{good}) \rightarrow \text{decide}(\text{yes}) \tag{15}$$

This newly learned rule does not contribute anything new, as all the knowledge is already contained in the domain knowledge. However, if the domain knowledge itself is very inefficient to use, new efficient rules may effectively extend the capabilities of the system by allowing new proofs that were previously computationally unachievable. Take the example of mathematics: the natural numbers can be defined by a small set of axioms, but mathematicians use many derived rules to solve actual problems.

In EBL new rules are added to the rule set, so in that sense it differs from algorithms discussed earlier where learned rules replaced old rules. This introduces a new problem: adding rules to the system may improve its performance because rules are tailored to certain often-occurring situations, but may also decrease performance if they are never used. This *utility problem* is an issue different from correctness: knowledge that is true may still be undesirable because it is useless. Possible solutions to the utility problem are to develop procedures that estimate the cost/benefit properties of a rule in advance, or to just introduce them into the system and keep track of how they fare (Minton, 1988).

LEARNING RULES IN COGNITIVE MODELS

Rule learning in cognitive modeling has aspects in common with both the purely inductive algorithms like version space learning and deductive algorithms like explanation-based learning. Human learners have a large store of background knowledge, strategic knowledge and domain knowledge, but still have to make generalizations from examples that are not fully deducible from the domain knowledge. A general view in cognitive modeling is that humans have a set of weak methods that, when supplied with some background knowledge and a particular case to work on, will produce the desired performance, and are also the basis for learning. Weak methods are problem-solving strategies that are independent of the particular problem, and are generally applicable. Examples of these strategies are: means-ends analysis, forward-checking search, analogy, etc.

In the Lisp learning example in the introduction, the weak method of analogy was used to generate a new Lisp program on the basis of an example and some background knowledge of Lisp. During this process some new rules were learned, and the mechanisms cognitive modelers use to achieve this rule learning show a resemblance to explanation-based learning. The difference is that learning and problem-solving happen at the same time, and domain knowledge is often incomplete.

Chunking in Soar

Newell and Rosenbloom (1981) proposed a rule mechanism called *chunking* that became an important component of the Soar cognitive architecture (Newell, 1990). Within Soar, learning rules are tied to impasses and subgoaling. Whenever Soar reaches a state in which it runs into some impasse (no applicable rules, an irresolvable choice between operators, etc.), it automatically creates the subgoal to resolve this impasse. When the subgoal is successfully completed and the impasse is resolved, a specialized rule is learned that summarizes all the processing required to achieve that subgoal. If Soar later encounters a similar impasse, it no longer needs a separate subgoal to process it. Instead it can use the learned rule to solve it in a single step. (*See* **Soar**)

Although Soar's basic set of methods encompasses several weak methods, the one reported most often is forward checking. Suppose we have the blocks-world problem in Figure 3.

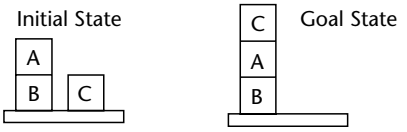

Figure 3. Example blocks-world problem.

If Soar were to solve this problem, it would discover that there are two possible operators in the initial state: 'Move block A to C' and 'Move block C to A'. If Soar had no additional knowledge on how to choose between these operators (called search-control knowledge), it would run into a so-called tie impasse. To resolve this impasse, Soar would create a subgoal by evaluating these two operators. Evaluation can be done by 'mental simulation': what would happen if each of the tied operators was applied? In this mental simulation Soar would quickly discover that 'Move C to A' is the best operator as it immediately accomplishes the goal. So the subgoal created by the impasse comes back with the resolution 'Move C to A is best', and in the main goal this operator is applied.

Learning occurs directly after the subgoal is resolved. The rule that is created has as a condition the circumstances in which the impasse occurred, and as action the result of the subgoal, in this case the 'best preference' for the operator that accomplishes the goal:

```
IF the problem-space is a simple-
blocks-world
  and the state has block X and block Y
  clear,
  and block X is on the table,
  and the goal state has block X on
  block Y,
THEN make a best preference for the
operator that move block X onto
block Y
```

The consequence of this rule is that whenever Soar encounters the situation described in the rule, an impasse no longer occurs and an operator is chosen immediately.

A problem with Soar's rule learning mechanism is that there is no solution to the utility problem: Soar can produce over-specific rules that are expensive to match and has no way to get rid of them once learned.

Production Learning in ACT

Anderson (1983) proposed a set of four rule learning mechanisms that were specified to work in the

ACT* cognitive architecture. An aspect of ACT* is that it has not only a memory for rules (procedural memory), but also a memory for facts (declarative memory). The following four mechanisms were used to learn new rules: (*See* **ACT**)

1. Proceduralization. If a rule accesses declarative memory, and uses the knowledge from declarative memory in its action, then learn a new rule that is identical to the old rule but has the retrieved knowledge instantiated into the rule, eliminating the declarative retrieval.
2. Composition. Collapse a sequence of rules into a single rule that performs all the actions of the individual rules of the sequence.
3. Generalization. If there are two rules that are similar, create a generalized version of these rules. This can be done by removing conditions or by substituting variables for constants.
4. Discrimination. If a rule is successful in one situation but not in another, add conditions to the rule to make a more restrictive version that only applies in successful situations.

In the Lisp learning example, proceduralization and composition are used to learn the two rules to write Lisp functions on the basis of the weak method of analogy.

Despite the relative success of the mechanisms in ACT*, they were too unconstrained, and were able to produce too many invalid rules and too many rules with poor utility. In the latest version of ACT (ACT-R 5.0), a constrained version of the four mechanisms is introduced. This single mechanism combines the proceduralization and composition mechanisms from ACT*. In ACT-R, the expressive power of production rules is more constrained when compared to earlier versions of ACT and to Soar. Each production rule is only allowed a single access to declarative memory. Also, this access is composed of two steps. Firstly, a rule has to issue a request to declarative memory for a certain fact as part of its action side, and then a second rule can match the retrieved fact on its condition side. Suppose we want to add three numbers. In the older ACT and Soar systems, this would require only a single rule. In ACT-R, we need three rules to accomplish this as shown in Table 3.

Using one of the older composition mechanisms, one general rule could be learned out of these three rules to do three-number additions in one step. From a cognitive perspective this is not desirable, as people generally cannot do these types of additions in one step, although they have ample experience with them. Also, in ACT-R it would no longer be possible, as only one retrieval from declarative memory is allowed in each rule.

Rule learning in ACT-R is aimed at composing two rules that fire in sequence into one new rule, while maintaining the constraint that only one retrieval from declarative memory is allowed. This is done by eliminating a retrieval request in the first rule and a retrieval condition in the second rule. The fact that has been retrieved is entered in the combined action of the new rule. Suppose that in the example above, the three numbers that are added are 1, 2 and 3, then this would produce two new rules, a combination of rules 1 and 2, and a combination of rules 2 and 3. Each of these two new

Table 3. ACT-R rules for adding three numbers

Rule 1	*Rule 2*	*Rule 3*
IF the goal is to add three numbers THEN send a retrieval request to declarative memory for the sum of the first two numbers	IF the goal is to add three numbers AND the sum of the first two numbers is retrieved THEN send a retrieval request to declarative memory for the sum of the currently retrieved sum and the third number	IF the goal is to add three numbers AND the sum of the first two numbers and the third number is retrieved THEN the answer is the retrieved sum

Table 4. Combined rules in ACT-R

Rule 1 & 2	*Rule 2 & 3*	*Rule 1 & 2 & 3*
IF the goal is to add 1, 2 and a third number THEN send a retrieval request to declarative memory for the sum of 3 and the third number	IF the goal is to add three numbers and the third number is 3 AND the sum of the first two numbers is retrieved and is equal to 3 THEN the answer is 6	IF the goal is to add 1, 2 and 3 THEN the answer is 6

rules can be combined with one of the original rules to learn a rule that combines all three rules as shown in Table 4.

