Planning: Neural and Psychological

Intermediate article

Vinod Goel, York University, Toronto, Ontario, Canada

CONTENTS

To plan is to formulate a scheme or method for attaining some goal. Scientists are just beginning to understand the psychological processes and brain systems involved.

INTRODUCTION

Planning is a quintessential human cognitive activity that involves the mental formulation of future states of affairs. In this article, we shall differentiate between planning and general problem solving, further differentiate between ill-structured and well-structured planning, review the components of both types of planning, and summarize some of the data on the neural basis of planning.

DEFINITION AND CHARACTERIZATION OF PLANNING

Planning is a form of problem solving. Problem solving, according to most definitions, requires at least the following conditions: (1) there are two distinct states of affairs; (2) the agent is in one state and wants to be in the other state; (3) it is not apparent to the agent how the gap is to be bridged; (4) bridging the gap is a consciously guided (at least at the top executive level), multi-step process. Planning problems also require an agent to chart a path from A to B in a modeling space, without 'bumping' into the world. All of the 'bumping' must be done in the modeling space, and some satisfactory path extracted. That is, the whole idea of planning is that we want to know the consequences of an action before the action is executed. The only way to do this is to execute the action in a modeling space and 'observe' the consequences. If the results are satisfactory, the plan can be executed in the real world. If the results are not satisfactory, the plan can be revised. This definition tries to capture an interesting commonsense notion of planning, such that planning is neither a ubiquitous activity nor an overly narrow activity.

Planning in the world versus planning in the laboratory

Real-world planning problems are largely ill-structured problems – that is, problems where the information content of the start state, goal state, and transformation function is incompletely specified. For example, planning a meal for a guest is an example of an ill-structured task. The start state is incompletely specified (e.g., how hungry will they be? how much time and effort do I want to expend?). The goal state is also incompletely specified (e.g., how much do I care about impressing the guest? should there be three or four courses? would salmon be appropriate? would they prefer a barbecue or an indoor meal?). Finally, the transformation function is also incompletely specified (e.g., should I have the meal catered, prepare it myself, or ask everyone to bring a dish? if I prepare it, should I use fresh or frozen salmon?).

By contrast, most laboratory planning tasks are largely well-structured problems. They are characterized by the presence of information in each of the components of the problem vector. The Tower of Hanoi provides a relevant example. It is a disk transfer problem consisting of three pegs and a number of disks. The start state is completely specified (e.g., the disks are stacked in descending order on peg 1). There is a clearly defined test for the goal state (stack the disks in descending order on peg 3). The transformation function is restricted to moving disks within the following constraints: (1) only one disk may be moved at a time; (2) any disk that is not currently being moved must remain on a peg; (3) a larger disk may not be placed on a smaller disk.

Another very important difference between ill-structured and well-structured problems concerns the nature of the constraints in the two cases. In the Tower of Hanoi, as in all puzzles and games, the constraints of the task are logical or constitutive. That is, if one violates a constraint or rule, one is simply not playing that game. For example, if I place a larger disk on a smaller disk, I am simply not doing the Tower of Hanoi task. However, the constraints that we encounter in real-world planning situations are of a very different character. Some of these constraints are nomological, and many of them are social, political, economic, cultural, etc. Most of us quickly learn that these constraints are not definitional or constitutive of the task. On the contrary, they are negotiable/breakable, depending on the circumstances.

Ill-structured problems have no right or wrong answers, although there are certainly better and worse answers. In well-structured problems there are right and wrong answers, and clear ways of recognizing when they have been reached. Furthermore, most real-world problems have consequential costs associated with errors. Resources and lives are often at stake. In well-structured games, errors may cause some embarrassment to the subject, but that is about the extent of the 'damage.' Lastly, in many real-world situations there is no immediate feedback from the world. Therefore it must be simulated, or self-generated. This requires considerable resource allocation for modeling and performance prediction. In games like the Tower of Hanoi, there is genuine feedback after every operator application. However, it is local feedback, and the final solution needs to satisfy global constraints.

While both examples, planning a dinner and solving the Tower of Hanoi, can be viewed as planning tasks (though see Goel and Grafman (1995)), the above characterization makes it clear that the differences between them may be greater than the similarities, an issue we shall return to below.

COGNITIVE AND COMPUTATIONAL COMPONENTS OF PLANNING

Components of a well-structured planning system

The components of a planning system differ depending on whether we are talking about well-structured or ill-structured planning. Classic information-processing accounts of human problem solving are quite adequate to account for well-structured planning (Figure 1). Such systems typically involve an information-processing system (IPS), a task environment, and a problem space. An information-processing system is a computational system with a memory, a processor, and sensory receptors and motor effectors. There are actually three separate memories – a long-term memory, a short-term memory and an external memory. Each is characterized by its organization and its read/write times. The processor performs some basic elementary processes, such as read, write, test, compare, discriminate, and replace symbols, but there is no necessary or sufficient set.

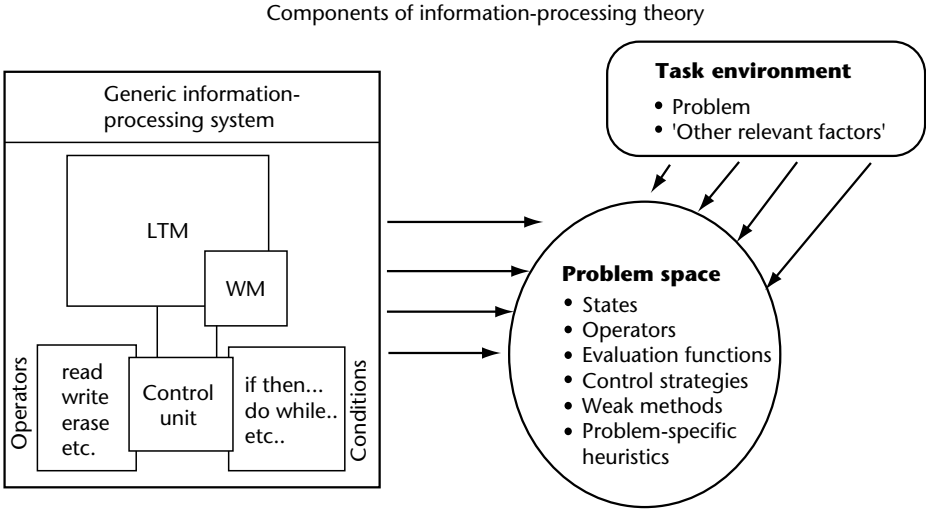

Figure 1. Characterization of a well-structured planning problem space. Abbreviations: LTM, long-term memory; WM, working memory.

These operations can be combined to perform any arbitrarily complex computation.

The task environment (TE) consists of a problem and 'any other relevant factors'. The problem space is a modeling space (constrained by the IPS and TE) where problem solving occurs as a computational process. It is defined by states, operators, evaluation functions and control strategies. States are symbolic representations of a problem at a given point in time. Operators are the procedures which transform one state into the next state. Evaluation functions measure the 'goodness' of the current state and guide the search. Weak method search strategies (e.g., means–ends analysis, breadth-first search, depth-first search) are hardwired into the information-processing system. Heuristic strategies use situation-specific knowledge to circumvent the search space. The strategy employed in any situation depends on the knowledge that the system has explicitly available.

Progress has been made in two directions with regard to understanding the cognitive and computational components of planning. Today there are many more sophisticated accounts of the structure of the information-processing system (e.g., connectionist and hybrid systems), and some progress has been made in specifying a set of mid-level computational procedures or 'modules' sufficient for planning tasks on top of the elementary operators of the information-processing system.

Components of an ill-structured planning system

The characterization of the problem space of ill-structured planning problems is more complex. Such problems have been characterized as having four component phases, namely *problem structuring*, *preliminary solutions*, *refinement* and *detailing* of solutions. Each phase differs with respect to the type of information that is dealt with, the degree of commitment to generated ideas, the level of detail that is attended to, the number and types of transformations that are engaged in, the mental representations needed to support the different types of information and transformations, and the corresponding computational mechanism. As one progresses from the preliminary phases to the detailing phases, the problem becomes more structured. This is depicted in Figure 2.

Problem structuring is an information-gathering phase in which explicit and implicit sources are used to fill in the information missing from the problem statement. Preliminary planning is a classic case of creative, ill-structured problem solving. It is a phase in which alternatives are generated and explored. This generation and exploration of alternatives is facilitated by the abstract nature of information being considered, a low degree of commitment to generated ideas, the coarseness of detail, and a large number of lateral transformations. A lateral transformation is one where movement is from one idea to a slightly different idea, rather than to a more detailed version of the same idea. Lateral transformations are necessary for the *widening of the problem space* and the exploration and development of kernel ideas.

The refinement and detailing phases are more constrained and structured. They are phases where commitments to a particular solution are made and then propagated through the problem space. They are characterized by the concrete nature of the information being considered, a high degree of commitment to generated ideas, attention to detail, and a large number of vertical transformations. A vertical transformation is one where

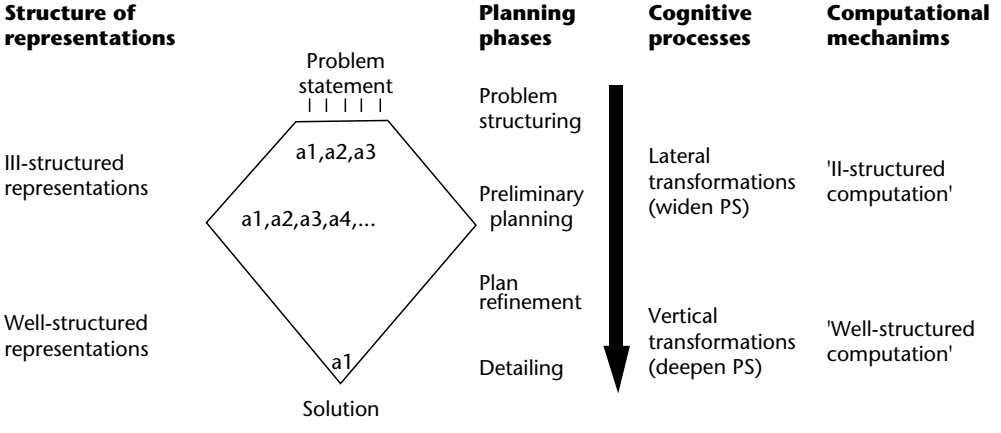

Figure 2. Characterization of an ill-structured planning problem space.

movement is from one idea to a more detailed version of the same idea. It results in a *deepening of the problem space*.

Lateral transformations are underwritten by mechanisms that support ill-structured mental representations, which are imprecise, ambiguous, fluid, indeterminate, vague, etc. In contrast, vertical transformations are underwritten by mechanisms that support well-structured mental representations, which are precise, distinct, determinate, and unambiguous. Furthermore, it has been argued that ill- and well-structured representations map onto different types of computational systems. This cognitive and computational dissociation between ill- and well-structured planning problems suggests a corresponding anatomical dissociation.

DISORDERS OF PLANNING FOLLOWING BRAIN DAMAGE

Disorders of planning have long been associated with frontal lobe lesions. The evidence comes both from informal anecdotal observations by physicians and clinicians and from laboratory experiments. Informal observations originate with Harlow's classic description of Phineas Gage, a railroad foreman who had a 4-foot iron tamping rod pass through his skull in a freak accident, and continue with Penfield's report on the behavior of his sister 15 months after the removal of her right frontal lobe. Harlow, a nineteenth-century physician who chronicled Gage's injury and subsequent behavior, noted that prior to the injury Gage was mild mannered and was 'considered a shrewd businessman, energetic and persistent in executing all his plans.' However, after the injury he would devise 'many plans of future operation but discard [ed] them before they were executed.' Penfield, upon observing his sister's inability to combine the individual components of a meal into a family dinner, noted that 'Although physical examination was negative and there was no change in personality or capacity for insight, nevertheless the loss of the right frontal lobe had resulted in an important defect. The defect produced was a lack of capacity for planned administration…'

Laboratory experiments on planning have been dominated by the two 'Tower tasks,' namely the Tower of Hanoi and the Tower of London. The Tower of Hanoi has been described above. The Tower of London is also a disk-transfer task, but without the constraint of not placing a larger disk on a smaller disk. The absence of the latter constraint, and the fact that the pegs accommodate different number of disks, makes the Tower of London a very different problem from the Tower of Hanoi (Goel and Grafman, 1995).

It is widely accepted that patients with lesions to the prefrontal cortex have difficulty completing the Tower of Hanoi (Goel and Grafman, 1995; Morris *et al*., 1997) and Tower of London (Owen *et al*., 1990) tasks. In fact, this connection seems so secure that the Tower tasks are considered to be 'frontal lobe' tasks, and they are used to determine frontal lobe involvement in a wide range of populations, including retarded children and adolescents, cerebellar patients, fragile X syndrome patients, Huntington disease patients, schizophrenics, and children with attention deficit hyperactivity disorder (ADHD).

During the past decade, a number of neuroimaging studies have confirmed the involvement of the prefrontal cortex in the Tower tasks. In positron emission tomography (PET) studies, the Tower of London task activates a large network, including prefrontal, cingulate, premotor, parietal and occipital cortices (Baker *et al*., 1996). In functional magnetic resonance imaging (fMRI) studies, the Tower of Hanoi task also activates the frontoparietal system, including the right dorsolateral and left inferior prefrontal cortex, bilateral parietal and premotor cortex (Fincham *et al*., 2002).

Recently, several experimental studies have used interesting real-world planning tasks to gain a better understanding of the role of the prefrontal cortex in ill-structured planning. Shallice and Burgess (1991) proposed and administered a Multiple Errands Test. Frontal lobe patients and normal controls were given a card with eight errands listed on it. These errands ranged from buying a loaf of bread to being at a certain place in 15 minutes' time, to finding yesterday's rate of exchange for the French franc. They were taken to an (unfamiliar) neighborhood near the hospital and asked to complete the errands within the following constraints: 'You are to spend as little money as possible (within reason) and take as little time as possible (without rushing excessively). No shop should be entered other than to buy something. Please tell one or other of us when you leave a shop what you have bought. You are not to use anything not bought on the street (other than a watch) to assist you. You may do the task in any order.' Frontal lobe patients engaged in more 'inefficient' actions (e.g., entering the same store twice), broke more rules (e.g., leaving a shop without paying), and failed to complete more tasks than normal controls.

Grafman and colleagues have used the 'scripts task' to explore planning deficits. Subjects are

requested to list as many actions as possible relevant to specified themes. The themes fall into three levels of familiarity, namely routine (e.g., preparing to go to work), nonroutine (e.g., taking a trip to Mexico) and novel (e.g., opening a beauty salon). After the list has been generated, subjects are asked to rank the actions in the correct order of execution. Finally, they are asked to rate each action with respect to importance on a 5-point scale ranging from 'least important' to 'most important'. Sirigu *et al*. (1995) reported no difference between frontal lobe patients and controls with regard to the size of the information domain, the speed of access, and the content retrieved. However, frontal lobe patients made more sequencing errors, boundary errors (i.e., failure to reach the end of a script or failure to stop at the end) and priority-setting errors (judgments of the importance of a particular action) than did controls. These results suggest that the content of scripts may remain intact after frontal lobe lesions, but that the organization, particularly temporal organization, is affected by the lesion.

Goel *et al*. (1997) administered a financial planning task to patients with focal lesions to the prefrontal cortex and to normal controls. The task involved a young couple needing help in planning their income, expenditures, investments and lifestyle to stabilize their finances, afford to purchase a home within the next two years, send their children to college in 15 to 20 years' time, and have sufficient funds to retire in 35 years. Subjects were required to help the couple achieve these four specific goals by various manipulations of income and expenditures and/or reallocation of certain assets. The findings indicate that patient performance is impoverished at a global level but not at a local level. That is, at a time-slice of the order of seconds, patient performance was indistinguishable from that of controls. They instantiated the same set of operators, in the same sequence and with the same frequency. However, when their performance was examined over a time scale of minutes to hours, differences began to emerge. Patients had difficulty in organizing and structuring their problem space. Once they began problem solving, they experienced difficulty in allocating adequate effort to each problem-solving phase. They also had difficulty in dealing with the fact that there were no right or wrong answers and there was no official termination point. In addition, they found it problematic to generate their own feedback. They invariably terminated the session before the details were fleshed out and all of the goals had been achieved. Finally, patients did not take full advantage of the fact that constraints on real-world problems are negotiable.

In a follow-up case study, Goel and Grafman (2000) tested an architect (patient PF), with a right prefrontal cortex lesion, in a real-world architectural design/planning task that required the patient to develop a new design for a laboratory space. His performance was compared with that of two age- and education-matched controls (an architect and a lawyer). The patient had superior memory and IQ scores and understood the task, and he even observed that 'this is a very simple problem'. His sophisticated architectural knowledge base was still intact, and he used it quite skillfully during the problem-structuring phase. However, the patient's problem-solving behavior differed from the controls' behavior in the following ways: (1) he had difficulty in making the transition from problem structuring to problem solving; (2) as a result, preliminary planning did not start until he was two-thirds of the way into the session; (3) the preliminary planning phase was minimal and erratic, consisting of three independently generated fragments; (4) there was no progression or lateral development of these fragments; (5) there was no carryover of abstract information into the preliminary planning or later phases; (6) the patient did not reach the detailing phase. This suggests that the key to understanding this patient's deficit is to understand the cognitive processes and mechanisms involved in the preliminary (ill-structured) planning phase.

FRACTIONATING THE NEURAL SUBSTRATES OF PLANNING

While there is mounting evidence for the involvement of the prefrontal cortex in planning, little is known about the differential involvement of the prefrontal cortex in different types of planning or different components of planning. However, it is possible to make a start along these lines. We have already discussed the cognitive and computational differences between ill- and well-structured planning. There is some evidence that the distinction may have a neural basis. Well-structured representations and computations may map on to left-hemisphere processes, while ill-structured representations and computations map on to right-hemisphere processes. That is, the inarticulate, ill-structured representational/computational system may be underwritten by the right prefrontal cortex, while the articulate, well-structured representational/computational system is underwritten by the left prefrontal cortex.

This claim is consistent with the pathology and performance of both Penfield's patient and patient PF reviewed above. Furthermore, at least five recent case studies have described frontal lobe patients with an anatomical and neuropsychological profile similar to that of PF. Like PF, these patients had difficulty in coping with real-world (ill-structured) situations despite having a high IQ. The majority, like PF, had lesions in the right dorsolateral prefrontal cortex (DLPFC). In addition, several imaging studies suggest that the right prefrontal cortex plays a special role in open-ended (i.e., ill-structured) inference tasks with no right or wrong answers (Goel and Dolan, 2000). By contrast, left hemisphere frontal lesions tend to affect more well-structured tasks, including the Tower tasks. For example, left-hemisphere patients are more impaired than right-hemisphere patients on Tower of Hanoi problems, with significant goal–subgoal conflict (Morris *et al*., 1997).

In terms of components of planning, there is an important distinction between *making* and *executing* a plan. The success of the former hinges on cognitive activity, while the success of the latter involves affective traits such as initiative, determination, and 'staying power'. There is growing evidence that the DLPFC is involved in cognitive components of tasks, while the medial ventral prefrontal cortex (MVPFC) plays a more affective role. If this is correct, one would expect patients with DLPFC lesions to have difficulty with plan formulation, and patients with MVPFC lesions to have difficulty with plan execution. Consistent with this, Phineas Gage, who devised 'many plans of future operation but discard[ed] them before they were executed', had a lesion to the MVPFC. Patient PF, who had difficulty in constructing plans, suffered a frontal dorsal lesion (Goel and Grafman, 2000). Neuroimaging studies of the Tower tasks are also attributing plan formulation (as opposed to execution) functions to the dorsolateral and rostral prefrontal cortex.