Compared to the original rules, these rules are very specialized: they work only for certain numbers. The implication is that people will only learn specific rules for very common additions: it is likely that one immediately knows the sum of 1, 2 and 3, but not of 9, 3 and 4.

Although the example is about addition, production learning can also be used to transform general production rules into task-specific rules, and to incorporate previous experiences into rules. The utility problem is handled in two ways: by constraining the size of the rules, rules with many conditions are impossible; rules that are learned are introduced only gradually in the system, ensuring a relatively slow but safe proceduralization.

SUMMARY

Rule learning is a fundamental issue in both machine learning and cognitive modeling. This article has focused on incremental learning mechanisms, in which a current hypothesis is continuously updated on the basis of examples, involving both processes of generalization and specialization. Learning can be with or without domain or background knowledge. If no background knowledge is provided, in algorithms like single-hypothesis learning and version space learning, learning is purely inductive. Explanation-based learning on the other hand deduces its knowledge from the domain theory, guided by examples.

Learning in cognitive modeling often employs a mixture of inductive and deductive methods, as background knowledge is often available but almost never complete. The most common method employed is to instantiate general problem-solving methods with specific knowledge and examples, producing task-specific rules.

CONTENTS

Case-based reasoning is a process for reasoning by remembering prior experiences and adapting their lessons to new circumstances. Cognitive science research on case-based reasoning has developed computational models of how humans learn from experience, and suggests principles for providing more effective support for human learning.

REASONING FROM REMEMBERED EVENTS

When people justify their decisions, or give advice to others, they often support their conclusions with anecdotes about prior experiences. A study of the use of anecdotes in medicine, for example, found that doctors confronted with difficult problems often call upon other doctors with requests 'not for the latest news of research from the journals but for … anecdote[s]: "Anybody had any experience with this?"' (Hunter, 1986). Likewise, when people encounter new situations, they often remember prior experiences and apply their lessons. Remembered prior cases can guide the interpretation of new situations, help to predict new outcomes, suggest solutions to new problems, and warn of potential failures to avoid. In medicine, for example, experiences with prior patients help doctors to interpret their patients' descriptions of their problems, predict the outcomes of diseases, select appropriate treatments, and predict difficulties that may arise.

The process of reasoning and learning from experiences is called 'case-based reasoning' (CBR). Case-based reasoners interpret new situations and solve new problems by adapting the lessons of prior cases. They learn by integrating their own new experiences, and experiences presented to them, into their memories for future use. Their proficiency at reasoning comes from having the right cases in memory, being able to access them at the right times, and being able to apply them in the right ways.

Case-based reasoning has been studied both as a model of human cognition and as an artificial intelligence approach. Cognitive science has developed computational models of the CBR process to specify theories of human cognitive processing, provide testable hypotheses about these processes, and illuminate the constraints on human reasoning relating to information processing. The resulting principles have been the basis of computer systems that reason and learn, as well of systems that aid human reasoning and learning by providing people with useful cases with which to augment their own memories. More recently, the model of cognition developed in CBR research has been the basis of interactive learning environments and theories of how to help students to extract concepts, acquire skills, and improve their ability to transfer knowledge to new situations. This article introduces the CBR process, discusses issues and methods arising from CBR research, and describes the ramifications of the CBR model for understanding and supporting human reasoning and learning.

CASE-BASED REASONING AND THE UTILITY OF ANALOGY

Analogical reasoning transfers lessons from one domain to another, by comparing similar objects, processes, or ideas in order to map information from one to the other. (For a collection of recent research on analogy, see Gentner *et al.*, 2001.)

Case-based reasoning is an analogical reasoning process that focuses on making analogies to one's previous experiences. CBR research studies the memory processes required to retrieve analogous experiences (e.g. Schank, 1999), the processes for comparing them to new situations and adapting their lessons to new needs, and the learning processes that index new experiences in memory to be retrieved when they are relevant in the future.

Analogical reasoning is essential both to everyday reasoning and to more specialized reasoning tasks, and is used by novices and experts alike. When similar problems have been encountered before, it enables reasoners to propose solutions to problems quickly, avoiding the need to derive those answers from scratch. It also enables reasoners to propose solutions in domains that are not completely understood; it provides a method for evaluating candidate solutions when no algorithmic method is available; and it enables interpretation of open-ended and ill-defined concepts by analogy to their prior use. For example: an architect with a difficult assignment may save time by adapting a previous design for similar requirements, rather than starting from scratch; a doctor may choose between treatments by considering their effectiveness with similar patients; an employer may evaluate the promise of a prospective employee based on experience with a similar candidate in the past; a lawyer may try to show that there are mitigating circumstances for a crime by analogy with similar cases in which a sentence was reduced; a parent trying to interpret what a child means by a 'fun' present might do so by considering the other presents the child has enjoyed.

Storing and reasoning from specific experiences, rather than more abstract rules or patterns, provides two other advantages. First, it enables a simple learning process: experiences can be stored without distilling them into abstract rules. Second, cases are often easier to apply than general rules, because they store information at an operational level: they include the specific details which may be useful to reapplying the solution. For example, when a doctor remembers the treatment for a patient with a rare disease, reapplying specifics (e.g. the name of a local physical therapist with appropriate specialized training) may save effort or improve results. Numerous studies provide evidence for human reasoning and learning from specific examples, for tasks such as learning to use a word processor, learning computer programming, mathematical problem solving, medical diagnosis, explanation of events, and decision-making (Kolodner, 1993).

Models of case-based reasoning have been developed for a wide range of tasks including problem solving, planning, design, understanding and explanation, diagnosis, parsing, and legal reasoning (Kolodner, 1993; Leake, 1996). These tasks can be divided into two broad classes: problem solving and interpretation. Problem-solving CBR uses cases to suggest solutions; interpretive CBR uses cases as the basis for interpretation or classification. Both types of CBR involve four main steps, as summarized in Figure 1: retrieval of relevant prior cases; adaptation of their lessons to new needs; evaluation and application of candidate solutions; and learning by storing new cases arising from experience.

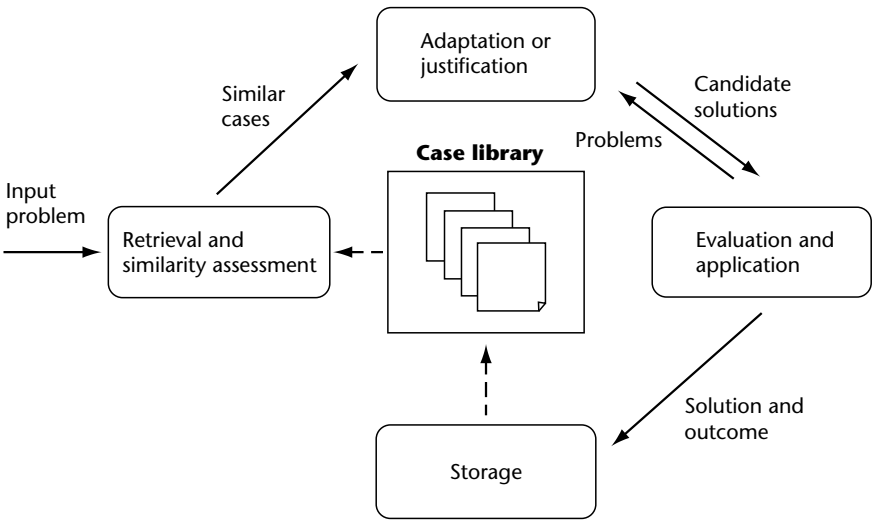

Figure 1. The case-based reasoning cycle.

These four steps are described in outline below. Note that cycles of steps may be repeated or restarted, and each step may draw on case-based reasoning or other methods to support its own processing.

Case Retrieval and Similarity Assessment

Case-based reasoning begins by retrieving cases relevant to the current problem, based on features of the current situation. In problem-solving CBR, cases are retrieved based on the problem and the constraints on the solution (for example, cases for medical treatments might be retrieved based on both the disease to treat and factors such as the patient's allergies). In interpretive CBR, cases are retrieved according to either the situation to classify, or a candidate interpretation to support (for example, when a lawyer is arguing to support a client's viewpoint). In this process, the reasoner generates cues to guide the search for relevant cases in memory, establishes correspondences between the current situation and the retrieved cases, and assesses the similarity of the retrieved cases and the new situation, to identify differences to address.

Case Adaptation or Justification

In problem-solving CBR, the solution to the previous problem is adapted to the new situation (for example, a doctor may adjust a remembered treatment based on the patient's age or weight), or the partial solutions suggested by several cases are merged. In interpretive CBR, a 'justification structure' is constructed to compare and contrast the case with the new situation and show how its lessons apply. Justification structures record the relationships between the prior case and the new situation, and provide reasoning to support a new conclusion in terms of the original conclusion and the relevant similarities and differences. Thus, a justification structure in a legal domain might show how differences between the current circumstances and a prior crime (for example, that one was premeditated and the other was not) suggest that the new crime should be classified as more serious.

Case Evaluation and Application

When a candidate solution or interpretation has been generated, it is evaluated to identify problems needing revision, and a cycle of evaluation and adaptation or justification is repeated until an acceptable solution has been generated (or the process is abandoned). The candidate solution is then applied to the real problem (or a simulation), providing feedback on the solution's performance. For example, after a doctor selects a candidate treatment, it may be necessary to revise it to avoid bad interactions with drugs that the patient is taking for other complaints. The results of applying the treatment provide the doctor with feedback on the effectiveness of different treatments on particular patients.

Case Storage

Every reasoning episode provides a new case for storage and future use. Success cases provide solutions to reuse; failure cases provide warnings of potential problems and suggest possible repairs when those problems occur. In case storage, execution feedback is analyzed and explained to identify useful lessons, which – in conjunction with predictions of when the case may apply – determine the indices under which the case is stored. For example, if an initial treatment caused a bad reaction to another drug that the patient was taking, requiring a change in medication, the new case would be indexed as useful for avoiding the interaction.

MEMORY ORGANIZATION AND RETRIEVAL

In order to build a useful memory of cases, case-based reasoners must extract the lessons of new cases, predict how those lessons might be used in the future, and encode the cases in ways that will make them recognizably useful in those situations. The process of encoding cases to be accessible at the right times is known as 'indexing': the features that predict the cases' applicability are regarded as indices organizing the memory of cases. The appropriateness of the indices used to label a case will depend on the adequacy of the reasoner's background knowledge for analyzing the case's potential applicability, and on the effort put into the case analysis.

At retrieval time, the reasoner must generate cues to retrieve cases that are relevant to the current circumstances, based on the reasoner's goals and understanding of the new situation. The retrieval process begins with the reasoner performing 'situation assessment' to identify indices that might have been used to index relevant stored cases. The reasoner then uses those indices as a probe into memory, and assesses the results of retrieval to decide which retrieved cases are most appropriate.

The extent to which a reasoner is able (and willing) to analyze the new circumstances determines the quality of the probe into memory. By using the right probes, a reasoner may be able to retrieve useful cases that were encoded in quite different contexts. Seeing a corporate lawsuit as a contest of strength, for example, might lead to retrieving sports cases that suggest useful competitive strategies. The more creative a reasoner is at interpreting a situation, the more likely the reasoner will be to find new and surprising connections.

The indices used to describe cases make up the reasoner's 'indexing vocabulary'. In general, indexing vocabularies have two parts: a set of features, and a set of associated values. For straightforward retrievals, indexing features should be those that are naturally articulated in the process of reasoning or doing the tasks for which the case will be relevant. Indices may be specific to a domain, as in 'has pneumonia', which (in conjunction with other indices, such as 'is a toddler') might be used to retrieve cases suggesting treatments. Indices may also be abstract, applying to many domains. For example, the index 'bad balance interaction' can apply to domains ranging from medicine (when the dosage of two medicines was not properly coordinated), to cooking (when an addition to a soufflé results in too much liquid for the quantity of eggs), to manufacturing (when the force of a press for stamping metal was not commensurate with the size of the piece to be stamped).

CBR research uses two methods to determine the features and values used to index cases. The 'functional' approach examines a corpus of cases and the tasks that must be supported, considering what each case can be used for and the ways in which it needs to be described to make it available. The 'reminding' approach examines the kinds of remindings that are natural among humans who do the designated task, looking for similarities between new situations and retrieved cases, but not with cases that are not retrieved. Both approaches provide testable hypotheses for the kinds of indices that are important in human retrieval.

Once indices have been selected, cases are retrieved according to the similarities of their relevant features. One model of this process is 'nearest-neighbor' retrieval, in which the similarity between cases is based on a weighted sum of the distances between their corresponding features. (For example, a case-based reasoner seeking cases to suggest medical treatments might weight symptoms heavily but give no weight to the patients' names.) If the features considered for retrieval of two cases C and C' are each represented as a set of N attributes $\{a_i\}$ and $\{a'_i\}$, and each attribute's importance is assigned a nonnegative weight w_i, and d_i is a distance metric over the set of possible attributes of the i^{th} feature, then the degree of dissimilarity between C and C' may be defined as $d(C, C') = \sqrt{\sum_{i=1}^{N} w_i \times d_i(a_i, a'_i)^2}$.

For large sets of cases, another model of retrieval, 'discrimination trees', provides efficient retrieval at the cost of decreased flexibility for changing the features used for retrieval. Discrimination trees model case access as a traversal of a tree representing an ordered sequence of questions about indexing features.

ADAPTING CASES TO NEW NEEDS

After a relevant case has been retrieved, it is often necessary to perform additional reasoning to apply its lessons to the new circumstances. In legal case-based reasoning, for example, it may be necessary to show why the desired case is more relevant than the cases that opposing lawyers have proposed to support different conclusions (Rissland, 1998). In problem-solving CBR, the retrieved solution must be adapted to provide a suitable solution for the new problems. For example, a doctor may need to replace the drug used in a treatment with an alternative drug, in order to avoid aggravating a patient's allergy, or may need to perform parameter adjustment to adapt the dose for a previous adult patient to suit a child.

Research into case adaptation focuses on understanding the types of adaptations used by case-based reasoners and the knowledge those adaptations require. The operations may range from limited substitutions to complex structural changes; the knowledge required may include specialized knowledge, general heuristics, or domain models. The case adaptation process is often modeled by rule-based production systems using fixed adaptation knowledge, but researchers are also investigating how this knowledge may itself be learned by case-based reasoning or other methods. Flexibility, and sometimes even creativity, results from retrieving cases in unexpected contexts and adapting them to new needs.

WHAT TO REMEMBER, WHAT TO FORGET, AND WHAT TO GENERALIZE

Case storage presents a range of challenges. First, as discussed above, enabling access to cases in apparently disimilar situations depends on indexing cases to make them accessible whenever they are relevant. Thus careful case analysis is needed to

predict the relevant features for indexing. For example, if a newly-prescribed drug has the side effect of interfering with a drug previously prescribed to a patient, it may be appropriate to index the case for the doctor's response both by the specific drugs involved and by very general indices such as 'side effect disables needed condition'. This would enable the case to be retrieved in situations with very different specifics, but where the case's solution (for example, separating the interacting elements by administering them at different times) might still be applicable.

Secondly, it may not be beneficial to retain all new cases. As a case-based reasoner's memory grows, the reasoner has access to more cases, increasing the likelihood of being able to retrieve very similar cases, but also increasing retrieval costs, possibly negating the efficiency benefits from additional cases, or exceeding available storage. These problems are being studied in research on 'case-base maintenance', which focuses on how to determine which cases to remember and which to forget, as well as how to update the case library and other system knowledge sources over time.