CONCLUSION

Planning is a human problem-solving activity that involves the need to model and predict the consequences of actions prior to their execution in the world. Planning problems can either be well- or ill-structured. While laboratory problems are typically well-structured, real-world planning has both ill- and well-structured components. There are cognitive and computational grounds for believing that the two forms of planning problems engage quite different mechanisms. Patient and neuroimaging data suggest that the prefrontal cortex plays a critical role in planning, but little is known about the specific contributions that different parts of the prefrontal cortex make to different types and components of planning. However, we can draw some tentative conclusions about the differential roles of the right and left prefrontal cortex in ill- and well-structured planning tasks, respectively, and of the DLPFC and MVPFC in plan formulation and execution, respectively.

Prosopagnosia

Introductory article

Andrew W Young, University of York, York, UK

CONTENTS

Prosopagnosia is a neurologically based impairment of the ability to recognize faces.

THE DEFICIT AND BRAIN LESIONS THAT CAN CAUSE PROSOPAGNOSIA

Most of us recognize the faces of individuals whom we know with such ease that it comes as a surprise to discover that some people are unable to do this. Prosopagnosic individuals experience great difficulty with face recognition, and must rely on other cues (such as the person's voice) to identify those whom they know.

Prosopagnosia is by definition regarded as a form of visual agnosia. For a person to be considered prosopagnosic, it is therefore necessary to establish that the problem with regard to face recognition is not due to blindness (a prosopagnosic person can still see) or general intellectual impairment (people are still recognized from non-facial cues).

Prosopagnosia should not be confused with other types of impairment that can compromise face recognition. In prosopagnosia, recognition from cues other than the face is usually possible. In contrast, cases of inability to recognize people from face, voice and name have been described, and these seem to reflect loss of semantic information about the identities of individuals. There are also reports of problems with regard to name retrieval (anomia), in which familiar people are successfully recognized and appropriate semantic information is accessed, but their names cannot be recalled. Impairment of the ability to recognize faces therefore reflects damage to an underlying system which can break down in different ways.

Although prosopagnosia is generally considered to be a rare deficit, there are now several hundred case descriptions in the literature. These include cases where brain injury early or late in life has led to the inability to recognize previously familiar faces, and developmental cases where the disorder has been present from birth.

In cases that are due to brain injury, the underlying pathology involves lesions that affect ventro-medial regions of the occipito-temporal cortex. These include the lingual, fusiform, and parahippocampal gyri, and more anterior parts of the temporal lobes. Functional imaging studies of normal observers have confirmed the importance of these regions with regard to face perception, and especially part of the fusiform gyrus now known as the fusiform face area. Bilateral lesions are usually present in the relatively small number of cases of prosopagnosia that have come to autopsy, but cases involving unilateral lesions of the right cerebral hemisphere have been reported in several computed tomography (CT) and magnetic resonance imaging (MRI) studies, and the functional imaging findings for normal individuals also highlight the importance of the right hemisphere.

Deficits that are commonly associated with prosopagnosia include a visual field defect in the left upper quadrant, achromatopsia (loss of color vision), and topographical disorders (inability to find one's way about). These are useful clinical pointers, but they are thought to be due to the anatomical proximity of otherwise unrelated processes, rather than having any direct functional significance. Cases of prosopagnosia without each of these associated deficits have been described, and they have also each been reported in the absence of prosopagnosia.

People with prosopagnosia know when they are looking at a face, and can describe its features, but the loss of any sense of overt recognition is often complete, with no feeling of familiarity. In contrast, other aspects of face processing, such as the ability to interpret facial expressions or to match views of unfamiliar faces, can remain surprisingly well preserved in some (although not all) cases.

There is evidence that although these aspects of face perception may be well preserved in some cases of prosopagnosia, they may be supported by unusual mechanisms and strategies. For example, the matching of pictures of unfamiliar faces by prosopagnosic individuals is often achieved by a painstaking feature-by-feature inspection, as if the face's general appearance is somehow no longer perceived 'as a whole'. Many investigators have emphasized that recognizing a face involves sensitivity to the spatial positioning of the facial features (the face's configurational properties) as well as to the features themselves. For a normal perceiver, accurate perception of the facial configuration is strongly dependent on the face being seen in its usual upright orientation – we are not good at detecting configurational changes in inverted (upside-down) faces. This sensitivity to the face's orientation may be absent (or even paradoxically reversed) in prosopagnosia, which suggests that there is a disruption of configurational encoding.

PROSOPAGNOSIA AND OTHER DEFICITS OF RECOGNITION OF VISUAL OBJECTS

In prosopagnosia, even the most familiar faces may go unrecognized, such as those of famous people, friends and family, and the affected individual's own face when seen in a mirror. The deficit encompasses both premorbidly familiar faces and the faces of people who have been encountered only since the illness onset.

The ability to recognize everyday objects is usually not as severely affected as the ability to recognize faces, and many prosopagnosic patients are able to read without much difficulty. In a case of early acquired deficit, a child who had remained unable to recognize any faces since suffering meningitis and subsequent complications in infancy was nonetheless able to learn to read. This supports the view that reading and face recognition depend on different types of visual analysis.

A hypothesis that fits such facts neatly has been proposed by Farah, who suggested that the brain uses separate mechanisms to recognize visual stimuli consisting of decomposable parts (e.g., words, whose constituent letters are all easily recognized subunits) and visual stimuli that we recognize as wholes (e.g., faces, whose individual features are relatively difficult to recognize in isolation). In prosopagnosia, the whole-based mechanism is impaired but the part-based mechanism may be much less affected. This theory is consistent with the findings of altered inversion effects in cases of prosopagnosia.

IS FACE RECOGNITION SPECIAL?

The assumption underlying much of the interest in prosopagnosia has been that it might indicate whether the brain has an evolved neural substrate for the important social task of face recognition. Fodor has been one of the most influential of many authorities who have seriously entertained the idea of a 'module' for face recognition.

A strongly debated issue has therefore been whether prosopagnosia is specific to face recognition. There is now no doubt that most people with prosopagnosia have problems with certain other visual stimuli (as would be expected from Farah's hypothesis about whole and part-based recognition), but it is uncertain whether these problems with regard to recognition of objects other than faces are an essential feature of the condition (as Farah's hypothesis implies), or whether they reflect separate problems that are likely to coexist with impairment of face recognition. The latter view is supported by occasional reports of highly circumscribed impairments. One of De Renzi's cases could find his own belongings when they were mixed in with similar objects, identify his own handwriting, pick out a Siamese cat among photographs of other cats, recognize his own car without reading the number plate, and sort domestic coins from foreign coins. In all of these tasks he was therefore able to identify individual members of visual categories with high inter-item similarity, yet he could not recognize the faces of relatives and close friends. Just as strikingly, the deficit can affect mainly *human* faces. When McNeil and Warrington's prosopagnosic patient took up farming, he was able to learn to recognize his sheep, and he correctly identified several of them from photographs of their faces!

Although they are exceptionally rare, such cases imply that the possibility of face-specific deficits must be taken seriously. This has been thought to be consistent with evidence of an abundance of face-responsive cells in the brains of primate species. However, many of these cells are in regions of the brain that do not seem to be related to face recognition *per se*, but which are likely to be involved in other important social abilities.

The development of functional imaging methods has opened up the possibility of resolving the issue by studying the neurologically normal human brain. At present, however, functional imaging studies have simply intensified the debate.

Although the fusiform face area is strongly implicated in face recognition, it has been shown that parts of the fusiform gyrus can also acquire responsiveness to novel visual stimuli that share some face-like properties.

As with previous controversies in this field, some of the debate centers around differences in what is meant by the claim of a 'special' face recognition system. It is evident that fusiform cells show a degree of plasticity, but this does not in itself rule out the possibility that some of them form an evolved substrate for face recognition.

CONSCIOUS AND NON-CONSCIOUS FACE RECOGNITION

Prosopagnosic patients usually fail all tests of overt recognition of familiar faces. They cannot name the face, give the person's occupation or other biographical details, or even state whether the face is that of a familiar person (all faces seem unfamiliar to them). Surprisingly, however, there is substantial evidence of covert recognition from physiological and behavioral measures.

Bauer initiated this line of research by measuring skin conductance while prosopagnosic patient L.F. viewed a familiar face and listened to a list of five names. When the name belonged to the face at which L.F. was looking, there was a greater skin conductance change than when someone else's name was read out. Yet if L.F. was asked to choose which name in the list was correct for the face, his performance was found to be at chance level. Thus there was a marked discrepancy between L.F.'s inability to identify the face overtly and the relatively good recognition that was demonstrated using the indirect skin conductance measure.

A number of other indices of non-conscious, covert recognition in prosopagnosia have been developed. Matching of familiar faces is better than for unfamiliar faces, priming has been found from familiar faces on to the recognition of name targets, and learning of correct face–name pairings is better than learning of incorrect pairings. All of these effects can be demonstrated when overt recognition of the faces is at the level that would be expected by chance.

However, not all prosopagnosic patients show covert recognition. As might be expected, when there is evidence of substantial impairment of face perception, covert as well as overt performance can decline to chance level.

There is a parallel between preserved covert recognition abilities and those aspects of recognition that operate automatically for normal people. We cannot look at a familiar face and choose not to recognize it – the mechanisms responsible for visual recognition are not open to conscious control in this way. It seems that some of these automatic aspects of recognition continue to function in some cases of prosopagnosia. Young and Burton simulated this pattern by halving some of the connection strengths in a computer model of the architecture of the recognition system. The network was then no longer able to classify face inputs as familiar, yet it continued to display priming effects. This helps us to understand how covert responses can be preserved when there is no overt discrimination, but it does not solve the more difficult issue of what is involved in awareness of recognizing a face.

Despite the extensive range of covert effects demonstrated in the laboratory, prosopagnosic patients do not act as if they recognize faces in everyday life. Instead, most of them are acutely conscious of their problems in face recognition. However, overt recognition can sometimes be provoked in formal experimental settings. Sergent and Poncet found that their patient P.V. could achieve overt recognition of some faces if several members of the same occupational category were presented together. This only happened when P.V. could determine the category herself. Otherwise she continued to fail to recognize the faces overtly even when the occupational category was pointed out to her. The findings have been replicated in other cases, and it seems that the simultaneous presentation of several faces from the same category may temporarily raise their activation above the threshold needed for a sense of overt recognition. Computer simulation work by Morrison and his colleagues has demonstrated one possible mechanism whereby this might occur.

Findings of provoked overt recognition in prosopagnosia show that the boundary between awareness and lack of awareness is not as completely impassable as it seems to the patient's everyday experience. However, the circumstances under which this has been found to occur are currently very limited, and it has not yet been possible to find a way to provide significant remedial assistance in real life.

Reasoning is the cognitive activity of drawing inferences from given information. All arguments in reasoning involve the claim that one or more propositions (the premises) provide some grounds for accepting another proposition (the conclusion).

INTRODUCTION

Reasoning is the cognitive activity of drawing inferences from given information. All arguments in reasoning involve the claim that one or more propositions (the premises) provide some grounds for accepting another proposition (the conclusion). Consider the following example. George returns from the grocery store accompanied by his young daughter and tells her that kiwi are perishable fruit, and that perishable fruit are placed in the refrigerator. Even though she has never seen kiwi before, she promptly places the kiwi in the refrigerator. How did she know that she should put them in the refrigerator? Furthermore, after seeing the purchased kiwi, she formed the belief that all kiwi have a brown, furry skin. Notice that she was not explicitly told that kiwi should be placed in the refrigerator, and she saw only the three purchased kiwi, yet we are not surprised by her actions. Her behavior is not a mystery. It is just an example of the reasoning brain at work. The former inference is an example of deductive reasoning, while the latter is an example of inductive reasoning.

A key feature of deductive arguments is that conclusions are contained within the premises and are independent of the content of the sentences. They can be evaluated for *validity*, a relationship between premises and conclusion involving the claim that the premises provide absolute grounds for accepting the conclusion. The reader is referred to Johnson-Laird's article on deduction for background information on the cognitive theories of deductive reasoning.

In inductive reasoning the conclusion reaches beyond the original set of premises, allowing for the possibility of creating new knowledge. Induction has long been a concern of philosophers, and it has been empirically studied by cognitive scientists for the past 25 years. Cognitive/computational models of induction typically view it as a form of hypothesis generation and selection, where one must search a large database and determine which items of information are relevant and how they are to be mapped on to the present situation. The determination of hypothesis relevance is the crucial component of induction. In the above example, the inference that 'all kiwi have a brown, furry skin', which was drawn after seeing three kiwi, seems to be plausible. However, each of the three kiwi also had a small sticker attached stating the name of the store at which they were purchased ('IGA'). Yet from seeing this sticker on three kiwi fruits we do not conclude that all kiwi have an IGA sticker on them. The former inference is plausible, but the latter is not. The logic of the two inferences is identical. However, we recognize that the property of having 'brown furry skin' is a relevant property for generalization across members of a species, but that the property of having an 'IGA' sticker is a matter of individual accident. The puzzle of induction is, to a large extent, the question of how we make these judgments of relevance. Given that almost nothing is known about the cognitive, computational, and neural basis of inductive inference, we shall restrict ourselves to deductive reasoning in this article.

REASONING AND THE BRAIN

There are two main ways in which cognitive neuroscientists investigate the neural mechanisms that

underlie reasoning processes. One approach is to study patients who have damage to specific brain regions and to observe whether they have difficulty in solving certain types of reasoning problems and, if so, which specific cognitive impairments can explain their reasoning deficits. The second approach is to study normal subjects and patients using functional neuroimaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), which allow the investigator to view which brain areas become selectively activated by specific reasoning processes and tasks.

Patient studies

Patient studies of logical reasoning have been few and infrequent. Gazzaniga and colleagues have administered simple reasoning tasks to split-brain patients and concluded that reasoning is a left-hemisphere phenomenon (Gazzaniga and Smylie, 1984). For example, they report that the left hemisphere will readily infer 'boiling water' when presented with 'water' and 'pan', while the right hemisphere seems to be incapable of such inferences. Gazzaniga goes on to postulate a 'left-brain interpreter' – that is, a mechanism which continuously elaborates and interprets information presented to it, and which readily draws inferences.

Caramazza *et al*. (1976) administered to brain-damaged patients two-term problems such as the following: 'Mike is taller than George. Who is taller?' They reported that left-hemisphere patients showed impairment for all forms of the problem, but right-hemisphere patients were impaired only when the form of the question was incongruent with the premise (e.g. 'Who is shorter?').

Read (1981) tested temporal-lobectomy patients by presenting them with three-term relational problems with semantic content (e.g. 'George is taller than Mary. Mary is taller than Carol. Who is tallest?'). The subjects were told that using a mental imagery strategy would help them to solve these problems. Read reported that the performance of left-temporal-lobectomy patients was more impaired than that of right-temporal-lobectomy patients. Left-temporal-lobectomy patients reported less use of mental imagery to solve the problems, and they also did not show deficits on standard neurological tests of verbal comprehension. Read concluded that 'The form of imagery utilized in solving deductive–recent problems is based upon verbal symbolic affirmation, and as such is mediated by the left hemisphere' (Read, 1981).

Golding (1981) evaluated responses to the Wason Four-Card Selection Task (Wason, 1966), which is perhaps the most widely used task for exploring the role of content in reasoning. In this task subjects are shown four cards (Figure 1). They can see what is on one side of each card, but not what is on the other side. They are given a rule of the form if *p* then *q* ('If a card has a vowel on one side, it has an even number on the other side') and asked which cards they would turn over in order to verify the rule. The visible values on the cards correspond to the *p*, *not-p*, *q*, and *not-q* cases of the rule. According to standard propositional logic, the correct choices are *p* (to verify that *q* is on the other side) and *not-q* (to verify that *p* is not on the other side). Although no control subjects and only one left-hemisphere-damaged subject selected the *p* card and *not-q* card (the logically correct answer), 50% of the right-hemisphere-damaged subjects chose both cards. Because control subjects tended to select those cards that matched the items described in specific test sentences, Golding proposed that the perceptual aspects of the task interfered with control subjects' verbal reasoning (e.g. when given the sentence 'Whenever there is a circle on one half of the card, there is yellow on the other half of the card,' control subjects selected the circle card or the circle and yellow cards). According to Golding, right-hemisphere-damaged patients with impaired visual processing showed superior verbal reasoning skills owing to a lack of visual perceptual interference.

Adolphs *et al*. (1996) administered a Wason selection task, using both familiar and unfamiliar stories, to patients with dorsolateral frontal lesions or ventromedial frontal lesions, and to normal controls. When given an arbitrary rule (as in Figure 1), typically fewer than 15% of normal subjects will turn over both the *p* card (A) and the *not-q* card (3). The introduction of meaningful content in a rule (e.g., 'If anyone is drinking beer, then that

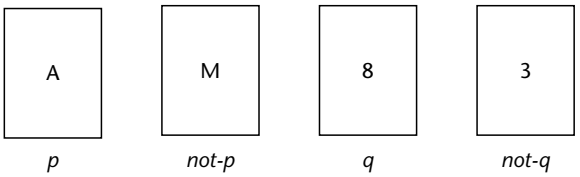

Figure 1. The Wason Four-Card Selection Task. Each card has a letter on one side and a number on the other side. The task is to determine which cards need to be turned over in order to verify the rule 'If a card has a vowel on one side, it has an even number on the other side.'

person must be over 19 years old') greatly facilitates performance. They reported that subjects in all three groups performed equally poorly when given unfamiliar stories (arbitrary rules). However, both dorsolateral patients and normal subjects chose the *p* and *not-q* cards (the logically correct selections) when the story involved familiar material. In contrast, the ventromedial patients, who had damage to the medial orbitofrontal cortex (five out of six cases had bilateral damage), did not show this facilitatory effect with familiar material. The authors concluded that in general people may reason by analogy, retrieving past experiences (including the emotion experienced) when confronted with a familiar situation. Ventromedial prefrontal patients may fail to retrieve or appropriately use past experiences when reasoning.

Waltz *et al*. (1999) found that compared with patients with damage to the temporal cortex, patients with frontal-lobe dementia were dramatically impaired in their ability to make inferences with regard to the integration of multiple relational representations. If problems varied on only one dimension, there were no between-group differences (including controls). If a problem only required judgments about canonical ordering, then patients with frontal-lobe dementia could solve the problem, but if they had to reorder the relationships to make the judgment, they failed to solve it.

In summary, studies of patients with focal lesions indicate that the left hemisphere helps to interpret stimuli as linguistic elements for further processing and inferential processes. Damage to the left hemisphere interferes with deductive reasoning. The right hemisphere may become more involved when distant relationships are being processed, and thus right-hemisphere lesions affect the processing of apparently incongruent stimuli. It is likely that left-hemisphere lesions lead to an inability to develop certain forms of mental imagery that are used when developing mental models of relationships. If a subject needs to use past experience to solve a problem, then the ventromedial prefrontal cortex may be important.

Neuroimaging studies

Goel *et al*. (1997) conducted an imaging study of deductive reasoning. Ten normal volunteers performed reasoning tasks while their regional cerebral blood flow pattern was recorded using the [^{15}O] H_2O positron emission tomography (PET) blood flow technique. Subjects were presented with arguments such as 'All apples are red; all red fruit are sweet; therefore all apples are sweet', and were then asked to make judgments about the validity of the conclusion. The deduction condition (versus a semantic baseline) resulted in activation of the left inferior frontal gyrus (Brodmann areas 45 and 47) and a region of the left superior occipital gyrus (Brodmann area 19). These brain areas are known to mediate aspects of language processing, and as such the results provide support for sentential theories of reasoning, at the expense of spatial models.

However, given that many people have the phenomenological experience of mapping syllogisms on to Venn-like diagrams, it is difficult to accept that the visuospatial system plays no role in deductive reasoning. Perhaps the absence of performance-associated brain activation in regions that are known to be involved in spatial processing (i.e. right hemisphere and parietal regions) was just a function of the fact that the deductive reasoning items which were used (a combination of categorical syllogisms, implications, disjunctions, and conjunctions) did not involve overt spatial relationships (e.g. John is standing behind Mary). Perhaps if the arguments explicitly required spatial encoding, then we might find right-hemisphere and parietal activation.

Goel *et al*. (1998) conducted another imaging experiment, this time using explicitly spatial arguments. Again they found unilateral (left-hemisphere) activation confined to the dorsolateral prefrontal cortex, the anterior cingulate, and the middle and superior temporal lobes. They did not find any significant activation in cortical regions known to be associated with spatial encoding and spatial working memory. These results were consistent with the first study (and a number of other patient studies), and demonstrated a lack of involvement of classic spatial encoding regions in reasoning.

However, the results of another study by Goel *et al*. (2000) may go some way towards resolving these counterintuitive results. In an fMRI study of deductive reasoning, using sentences with semantic content (e.g. 'All apples are red; all red fruit are sweet; therefore all apples are sweet') and without semantic content (e.g. 'All A are B; all B are C; therefore all A are C), they found evidence for the engagement of both linguistic and spatial systems, but under circumstances not predicted by cognitive theories. During content-based reasoning, a left-hemisphere temporal system was recruited. By contrast, a formally identical reasoning task that lacked semantic content activated a bilateral parietal system. This dissociation is remarkable because the logically relevant information is identical in

both conditions. Based on brain activation profiles, the two systems shared common neural components in bilateral basal ganglion nuclei, right cerebellum, bilateral fusiform gyri, and left prefrontal cortex. Goel *et al*. concluded that syllogistic reasoning is implemented in two distinct systems whose engagement is primarily a function of the presence or absence of semantic content. Furthermore, when a logical argument results in a belief–logic conflict, the nature of the reasoning process is changed by recruitment of the right prefrontal cortex.

The involvement of a parietal visual–spatial system in the abstract syllogism condition raises the question of whether argument forms involving three-term relational items (e.g. 'The apples are in the barrel; the barrel is in the barn; therefore the apples are in the barn' and 'Apples are more expensive than pears; pears are more expensive than oranges; therefore apples are more expensive than oranges') are sufficient to engage the parietal system. Goel and Dolan (2001) addressed this question in an event-related fMRI study of three-term relational reasoning, using sentences with concrete content (e.g. 'The apples are in the barrel; the barrel is in the barn; therefore the apples are in the barn') and abstract content (e.g. 'A are in B; B is in C; therefore A is in C'). They reported that both concrete and abstract three-term relational arguments activate a similar bilateral occipital–parietal–frontal network. However, the abstract reasoning condition engendered greater parietal activation than the concrete reasoning condition. It appears that arguments involving relationships that can be easily mapped on to explicit spatial relationships engage a visuospatial system, irrespective of concrete or abstract content.

The only other imaging study of deductive reasoning to date is that by Osherson *et al*. (1998), who performed a [^{15}O] H_2O PET study to compare deductive reasoning with probabilistic reasoning and language-comprehension tasks involving the same stimuli. They reported that deductive reasoning compared with probabilistic reasoning activated occipital and parietal regions, with a right-hemispheric prevalence. The comparison most relevant to us, namely deductive reasoning (using arguments such as 'None of the bakers play chess; some of the chess players listen to opera; some of the opera listeners are not bakers') versus language comprehension, resulted in activation in the left dorsal frontal gyrus (BA6), left cuneus (BA18), thalamus, caudate, and cerebellum.

In summary, the functional neuroimaging results demonstrate that the left hemisphere, and in particular the left prefrontal cortex, are very important for deductive reasoning. The more anterior the activation, the more likely it is that there is a semantic content requirement for reasoning to solve the problem.

ASSESSMENT OF THE STUDIES

The neuroimaging and patient studies to date support some form of dual-mechanism theory of deductive reasoning. The presence of semantic content engages the language system in the reasoning process. The absence of semantic content engages the visuospatial system in the identical reasoning task. At an anatomical level, these data predict that the left hemisphere is necessary and often sufficient for logical reasoning, whereas the right hemisphere is sometimes necessary but never sufficient. There is considerable consistency between the neuroimaging findings and the lesion data reported above.

As described above, both brain-lesion patients and functional neuroimaging studies suggest that each hemisphere and specific brain regions may contribute different cognitive processes to human reasoning. One interpretation of the results of these studies is that the right hemisphere may be involved in formal reasoning independent of the content of the task. Therefore the right hemisphere would be more adept at abstract reasoning. In contrast, the left hemisphere may use past experiences (factual, emotional), and would thus be more adept when reasoning involves familiar scenarios. The ventromedial prefrontal neural network would play a role when the behavioral relevance of possible responses could aid selection of the appropriate action.

The left hemisphere may also store in memory emotional states associated with personally experienced events. When an individual encounters a familiar scenario, representations of related past emotional experiences are retrieved by the left hemisphere and incorporated into the reasoning process. In the absence of or failure to activate such representations, the right hemisphere is engaged in the reasoning process.

Asymmetrical advantages of processing based on receptive-field size offer another explanation for hemispheric differences in reasoning skills. Beeman (1993) provided evidence that large semantic receptive fields account for the right hemisphere's role in understanding discourse and metaphor. A similar explanation may underlie hemispheric differences in reasoning. Large receptive fields in the right hemisphere would permit individuals to

activate all possible relationships, local and distant, between the items in the problem to be solved. Overlap between relational features from the activation of multiple relationships would give the right hemisphere an adaptive advantage over the left hemisphere for reasoning involving unfamiliar situations. By comparison, the left hemisphere's fine coding would allow individuals to focus on the main feature or event and the local relationships between the items in the problem. As a result, the left hemisphere would have an adaptive advantage over the right hemisphere in logical reasoning involving familiar content.

One clear conclusion to be drawn from the cognitive neuroscience investigation of reasoning is that there is no reasoning module, and that several different cognitive-processing components are required to reason, depending on the type of task with which the subject is faced and the particular strategies with which the subject prefers to reason.

FUTURE DIRECTIONS

The cognitive neuroscience investigation of reasoning is still in its infancy. It is clear from this article that we are only crudely able to map reasoning processes primarily to the left hemisphere and to the prefrontal cortex. More posterior cortices may contribute to reasoning when visuospatial representations are used by subjects to think about the elements of the reasoning task they are performing. The semantic content of the elements of the problem will require temporal-lobe processing, and more personal or familiar content will utilize the functions of the prefrontal cortex. The latter does not fully mature until the end of the teenage years in humans, and it is of interest to note that reasoning ability matures over the same time frame.

Reasoning does not stand alone as a cognitive process. Humans frequently reason during problem-solving tasks, when forming metaphors, and when developing a plan to achieve a goal. People also reason in social and non-social situations, and it may be that overlapping but different cognitive systems and neural regions are used for each type of reasoning. Future cognitive neuroscience studies that incorporate these factors into the design of reasoning tasks will enrich our understanding of the neural basis of reasoning processes.

Receptive Fields

Introductory article

Aniruddha Das, Columbia University, New York, USA

CONTENTS

The receptive field of a neuron is the extended region of sensory space to which the neuron responds, including those stimuli that directly activate or suppress the neuron's activity, as well as those stimuli that can modulate the neuron's response to other stimuli, but have no direct effect by themselves.

INTRODUCTION

Neurons in the sensory systems of touch (somatosensory), hearing (auditory) and vision can be defined in terms of their receptive fields (RFs), namely the regions of sensory space that drive them most vigorously.

While neurons early in a sensory pathway have compact RFs that respond to simple stimuli, neurons at higher stages in the same pathway could have large RFs with complex properties, such as the 'face-selective' cells in the higher visual inferior temporal (IT) region. Determining the transformations in RF properties on passing from stage to stage in a sensory pathway and deducing the cortical circuitry that underlies such a transformation lies at the heart of understanding sensory processing.

The RFs of neurons, particularly at higher centers, can be highly plastic and modifiable. Their response properties may vary depending on the task in which the individual is engaged, may be modulated by attention, and can change over time with sensory training or changes in sensory stimulation. In particular, RFs can 'learn' to select features that are most important in the individual's environment and thus adapt constantly, although within limits, to changes in that environment.

This article will draw heavily on the visual system to illustrate the principles of RF structure, layout, response properties and plasticity, since vision is the best-studied sensory system. However, the principles described here apply to all sensory systems, and these parallels will be mentioned explicitly wherever possible.

HISTORICAL PERSPECTIVE

The concept of the receptive field (RF) was first suggested by the British physiologist Sir Charles Sherrington in the 1890s when he was studying the scratch reflex in dogs. He used this term in the book *The Integrative Action of the Nervous System* (published in 1906) to capture his observation that the reflex was spatially localized on the animal's body. Touching any spot on the dog's back elicited a scratch response directed to the same spot, which Sherrington named the receptive field for that reflex response.

In 1938, H. Keffer Hartline, then working at Johns Hopkins University, introduced the use of the term 'receptive field' to describe the response properties of single nerve fibers. Using a painstaking procedure he dissected out single fibers from the optic nerve of the horseshoe crab (*Limulus polyphemus*), laid them out on a cotton wick soaked in saline to make electrical contact, and then recorded the responses of these fibers while the *Limulus* eye was being stimulated with small spots of light. Each fiber (the axon of a retinal ganglion cell) only responded to light falling on a well-localized spot on the animal's retina, which Hartline defined as the RF for that particular nerve fiber. With similar recordings from frog and later mammalian (cat) optic nerve fibers, Hartline showed that some neurons responded only when a spot of light was turned on in their RF, some responded only when the spot was turned off, while others responded at both light on and light off. This was clear evidence that fairly elaborate visual processing was occurring even in the retina, with RFs reflecting the interactions between excitatory and inhibitory neurons.

In the 1940s, Stephen Kuffler, then also at Johns Hopkins University, exploited the invention of

metal microelectrodes (by Ragnar Granit) to refine Hartline's discoveries by showing that the RFs of retinal ganglion cells had a complex spatial structure. By stimulating different parts of a (cat) retinal ganglion cell RF using small spots of light, Kuffler showed that these RFs had two distinct regions – one excitatory and the other inhibitory – arranged in a concentric manner. He also introduced a more nuanced view of the RF by suggesting that the latter should encompass:

> not only the areas from which responses can actually be set up by the retinal illumination…but also areas which show a functional connection, by an inhibitory or excitatory effect on a ganglion cell. This may well involve areas which are somewhat remote from a ganglion cell and by themselves do not set up discharges.

This idea anticipates the current notion of RFs that includes regions exerting purely modulatory influences on a neuron (see later section on feedback and non-classical effects). Kuffler's colleagues David Hubel and Torsten Wiesel were the first to characterize the RFs of cortical neurons. They showed that neurons in primary visual cortex (V1) had RF properties (orientation preference, direction preference and binocularity) which were more complex than the properties of lateral geniculate nucleus (LGN) neurons providing input to the cortex. However, these RF properties could be explained by the input circuitry to V1. These findings led to the concept of each sensory system as a hierarchical sequence of processing stages, with the neural circuits at each stage generating progressively more elaborate RFs, leading up to the final sensory percept.

Early in the development of the concept of RFs, Humberto Maturana, Jerome Lettvin and their colleagues proposed the attractive hypothesis that RFs were specifically tuned to extract features of importance to the particular species. Working at Massachusetts Institute of Technology (MIT) in the late 1950s, they showed that the different types of RF in frog retina in effect acted as a 'bug detector' that was most sensitive to moving objects of the same size, visual contrast and speed as the worms that formed the animal's diet. Research conducted since then suggests that the visual systems in all species are tuned along broad 'ecological' principles. In species with more complex visual systems and ecological needs than those of frogs, such tuning does not emerge as a hard-wired response in the retina. Rather, at every level of visual processing, from the retina to the cortex, RFs appear to be attuned to those features of the visual surround that are important to the species. This tuning to ecologically relevant features becomes progressively more specialized in the higher levels of each visual system (see later sections on receptive-field organization and feedback and non-classical effects). Such principles of ecological tuning also operate in other sensory modalities. For example, songbirds have neurons that are precisely tuned for the particular song, of the species, with the ability to make fine discriminations between various 'dialects' in the song. Similarly, the auditory circuits that bats use for sonar ranging are tuned to pick up reflections from objects of the same size and speed as their prey, namely insects.

DIFFERENT SENSORY SYSTEMS

General Principles of Organization and Sensory Discrimination

The RF is a useful concept in the sensory systems of vision, touch and hearing because stimuli in all three systems form sensory spaces. Individual stimuli can be positioned in terms of a metric or distance relative to other stimuli, such that the more similar a pair of stimuli, the shorter the distance. This idea of a smooth and well-defined metric holds not only for simple stimulus attributes such as the position of a light touch to the body or the pitch of a pure tone, but also for complex stimuli such as faces that can be arranged along some continuum from 'more' to 'less' similar.

Individual neurons in all three systems respond over compact regions of sensory space. In other words, neurons are activated optimally by one particular stimulus, but stimuli with 'nearby' properties also activate the neuron in proportion to their similarity to the 'best' stimulus. As a corollary, neurons form smooth maps, with neurons that are closer to each other anatomically (e.g. on cortex) having RFs that are closer to each other in the stimulus space. Each stimulus activates a compact region of the neuronal map, its point image – that is, the patch of neurons whose RFs overlap with the given stimulus. The size of the minimal point image is uniform within a cortical region, independent of the stimulus. This means that the smaller the RF, the higher the cortical magnification (the cortical distance between two neurons whose RFs are separated by some unit distance in sensory space), and the better the level of discrimination between stimuli.

The senses of smell and taste are more difficult to describe in terms of uniform sensory spaces with

well-defined distances between distinct sensations, and the concept of the RF does not translate well to these two sensory systems.

Particular Sensory Systems

Here we shall consider the relationships between RFs, sensory spaces, cortical maps and stimulus discriminability.

Somatosensory system (touch)

Each neuron in the somatosensory system responds to stimuli in a circumscribed region of the body, which defines the RF (Figure 1). Some RFs do not lie on the body surface, but rather they carry proprioceptive information from muscle stretch receptors and limb joints. Neurons are selective for distinct features of the stimuli that fall within their RFs, such as discriminative touch, deep vibration, or sensations of heat or cold. In primates, the primary somatosensory cortex (S1) is subdivided into four distinct areas, namely 3a, 3b, 2 and 1, with neurons in each area being specialized for different stimulus features. Each cortical area contains a complete, independent map of the body surface that obeys the topological constraints of the body. Thus neurons that lie close together in the cortex have RFs that lie close to each other on the body, and RFs obey body boundaries, forming contiguous patches of the body and never consisting, for example, of unconnected islands on different fingers or different parts of the body. For touch stimuli, humans have the best two-point discrimination (i.e. the shortest separation between two light taps on nearby points that can still be told apart as distinct) on the lips and the fingertips, where the primary somatosensory cortical (S1) RFs are finest. On the arms, legs and body trunk, for which the

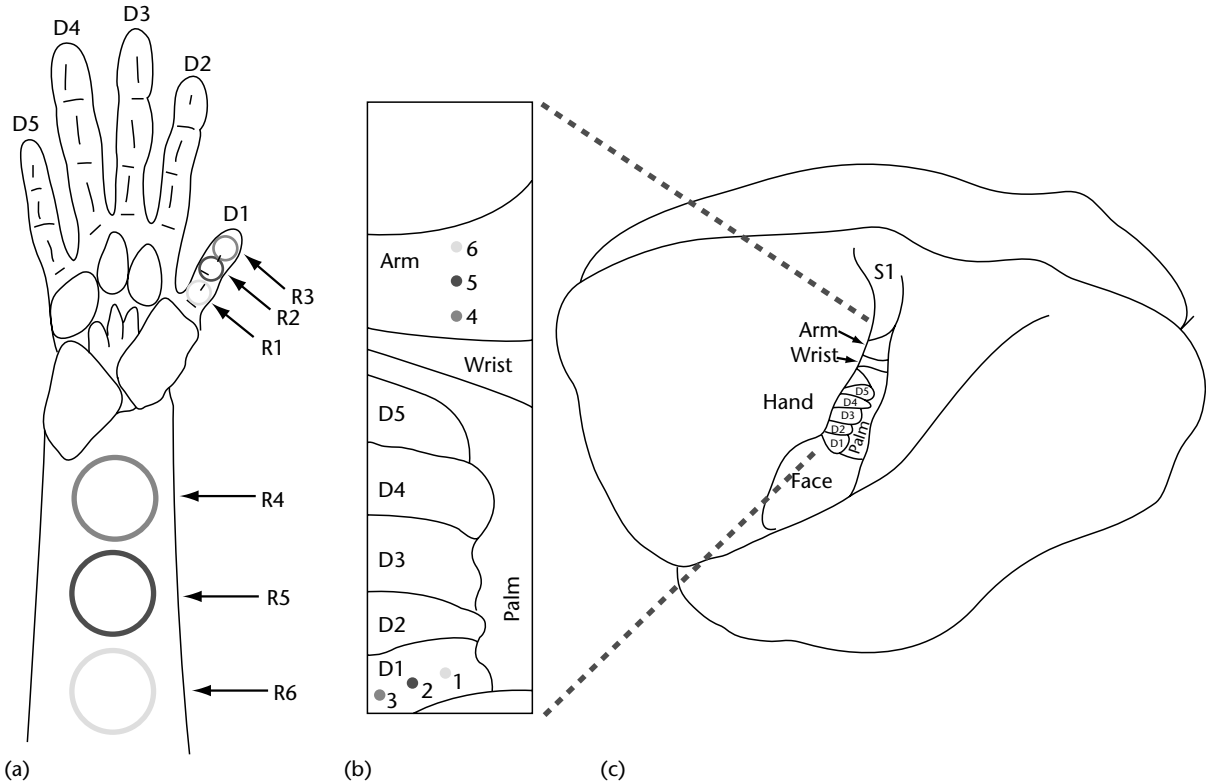

Figure 1. RFs and map layout of somatosensory cortex. (a) Schematic of an owl monkey arm. (b) Expanded schematic view of the region of primary somatosensory cortex (S1) that represents the arm, the wrist, and the palm and fingers of the hand. Cortical points 1, 2 and 3 represent three neurons with just non-overlapping RFs R1, R2 and R3 on the thumb (D1, i.e. digit 1). Points 4, 5 and 6 represent three neurons with just non-overlapping RFs R4, R5 and R6 on the arm. As cortical magnification is inversely proportional to RF size, points 4, 5 and 6 have the same separation between them, on the cortex, as points 1, 2 and 3. Thus the cortical point images due to stimuli at R1 and R2 will be as well separated as those due to stimuli at R4 and R5 – giving as good a two-point discrimination between light touches at points R1 and R2 as at R4 and R5. (c) Side view of the owl monkey brain showing the location of primary somatosensory cortex (S1), region 3a. (Modified from Kandel *et al*. (1991) *Principles of Neural Science*.)

RFs are much coarser, such spatial discrimination is correspondingly poorer (Figure 1).

Auditory system (hearing)

In the vertebrate auditory system, RFs for neurons early in the auditory pathway can be defined in terms of pure tone frequencies. Each neuron has a characteristic tuning profile with sharp tuning to a best frequency. At each stage in the auditory pathway, from the cochlea in the inner ear to the auditory cortex, neuronal best frequencies form smooth tonotopic maps that are laid out on an exponential scale, with frequencies increasing in geometric progression per unit distance on the map. Thus neurons that are equally spaced apart on a map have best frequencies that are multiples of each other. This probably explains why we perceive the frequency (pitch) scale in octaves (i.e. factors of 2), with tones an octave apart appearing to be equally spaced. Furthermore, a fixed small separation on the map translates in to a frequency difference that is not fixed, but rather which is proportional to the frequency at that point on the map. This explains why the frequency limen or just noticeable difference (JND) between tones (i.e. the minimum frequency difference required to tell two pure tones apart) is roughly proportional to the frequency of the tones.