Thirdly, when several cases are indexed in the same way and all predict the same solution, it may be useful to generalize from them. One model of the interaction between abstract and specific knowledge is proposed by the 'memory organization packages' (MOP) model proposed in dynamic memory theory (Schank, 1999). In this model, episodes in memory are organized by hierarchical MOPs at different levels of generality that collect constituent 'scenes'. Scenes are lower-level components which normally describe events that take place in a single location, with a single purpose, and in a single time interval, and can be shared by a number of MOPs (for example, the act of payment after a professional office visit corresponds to a 'pay' scene shared by the MOPs for 'doctor visits' and 'dentist visits'). Specific case details are stored under the scenes to which they refer, so that the only case information that must be stored is deviations from the routine expectations for the scene. When a case must be retrieved, its details are reconstructed; when several cases share details, the shared details provide the basis for a generalized MOP capturing the common features.

RELATIONSHIP TO OTHER FORMS OF LEARNING

The learning in case-based reasoning contrasts with both inductive and theory-driven models of learning. In contrast to traditional symbolic and neural network approaches to inductive learning, which define concepts by generalizations and discard the examples on which the generalizations are based, case-based reasoners retain and reason from specific prior cases. This enables new information take effect immediately – there is no need to 'retrain' the reasoner – and enables effective incremental learning. No matter how few cases are contained in the case library, performance on the problems those cases address will be correct, and as soon as a case has been stored by a CBR system, that case is available for use.

Theory-driven learning (often called explanation-based learning) uses general rules about a domain to form an explanation of the relevant features, in order to use that explanation to guide generalization. Unlike inductive generalization, explanation-based generalization can reliably learn from single examples. However, it cannot learn without a domain theory, and it performs all generalization at storage time, when it may not be clear which generalizations will be useful, or whether any generalizations will be useful. Instead of generalizing cases at storage time, CBR adapts cases in response to new problems, and makes only the changes needed to address those problems. The analysis of a current experience still plays an important role in the quality of learning, however, by determining the quality of the indexing for a case (to ensure that it will be retrieved in appropriate future situations) and for understanding the current situation and execution feedback (to ensure that the right lessons are stored).

IMPLICATIONS FOR HUMAN–MACHINE SYSTEMS AND THE LEARNING SCIENCES

Psychological studies show that case-based reasoning is a natural reasoning process for people, and computational models of the CBR process illuminate specific requirements for any case-based reasoning process to be effective. An active area of current research and applications is to bring these two strands together: to design interactive computer systems that exploit understanding of the CBR process to provide more effective support for human case-based reasoning. Two important applications are interactive case-based aiding systems, which support human problem solving by making relevant cases available to users to supplement their own experiences, and educational systems, in which computational models of CBR provide concrete suggestions about what makes a good problem, how courses of instruction should

be designed, and the kinds of resources that should be made available to student learners.

Case-based aiding systems support problem solving by providing external memories of solutions and warnings from stored prior experiences. Many case-based aiding systems have been developed to aid the design process by providing access to suggestions and lessons from prior designs, and many systems are in use to aid diagnosis and other tasks. For example, in aeronautical engineering, case-based aiding systems have been developed to guide the positioning of composite parts in curing ovens and to help with diagnosis of jet engine problems. ASK systems (Ferguson *et al*., 1992) enable users to browse a case library of experts' stories, in a rather conversational way. For example, one ASK system has been developed to capture the expertise of military transportation planners, providing a resource of first-person stories that current planners can apply to their problems. When the user browses a story, the system presents a set of specific questions that the story might raise, such as questions about the context of the story, results, or warnings arising from it. Each question provides a link for interested users to follow to access cases relevant to that question.

Goal-based scenarios (GBS) (Schank *et al*., 1993/1994) apply the lessons of CBR research to the design of environments for skill-centered learning by doing. Students learn by case acquisition as they perform activities in pursuit of compelling goals. In addition, CBR methods are used to retrieve anecdotes of others' prior experiences to present to learners at useful times. For example, in the GBS 'Broadcast News', students play the role of a newsreader, editing a report on some current or past event to make sure that it is understandable to the viewing public. They practice writing skills, particularly describing events and people in ways that others can understand and summarizing to make sure the most important points are made. Meanwhile they are learning about current events or history. As they are working, they may ask for help with a specific editing problem, and a short video will play describing how some expert newsreader or editor dealt with a similar editorial decision. When they have finished, they present their stories to the rest of the class, and the class discusses both the content being presented and the skills involved in getting to that presentation.

'Learning by design' (LBD) (Hmelo *et al*., 2000; Kolodner *et al*., 1998) focuses on learning scientific theory and practices (skills) in the context of design challenges. Middle-school students generate questions and conduct investigations in the context of a design challenge (for example, to design a propulsion system that will propel a miniature vehicle over several hills (for learning about forces and motion), or to design a way to save a basketball court from erosion by dirt from an adjacent hill (for learning about managing erosion)). LBD provides a set of classroom rituals, practices, and activities, informed by case-based reasoning's cognitive model (Schank, 1999), that work together to enable deep and transferable learning. For example, the 'gallery walk' is a time when students share experimental results or experiences, providing each other with a variety of examples of how some scientific law applies and is applied in the world. The discussions that accompany gallery walks help students to identify good and bad examples and ways of improving their practices and designs, and to explain the limitations of their designs. These discussions also provide an opportunity to draw out scientific principles from their experiences. Pilot and field tests have shown that LBD students learn scientific theory as well as or better than other students and that, in addition, they learn the value of collaboration and gain skill at many of the practices associated with being a scientist.

Learning by design and goal-based scenarios use the principles of CBR to support and refine students' own use of case-based reasoning. Both are designed to ensure that learners have the kinds of experience that can lead to the given learning objectives, and provide activities orchestrated so that attempting them, and interpreting the resulting experiences, will lead to learning the right lessons and selecting good indices for future recall and transfer. Likewise, because failure motivates explanations and focuses a reasoner on what he or she needs to learn, both LBD and GBS place students in circumstances in which they can fail safely and recognize failure, by giving them goals to achieve, helping them to generate ideas about how to achieve those goals, and giving them the opportunity to try out their ideas and experience the results. Both models promote iterative refinement of solutions – moving gradually towards better solutions and understanding of the underlying theory – through explanation of imperfect solutions, and refinement of both beliefs and solutions as a result of those explanations. LBD goes further by orchestrating sequences of experiences, sequencing challenges so that students refer back to and attempt to reuse what they learned in earlier challenges.

The goal of helping learners become better case-based reasoners provides guidance for teachers in

an LBD or GBS environment, or indeed in any environment where students are learning from experiences. CBR suggests that teachers should help students interpret their experiences and store them as well-articulated and well-indexed cases in their memories: helping learners to make connections between their intentions, plans, outcomes, and explanations; helping them to extract lessons from their experiences and associated applicability conditions; making sure they get timely feedback on the decisions they make; helping them explain their mistakes or poor predictions; and helping them rethink and revise the encodings of beliefs that were responsible for those mistakes. CBR suggests, also, that teachers should help learners learn to use cases effectively as they reason: providing students with opportunities to practice retrieving applicable cases from their memories, to judge which of several potential cases might be applicable in a new situation, and to merge, adapt, and apply lessons in new situations. Teachers should also help them to learn how to learn: providing a scaffolding to help students notice similarities and general rules by comparing cases, helping them discern applicability conditions for lessons they extract from cases, helping them to make abstractions for use in more sophisticated reasoning, and helping them to be aware of the reasoning they are doing.