Visual system

RFs in the visual system will be discussed in more detail in the section on receptive field organization. In the context of sensory discrimination, acuity is finest near the center of vision, the fovea, where the primary visual cortex (V1) RFs are smallest, and it drops off rapidly on moving away from the fovea, with increasing RF size. As in the somatosensory cortex, the cortical magnification factor (here the cortical territory devoted to unit angle of visual space) is inversely proportional to the RF size for that region of visual space.

Some regions of the brain contain RFs and maps in multiple sensory modalities. The superior colliculus (also known as the optic tectum), which has seven distinct neuronal layers, contains simultaneous visual, auditory, somatosensory and motor maps of space. These maps are spatially aligned over each other in the different layers. For example, neurons in the superficial layer that are visually driven with RFs at a particular location in space are located above neurons in the deeper auditory map that localize auditory stimuli to the same region of space. These sensory maps are aligned with the motor map in a yet deeper neuronal layer that guides the eyes to make saccadic (high-velocity) movements to the same point in space.

The relationship between individual neuronal RFs and sensory discrimination is not limited to such elementary sensory attributes as position or pitch, but extends to many complex properties of sensory stimuli. For example, our ability to discriminate between directions of motion of moving objects is linked to the direction-tuned responses of single neurons in the MT cortical region, part of the motion-detecting system in the visual cortex. Bill Newsome and his colleagues recorded from MT in monkeys that were shown patterns of moving dots and were trained to indicate which way they thought the dots were moving. Newsome showed that it was possible to predict the response of a monkey quite accurately from the responses of single MT neurons in whose RFs the pattern of moving dots fell.

RECEPTIVE-FIELD ORGANIZATION

In this section we shall trace the progressive transformation of RF sizes and response properties along the visual processing pathway – from stage to stage within the retina, and then via the lateral geniculate nucleus to the primary visual cortex and beyond. This detailed description will illustrate the following points.

- RF properties grow systematically more complex along a sensory processing pathway.
- The response properties at each stage can be explained on the basis of the underlying neural circuitry and the geometrical arrangement of inputs from previous stages.
- At each stage, RFs and response properties are well designed for extracting biologically important information and disregarding biologically irrelevant features.

The next section, on feedback and non-classical effects, will place caveats on some of the principles laid out in the current section. In particular, RFs do not show a strict hierarchy of complexity when moving along a sensory processing pathway. Rather, neurons at one cortical stage are strongly influenced by feedback within the same region as well as from 'higher' regions. However, it is very important to appreciate the simplified hierarchy of RFs and the neural circuitry that transforms RFs from one processing stage to the next, since much of the feedback and 'non-classical' effects appear to be built over the simpler hierarchical framework.

The emphasis here is on the visual system in primates and cats, since this is the system that has

been studied most thoroughly. Similar principles are expected to apply to other sensory systems.

The Retina: Photoreceptors to Bipolar Cells to Ganglion Cells

Photoreceptors (i.e. rods and cones) transduce light into electrical signals which are in turn transmitted to bipolar cells. Here the unimodal photoreceptor RFs are transformed into pairs of 'on' and 'off' RFs with (weak) concentric opponent surrounds (i.e. inhibitory input, mediated through horizontal cells, from neighboring photoreceptors on the retina). Bipolar cells feed into retinal ganglion cells (RGCs), with RFs that are 'on'–center 'off'–surround or 'off'–center 'on'–surround. 'On' bipolars feed 'on'–center RGCs and 'off' bipolars feed 'off'–center RGCs. The concentric RGC surrounds come from surrounding bipolar cells of the opposite type, mediated through amacrine cells. (Some RGCs, which carry blue–yellow signals, are not center–surround. Rather, they are blue 'on', from a blue-cone bipolar cell input with an overlapping yellow 'off', from a mix of red- and green-cone bipolar cell inputs. The blue-cone pathway is believed to be evolutionarily much older than the red- and green-cone pathway, as all mammals possess blue cones, while only the Old World primates, great apes and humans have red and green cones.)

RF sizes and distributions are matched to the optics of the eye. The aperture of the primate eye is such that the size and spacing of photoreceptors is well matched to the size and separation of just resolvable dots at the diffraction limit. Thus the photoreceptors, which form a close-packed mosaic over the retina, tile visual space fully and with optimal resolution. In the next stage up, each (foveal) cone photoreceptor connects to one 'on' and one 'off' bipolar cell. This generates parallel channels of opposite polarity looking at each point in a scene, each channel forming a complete mosaic that independently covers visual space. Similarly, 'on'–center and 'off'–center RGCs independently tile all of visual space.

The center–surround RF structure of RGCs is particularly suitable for two important and related tasks. First, it selectively identifies object boundaries in the visual input. Secondly, as a corollary, it compresses information for the bottleneck of the optic nerve. RGC centers and surrounds show a fine balance of excitation and inhibition. Thus RGCs respond vigorously to a contrast step (i.e. to brightness or color contrast within the RF) while ignoring uniform fields or smooth gradients. Visual input to the eye is thus tremendously compressed in the RGC response without losing much information since, in principle, it is only necessary to know edge positions and contrast in order to 'fill in' the rest and reconstruct an image. This high degree of visual processing and image compression in the retina (as opposed to further along the visual pathway) is likely to have evolved as a strategy for passing information efficiently along the optic nerve (i.e. the axonal output of RGCs). The optic nerve is constrained to be as lightweight and flexible as possible and with as small a cross-section as possible, to allow the eyes to move around rapidly and track moving objects. The image compression from photoreceptor to RGC allows the optic nerve to carry a large amount of biologically relevant information despite such constraints.

Having parallel 'on' ('on' bipolar to 'on'–center RGC, etc.) and 'off' channels looking at each point in space provides a high signal-to-noise ratio while also conserving metabolic energy. When scanning a visual scene, the number of visual edges that are encountered with a step-up in brightness equals, on average, the number of edges with a step-down in brightness. 'On'–center cells are quiet except at a step-up in brightness, while 'off'–center cells are quiet except at a step-down – each channel uses the full dynamic range of firing rate to signal the size of the step up or down. Over a region that is smooth and free from visual features, both channels are quiet, giving a stable baseline that signals 'no features'. If we had one common channel rather than separate 'on' and 'off' channels, then neurons would need to have a high, constant baseline level of firing, with increases and decreases signaling steps up and down, respectively. This would halve the dynamic range (i.e. from the midway point to maximum or zero), while being a constant drain on metabolic energy. Moreover, since neuronal firing is a noisy stochastic process, the baseline of constant, high neuronal activity would give a very noisy and variable measure of 'no features detected'. (As an aside, the existence of parallel and equivalent pathways for 'on' and 'off' is the likely reason why 'black' is perceptually as tangible a color as 'white', even though the two are physically so different – black being a reduction and white being an increase in light energy on the retina.)

Lateral Geniculate Nucleus (LGN)

RGC axons synapse with relay neurons in the lateral geniculate nucleus (LGN) with center–surround RFs very similar to the RGC RFs, with one addition, namely a systematic set of response delays. One class of LGN neurons relays RGC

inputs unchanged, while the class of lagged LGN neurons introduces a delay of 30 to 40 ms through local inhibitory interneurons. Lagged and direct LGN inputs are combined in the cortex in such a manner as to make cortical cells selective for the direction of motion of moving stimuli. By applying the principles of information theory, Joseph Atick and his colleagues showed that the range of LGN time lags was just right for an unbiased discrimination of visual motion over the range of speeds encountered in natural scenes.

Primary Visual Cortex (V1)

Neurons in the primary visual cortex (V1) – that is, the first cortical stage of visual processing – combine LGN inputs to generate RFs that are selective for oriented edges. In cat V1 this transformation occurs at the cortical input neurons whose RFs, described as 'simple cells' by their discoverers David Hubel and Torsten Wiesel, consist of alternating oblong excitatory and inhibitory subfields (unlike the concentric subfields of LGN RFs). Many models have been proposed, involving varying degrees of intracortical interactions, to explain the generation of this novel RF shape in V1. Current evidence favors Hubel and Wiesel's original suggestion, namely that each V1 neuron receives input from LGN cells whose RFs line up to form the oblong simple-cell subfields.

A number of RF response properties arise for the first time in V1. V1 neurons respond selectively to oriented lines. The orientation preference and sharpness of tuning is given accurately by a linear summation – or Fourier transform – of the RF subfields. In addition, these neurons respond selectively to a specific direction of motion of the oriented line, a property that can also be accounted for, at least qualitatively, by the linear combination of LGN inputs with their known phased time delays. Binocular RFs arise in V1 by combining, for the first time, inputs from the two eyes. The disparity or relative positional mismatch between the individual monocular inputs into a binocular RF is believed to inform depth perception. Simple-cell RFs are often modeled as Gabor functions, sinusoids defined over space and time (to incorporate directionality), with the appropriate orientation and period, within a Gaussian profile that determines the total extent of the RF. Disparity is modeled by introducing a relative phase shift between the Gabor sinusoid for each eye.

Simple-cell RFs are likely to be optimal for parsing natural scenes, which statistically consist of relatively redundant and featureless surfaces bounded by extended edges. A computer neural network that is instructed to form a sparse, optimal set of filters for picking out defining visual features and disregarding redundancies produces patterns remarkably reminiscent of simple-cell RFs. This suggests that simple-cell RFs are adapted to the statistics of the natural world. It also leads to the interesting question of whether these RF properties are the result of evolution and 'hard-wired' in the individual, or whether they are more plastic, adapting to the details of an individual's sensory history.

The architecture of V1 plays a critical role in the visual processing in this region. Neuronal RFs and response properties are organized systematically both in vertical depth and over its surface. Vertically, RF responses are organized in 'columns' that traverse all six cortical layers. All of the neurons in a column have the same RF location, orientation and color preference, etc., but neurons in the upper layers are more sharply orientation-tuned than those in the input layer, through interactions within the column. Across the surface of the cortex, RFs form smooth maps of space as well as of every other response property, and neurons that lie closer to each other on the cortex are more similar in RF position, preferred orientation, preferred color, binocularity, etc. (Figure 2). Each map is independent, though with a common periodic scale length such that each response property cycles through a full range of values over a cortical distance corresponding to a shift of one RF dimension in space. Thus V1 functions like a set of parallel computational modules over the cortex, simultaneously processing the input from each RF-sized tile of visual space, each module of cortical circuitry performing identical analyses over its segment of the image. Furthermore, the position of a neuron on the cortical map determines the response properties of other neurons within reach of its axonal and dendritic arbours, and thus the nature of the effective cortical circuits that determine the response of the neuron to complex visual stimuli (see the section below on feedback and non-classical effects).

Receptive Fields Beyond the Primary Visual Cortex

The primate visual cortex has about 40 distinct processing stages, which are organized roughly hierarchically, but with massive feedback from 'later' to 'earlier' stages as well as 'horizontal' interconnections between stages at the same level. These later stages form two parallel processing streams flowing out of V1, one of which is mainly for

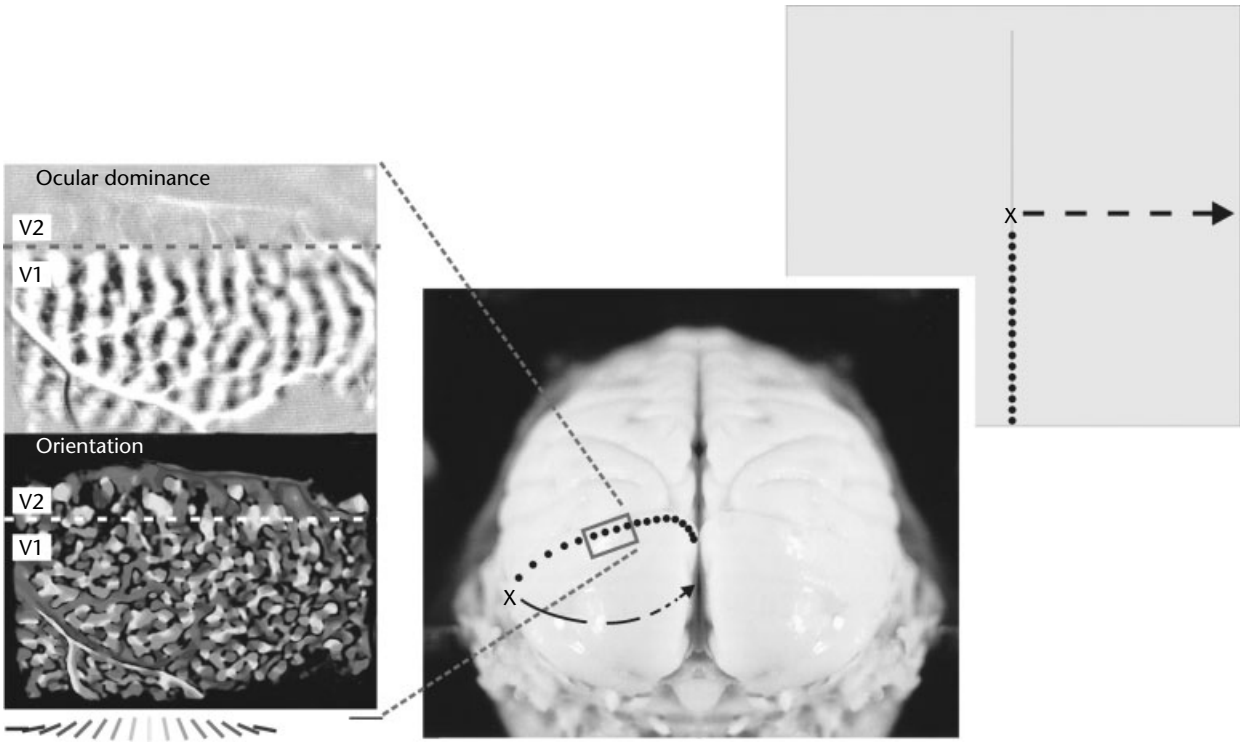

Figure 2. Layout of RFs on primary visual cortex. Center: the brain of a rhesus monkey, seen from the back. The large smooth region bounded by the dotted line on top is primary visual cortex, V1. If the monkey was looking at the screen shown on the right, with the letter X in its line of sight (fovea), then the X, the arrow and the lines on the screen would map on to the brain as shown. Note that even though the dots and dashes on the screen are uniform in size and separation, their projections on to the brain are magnified near the fovea and compressed near the periphery. (From Hubel DH (1988) *Eye, Brain and Vision*. Scientific American Library.) Left: optical images of ocular dominance (top) and orientation (bottom) obtained from the region of rhesus V1 similar to that enclosed in the red rectangle. In the ocular dominance map the dark green areas denote regions of V1 that are responsive to the right eye, while the white areas denote regions that are responsive to the left eye. In the orientation map, blue denotes those regions that respond best to horizontal lines, red denotes those responding to 45° lines, yellow denotes those responding to vertical lines and green denotes those that respond best to 135° lines. Note that the periodicity of the orientation map is similar to the spacing of the ocular dominance stripes.

extracting motion information, while the other is mainly for extracting form information (albeit with intercommunication between these two streams). Along both streams RFs become larger and progressively more complex. Thus in MT, the first stage in the 'motion' pathway, neurons not only respond to single moving edges as in V1, but they can also integrate motion cues over an extended region to signal the net motion of an object. In region MST, further along the motion pathway, neurons have RFs many tens of degrees in extent that are selective for complex motion patterns such as radial outflow or inflow and vortices. In the 'form' pathway, neurons in V4 respond better to specific feature combinations (e.g. a red triangle, or a green square) than to line edges. Neurons in the more advanced regions of the same pathway, such as in higher visual centers in the inferior temporal (IT) cortex, respond selectively even to such complex forms as faces. Specific excitatory and inhibitory circuits have been identified in some of the higher areas (e.g. TE) that can account for the complex feature selectivities of neurons in terms of interactions between neighboring groups of neurons with simpler response properties.

FEEDBACK AND NON-CLASSICAL EFFECTS

Current evidence suggests that the concept of strictly hierarchical sensory processing pathways discussed so far is an over-simplification. Rather, sensory perception appears to involve simultaneous processing of sensory features on a number of different scales, with interactions between different stages on the neural pathway.

At a perceptual level, our visual systems appear to be tuned to pick out not simple line elements, but rather features of intermediate complexity such as long contours, object boundaries or depth relationships between surfaces. These complex contextual effects often determine our perceptions of nominally simpler elements such as edges or surface colors. Moreover, our perceptions are strongly influenced by our state of attention or expectation, and they can change over time with specific perceptual training.

At a physiological level, the response of a neuron – even in V1 – can change by up to an order of magnitude in the presence of stimuli in the surround outside the neuron's RF. Furthermore, even V1 neurons are influenced by complex non-visual contexts such as the state of attention or the particular task in which an individual is engaged. The simple response properties of orientation, direction, color or disparity described in the last section are not adequate to describe neuronal response properties fully. Rather, these should be seen as forming a repertoire of components from which the more complex response of a neuron is put together. Again, most of the discussion will focus on the visual system, but only because this is the system that has been studied most thoroughly.

The Range and Variety of Modulatory Influences

Even in their earliest work on V1, Hubel and Wiesel noted that some V1 neurons had inhibitory zones outside the RF boundaries. For these neurons – which they labeled hypercomplex (now described as 'end stopped') – the response to an optimal bar stimulus inside the RF would start to diminish once the bar was lengthened beyond a critical value and started to encroach on the inhibitory end zones. Unlike RGC or simple-cell 'off' subfields, where a stimulus in the subfield alone suppressed the spike rate below spontaneous, these zones were 'silent' and nonlinear – a bar placed in the end zone alone had no effect.

Work in the 1970s by Colin Blakemore and Lamberto Maffei led to a distinction being made between the classical RF, as plotted using compact high-contrast stimuli, and the non-classical surround. A simple bar or grating stimulus inside the classical RF is adequate to activate a neuron. However, a stimulus in the non-classical surround has no effect by itself on a neuron's response, but facilitates or suppresses the neuron's response to a stimulus inside the classical RF.

A number of what were believed to be basic response properties of V1 neurons can be modified by the visual context. A neuron's orientation tuning can change scale, or can even be 'repelled' to a different preferred orientation by a surrounding field of oriented lines, in a manner reminiscent of tilt illusions. The RF size can be made effectively indefinite either by reducing the contrast of the stimulus bar, or by surrounding the RF with a noisy background. This appears to inactivate the inhibitory end zones of end-stopped neurons.

Modulation by visual context can be seen over a wide range of spatial scales and temporal latencies. Simple surround stimuli (small groups of lines or other figures in the immediate non-classical surround) lead to inhibition or facilitation with no perceptible delay. On the other hand, the modulatory effects of more complex attributes or background patterns show up after a delay of many tens of milliseconds. For example, Zipser and Lamme showed that the neuronal response to a given texture is on average higher if it is part of a closed 'figure' or 'foreground', rather than a 'background'. On another complex task, Roelfsema showed that the responses of V1 RFs to an optimally oriented line were consistently stronger if the animal was attending to the line rather than to a distractor. For both of these tasks, the difference only shows up late, around 80 to 100 ms after the start of the neuronal response.

Anatomical Substrates Underlying Non-classical Modulation

Each V1 neuron receives an estimated 20 000 to 40 000 synaptic inputs that could include LGN afferents, connections from other V1 neurons and feedback from higher visual areas. The LGN input – to neurons in the input cortical layers – is likely to set up the elementary response properties, while intra-V1 and feedback connections are likely to be responsible for the modulation by a larger visual context.

Intrinsic connections within V1

Pyramidal cells – that is, the excitatory neurons which constitute about 80% of the cortical population – form an extensive but precise network of connections with other excitatory and inhibitory neurons over V1. Locally they connect indiscriminately with neurons lying within range of the local arbour. At greater distances out to around 5 to 9 mm in the cortex their axonal collaterals connect selectively only with other neurons that are tuned to the same preferred orientation. However, the RFs of these distant target neurons are centered on very different parts of the visual field, covering

an area 10 times the size of a single RF. Thus the nearby connections sample a large range of orientations at the same point in space, while the distant connections sample a large visual context but at the same orientation. Through the orientation-selective distant interconnections, neurons with RFs along a smooth contour facilitate each other's activity, a process that is reflected in the way in which a flanking line can facilitate a neuron's response to (or our perception of) a dim-edge stimulus. This is likely to underlie our ability to pick out smooth curves from a jumbled background, and thus rapidly parse spatial scenes into contours and boundaries.

Feedback from higher visual areas

Neurons in V1 also receive extensive feedback connections (accounting for around 50% of the synaptic input, and arborizing at least as widely inside V1 as the intrinsic long-range connections) from areas V2, V3, V4 and MT. Feedback connections are likely to underlie the modulation of V1 responses by complex attributes of a figure, such as 'foreground' versus 'background', the level of attention being paid, or the task being performed. For example, Bullier and his colleagues showed that MT feedback is involved when V1 responses are modulated by large-scale motion. The response of a V1 neuron to a moving bar is enhanced when the bar is shown against a textured background moving in the opposite direction. This enhancement is reduced sharply and selectively on cooling and thus inactivating MT, the first stage in the 'motion detecting pathway'. However, cooling MT has no effect on the modulation of V1 responses by stationary backgrounds.

DYNAMIC PROPERTIES OF RECEPTIVE FIELDS

Recent research has shown that RF response properties do not form permanent, defining attributes of a neuron. Rather, even in the adult, RFs are dynamic and can change significantly, particularly following discrimination training or selective stimulation.

History: Phantom Limbs and RF Shifts following Surgical Manipulations

Plasticity of adult RF properties was first noted in the clinic through the phenomenon of phantom limbs. An amputee who has lost an arm retains a sensation of a 'phantom' arm that can feel pain and assorted bodily sensations. What is more interesting is that the face starts to develop a topographically accurate sensory map of the missing limb. For example, running a cotton wick down the patient's face generates the strong sensation of having it run down the missing arm, and the patient can even discriminate the phantom fingers that are being touched.

The systematic study of adult cortical plasticity, in monkey somatosensory cortex (S1), started in the 1980s. Mike Merzenich, John Kaas and their colleagues showed that surgically manipulating the sensory input coming to S1 from an animal's fingers (e.g. removing some input by amputating a finger, or shuffling the input by transposing an island of innervated skin from one finger to another, or synchronizing the input abnormally by suturing two fingers together) leads to dramatic shifts in the RFs of S1 neurons, and corresponding shifts in the cortical map of the hand and fingers. Similar surgically induced RF shifts were shown in the auditory system, where surgical ablation of a segment of the cochlea leads to shifts in the frequency map in the auditory cortex as well as subcortical stages (e.g. the inferior colliculus). Such RF shifts were also shown in the visual system, where a small scotoma or lesion of the retina leads to a remapping of visual space on V1. These RF shifts are very rapid, involving an immediate expansion by more than 10-fold in size, followed by a later consolidation to a new position (Figure 3).

Dynamic Changes in Receptive Fields and Perceptual Learning

The changes in RF position and size after lesions or injuries are just an extreme manifestation of the potential for dynamic RF plasticity which could last throughout life, and that presumably underlies our ability to learn new sensory discriminations.

RFs can be modified dynamically through passive sensory experience. For example, an 'artificial retinal scotoma' (a visual stimulus consisting of a blank patch within a bright and busy surround, simulating the effect of a lesion on the retina) causes V1 RFs inside the 'scotoma' to expand by 10-fold within seconds. This RF expansion, which can be reversed by stimulating inside the blank 'scotoma', is also believed to be related to the phenomenon of 'visual fill-in', where fixating steadily at a busy visual pattern with a small blank 'blind spot' causes the surrounding pattern to fill in the blind spot.

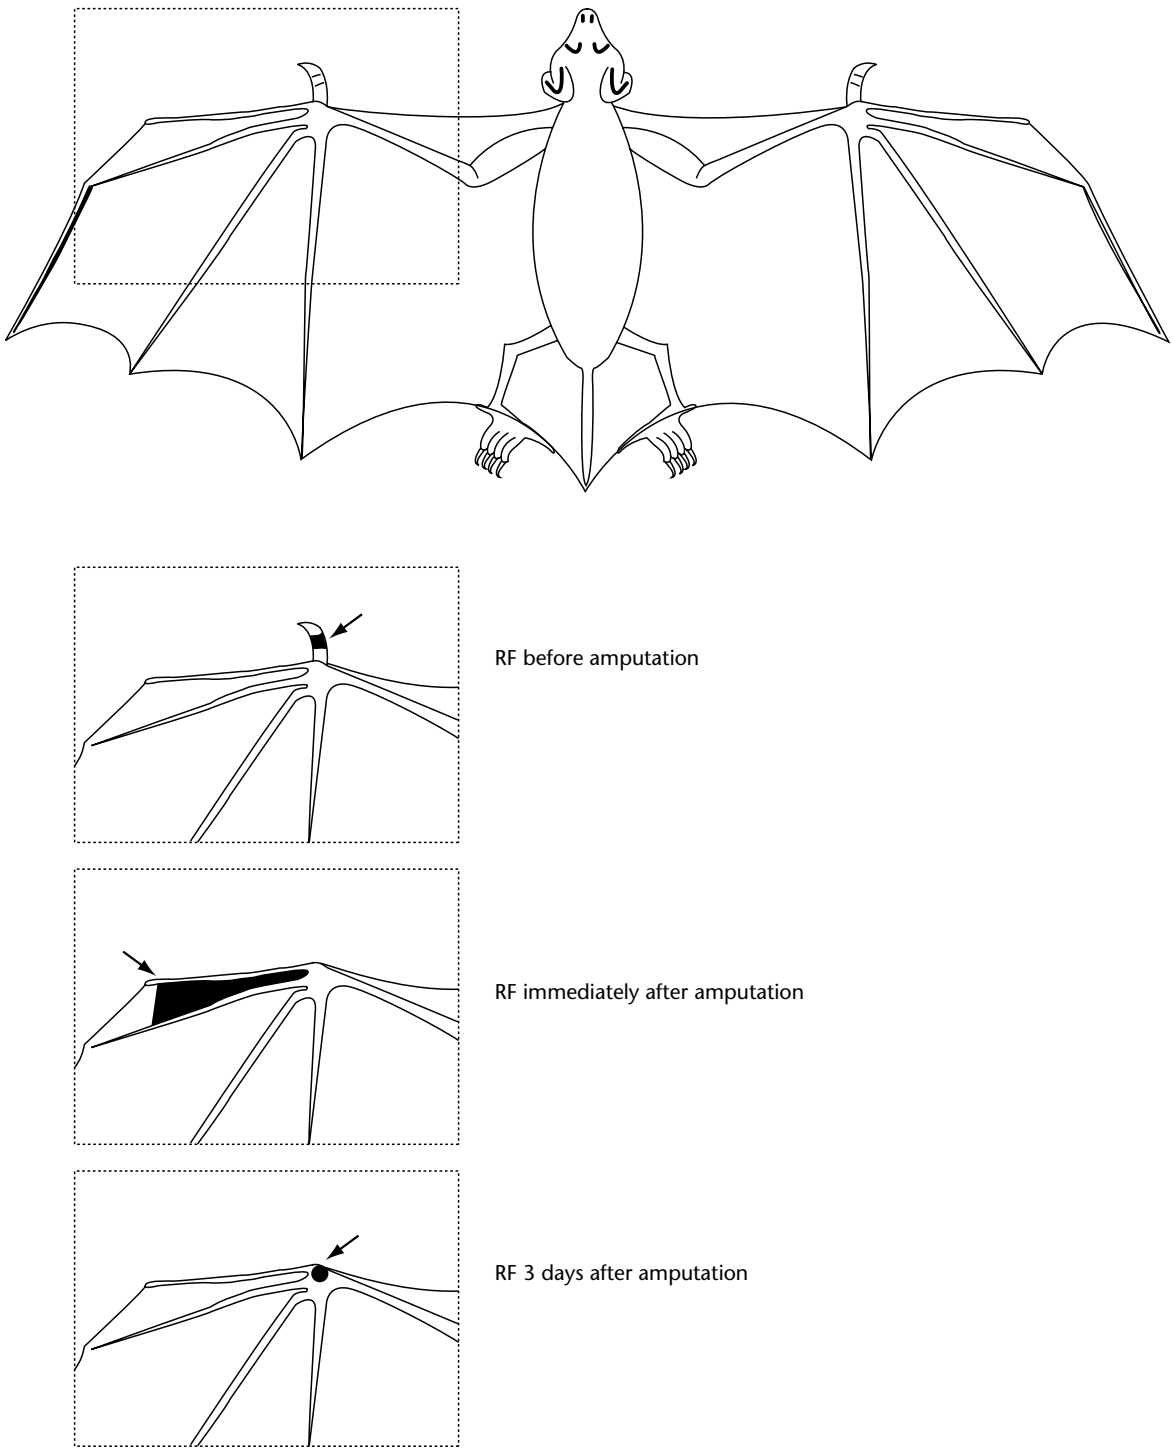

Figure 3. After a lesion in the periphery, RFs of neurons in the affected region of somatosensory cortex expand dramatically and rapidly. Then, over a period of days, they consolidate and shrink back to a new position bordering the lesion. The thumb of a flying fox (sketched at the top of the figure) was amputated after recording electrodes had been implanted in the somatosensory cortex to monitor RF size and position. The RF (see arrow pointing to RF, shown in red) of a typical neuron that received input from the thumb is shown in the sequence of sketches of the animal's forelimb. Immediately after amputation of the thumb, the RF of this neuron expanded to include a large area of the wing surface between digits 2 and 3. After 3 days, the neuron's RF had shrunk back to a more normal-sized region of the limb surface bordering the missing thumb.

RF shifts appear to be most marked and best consolidated when induced by specific sensory discrimination tasks. Furthermore, the magnitude of the shift is related to the degree of improvement of an individual's sensory discrimination thresholds. Recanzone and Merzenich trained monkeys to discriminate between frequencies of tactile vibration of a stylus pressed against a fixed spot on one finger and vibrating at a frequency (*c*. 25 Hz) higher than the normal flutter-frequency discrimination limit. At the end of the training, once the animal had improved its detection threshold manyfold – but *only* on the specific trained spot on that finger – not only did S1 show an abnormally large number of neurons with RFs on the trained spot, but also cortical neurons had developed an entirely new repertoire of responses, phase-locking to the unusually high frequency of the vibrating stylus. Training can induce changes in RF properties that are quite subtle. For example, training in a visual discrimination task leads to changes only in the modulation of a V1 neuron's response by the surrounding visual context. Furthermore, and even more interestingly, this changed RF response property was only manifested when the trained animal was engaged in the discrimination task, and not when it was passively shown the same stimulus.

Underlying Neural Networks and Mechanisms

Plastic changes are believed to be mediated by the same extensive neural networks that are responsible for feedback and non-classical effects. As was mentioned earlier, V1 pyramidal neurons connect with other neurons over the extensive range of their axonal collaterals, corresponding to a region of visual space more than 10 times larger than a single RF. Similar extensive networks of connections are seen in the somatosensory and auditory pathways. In each case the network for a given neuron involves tens of thousands of synapses with other neurons (both excitatory inhibitory). The tight constraints on the RF size, position and response properties measured at any given moment evidently involve a fine balance between excitation and inhibition over the extended input network to the neuron. The sudden imbalance caused by removing part of the input to the network (e.g. by surgically amputating a digit) (Figure 3) is presumed to underlie the rapid RF expansion that is seen. Furthermore, just as nonlinear interactions within the input network mediate the influence of a sensory surround on a neuron's RF, long-term plastic changes in synaptic strength in the network lead to long-term changes in RF properties.

The primary contributions to RF plasticity come from different stages of the pathway in the different sensory systems. In the visual system, the cortex (but not the LGN or retina) has extensive convergent and divergent connections where shifts in synaptic balance can alter RF properties significantly. In V1, the long-range axonal collaterals are involved in RF plasticity. However, little plastic change is seen, either in the retina or in the LGN. In the auditory and somatosensory systems, by contrast, many subcortical centers are capable of plastic change. For example, amputation causes extensive rewiring and RF shifts even at the dorsal horn of the spinal cord.

Modifying the Concept of Receptive Fields

With the complex sets of neural inputs that contribute to a neuron's response properties, many believe that the term 'receptive field' should actually incorporate the entire rich set of responses of which a neuron is capable – not just the 'classical' RF, but all of the contextual modulations and potential plastic modifications.

CONTENTS

Reinforcement learning is an approach to learning problems that takes account of the interaction of the learner with their reactive environment. Despite its early connections to animal learning, reinforcement learning has been an active field of study in engineering and computer science. New research is now starting to connect reinforcement learning to identifiable biological systems. These connections may well provide direct insights into goal-directed learning and decision-making in biological organisms.

INTRODUCTION

Brain research during the last 50 years has focused on the metaphor of learning through interactions with an environment. The central idea here is interaction. All mobile creatures, including humans, are embedded in a rich, reactive environment. We move our eyes – the visual scene changes. We push against a tree branch – we feel its roughness, and it even pushes back. We shift our attention – suddenly a sight or sound becomes clearer and easier to interpret. Even our bodies act as part of the reactive environment, as mere consideration of an action can cause a change in an animal's physiological state whether or not it actually moves. The learning mechanisms that are embedded in our nervous systems have evolved to deal with just such reactive aspects of environments.

Reinforcement learning takes account of the idea that learners are situated in real-world settings which react to and may even adapt to the actions of the learner. In the words of modern reinforcement learning pioneers Sutton and Barto 'Reinforcement learning is learning what to do – how to map situations to actions – so as to maximize a numerical reward signal.'

In this framework, learning is specified as a complete problem of an agent interacting with an environment. Thus the properties of the agent and the environment and the dynamics of interaction must be specified in a reinforcement learning problem. As a class of problems, reinforcement learning problems are most closely related to mathematical problems of optimal control. One of the most important ideas that is built into all reinforcement learning systems is the concept of a *goal-seeking agent*. In reinforcement learning, the learner possesses goals that influence their selection of actions, the way they update their memory, and so on. From a biological perspective, the critical issue is to determine the physical mechanisms that define and control the goals and actions of the learner.

In this article we shall outline one computational approach to reinforcement learning and its biological realization in living systems. Reinforcement learning appeals to the computational community because it can be formally written down as equations or simulations. It appeals to biologists because of its plausibility as an architecture and its growing connection to real biological data. The discovery that reinforcement learning is a powerful approach to machine-learning should come as no surprise. Biological systems appear to have long exploited the approach to solve many problems of real-time adaptation in complex environments.

THE THREE BASIC COMPONENTS OF REINFORCEMENT LEARNING

Every reinforcement learning system has three basic components: (1) a reward function, (2) a value function and (3) a policy. These relatively

abstract terms capture the idea of immediate evaluation (reward function), long-term judgment (value function) and action selection (policy).

The *reward function* formalizes the idea of a goal for a reinforcement learning system. It assigns to each state of the agent a single numerical quantity – the reward. The reward function defines what is good 'right now', and can be viewed as a built-in assessment of each state that is available to the agent (learner). It is also used to define the agent's goal – to maximize the total reward.

The *value function* formalizes the notion of longer-term assessments (judgments) of each state of the agent. It provides a valuation of the current state of the agent, taking into account the succession of states that could follow. Formally, for each state, value is defined as the total amount of reward that the agent can expect from that state onward into the distant future. These values would have to be stored in some fashion within the agent. In practice, the learner uses the reward function to improve their internal estimate of the value function.

In shorthand, rewards are immediate and values are long-term. For example, a rat may take many steps across an electrified grid (low reward) to reach food (high reward). All of those intermediate states (steps on the grid) have a very low reward, but possess high value because they lead directly to future states with food (high reward).

A *policy* formalizes exactly what the word implies – 'given this, do that'. Formally, a policy maps states to actions. In both biological and machine-learning examples, a policy is usually probabilistic. For a given state, a policy defines the probability of taking one of many possible actions in order to end up in one of many succeeding states. For example, a rat seeking food in a maze encounters a three-way junction. The policy assigns probabilities separately to each of the three actions that are available to the rat.

TRIAL AND ERROR

The idea of trial-and-error learning is familiar to everyone – to solve a problem, try some solution, assess how well it performed, and try again if it did not perform up to expectations. Reinforcement is intimately linked to trial-and-error learning. The basic idea of reinforcement derives from psychology, took its clearest form initially as Thorndike's law of effect, and depends on the concept of reinforcers. There are two types of reinforcers – positive and negative. The law of effect is simple. Actions or internal states followed by positive reinforcers are later more likely to occur, and actions or internal states followed by negative reinforcers are later less likely to occur. In one form or another, this idea has become one basis (almost a principle) for thinking about trial-and-error learning. An animal tries an action, assesses its success in terms of positive and negative reinforcement, and adjusts its later likelihood of taking that action.

The idea of trial-and-error learning is also central to reinforcement learning. Trial-and-error learning systems have been investigated from the earliest days of artificial intelligence. In fact, in 1954 one of the pioneers of artificial intelligence, Marvin Minksy, wrote his PhD thesis (*Theory of Neural-Analog Reinforcement Systems and its Applications to the Brain-Model Problem*), at Princeton University on reinforcement learning. In addition to his many other contributions, Minsky was one of the first to specify clearly the central problem in trial-and-error learning where some type of reward signal is used to criticize the outcome of a series of actions. This problem is known as the *temporal credit assignment problem*.

Temporal credit assignment is intuitively familiar. For example, an animal seeking food (high reward) may make many decisions before actually acquiring the food and receiving a large reward signal. A natural question then arises. How does the animal's brain assign credit to each of the individual decisions? Some decisions are critical to eventually obtaining food, while others may have been completely irrelevant. This type of problem arises whenever the rewards received are delayed in time from the events that lead to reward. In any real-world setting, an animal must *learn associations through time* (e.g. 'I go left here' is associated with 'I get three units of reward' an hour later).

Depending on the situation, there are numerous ways to solve the temporal credit assignment problem. One way to achieve trial-and-error learning using a delayed reward signal is *temporal difference (TD) learning*.

TD LEARNING

Here we shall describe in detail the way in which temporal difference (TD) learning frames and solves the temporal credit assignment problem described above. We shall begin with a description in terms of animal learning – that is, at the level of behavioral learning. In the later sections of this article we shall show that this same formal description can account for the pattern of activity that is recorded in midbrain dopamine neurons while alert animals are actively learning. The latter connection is important because it suggests that

dopamine neurons may be one part of a mechanism that implements reinforcement learning in mammals.

Animals are taken as living in what is technically known as a Markov decision problem. This construct formalizes the characteristics of problems such as maze tasks, in which there are different states (e.g. different locations in the maze), actions (e.g. directions in which to move) and rewards. The rewards can either depend on the animal's actions or be provided without regard to what the animal does (as in classical conditioning). This framework is general enough to model many standard behavioral tasks. The most important assumptions underlying the TD approach involve the nature of the presumed computational task solved by an organism. There are two main assumptions in TD.