SUMMARY

Cases provide a rich source of information at an operational level, and can be learned and reapplied in a wide range of circumstances, both to improve reasoning efficiency and to enable effective reasoning in domains that are imperfectly understood. Case-based reasoning research in cognitive science develops computational models of the memory, analogical reasoning, and learning processes required to reason and learn from cases. These models provide testable hypotheses about human reasoning and learning, and illuminate the constraints on the case-based reasoning process relating to information processing. This research has led to useful artificial intelligence technologies, often inspired by human case-based reasoning and sometimes exploiting knowledge about human CBR to assist humans' own processes of learning from cases. In educational applications, the CBR approach redefines 'transfer' as spontaneous reminding and use of experiences in new situations. This process can be improved by structuring learning environments to support and assist students' analysis and assimilation of cases and to encourage students to compare their cases with the cases of others, by sharing and examining anecdotes about prior experiences. CONTENTS

Machine learning is the study of methods for programming computers to learn.

INTRODUCTION

Machine learning is the study of methods for programming computers to learn. Computers are applied to a wide range of tasks, and for most of these it is relatively easy for programmers to design and implement the necessary software. However, there are many tasks for which this is difficult or impossible. For these tasks, machine learning provides a way to construct successful computer systems. These can be divided into four general categories.

First, there are problems for which there exist no human experts. For example, in modern automated manufacturing facilities, there is a need to predict machine failures before they occur by analyzing sensor readings. Because the machines are new, there are no human experts who can be interviewed by a programmer to provide the knowledge necessary to build a computer system. A machine learning system can study recorded data and subsequent machine failures and learn prediction rules.

Second, there are problems where human experts exist, but where they are unable to explain their expertise. This is the case in many perceptual tasks, such as speech recognition, hand-writing recognition, and natural language understanding. Virtually all humans exhibit expert-level abilities in these tasks, but none of them can describe the detailed steps that they follow as they perform them. Fortunately, humans can provide machines with examples of the inputs and correct outputs for these tasks, so machine learning algorithms can learn to map the inputs to the outputs.

Third, there are problems where phenomena are changing rapidly. In finance, for example, people would like to predict the future behavior of the stock market, of consumer purchases, or of exchange rates. These behaviors change frequently, so that even if a programmer could construct a good predictive computer program, it would need to be rewritten frequently. A learning program can relieve the programmer of this burden by constantly modifying and tuning a set of learned prediction rules.

Fourth, there are applications that need to be customized for each computer user separately. Consider, for example, a program to filter unwanted electronic mail messages. Different users will need different filters. It is unreasonable to expect each user to program his or her own rules, and it is infeasible to provide every user with a software engineer to keep the rules up-to-date. A machine learning system can learn which mail messages the user rejects and maintain the filtering rules automatically.

Machine learning addresses many of the same research questions as the fields of statistics, data mining, and psychology, but with differences of emphasis. Statistics focuses on understanding the phenomena that have generated the data, often with the goal of testing different hypotheses about those phenomena. Data mining seeks to find patterns in the data that are understandable by people. Psychological studies of human learning aspire to understand the mechanisms underlying the various learning behaviors exhibited by people (concept learning, skill acquisition, strategy change, etc.). In contrast, machine learning is primarily concerned with the accuracy and effectiveness of the resulting computer system. To illustrate this, consider the different questions that might be asked about speech data. A machine learning approach focuses on building an accurate and efficient speech recognition system. A statistician might collaborate with a psychologist to test

hypotheses about the mechanisms underlying speech recognition. A data mining approach might look for patterns in speech data that could be applied to group speakers according to age, sex, or level of education.

ANALYTICAL AND EMPIRICAL LEARNING TASKS

Learning tasks can be classified along many different dimensions. One important dimension is the distinction between empirical and analytical learning. Empirical learning is learning that relies on some form of external experience, while analytical learning requires no external inputs. Consider, for example, the problem of learning to play tic-tac-toe (noughts and crosses). Suppose a programmer has provided an encoding of the rules for the game in the form of a function that indicates whether proposed moves are legal or illegal and another function that indicates whether the game is won, lost, or tied. Given these two functions, it is easy to write a computer program that repeatedly plays games of tic-tac-toe against itself. Suppose that this program remembers every board position that it encounters. For every final board position (i.e. where the game is won, lost, or tied), it remembers the outcome. As it plays many games, it can mark a board position as a losing position if every move made from that position leads to a winning position for the opponent. Similarly, it can mark a board position as a winning position if there exists a move from that position that leads to a losing position for the opponent. If it plays enough games, it can eventually determine all of the winning and losing positions and play perfect tic-tac-toe. This is a form of analytical learning because no external input is needed. The program is able to improve its performance just by analyzing the problem.

In contrast, consider a program that must learn the *rules* for tic-tac-toe. It generates possible moves and a teacher indicates which of them are legal and which are illegal as well as which positions are won, lost, or tied. The program can remember this experience. After it has visited every possible position and tried every possible move, it will have complete knowledge of the rules of the game (although it may guess them long before that point). This is empirical learning, because the program could not infer the rules of the game analytically – it must interact with a teacher to learn them.

The dividing line between empirical and analytical learning can be blurred. Consider a program like the first one that knows the rules of the game. However, instead of playing against itself, it plays against a human opponent. It still remembers all of the positions it has ever visited, and it still marks them as won, lost, or tied based on its knowledge of the rules. This program is likely to play better tic-tac-toe sooner, because the board positions that it visits will be ones that arise when playing against a knowledgeable player (rather than random positions encountered while playing against itself). So *during the learning process*, this program will perform better. Nonetheless, the program did not *require* the external input, because it could have inferred everything analytically.

The solution to this puzzle is to consider that the overall *learning task* is an analytical task, but that the program solves the task empirically. Furthermore, the task of playing well against a human opponent *during the learning process* is an empirical learning task, because the program needs to know which game positions are likely to arise in human games.

This may not seem like a significant issue with tic-tac-toe. But in chess, for example, it makes a huge difference. Given the rules of the game, learning to play optimal chess is an analytical learning task, but the analysis is computationally infeasible, so methods that include some empirical component must be employed instead. From a cognitive science perspective, the difference is also important. People frequently confront learning tasks which could be solved analytically, but they cannot (or choose not to) solve them this way. Instead, they rely on empirical methods.

The remainder of this article is divided into five parts. The first four parts are devoted to empirical learning. First we discuss the fundamental questions and methods in supervised learning. Then we consider more complex supervised learning problems involving sequential and spatial data. The third section is devoted to unsupervised learning problems, and the fourth section discusses reinforcement learning for sequential decision-making. The article concludes with a review of methods for analytical learning.

FUNDAMENTALS OF SUPERVISED LEARNING

Let us begin by considering the simplest machine learning task: *supervised learning* for classification. Suppose we wish to develop a computer program that, when given a picture of a person, can determine whether the person is male or female. Such a program is called a *classifier*, because it assigns a class (i.e. male or female) to an object (i.e. a photograph). The task of supervised learning is to

construct a classifier given a set of classified training examples – in this case, example photographs along with the correct classes.

The key challenge for supervised learning is the problem of *generalization*: after analyzing only a (usually small) sample of photographs, the learning system should output a classifier that works well on all possible photographs.

A pair consisting of an object and its associated class is called a *labeled example*. The set of labeled examples provided to the learning algorithm is called the *training set*. Suppose we provide a training set to a learning algorithm and it outputs a classifier. How can we evaluate the quality of this classifier? The usual approach is to employ a second set of labeled examples called the *test set*. We measure the percentage of test examples correctly classified (called the *classification rate*) or the percentage of test examples misclassified (the *misclassification rate*).

The reason we employ a separate test set is that most learned classifiers will be very accurate on the training examples. Indeed, a classifier that simply memorized the training examples would be able to classify them perfectly. We want to test the ability of the learned classifier to generalize to new data points.

Note that this approach of measuring the classification rate assumes that each classification decision is independent and that each classification decision is equally important. These assumptions are often violated.