Assumption 1

First, the computational goal of learning is to use a set of sensory cues $\boldsymbol{x}(t) = \{x_1(t), _2(t), x_3(t), \ldots\}$ (e.g. characterizing the current state of an organism) to fit a 'value' function $V^*(\boldsymbol{x}(t))$ that 'values' the current state as the *average discounted sum of all future rewards from time t onward*:

$$V^*(\boldsymbol{x}(t)) = E\{\gamma^0 r(t) + \gamma^1 r(t+1) + \gamma^2 r(t+2) + \cdots\}$$

E is the expected value operator (the average), $r(t)$ is the reward at time t, $r(t+1)$ is the reward at time $t+1$, and so on; γ is a discount factor that ranges between 0 and 1 and captures the idea that rewards in the near future are more valuable than rewards in the distant future. If the true (optimal) $V^*(\boldsymbol{x}(t))$ could be estimated by a system, then the system could use such an estimate to update its internal model of future rewards and future actions predicated on the expected receipt of those rewards. This would give the system a way to simulate possible future action sequences and value them according to their expected long-term returns. In this description, the indices on the x's denote different sensory cues.

Assumption 2

This is the Markovian assumption – that is, the appearance of future sensory cues and rewards depends only on the immediate (current) sensory cues and not on the past sensory cues. This is a relatively restrictive assumption about the structure of the environment. However, it has proved to be useful even in real-world settings.

Adjusting the Predictions (Weights)

The strategy of TD learning is to use a set of sensory cues $\boldsymbol{x}(t) = \{x_1(t), x_2(t), x_3(t), \ldots\}$ present in a learning trial along with a set of adaptable weights $\boldsymbol{w}(t) = \{w_1(t), w_2(t), w_3(t), \ldots\}$ to make an estimate $V(\boldsymbol{x}(t))$ of the true $V^*(\boldsymbol{x}(t))$. In this formulation, the weights act as predictions of future reward. For completeness, we shall include a remark about the weights. The weight associated with each sensory cue (e.g. $w_1(t)$ associated with sensory cue 1) is actually a collection of weights – one for each time point following the appearance of sensory cue 1.

Local Data Anticipate Long-Term Reward

The difficulty in actually adjusting weights to estimate $V(\boldsymbol{x}(t))$ is that the system (i.e. the animal) would have to wait to receive all of its future rewards in a trial $r(t+1), r(t+2), r(t+3)$ etc. in order to assess its predictions. The latter constraint would require the animal to remember over time which weights need changing and which weights do not. Fortunately, there is information available at each instant in time that can act as a surrogate prediction error. This possibility is implicit in the definition of $V^*(\boldsymbol{x}(t))$, since it satisfies a condition of consistency through time:

$$V^*(\boldsymbol{x}(t)) = E\ [r(t) + \gamma V^*(\boldsymbol{x}(t+1))]$$

Since the estimate V satisfies the same condition, an error δ in the estimated value function V (estimated predictions) can now be defined using information available at successive timesteps (i.e. taking the difference between both sides of the above equation and ignoring the expected value operator E for clarity).

$$\delta(t) = r(t) + \gamma V(\boldsymbol{x}(t+1)) - V(\boldsymbol{x}(t))$$

δ is called the *TD error* and it acts as a surrogate *prediction error* signal which is instantly available at time $t+1$. If the estimated predictions are correct, then $V(\boldsymbol{x}(t)) = V^*(\boldsymbol{x}(t))$, and the average prediction error is 0 (i.e. $E[\delta(t)] = 0$). In other words, if the system can adjust its weights (predictions) appropriately, then it can learn to expect future rewards predicted by the collection of sensory cues.

This section is somewhat technical, but it does emphasize the fact that local information can be used to make estimates of reward in the distant future. That is, it presents a method by which the temporal credit assignment problem is solved. It is not the only method for such a task, but its importance has recently been enhanced because this

theoretical description of TD learning appears to match the information that is encoded in the spike trains of midbrain dopamine neurons.

MIDBRAIN DOPAMINE SYSTEMS

In the mammalian brain, midbrain dopamine systems play a major role in reward processing and reward-dependent learning. Recent physiological and computational research strongly suggests that the information which is constructed and broadcast by midbrain dopamine systems represents a prediction error analogous to that described above.

Some of the basic electrophysiological findings are shown in Figure 1. After repeated pairings of visual and auditory cues followed by reward, dopamine neurons change the time of their phasic activation from just after the time of reward delivery to the time of cue onset. In one task, a naive monkey is required to touch a lever following the appearance of a small light. Before training, most dopamine neurons show a short burst of impulses following reward delivery. After training, the animal learns to reach for the lever as soon as the light is illuminated, and this behavioral change correlates with two remarkable changes in the dopamine neuron output. First, the primary reward no longer elicits a phasic response, and secondly, the onset of the (predictive) light now causes a phasic activation in dopamine cell output.

In trials where the reward is not delivered at the appropriate time following the illumination of the light, dopamine neurons are depressed dramatically below their basal firing rate at precisely the time when the reward should have been delivered. This well-timed decrease in spike output shows that the expected time of reward delivery based

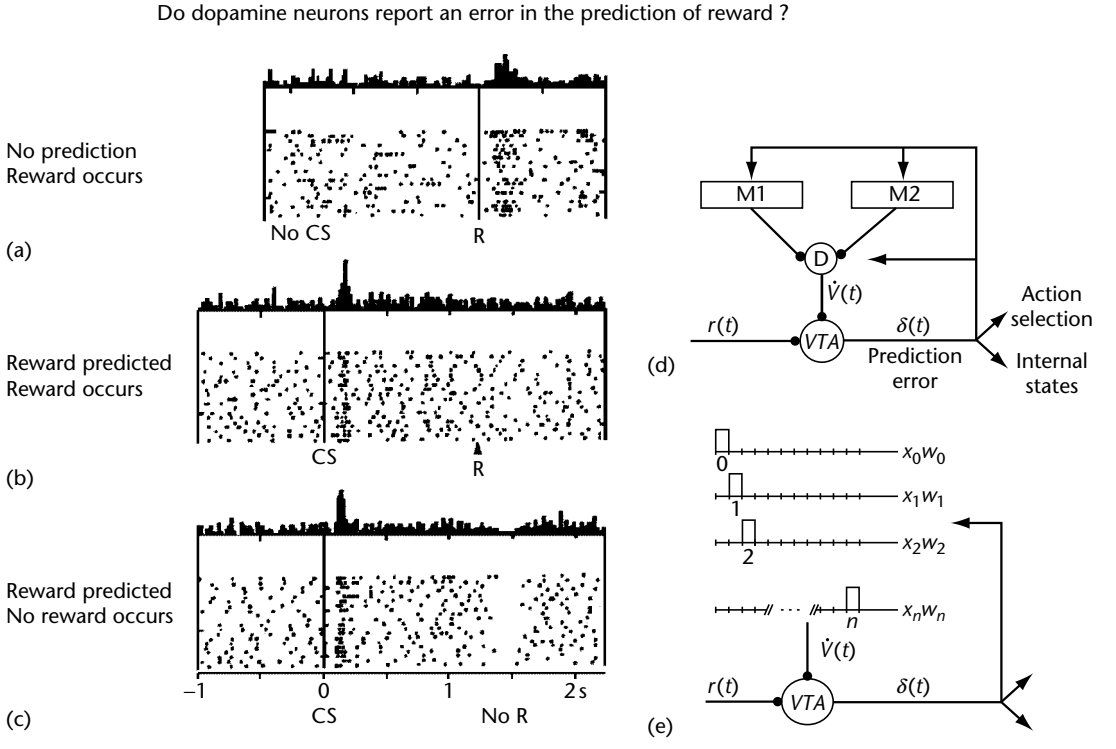

Figure 1. Left-hand panel. Dopaminergic predictor neurons during simple classical conditioning: plots of spike output of midbrain dopaminergic neurons recorded in alert primates during simple conditioning tasks. (a) Unpredicted delivery of reward (juice) causes a phasic increase in activity. This occurs for no conditioned stimulus (CS) (e.g. the light) or for a neutral CS (meaningless to a naive monkey). (b) After a number of trials involving a CS followed by juice delivery, the neurons stop responding to the presentation of the juice and instead give a phasic response just after the onset of the CS. (c) On error trials the cue is presented, but no reward is delivered. The neuron firing rate drops to 0 at the time when the reward would have been delivered if no mistake had been made. Right-hand panel. (d) Architecture of computational model mimics architecture of neuromodulatory systems in bees and humans. (e) Representation of a stimulus over time. There must be some representation of a stimulus over time in order to learn predictions. (Adapted from Schultz *et al*. (1997) *Science* **275**: 1593–1599.)

on the illumination of the light is also encoded in the fluctuations in dopaminergic activity.

From the results shown in Figure 1, it can be seen that dopamine neurons do not simply report the occurrence of rewarding events. Instead, their outputs appear to code for an error between the actual reward received and predictions of the time and magnitude of the reward. These neurons are only activated if the time of the reward is uncertain (i.e. unpredicted by any preceding cues). Dopamine neurons are therefore excellent feature detectors of the scalar 'goodness' of environmental events relative to learned predictions about those events. They emit a positive signal (increased spike production) if an appetitive event is better than predicted, no signal (no change in spike production) if an appetitive event occurs as predicted, and a negative signal (decreased spike production) if an appetitive event is worse than predicted. These observations have led to the hypothesis that these neurons are *predictor neurons* which distribute a prediction error signal (like $\delta(t)$ described above) to target neural structures in the form of changes in dopamine delivery.

Details of the way in which the dopamine signal is used neurally to implement full TD learning are beyond the scope of this article. The important point is that the electrical recordings from dopamine neurons show that they are part of a circuit in the brain that is capable of making predictions about future reward. This is one of the few instances where brain activity can be clearly connected to a well-understood computational learning procedure. Confirmation of the degree to which this description is incomplete or incorrect awaits future experimental and computational research. However, this work has provided a new way to interpret activity in dopamine neurons.

Dopamine neurons have long been known to be involved in reward processing. However, until recently it was thought that dopamine delivery was equivalent to reward. That is, the dopamine delivery itself was a positive reward signal. The experimental results described above, when combined with the computational interpretation in terms of TD learning, show that this cannot be the case. After training, there is no increased dopaminergic activity in response to the delivery of the rewarding fluid. The theory that dopamine is equivalent to reward is not consistent with this clear finding. However, an interpretation in terms of a prediction error is consistent, although this is not the end of the story. Dopaminergic activity is also seen in other contexts involving attention and orienting behavior. The connection to reinforcement learning has helped to frame the experimental issues in more sophisticated and formal terms.

One consequence of the TD model of dopaminergic function has recently been explored in human subjects using functional magnetic resonance imaging (fMRI).

PREDICTABILITY, REWARD AND HUMAN BRAIN RESPONSE

Reinforcement learning represents a general framework for describing how animals learn to interact with their environment. Therefore it is reasonable to extend this to the study of human reward pathways. Although these mechanisms are not thought to be fundamentally different in humans, the challenge lies in separating the core processes associated with reward prediction from secondary higher cognitive functions. For example, a temporal-difference model of reinforcement learning might predict that dopamine is released in proportion to prediction errors. While a monkey might learn a particular task by trial and error, humans are quite adept at using complex and abstract strategies that circumvent such laborious methods.

One relevant approach to studying humans is suggested directly by TD models. The core property that drives learning in TD models is predictability. Learning only occurs because there is some regular relationship between sensory cues and future reward. If there were no such relationship, then there would be nothing to learn. This can be used to advantage in humans. By simply altering the probability that one type of cue predicts a reward, one should be able to manipulate the response of dopaminergic systems in the brain. Furthermore, these manipulations can be subtle and therefore not consciously detectable by humans. These issues are important factors in experimental design if the aim is to prevent people from using conscious learning strategies.

It is worth noting that reward for a human may be different to reward for a monkey. We assume that human 'rewards' represent a lifetime of various types of conditioning that leads to the abstract assignment of reward to neutral objects (e.g. money). Understanding the way in which constructs such as money acquire reinforcing value are important but complex questions to address experimentally. However, it is worth first understanding how humans respond to the predictability of primary rewards, such as food and water.

In a simple experiment using fMRI, it has been shown that, just as in monkeys, the activity of dopaminergic projection sites in the human brain

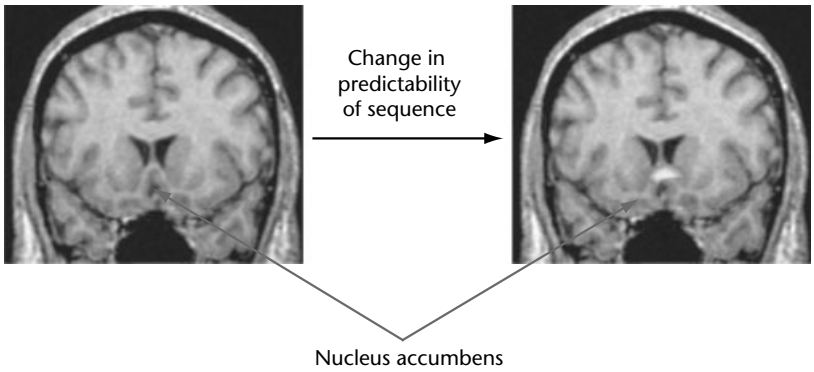

Figure 2. Change in predictability of a sequence of gustatory stimuli activates targets of dopamine projections. A sequence of squirts of fruit juice and water was delivered to the mouths of subjects. When the sequence of squirts changed from predictable to unpredictable, there was a larger activation in the nucleus accumbens, a region that is known to be involved in reward processing. (Adapted from Berns *et al*. (2001) *Journal of Neuroscience* **21**: 2793–2798.)

is modulated by the predictability of rewarding events. When subjects received squirts of fruit juice and water in their mouths, the activity in the nucleus accumbens was significantly amplified when the pattern of squirts was unpredictable (Figure 2). Since the participants were unaware of the differences in predictability, the fMRI activity changes cannot be ascribed to other top-down attentional processes.

SUMMARY

Reinforcement learning is one approach to the essential elements of learning problems that are encountered in real-world situations. There are numerous approaches to reinforcement learning, but here we have singled out temporal difference (TD) learning because it has growing connections to real biological data. We have reviewed one connection to the mammalian dopamine system and shown how a TD model accounts for changes in spike activity in dopaminergic neurons in alert monkeys during learning tasks. The same model provided an excellent starting point for the design of similar experiments in humans. One example of such an experiment using fMRI has been outlined, and the response of a target of dopamine projections, namely the nucleus accumbens, was shown to be activated by changes in the predictability of stimuli. This result was anticipated from the reinforcement learning model of the dopamine system, and it provides an excellent example of the way in which computational approaches to learning problems are informing the design and interpretation of experiments.

Reorganization of the Brain

Intermediate article

Jon H Kaas, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

The complex normal organization of the brain in patterns of interconnected nuclei and areas emerges during brain development, but it can be altered or reorganized through life by sensory experience and damage to sensory and motor pathways. The reorganization process allows neurons to acquire new functional properties and roles in behavior.

INTRODUCTION

The mature mammalian brain is organized into systems of interacting nuclei and cortical areas. These nuclei and areas consist of neurons that are interconnected locally to form small computational groups. These local circuits then interconnect less strongly with other circuits within the same structure and to varying extents with circuits in other nuclei and areas to form processing systems. Systems then interconnect to produce a coherent, functioning brain. The complex normal organization of the brain emerges during development as a result of interactions between genetic instructions and information from the environment. Changes in experience or damage to part of a system will often alter the course of development to produce a different adult organization. The capacity for such organizational change is often referred to as 'developmental plasticity'.

Changes in the course of brain development typically occur during early sensitive or critical periods, after which the same damage or experiences fail to produce the same dramatic alterations. Because the developing brain is so much more responsive to injury or experience, many early investigators assumed that the organization of the mature brain is fixed and immutable. In addition, many felt that the stable performance of sensory, motor, and other systems must depend on a stable organization of the processing machinery. Of course we all realize that the brain must change when we learn, but often we assume that only certain learning centers in the brain are designed to be modified, and the rest of the brain is highly stable. Specialized learning systems do exist: in parts of the brain such as the hippocampus, neurons are capable of rapidly changing their functional connections during learning and experience. However, it is now known that other parts of the mature brain also are highly plastic. The internal organizations of nuclei and areas can be quite changeable. This has been best demonstrated in the sensory and motor systems, where normal organizations are well understood, and alterations are easily revealed by microelectrode recordings, electrical stimulation, and other procedures. These indicate that the basic sensory and motor processing structures in the brain are plastic throughout life, and that this plasticity is important for maintaining, changing, and improving brain functions.

Although evidence for brain plasticity largely stems from research on sensory and motor systems, conclusions based on this evidence may apply broadly, and all parts of the brain are likely to be susceptible to change.

REORGANIZATION IN SENSORY SYSTEMS AFTER DAMAGE

Sensory systems are processing hierarchies that start with a sensory surface of receptors, such as the rods and cones of the retina, the hair cells of the inner ear, and the mechanoreceptors of the skin. These sensory sheets send orderly projections to nuclei in the brainstem and thalamus, where they activate neurons in a pattern that reflects the spatial arrangement of the receptors in the receptor sheet. Thus, these target nuclei form topographic maps of the retina, cochlea, or skin. These nuclei in turn project in almost a point-to-point fashion to other

nuclei or cortical areas to create additional sensory maps, and this topographic relay of information continues through a number of brain structures. The early maps in the processing network most closely reflect the order of the receptor sheet, while higher-order maps become less topographic. The topographic orders of early maps in each system can be revealed by recording from neurons in many locations in the map, and determining what positions on the sensory surface stimuli activate neurons at each recording site. Because the normal organizations of these sensory maps can be revealed in detail by microelectrode recording methods, and normal maps prove to be highly constant in topographical organization from animal to animal, it is possible to determine whether these maps can be altered in internal organization by injury or experience.

Perhaps the most easily demonstrated changes in brain maps are those that follow partial sensory loss and deprivation. As one example, damage to a sensory nerve of inputs from the skin will remove a normal source of activation for neurons distributed across all maps of the skin in the somatosensory system. One might expect that the neurons in maps that normally respond to the removed inputs would no longer be activated by sensory stimuli. However, when this possibility was tested in somatosensory cortex of monkeys after section of the sensory nerve that contains the afferents from the thumb half of the glabrous hand, deprived neurons gradually became responsive to touch on other normally innervated parts of the hand (Florence *et al*., 1997).

In monkeys, primary somatosensory cortex consists of a long, narrow strip of tissue that extends mediolaterally across the central part of the cerebral hemisphere. The skin of the opposite side of the body is represented systematically from foot to face, in a medial to lateral sequence in this strip, with the hand representation lateral near that of the face. Digits one to five are represented in order in a lateromedial sequence. Section of the afferents from the glabrous surface of digits one to three deactivated about half of the map of the hand in primary cortex, but starting immediately and proceeding over a few weeks, the deprived cortical neurons became responsive to touch on the normally innervated dorsal surfaces of the digits and other parts of the hand. A similar reactivation of neurons occurs in the subcortical nuclei, the cuneate nucleus in the lower brainstem and the ventroposterior nucleus in the thalamus. Thus, the reorganization of the cortical map depends, at least in part, on the relay of reorganized patterns of responsiveness from subcortical structures. Primary somatosensory cortex relays a reorganized pattern to other areas of the somatosensory cortex, so that all areas in the system respond in a new manner. More extensive sensory losses can lead to even greater reorganization of sensory systems. Such changes are so large that they can be measured by noninvasive brain imaging techniques in humans. In individuals who had undergone amputation of an arm, the deprived portions of the map in primary cortex responded to touch on the stump of the limb or the face. Reorganization occurs in the thalamus as well, so that neurons formerly activated from the missing forelimb became responsive to the stump (Davis *et al*., 1998). Recordings from monkeys with major loss of sensory inputs indicate that reactivations of cortex can take as long as 6–8 months to complete (Florence *et al*., 1997).

Reorganization of sensory representations also occurs in auditory or visual nuclei and cortical areas after damage to the receptor sheet. After damage to the retina, the extent of reorganization appears to be much more extensive in the cortex than subcortically in the thalamus (Chino, 1997; Kaas *et al*., 2001). Thus, representations at higher levels in the visual system and perhaps in other systems may be more mutable than subcortical representations. Reorganizations also occur after damage to subcortical or cortical maps. For example, if part of the map of the hand in primary somatosensory cortex is removed by a lesion, adjacent parts of the map may change so that remaining neurons take on the role of those that were lost to different inputs from the hand, and the hand map reorganizes to recover some of the missing parts of the representation. Other cortical areas with inputs from primary cortex may reorganize even more extensively. If all of the hand representation is lesioned in primary somatosensory cortex, regions of higher-order maps that normally represent the hand may come to represent other parts of the body, such as the foot.

In summary, sensory maps respond to a loss of activating inputs, caused by damage to peripheral nerves or the central nervous system, by reorganizing so that deprived neurons become responsive to the remaining inputs. The recovery may be less extensive in subcortical structures and most extensive in higher-order cortical representations. Changes in maps can be rapid, but extensive reactivations may take months to emerge. These observations suggest the participation of a range of different mechanisms of recovery, and the possibility of several functional consequences.

REORGANIZATION IN MOTOR SYSTEMS AFTER DAMAGE

Reorganizations of the motor system follow damage to motor nerves, the loss of muscles for movement (such as after the loss of a limb), and damage to other parts of the motor system such as lesions of primary motor cortex (Nudo *et al*., 1997). The reorganization of primary motor cortex, M1, has been studied in rats after section of a motor nerve to the facial vibrissae, and in monkeys and humans who have suffered injuries requiring therapeutic limb amputations. In normal mammals, primary motor cortex systematically represents movements of the opposite side of the body. The internal organization of the representation can be demonstrated by stimulating locations throughout M1 with small electrical currents delivered with microelectrodes. In humans, the stimulations can be done harmlessly but somewhat less precisely through the skull with sudden, focused magnetic pulses that cause small, localized currents to flow in the brain (transcranial magnetic stimulation).

Rats normally devote a large part of M1 to moving the important sensory whiskers on the side of their face. As these whiskers move across objects, surface features can be detected by the rats. When the motor nerve to these whiskers is cut so the whiskers can no longer be moved, electrical stimulation of sites throughout the proportionally large whisker representation in M1 move the forepaw or eyelids instead. Similarly, in monkeys who have lost a forelimb, stimulating the large portion of M1 that normally moves digits and other parts of the forelimb moves instead the remaining stump of the limb (Wu and Kaas, 1999). Normally only a few sites are capable of evoking movements of the upper arm and shoulder. Comparable results have been obtained from deprived parts of M1 in humans with limb amputations. While some of the stimulation sites in reorganized cortex require higher than normal levels of current to be effective, many require only normal levels of current. Thus, primary motor cortex, when deprived of a normal muscle outlet, acquires control over the remaining adjacent muscles.

Motor cortex in primates includes not only the primary motor area, M1, but also the dorsal, ventral, supplementary, and cingulate premotor areas. Electrical stimulation in all of these premotor areas also evokes movement, but little is known about their capacity to reorganize after motor nerve damage or limb loss. However, limited results from monkeys suggest that the dorsal and ventral premotor areas do reorganize after forelimb loss, much as M1 reorganizes. The motor system also appears to reorganize after damage to motor cortex. There is considerable clinical evidence in humans for functional recovery after parts of motor cortex are damaged by stroke, but the nature of such reorganization has been difficult to determine. However, experiments in monkeys in which the normal organization of M1 is first determined with stimulating microelectrodes, followed by removal of a small portion of the region devoted to hand and digit movements, have found that the hand region of M1 reorganizes so that missing portions of the hand representation are recovered. This recovery seems to depend on training the monkey to use the impaired hand in a skillful manner. Thus, it appears that the reorganization of M1 after damage depends on use and practice, while the return of skilled movements depends on the cortical reorganization.

REORGANIZATION IN SENSORY SYSTEMS RESULTING FROM EXPERIENCE

Much of the research on the reorganization of sensory systems with experience has been on the somatosensory cortex of monkeys. When monkeys were given new sensory experiences, changes were observed in the organization of primary somatosensory cortex, S1 (Brodmann's area 3b). The observed changes were less extensive than those generally observed after damage to the somatosensory system. In one experiment, certain fingers received extensive amounts of sensory stimulation, and the representations of those fingers in S1 enlarged slightly. In other experiments, the simultaneous stimulation of several digits over long periods caused the detailed order of the representation of the fingers to become less precise, and neurons to acquire enlarged receptive fields.

The alterations in the map in somatosensory cortex appear to be predictable from the patterns of new stimulation. This is highly apparent with increased stimulation. Even electrical stimulation of receptors and afferents in a digit may increase the size of the cortical representation of that digit, and electrical stimulation of cortical sites increases the size of the representation of the body part that activates that site. Monkeys with long-standing abnormal use of a hand, such as after an induced motor disorder (dystonia) or hand injury, have abnormal maps of the hand in S1. In rats, the repeated stimulation of two adjacent whiskers on the face changed the responsiveness of S1 neurons to a second whisker. In humans, measures of patterns of brain activity

induced by stimulating fingers and other body parts have provided evidence for enlarged representations of the fingers in somatosensory cortex of Braille readers (Pascual-Leone and Torres, 1993) and skilled players of stringed instruments.

The effects of experience on somatosensory maps other than S1 are largely unknown, but presumably alterations take place in higher-order cortical maps as well, as changes in primary sensory areas would be relayed to higher-order representations. It is uncertain whether experience alters subcortical somatosensory representations.

There have been a number of studies of neurons in the primary auditory cortex of mammals (Weinberger, 1995). Neurons alter their responses to tones after a tone is paired with a foot shock so that they respond more to the paired tone and less to other tones. Shifts in the best frequency for groups of neurons alter the tonotopic organization of primary auditory cortex so that behaviorally significant tones have increased representations.

REORGANIZATION IN MOTOR SYSTEMS RESULTING FROM EXPERIENCE

It seems reasonable to suppose that as a skill is learned, motor cortex reorganizes to improve its mediation of that skill. This assumption has some experimental support, but individual differences in the detailed organization of motor cortex make it difficult to detect small changes. Nevertheless, there is evidence of use-dependent reorganization of the hand representation in M1 (Nudo *et al*., 1997). In humans, results from transcranial magnetic stimulation studies indicate that the representation in M1 of movements used in a highly repeated task are enlarged, and even short previous training on synchronous movements can produce a temporary change in the effects of stimulation on the motor map. However, functional magnetic imaging studies of cortical activation also indicate that complex motor tasks may actually cause less activation of motor areas of cortex when they are highly learned. This result suggests that fewer cortical neurons are needed for the same tasks after long-term practice. Thus, motor cortex sometimes reorganizes by reducing the number of circuits devoted to the task, possibly by increasing the effectiveness of those most critical for the task.

MECHANISMS OF REORGANIZATION

Reorganization of sensory and motor systems depends on two major mechanisms. First, the functional circuitry of these systems can be changed by increasing or decreasing the effectiveness of existing patterns of connections. There are many ways of altering the effectiveness of existing connections, and this type of change may be responsible for most of the plasticity that occurs in sensory and motor systems. Second, new connections may grow, even in the mature nervous system. Local growth and retraction of axons and dendrites may be common, but such limited growth would be difficult to detect by most anatomical procedures. Axons do extend considerable distances in the cortex and brainstem, but extensive new growth has been seen only under conditions of severe sensory deprivation with major reorganizations.

The responsiveness of neurons is normally under a number of excitatory and inhibitory influences. When these influences are in balance, the response properties of neurons are relatively stable. However, any change to the system would immediately alter the balance, and much of the immediate plasticity of brain systems is simply a reflection of rebalancing a dynamic system after inputs have been added or subtracted. For example, reduction in the excitatory drive of some inhibitory neurons causes their target neurons to become more excitable and respond to previously subthreshold inputs. To the extent that this creates new or larger receptive fields for these neurons, the details of sensory and motor representations are altered. Such changes are sometimes referred to as the 'unmasking' of 'silent synapses'. Altered responsiveness can also result from the release of neuromodulators during times of attention, distress, or motivation (Kilgard and Merzenich, 1998). Neurotrophic factors are also released to influence seasonal changes in neural circuits and behavior.

Perhaps most importantly, neurons are altered by activity patterns so that they become more responsive to frequent stimulus conditions and less responsive to other stimulus conditions. Experience and sensory events can lead to long-term potentiation (LTP) or long-term depression (LTD), which are long-lasting enhancements or reductions of synaptic effectiveness between neurons. The strengthening of synapses between neurons that are activated at the same time is known as Hebbian plasticity, after the speculations of the neuropsychologist Donald Hebb on the mechanisms of learning (Hebb, 1949). Hebbian plasticity appears to be based on LTP and LTD. The induction of LTP depends on the joint activation by excitatory inputs of both *N*-methyl-D-aspartate (NMDA) receptors and the non-NMDA glutamate receptors

(Rauschecker, 1991). The resulting depolarization of the activated neuron relieves a voltage-dependent block of the NMDA receptor, which allows calcium ions to flow through the receptor channel into the neurons to initiate cellular modifications that increase synaptic strengths. The cellular aspects of LTD are less well understood. Levels of neural activity also regulate the expression of neurotransmitters and transmitter receptors. Thus, a reduction of brain activity due to a nerve injury is followed by reduced expression by deprived neurons of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) and the receptors for GABA (Jones, 1993). With less inhibition, the neurons become responsive to the remaining, previously ineffective connections.

Neurons also grow and form new connections. Increased activity may cause neurons to grow more dendrites and more dendritic spines, forming additional synapses to make circuits more effective. Axons may grow under a number of conditions. Groups of neurons that have become deactivated appear to cause growth in nearby neurons and attract new inputs. Such new growth, at least over longer distances, is normally inhibited, but the inhibition factors may be reduced or overcome by neurotrophic factors under conditions of deprivation. Finally, it appears that a small number of new neurons are generated, even in the mature brain. These new neurons may be important in some types of adult plasticity.

FUNCTIONAL CONSEQUENCES OF REORGANIZATION

While the reality of brain reorganization in mature mammals is well established, the functional consequences of these reorganizations are not so clear. The more limited reorganizations that occur with perceptual and skill learning are thought to be responsible for the improved performance (Pascual-Leone and Torres, 1993; Zahary *et al*., 1994). Changes in abilities have been shown to correlate with the reorganizations, but more direct evidence is lacking. Some progress might be made by evaluating the transfer of perceptual and motor skills from one part of the body to another: if these skills depend on reorganizations that are limited to sectors of a representation, they should not transfer when other body parts with unaltered representations are used. Some types of visual perception learning are highly specific for retinal location, suggesting that map reorganization with training does account for the learning. Individuals typically do recover to some extent from brain damage and sensory loss, and it is tempting to conclude that map reorganizations account for some or most of the recovery. Again, there is evidence that reorganization is at least sometimes correlated with recovery. For example, motor skills recover with motor map reorganization after partial lesions of motor cortex (Nudo *et al*., 1977). Further evidence on the role of reorganization in recovery is needed, however.

In some situations, reorganizations may mediate misperception and motor errors. Reorganizations probably account for elicited phantom sensations (Ramachandran and Blakeslee, 1998). Nearly all people with limb amputations have the sensation that the limb is still present, and this could be the result of spontaneous neural activity in the deprived portions of the somatosensory system. In addition, it is also possible to evoke sensations in the missing limb by touching other parts of the body. After forearm amputations in humans and monkeys, the deprived forearm portions of the somatosensory cortex and thalamus become responsive to touch on the limb stump and the side of the face. Touching the stump or face may be felt not only on the stump or face but also on the missing limb. It seems likely that these perceptions are the consequence of activating neurons in the stump or face portions of the central representations, as well as in the reactivated forearm portions. Although the forearm parts of the representation start to respond to new inputs, neural activity in these reactivated sectors continues to signal sensations to the missing limb. Such reorganizations may also be responsible for the perceptual filling in of scotomas after retinal lesions (Chino, 1997), tinnitus after damage to the auditory system (Muhlnickel *et al*., 1998), and focal dystonias after long, intense practice of motor skills (Byl *et al*., 1996).

In summary, map reorganizations may mediate desirable changes in abilities, and misperceptions and motor errors, depending to some extent on the magnitude of the reorganization. A goal of further research should be to understand how to foster reorganizations that mediate behavioral recoveries and new learning, while preventing and restricting those that mediate undesirable sensations and performances.

Reticular Activating System

Introductory article

Martin Sarter, Ohio State University, Columbus, Ohio, USA

Gary G Berntson, Ohio State University, Columbus, Ohio, USA

CONTENTS

The reticular activating system consists mostly of ascending noradrenergic and cholinergic projections originating in the brainstem. These projections enter the cortex, thalamus and basal forebrain, and mediate increases in wakefulness and arousal. Contemporary hypotheses describe these systems as actively regulated afferent components of forebrain circuits mediating defined cognitive processes.

INTRODUCTION

Beginning with the experiments carried out by Bremer and by Moruzzi and Magoun in the 1930s and 1940s, findings in support of the view that the brainstem contains a globally activating neuronal system gave birth to the concept of a homogeneously organized ascending reticular activating system. Interestingly, the term 'activation' originally referred to the increase in the readiness of forebrain neuronal networks to process other afferent information, and the generalization of this term to various forms of behavioral 'arousal' has suffered from insufficient conceptual definition and empirical support, to the extent that the scientific value of the construct 'arousal' has been questioned.

Traditional descriptions of the anatomy of the brainstem ascending systems focused on the 'reticular' character of these projections, a term that refers to the absence of clear anatomical segregation of the various cell groups in the brainstem giving rise to long ascending projections to the forebrain, and to the extensive branching or collateralization of these ascending projections. Modern anatomical techniques revealed a more precise anatomical organization of these projections and their terminal fields in the forebrain. Contemporary research designed to determine the functions of the different branches of the ascending activating system in interaction with their forebrain target circuits has yielded specific hypotheses about the dissociable functions of selected branches of this system in different behavioral and cognitive conditions. Two branches of the reticular activating system are most closely documented to mediate forebrain activating effects: the ascending noradrenergic system and the ascending cholinergic system. The ascending noradrenergic system is conceptualized as a neuronal system promoting cognitive processing in forebrain circuits particularly in response to novel, affective or stress-like stimuli and their associated changes in autonomic reactivity. Increases in activity in the brainstem ascending cholinergic system primarily promote dreaming cognition during rapid eye movement (REM) sleep via activation of mostly thalamic and basal forebrain corticopetal projections.

ANATOMY OF ASCENDING NORADRENERGIC AND CHOLINERGIC PROJECTIONS

Noradrenergic Projections

Although several noradrenergic cell groups in the dorsomedial and caudal ventrolateral medulla send their axons to the forebrain, the ascending projections of the locus caeruleus (LC) most extensively have been demonstrated to mediate 'arousal', awakening or increased alertness. The LC is situated close to the fourth ventricle in the pons, and in humans contains about 13 000 neurons per hemisphere; these project to all major regions in the mesencephalon, diencephalon and telencephalon. Projections from the LC to the forebrain are highly collateralized, with single neurons innervating widespread telencephalic areas. Although anatomical studies have qualified traditional statements about the 'diffuse' organization of noradrenaline (NA) inputs to the cortex by

demonstrating species-specific differences in the regional and laminar density of NA inputs, NA is released predominantly from nonjunctional varicosities, supporting the hypothesis that NA acts in a widespread, diffuse and modulating fashion, thereby globally gating the information processing in its target sites. Among the subcortical target sites that are important in cognitive functions (below) are the cholinergic neurons of the basal forebrain. The cholinergic basal forebrain, consisting primarily of the nucleus basalis of Meynert, the substantia innominata, the horizontal limb of the diagonal band of Broca and the preoptic area, has been conceptualized as the most rostral extension of the reticular activating system. Basal forebrain cholinergic neurons are predominantly depolarized via α_1-adrenergic receptors, driving cholinergic cells into a tonic mode of firing and increasing their rate of repetitive spike discharge. The widespread innervation of the cortex by cholinergic projections from the basal forebrain supports this notion, and NA inputs to the basal forebrain are organized to increase the responsivity of this structure's neurons to other (telencephalic) inputs.

The LC receives inputs primarily from two areas in the rostral medulla, the nucleus paragigantocellularis (nPG) and the nucleus prepositus hypoglossi (nPH). The nPG projects to sympathetic preganglionic neurons, mediating autonomic activation which, via the parallel projection to the LC, also activates the ascending NA system. The role of the inhibitory input from the nPH is less clear. Functionally, the afferent organization of the LC suggests that this system mediates the activational (specifically cognitive) consequences of stimuli that increase sympathetic reactivity. The finding that activation of the prefrontal cortex stimulates LC neurons furthers the hypothesis that the ascending NA system is wholly integrated in the neuronal systems mediating cognitive functions.

Cholinergic Projections

The cholinergic cell bodies in the brainstem which mediate forebrain activation, particularly during REM sleep, originate mainly from the pedunculopontine tegmental (PPT) and laterodorsal tegmental (LDT) region. The ability of these tegmental cholinergic neurons to induce cortical desynchronization has traditionally been assumed to depend on connections via the thalamus, mostly via dorsal, intralaminar, reticular thalamic nuclei. However, the PPT and LDT also project to the basal forebrain, and it appears that the increased cortical acetylcholine efflux during REM sleep is due mainly to stimulation of corticopetal cholinergic neurons in the basal forebrain by these ascending cholinergic projections. Thus, lesions of the PPT in animals resulted in a decreased cholinergic innervation of the basal forebrain, and electrical stimulation of the PPT appears to be sufficient to produce an increase in cortical acetylcholine release via projections terminating in the basal forebrain. Although the exact distribution of cholinergic terminals in the basal forebrain remains unsettled and may include direct contacts of cholinergic terminals with this structure's corticopetal cholinergic neurons, it seems more likely that the majority of cholinergic inputs do not synapse directly onto basal forebrain cholinergic neurons. It is not clear whether other PPT neurons, such as glutamatergic neurons, project to the basal forebrain.

EVOLUTION OF THE CONCEPT OF THE RETICULAR ACTIVATING SYSTEM

In addition to early anatomical work on the reticular formation and its relay to widespread cortical areas via 'nonspecific' thalamic nuclei, functional studies contributed to the construct of a generalized ascending reticular activating system. Stimulation of the reticular formation was reported to induce cortical activation and behavioral arousal, for example, whereas reticular lesions could yield cortical deactivation and coma. This was in keeping with the emerging concept of 'general arousal' in psychology, and these perspectives merged into the construct of a generalized arousal system.

The unitary anatomical-functional concept of the 'arousing' functions of the reticular activating system did not fare well empirically. More refined anatomical studies continued to reveal greater complexity and specificity in ascending activating systems, and the construct of 'generalized' arousal became increasingly untenable. For example, various psychophysiological (heart rate, electrodermal responses, cortical electroencephalography) and behavioral (e.g. reaction time) indices of arousal or activation are not well correlated, and the functional manifestations of manipulations of arousal do not correspond with descriptions that assume a linear continuum from low to high arousal. Rather, modern approaches have returned to the original meaning of 'activation', conceptualizing the functions of the ascending systems in terms of fostering or modulating the cognitive processes mediated through neuronal target circuits in the forebrain. Thus, the activating effects of the noradrenergic or cholinergic ascending systems may be limited to interactions with other afferent projections of their

respective target neurons in the forebrain. Such hypotheses include the view that the activating effects of ascending systems do not represent a mere passive, 'bottom up' contribution to forebrain functions. Rather, these ascending systems appear to be regulated by interactions among the stimulus-situation, task-demands, and 'top down' cognitive influences. In short, ascending systems represent integrated components of the forebrain neuronal systems mediating complex behavioral and cognitive functions.