The independence assumption could be violated if there is some temporal dependence in the data. Suppose, for example, that the photographs were taken of students in classrooms. Some classes (e.g. early childhood development) primarily contain girls, other classes (e.g. car repair) primarily contain boys. If a classifier knew that the data consisted of batches, it could achieve higher accuracy by trying to identify the point at which one batch ends and another begins. Then within each batch of photographs, it could classify all of the objects into a single class (e.g. based on a majority vote of its guesses on the individual photographs). These kinds of temporal dependencies arise frequently. For example, a doctor seeing patients in a clinic knows that contagious illnesses tend to come in waves. Hence, after seeing several consecutive patients with the flu, the doctor is more likely to classify the next patient as having the flu too, even if that patient's symptoms are not as clearcut as the symptoms of the previous patients.

The assumption of equal importance could be violated if there are different costs or risks associated with different misclassification errors. Suppose the classifier must decide whether a patient has cancer based on some laboratory measurements. There are two kinds of errors. A *false positive* error occurs when the classifier classifies a healthy patient as having cancer. A *false negative* error occurs when the classifier classifies a person with cancer as being healthy. Typically false negatives are more costly than false positives, so we might want the learning algorithm to prefer classifiers that make fewer false negative errors, even if they make more false positives as a result.

The term supervised learning includes not only learning classifiers but also learning functions that predict numerical values. For example, given a photograph of a person, we might want to predict the person's age, height, and weight. This task is usually called *regression*. In this case, each labeled training example is a pair of an object and the associated numerical value. The quality of a learned prediction function is usually measured as the square of the difference between the predicted value and the true value, although sometimes the absolute value of this difference is measured instead.

An Example Learning Algorithm: Learning Decision Trees

There are many different learning algorithms that have been developed for supervised classification and regression. These can be grouped according to the formalism they employ for representing the learned classifier or predictor: decision trees, decision rules, neural networks, linear discriminant functions, Bayesian networks, support vector machines, and nearest-neighbor methods. Many of these algorithms are described in other articles in this encyclopedia. Here, we will present a topdown algorithm for learning decision trees, since this is one of the most versatile, most efficient, and most popular machine learning algorithms. (*See* **Connectionism**; **Backpropagation**; **Bayesian Belief Networks**; **Perceptron**; **Pattern Recognition, Statistical**; **Learning through Case Analysis**)

A decision tree is a branching structure as shown in Figure 1. The tree consists of nodes and leaves. The *root node* is at the top of the diagram, and the leaves at the bottom. Each node tests the value of some *feature* of an example, and each leaf assigns a class label to the example. This tree was constructed by analyzing 670 labeled examples of breast cancer biopsies. Each biopsy is represented by 9 features such as Clump Thickness (CT), Uniformity of Cell Size (US), and Uniformity of Cell Shape (USh). To

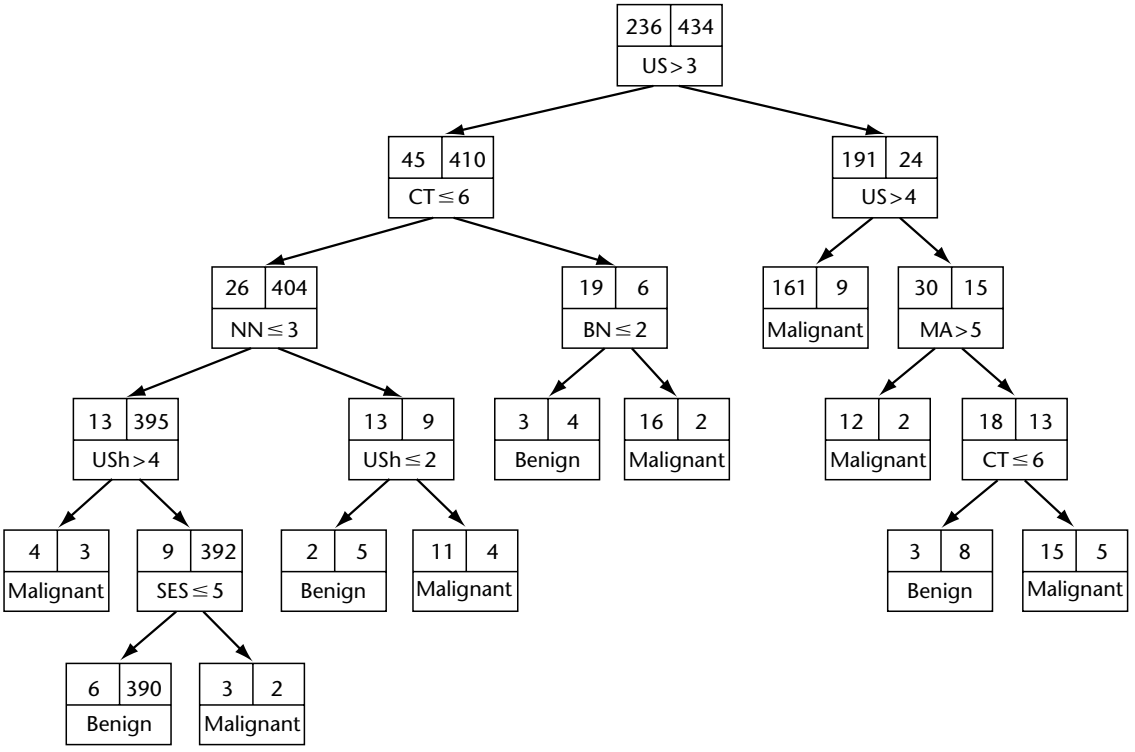

Figure 1. Decision tree for diagnosing breast cancer. US = Uniformity of Cell Size; CT = Clump Thickness; NN = Normal Nucleoli; USh = Uniformity of Cell Shape; SES = Single Epithelial Cell Size; BN = Bare Nuclei; MA = Marginal Adhesion.

understand how the decision tree works, suppose we have a biopsy example with US = 5, CT = 7, and BN = 2. To classify this example, the decision tree first tests if US > 3, which is true. Whenever the test in a node is true, control follows the left outgoing arrow; otherwise, it follows the right outgoing arrow. In this case, the next test is CT ≤ 6 which is false, so control follows the right arrow to the test BN ≤ 2. This is true, so control follows the left arrow to a leaf node which assigns the class 'Benign' to the biopsy.

The numbers in each node indicate the number of Malignant and Benign training examples that 'reached' that node during the learning process. At the root, the 670 training examples comprised 236 Malignant cases and 434 Benign cases. The decision tree is constructed top-down by repeatedly choosing a feature (e.g. US) and a threshold (e.g. 3) to test. Different algorithms employ different heuristics, but all of these heuristics try to find the feature and threshold that are most predictive of the class label. A perfect test would send all of the Benign examples to one branch and all of the Malignant examples to the other branch. The test US > 3 is not perfect, but it is still very good: the left branch receives 410 of the 434 Benign cases and only 45 of the 236 Malignant ones, while the right branch receives 191 of the 236 Malignant cases and only 24 of the Benign ones. After selecting this test, the algorithm splits the training examples according to the test. This gives it $45 + 410 = 455$ examples on the left branch and $191 + 24 = 215$ on the right. It now repeats the same process of choosing a predictive feature and threshold, and splitting the data until a termination rule halts the splitting process. At that point, a leaf is created whose class label is the label of the majority of the training examples that reached the leaf.

One advantage of decision trees is that, if they are not too large, they can be interpreted by humans. This can be useful both for gaining insight into the data and also for validating the reasonableness of the learned tree.

The Triple Trade-off in Empirical Learning

All empirical learning algorithms must contend with a trade-off among three factors: (1) the size or complexity of the learned classifier, (2) the amount of training data, and (3) the generalization accuracy on new examples. Specifically, the

generalization accuracy on new examples will usually increase as the amount of training data increases. As the complexity of the learned classifier increases, the generalization accuracy first rises and then falls. These trade-offs are illustrated in Figure 2. The different curves correspond to different amounts of training data. As more data are available, the generalization accuracy reaches a higher level before eventually dropping. In addition, this higher level corresponds to increasingly more complex classifiers.

The relationship between generalization accuracy and the amount of training data is fairly intuitive: the more training data given to the learning algorithm, the more evidence the algorithm has about the classification problem. In the limit, the data would contain every possible example, so the algorithm would know the correct label of every possible example, and it would generalize perfectly.

In contrast, the relationship between generalization accuracy and the complexity of the learned structure is less obvious. To understand it, consider what would happen if we allowed the decision tree to grow extremely large. An advantage of such a large tree is that it can be proved that if the tree becomes large enough, it can represent *any* classifier. We say that such trees have *low bias*.

Unfortunately, however, such a very large tree would typically end up having only a few training examples in each leaf. As a result, the choice of the class label in each leaf would be based on just those few examples, which is a precarious situation. If there is any noise in the process of measuring and labeling those training examples, then the class label could be in error. The resulting classifier is said to have *high variance*, because a slight change in the training examples can lead to changes in the classification decisions. Such a decision tree has merely memorized the training data, and although it will be very accurate on the training data, it will usually generalize very poorly. We say that it has 'overfit' the training data.

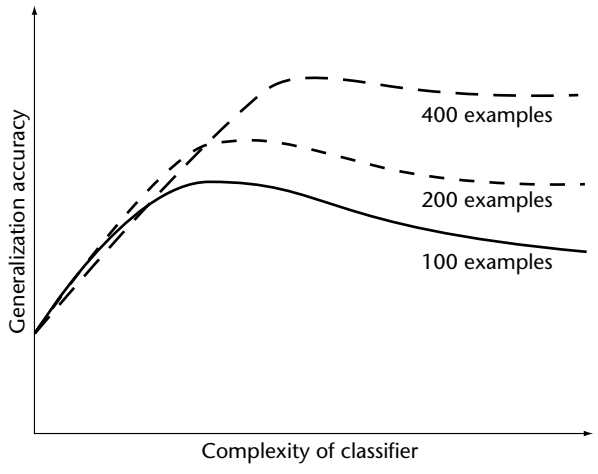

Figure 2. Generalization accuracy as a function of the complexity of the classifier, for various amounts of training data.

At the other extreme, suppose we consider a degenerate decision tree that contains only one decision node and two leaves. (These are known as 'decision stumps'.) The class label in each leaf is now based on hundreds of training examples, so the tree has *low variance*, because it would take a large change in the training data to cause a change in the classifier. However, such a simple decision tree might not be able to capture the full complexity of the data. For diagnosing breast cancer, for example, it is probably not sufficient to consider only one feature. Formally, such a classifier is said to have *high bias*, because its representational structure prevents it from representing the optimal classifier. Consequently, the classifier may also generalize poorly, and we say that it has 'underfit' the training data.

An intuitive way of thinking about this trade-off between bias and variance is the following. A learning algorithm faces a choice between a vast number of possible classifiers. When very few data are available, it does not have enough information to distinguish between all of these classifiers – many classifiers will appear to have identical accuracy on the training data and if it chooses randomly among such apparently good classifiers, this will result in high variance. It must reduce the number of possible classifiers (i.e. by reducing their complexity) until it does have enough data to discriminate among them. Unfortunately, this reduction will probably introduce bias, but it will reduce the variance.

In virtually every empirical learning algorithm, there are mechanisms that seek to match the complexity of the classifier to the complexity of the training data. In decision trees, for example, there are *pruning procedures* that remove branches from an overly large tree to reduce the risk of overfitting. In neural networks, support vector machines, and linear discriminant functions, there are *regularization methods* that place a numerical penalty on having large numerical weights. This turns out to be mathematically equivalent to limiting the complexity of the resulting classifiers.

Some learning algorithms, such as the naive Bayes method and the perceptron algorithm, are not able to adapt the complexity of the classifier. These algorithms only consider relatively simple

classifiers. As a result, on small training sets, they tend to perform fairly well, but as the amount of training data increases, their performance suffers, because they underfit the data (i.e. they are biased).

Prior Knowledge and Bias

Most machine learning algorithms make only very general and very weak assumptions about the nature of the training data. As a result, they typically require large amounts of training data to learn accurate classifiers. This problem can be solved by exploiting prior knowledge to eliminate from consideration classifiers that are not consistent with the prior knowledge. The resulting learning algorithms may be able to learn from very few training examples.

However, there is a risk to introducing prior knowledge. If that knowledge is incorrect, then it will eliminate all of the accurate classifiers from consideration by the learning algorithm. In short, prior knowledge introduces bias into the learning process, and it is important that this bias be correct.

SUPERVISED LEARNING FOR SEQUENCES, TIME SERIES, AND SPATIAL DATA

Now that we have discussed the basic supervised learning problem and the bias–variance trade-off, we turn our attention to more complex supervised learning tasks.

Consider the problem of speech recognition. A speech recognition system typically accepts as input a spoken sentence (e.g. 5 seconds of a sound signal) and produces as output the corresponding string of words. This involves many levels of processing, but at the lowest level, we can think of a sentence as a sequence of labeled examples. Each example consists of a 40 ms segment of speech (the object) along with a corresponding phoneme (the label). However, it would be a mistake to assume that these labeled examples are independent of each other, because there are strong sequential patterns relating adjacent phonemes. For example, the pair of phonemes /s/ /p/ (as in the English words 'spill' and 'spin') is much more common than the pair /s/ /b/ (which almost never appears). Hence, a speech recognition system has the opportunity to learn not only how to relate the speech signal to the phonemes, but also how to relate the phonemes to each other. The hidden Markov model (HMM) is an example of a classifier that can learn both of these kinds of information. (*See* **Speech Recognition, Automatic**; **Speech Perception and Recognition, Theories and Models of**)

A similar problem arises in time series analysis. Suppose we wish to predict the El Niño phenomenon, which can be measured by the temperature of the sea surface in the equatorial Pacific Ocean. Imagine that we have measurements of the temperature every month for the past 20 years. We can view this as a set of labeled training examples. Each example is a pair of temperatures from two consecutive months, and the goal is to learn a function for predicting the temperature next month from the temperature in the current month. Again it is a mistake to treat these examples as independent. The relationship between adjacent months is similar to the relationship between adjacent phonemes in speech recognition. However, unlike in speech recognition, we must make a prediction every month about what the next month's temperature will be. This would be like trying to predict the next word in the sentence based on the previous word.

Spatial data present learning tasks similar to sequential data, but in two dimensions. For example, a typical spatial task is to predict the type of land cover (trees, grasslands, lakes, etc.) on the ground based on satellite photographs. Training data consist of photographs in which each pixel has been labeled by its land cover type. Methods such as Markov random fields can be applied to capture the relationships between nearby pixels.

Supervised Learning for Complex Objects

So far we have discussed the task of classifying single objects and the task of classifying a one- or two-dimensional array of objects. There is a third task that is intermediate between these: the task of classifying complex objects. For example, consider the problem of deciding whether a credit card has been stolen. The 'object' in this case is a *sequence* of credit card transactions, but the class label (stolen or not stolen) is attached to the entire sequence, not to each individual transaction. In this case, we wish to analyze the entire sequence to decide whether it provides evidence that the card is stolen.

There are three ways to approach this problem. The first method converts it into a simple supervised learning problem by extracting a set of features from the sequence. For example, we might compute the average, minimum, and maximum dollar amounts of the transactions, the variance of the transactions, the number of transactions per day, the geographical distribution of the transactions, and so on. These features summarize the

variable length sequence as a fixed length feature vector, which we can then give as input to a standard supervised learning algorithm.

The second method is to convert the problem into the problem of classifying labeled sequences of objects. On the training data, we assign a label to each transaction indicating whether it was legitimate or not. Then we train a classifier for classifying individual transactions. Finally, to decide whether a new sequence of transactions indicates fraud, we apply our learned classifier to the entire sequence and then make a decision based on the number of fraudulent transactions it identifies.

The third method is to learn explicit models of fraudulent and non-fraudulent sequences. For example, we might learn a hidden Markov model that describes the fraudulent training sequences and another HMM to describe the non-fraudulent sequences. To classify a new sequence, we compute the likelihood that each of these two models could have generated the new sequence and choose the class label of the more likely model.

UNSUPERVISED LEARNING

The term unsupervised learning is employed to describe a wide range of different learning tasks. As the name implies, these tasks analyze a given set of objects that do not have attached class labels. In this section, we will describe five unsupervised learning tasks.

Understanding and Visualization

Given a large collection of objects, we often want to be able to understand these objects and visualize their relationships. Consider, for example, the vast diversity of living things on earth. Linnaeus devoted much of his life to arranging living organisms into a hierarchy of classes with the goal of arranging similar organisms together at all levels of the hierarchy.

Many unsupervised learning algorithms create similar hierarchical arrangements. The task of *hierarchical clustering* is to arrange a set of objects into a hierarchy so that similar objects are grouped together. A standard approach is to define a measure of the similarity between any two objects and then seek clusters of objects which are more similar to each other than they are to the objects in other clusters. *Non-hierarchical clustering* seeks to partition the data into some number of disjoint clusters.

A second approach to understanding and visualizing data is to arrange the objects in a low-dimensional space (e.g. in a 2-dimensional plane) so that similar objects are located nearby each other. Suppose, for example, that the objects are represented by 6 real-valued attributes: height, width, length, weight, color, and density. We can measure the similarity of any two objects by their Euclidean distance in this 6-dimensional space. We wish to assign each object two new dimensions (call them x and y) such that the Euclidean distance between the objects in this 2-dimensional space is proportional to their Euclidean distance in the original 6-dimensional space. We can then plot each object as a point in the 2-dimensional plane and visually see which objects are similar.

Density Estimation and Anomaly Detection

A second unsupervised learning task is density estimation (and the closely related task of anomaly detection). Given a set of objects, $\{e_1, e_2, \ldots, e_n\}$, we can imagine that these objects constitute a random sample from some underlying probability distribution $P(e)$. The task of density estimation is to learn the definition of this probability density function P.

A common application of density estimation is to identify anomalies or outliers. These are objects that do not belong to the underlying probability density. For example, one approach to detecting fraudulent credit card transactions is to collect a sample of legal credit card transactions and learn a probability density $P(t)$ for the probability of transaction t. Then, given a new transaction t', if $P(t')$ is very small, this indicates that t' is unusual and should be brought to the attention of the fraud department. In manufacturing, one quality control procedure is to raise an alarm whenever an anomalous object is produced by the manufacturing process.

Object Completion

People have an amazing ability to complete a fragmentary description of an object or situation. For example, in natural language understanding, if we read the sentences, 'Fred went to the market. He found some milk on the shelf, paid for it, and left,' we can fill in many events that were not mentioned. For example, we are quite confident that Fred picked up the milk from the shelf and took it to the cash register. We also believe that Fred took the milk with him when he left the market. We can complete this description because we know about 'typical' shopping episodes.

Similarly, suppose we see the front bumper and wheels of a car visible around the corner of a building. We can predict very accurately what the rest of the car looks like, even though it is hidden from view.

Object completion involves predicting the missing parts of an object given a partial description of the object. Both clustering and density estimation methods can be applied to perform object completion. The partial description of the object can be used to select the most similar cluster, and then the object can be completed by analyzing the other objects in that cluster. Similarly, a learned probability density $P(x_1, x_2)$ can be used to compute the most likely values of x_2 given the observed values of x_1. A third approach to object completion is to apply a supervised learning algorithm to predict each attribute of an object given different subsets of the remaining attributes.

Information Retrieval

A fourth unsupervised learning task is to retrieve relevant objects (documents, images, finger prints) from a large collection of objects. Information retrieval systems are typically given a partial description of an object, and they use this partial description to identify the K most similar objects in the collection. In other cases, a few examples of complete objects may be given, and again the goal is to retrieve the K most similar objects.

Clustering methods can be applied to this problem. Given partial or complete descriptions of objects, the most similar cluster can be identified. Then the K most similar objects can be extracted from that cluster.

Data Compression

There are many situations in which we do not want to store or transmit fully detailed descriptions of objects. Each image taken by a digital camera, for example, can require 3 megabytes to store. By applying image compression techniques, such images can often be reduced to 50 kilobytes (a 60-fold reduction) without noticeably degrading the picture. Data compression involves identifying and removing the irrelevant aspects of data (or equivalently, identifying and retaining the essential aspects of data). Most data compression methods work by identifying commonly occurring subimages or substrings and storing them in a 'dictionary'. Each occurrence of such a substring or subimage can then be replaced by a (much shorter) reference to the corresponding dictionary entry.

LEARNING FOR SEQUENTIAL DECISION-MAKING

In all learning systems, learning results in an improved ability to make decisions. In the supervised and unsupervised learning tasks we have discussed so far, the decisions made by the computer system after learning are non-sequential. That is, if the computer system makes a mistake on one decision, this has no bearing on subsequent decisions. Hence, if an optical character recognition system misreads the postal code on a package, this only causes that package to be sent to the wrong address. It does not have any effect on where the next package will be sent. Similarly, if a fraud detection system correctly identifies a stolen credit card for one customer, this has no effect on the cost (or benefit) of identifying the stolen credit cards of other customers.

In contrast, consider the problem of steering a car down a street. The driver must make a decision approximately once per second about how to turn the wheel to keep the car in its lane. Suppose the car is in the center of the lane but pointed slightly to the right. If the driver fails to correct by turning slightly to the left, then at the next time step, the car will move into the right part of the lane. If the driver again fails to correct, the car will start to leave the lane. In short, if the driver makes a mistake at one decision point, this affects the situation that he or she will confront at the next decision point. The hallmark of sequential decision-making is that the decision-maker must live with the consequences of his or her mistakes.

Sequential decision-making tasks arise in many domains where it is necessary to control a system (e.g. steering of robots, cars, and spacecraft; control of oil refineries, chemical plants, power plants, and factories; management of patients in intensive care). The system under control is also referred to as 'the environment'.

Many of these control problems can be modeled as *Markov decision problems (MDPs)*. In a Markov decision problem, the environment is said to have a current 'state' that completely summarizes the variables in the system (e.g. the position, velocity, and acceleration of a car). At each time step, the controller observes the state of the environment and must choose an action (e.g. steer left or steer right). The action is then executed, which may cause the environment to move to a new state. The controller then receives an immediate 'reward' which is a measure of the cost of the action and the desirability of the current state or the new state. For example, in steering a car, there might be a reward of zero for all actions as long as the car remains in

its lane. But the controller would receive a penalty whenever the car departed from the lane. The controller makes its decisions according to a control *policy*. The policy tells, for each state of the environment, what action should be executed. The optimal policy is one that maximizes the sum of the rewards received by the controller.

Reinforcement learning is the task of learning a control policy by interacting with an *unknown* environment. There are two main approaches to reinforcement learning: model-based and model-free methods.

In model-based reinforcement learning, the learner executes a control policy for the purpose of learning about the environment. Each time it executes an action a in state s and observes the resulting reward r and next state s', it collects a four-tuple $\langle s, a, r, s' \rangle$ that records the experience. After collecting a sufficient number of these four-tuples, the learner can learn a *probability transition function* $P(s'|s, a)$ and a *reward function* $R(s, a, s')$. The probability transition function says that if action a is executed in state s, then the environment will move to state s' with probability $P(s'|s, a)$. The reward function gives the average value of the reward that will be received when this happens: $R(s, a, s')$. Given these two functions, it is possible to apply *dynamic programming* algorithms to compute the optimal control policy.