ATTENTIONAL BIAS IN FEAR AND ANXIETY

The locus caeruleus, based on its anatomical connections described above, imports information about the sympathetic activation produced by novel, emotionally charged or stress-like stimuli to the forebrain. Functionally, LC-mediated increases in the responsivity of forebrain targets are thought to bias attentional information processing toward such stimuli and contexts. Thus, attentional processing in response to urgent (particularly aversive) stimuli is optimized by increased activity in noradrenergic ascending projections. A persistent attentional bias towards fear- and anxiety-related stimuli in people with anxiety disorders may be mediated in part by an overactive noradrenergic ascending system.

Although it is likely that a wide range of diencephalic and telencephalic (including cortical) target systems of the LC-NA system mediate such attentional biasing, the basal forebrain represents a prime target for this function. Corticopetal cholinergic projections from the basal forebrain are necessary for the mediation of attentional functions ranging from the detection, selection and discrimination of relevant stimuli to the allocation of processing resources to competing attentional tasks. Noradrenergic modulation of basal forebrain neurons may be sufficient to permit telencephalic (glutamatergic) afferents to stimulate basal forebrain. Collectively, noradrenergic inputs to the basal forebrain are hypothesized to initiate attentional processing via telencephalic inputs and the basal forebrain's corticopetal projection systems (Figure 1).

The crucial role of the corticopetal cholinergic system of the basal forebrain in the processing of fear- and anxiety-related information and in the associated increases in autonomic reactivity has been demonstrated in experiments involving cognitive processing (as opposed to the effects of unconditioned stimuli and classically conditioned stimuli for aversive events). Enhanced autonomic responses in such contexts were shown to depend on the integrity of basal forebrain cholinergic neurons, specifically on cholinergic projections to the medial prefrontal cortex.

The reasons for the affective nature of the attentional processing induced via noradrenergic activation may be at least twofold. First, activation of the LC itself reflects sympathetic activation and thus may signify the presence of affectively significant, novel or stressful stimuli. Second, the basal forebrain receives input from several sites involved in the descending processing of fear- and anxiety-related information – notably the amygdala. Interconnections between the basal forebrain, the amygdala and the prefrontal cortex represent a parsimonious neuronal system through which the processing in basal forebrain circuits is predominately enhanced in fear- and anxiety contexts (Figure 1). Additionally, descending activation of the LC by the prefrontal cortex may further foster the attentional processing of fear- and anxiety-related stimuli through a 'top down' influence.

The LC-mediated influence of sympathetic activity on forebrain cognitive processing requires additional comment. Although the assumption that peripheral variables can affect high-level processing may appear speculative, in fact such influences have been demonstrated for central regulation of autonomic, immune, and endocrine as well as behavioral processes. Indeed, sympathetic influences on the ascending LC system probably represent only one of a range of interactions among upper and lower levels of the neuroaxis in the generation of affective reactions and their cognitive components. In this regard, the LC represents a major ascending pathway contributing to the integration of lower-level information in higher-level cognitive processes, and experimental investigations into its role may eventually yield a scientifically useful version of William James's hypothesis about the role of visceral afferent feedback in affective reactions. (*See* **Autonomic Nervous System**)

CONCLUSION

The monolithic concept of a reticular activating system is rapidly being replaced by hypotheses concerning the precise functions of defined groups of neurons in the brainstem, their ascending (and descending) projections, and their interactions with other brainstem nuclei. Importantly, this development is not just fueled by the ever more detailed anatomical description of the efferent and afferent organization of brainstem neurons and their

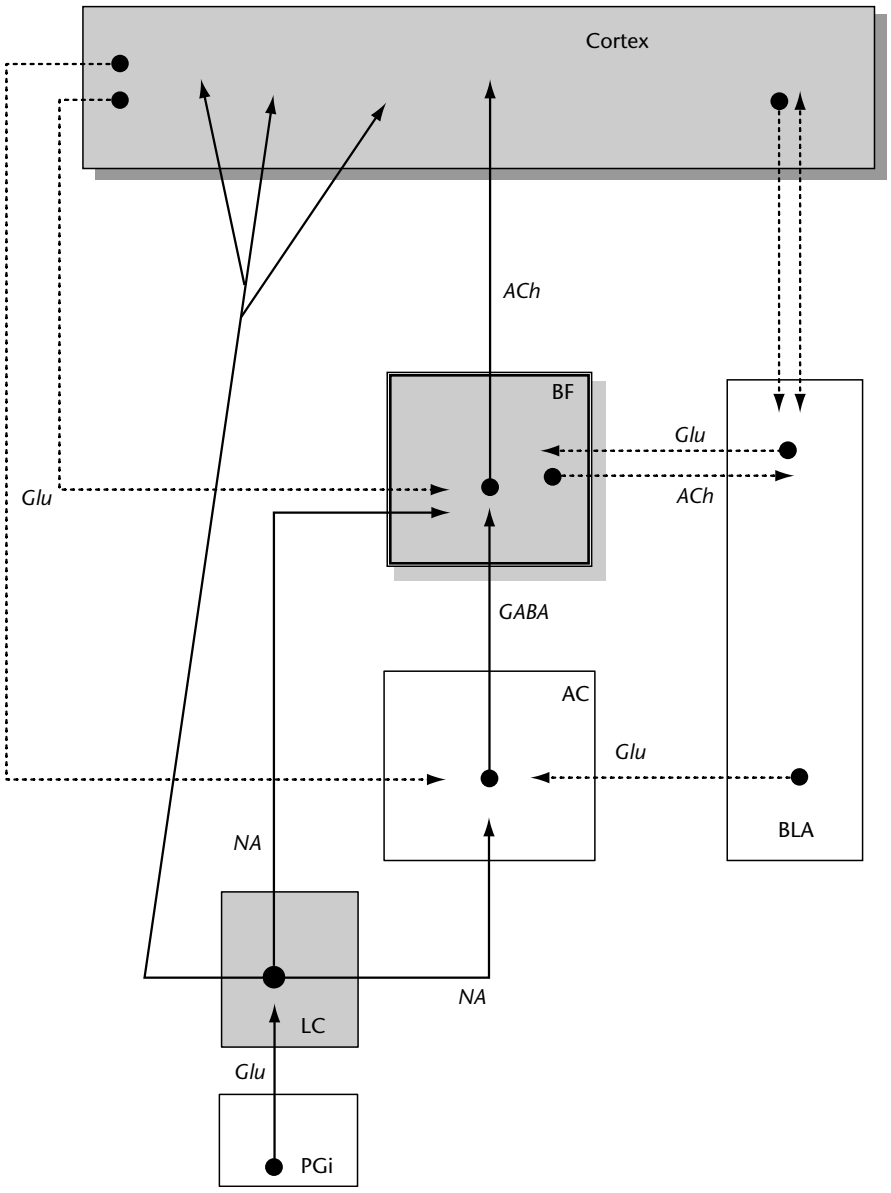

Figure 1. Role of the noradrenergic ascending projections to the cortex and basal forebrain. Novel, salient or emotionally charged stimuli activate ascending noradrenergic systems, possibly via afferents of the locus caeruleus originating in the nucleus paragigantocellularis, a sympathoexcitatory structure. Noradrenergic stimulation of neurons functionally recruits telencephalic circuits in the basal forebrain, consisting mostly of cortical, amygdaloid and accumbal inputs to corticopetal projections, for the processing of attentional information. AC, nucleus accumbens; ACh, acetylcholine; BF, basal forebrain; BLA, basolateral amygdala; GABA, γ-aminobutyric acid; Glu, glutamate; LC, locus caeruleus; NA, noradrenaline (norepinephrine); PGi, nucleus paragigantocellularis.

physiological analysis, but by hypotheses about the active regulation of the activity of ascending systems in different behavioral and cognitive contexts, and about the significance of activity in these systems for the cognitive processes mediated through their forebrain neuronal target circuits. The traditional, broad concepts of a 'reticular activating system' and 'arousal' cannot capture the significance of such hypotheses and thus should be replaced.

Reward, Brain Mechanisms of

Introductory article

Roy A Wise, National Institute on Drug Abuse, Baltimore, Maryland, USA

CONTENTS

Direct electrical or chemical stimulation of the brain can be powerfully rewarding. The neurons activated by such rewards are partially known and are the focus of intense investigation. These neurons are thought to participate in normal motivation and in the control of behavior through the natural pleasures of life.

INTRODUCTION

Rewards are stimuli or events that increase the probability of the behavioral acts that they regularly follow. Specialists attempting to identify this class of events objectively have used the terms 'reinforcement' and 'incentive motivation' to characterize the effects of such stimuli; the approximations 'liking' and 'wanting' have captured recent attention in attempts to characterize these two aspects of reward. 'Reinforcement' refers to the effects of the stimulus on the brain circuitry that generated the act being reinforced; it is presumed that the neural elements of this circuitry remain in a plastic state for some time after the act, and that the reinforcing stimulus or event has the ability to stamp in or reinforce the synaptic connections between these elements. Two types of reinforcement have been suggested, one in which the associations between active stimulus elements are strengthened, and one in which the associations between stimulus and response elements are strengthened. Thus far, cellular correlates of only the first type – Pavlovian reinforcement – have been identified.

Pavlov made the important distinction between two types of stimuli: signal stimuli, which elicited reflex responses, and nonsignal stimuli, which did not. The distinction is not a clean one, because even so-called 'neutral' or nonsignal stimuli elicit a reflexive orienting response – a response consisting of eye, head, and whole body movements toward the stimulus, along with autonomic responses such as papillary dilation and changes in galvanic skin response. However, these responses to a nonsignal stimulus disappear (habituate) as the stimulus becomes familiar and predictable. A nonsignal stimulus can become a signal stimulus if it is associated in time with a signal stimulus. A well-known example is the nonsignal bell that becomes a conditioned (signal) stimulus when associated with the unconditioned (signal) stimulus of food. A conditioned stimulus can again become a nonsignal stimulus if it is not occasionally reassociated with its unconditioned stimulus. Pavlov gave the name 'reinforcement' to the renewal of the signal status of the conditioned stimulus by presentation of the conditioned and unconditioned stimulus together. The learning that Pavlov studied can be termed 'stimulus' learning, in that it deals with the learned association of one stimulus with another.

Thorndike used the phrase 'stamping-in' to suggest a similar strengthening of the association between a stimulus and a response. Thorndike came to use Pavlov's term – used even earlier by William James – to refer to the stamping-in associated with response learning. Skinner, in an attempt to better characterize response learning, also used the term 'reinforcement', defining a reinforcer as a stimulus that increases the probability of the acts that regularly precede it. In popular terminology, the term 'reward' is typically used in relation to this form of learning. However, it is clear that stimulus reinforcement has an important, perhaps critical, role in response learning.

Rewards not only stamp in stimulus and response associations; they also energize behavior and increase its probability proactively. The taste of a rewarding stimulus often focuses subsequent attention on stimuli previously associated with that reward and increases the probability of behaviors that led to that reward in the past. Familiar examples are the eating of one salted peanut or potato chip. The taste of one energizes searching

behavior that is satisfied only with more. The motivational arousal ('wanting') caused by initial exposure to a reward or to stimuli associated with a reward is termed 'incentive motivation'. Like reinforcement, it is one of the fundamental effects of rewards.

The familiar rewards are the everyday pleasures of life: food when we are hungry, water when we are thirsty, heat when we are chilled, and cold when we are overheated. The ability of these to establish strong response habits is well known; their ability to serve as incentive motivational stimuli is less widely articulated, but is also well known. Consider, for example, sexual arousal. Sexual arousal is not constant; it is strongly modulated by hormonal states in the female and by sensory stimuli in the male. In lower animals, it is strongly stimulated by the smell of a receptive female; in the human male it can be strongly stimulated by the sight of genital or perigenital flesh or, in some cultures, by the sight of a shapely breast. The sexual arousal activated by olfactory or visual stimuli illustrates powerful cases of incentive motivation.

BRAIN STIMULATION REWARD

Our understanding of the brain mechanisms of reinforcement and incentive motivation has been stimulated and advanced by studies in which deep structures in the brain were stimulated electrically in freely moving animals. Stimulation of the depths of the brain – the lateral hypothalamus and adjacent structures through which course common neuronal fibers (axons from motivationally important cells of unknown origin and termination) – can cause a sated animal to seek out and eat food, or to respond appropriately to a variety of other natural incentives such as prey or a sexual partner. Stimulation in the same brain sites – and, indeed, many more – is strongly reinforcing. The fibers passing near the sites where such stimulation has motivational effects are presumed to form a critical portion of the neural circuitry of reward.

The first experiments on the rewarding effects of direct brain stimulation were carried out by James Olds and Peter Milner, who noticed that rats would quickly return to a place in their environment where they had received the stimulation. That place had become, through association with the stimulation, an incentive stimulus, one that was approached in preference to others. Olds and Milner promptly noted the ability of this stimulation to establish lever-pressing habits. This behavior is termed 'intracranial self-stimulation'. Hungry rats will work for such stimulation in preference to food, and will, if access to food and stimulation is restricted to a brief period each day, starve as a consequence of their preference for the stimulation. Such studies have established the medial forebrain bundle as a locus of brain reward circuitry. Unfortunately, the medial forebrain bundle comprises fifty or sixty sets of nerve fibers, and it remains unclear which of these plays an important role in reward function. Pharmacological studies have, however, given some initial clues.

A ROLE FOR THE MESOLIMBIC DOPAMINE SYSTEM

The medial forebrain bundle fibers most clearly associated with reward function are the ascending fibers of the mesolimbic dopamine system which project from the ventral tegmental area of the midbrain to several forebrain structures including the nucleus accumbens. While lever-pressing habits can be disrupted by a variety of pharmacological agents (sedatives, noradrenergic antagonists, and, indeed, strong doses of drugs that are themselves rewarding), the drugs that affect self-stimulation in ways that parallel the effects of reducing the reward itself are antagonists of dopamine neurotransmission. Such drugs do not attenuate the lever-pressing of the first few seconds of a test session, where the animal has not yet learnt the consequences of the drug state, but they cause a gradual reduction of the behavior as if the animal finds the usual reward less than normally satisfying. Such drugs do not reduce the maximum levels of work that are sustained by the reward in question, but they increase the amount of reward that is required to motivate maximal response levels. Indeed, it is possible to determine the number of extra pulses of brain stimulation that is necessary to compensate for a given dose of a dopamine antagonist. Moreover, dopamine *agonists* have the opposite effect, reducing the number of brain pulses necessary to maintain a given rate of responding, and a dopamine agonist that reduces the number of required pulses by 10% will just offset the effects of a dopamine antagonist that increases the number of required pulses by 10%.

FIRST-STAGE FIBERS

There are perhaps fifty fiber pathways of the medial forebrain bundle that are directly activated by rewarding stimulation; it is unlikely that more than a few of these play a role in reward function. These directly activated neurons are termed

'first-stage' neurons, and they have not yet been identified. Pulse-pair studies have helped narrow the list of possibilities. Pulse-pair studies take advantage of the facts that (a) nerve fibers need time to recharge after each nerve impulse, and (b) different sizes and types of nerve fibers need different amounts of time for such recharging. Large, myelinated fibers recharge much more quickly than small, unmyelinated ones. By administering rewarding stimulation in trains of pairs of closely spaced pulses rather than in trains of equally spaced pulses, electrophysiologists have been able to determine the range of refractory periods of the populations of fibers at the electrode tip that participate in brain stimulation reward function. The procedure is to vary the interval between the pulses in each pair, identifying the amount of time needed for the second pulse in each pair to add reward value to that seen from the first pulse alone, and identifying the amount of time needed for full recovery such that the second pulse in each pair adds as much reward as does the first. This gives the range of refractory periods for the population of neurons contributing to the rewarding effects of the stimulation. The range of refractory periods is quite short (0.4–2.0 ms), suggesting that the reward-relevant fiber populations are large and myelinated. This rules out the dopamine-containing fibers as first-stage fibers, because they are small and unmyelinated. Which of several sets of large myelinated fibers contribute to the first-stage mechanism remains to be determined.

Further evidence that the dopaminergic fibers of the medial forebrain bundle do not serve as the first-stage transduction fibers of brain stimulation reward circuitry comes from pulse-pair studies involving two electrodes positioned along the length of the bundle. When the first pulse of a pulse pair is delivered at one electrode and the second is delivered some distance along the pathway, the time that must be given before the second pulse will be completely effective represents not only the time for the fiber to recover from the action potential triggered by the first pulse, but also the time it takes that action potential to reach the second electrode site. By subtraction one can estimate the conduction velocity of the neurons that contribute to the rewarding effect of the stimulation. The conduction velocities are fast – of the order of 2.5 meters per second – again implicating the large, myelinated fibers.

The conduction velocity experiment does not depend on which end of the first-stage neurons receives the first pulse of each pulse pair. However, if anodal current, which hyperpolarizes rather than depolarizes neurons, is given at one of the stimulation sites, and cathodal, depolarizing current is given at the other, the direction of conduction of the reward signal can be determined. If anodal stimulation at the caudal electrode blocks the rewarding effect of cathodal stimulation at the rostral electrode, and if anodal stimulation at the rostral electrode does not block the rewarding effect of cathodal stimulation at the caudal electrode, then the reward signal is conducted in the rostral–caudal direction. This test has shown that the bulk of the first-stage elements of medial forebrain bundle brain stimulation reward conduct in the rostral–caudal direction, opposite to the normal direction of conduction of the mesolimbic dopamine neurons.

Thus the critical role of the dopamine system in the rewarding effects of medial forebrain bundle stimulation must result from transsynaptic activation of the mesolimbic dopamine system by the large, myelinated, caudally projecting first-stage reward neurons or their efferents. The first-stage fibers project very close to the dopaminergic cell bodies of the ventral tegmental area, but the currently favored hypothesis is that they project beyond the ventral tegmental area to synapse on the cholinergic neurons of the pedunculopontine tegmental nucleus, which, in turn, projects back to the ventral tegmental dopamine cells.

CHEMICAL STIMULATION OF REWARD CIRCUITRY

The pharmacological studies implicating dopamine systems in brain stimulation reward suggest that pharmacological activation of the dopamine system should, like stimulation-induced activation, be rewarding in its own right. There is now considerable evidence to support this suggestion. Rats will learn to lever-press for direct injections of dopamine or direct dopamine agonists into the nucleus accumbens. Cocaine and amphetamine are indirect dopamine agonists – drugs that elevate synaptic levels of endogenous dopamine – and they too are self-administered into this nucleus. Morphine, heroin, nicotine, alcohol, and cannabis also elevate nucleus accumbens dopamine levels: nicotine by stimulating the dopamine neurons directly, morphine and heroin by disinhibiting the dopamine neurons, and alcohol, and cannabis by mechanisms that have not yet been elucidated. Morphine and other μ-opioids are self-administered directly into the region of dopamine cell bodies in the ventral tegmental area, and their potency for such self-administration is the same as their potency for elevating nucleus accumbens dopamine levels.

Not all drugs of abuse act at the level of the dopaminergic link in brain reward circuitry, however. It is not clear where barbiturates or benzodiazepines trigger their rewarding actions, but it seems likely that they do so in one or more synapse of the output neurons of nucleus accumbens. The output neurons of nucleus accumbens are medium-sized spiny neurons that express γ-aminobutyric acid (GABA) as their neurotransmitter, and barbiturates and benzodiazepines act at GABA receptors. The medium spiny neurons appear to be a site at which phencyclidine exerts its habit-forming actions; phencyclidine blocks excitatory amino acid receptors of the *N*-methyl-D-aspartate (NMDA) subtype. These receptors are localized on medium spiny neurons of the nucleus accumbens, and phencyclidine and other NMDA antagonists are self-administered into this region. While phencyclidine can alter local dopamine levels – like cocaine, it is a dopamine uptake inhibitor and can elevate synaptic dopamine levels – it blocks NMDA receptors at a concentration an order of magnitude lower than is needed to block dopamine uptake. Moreover, dopamine blockers do not block the rewarding effects of phencyclidine, and NMDA blockers that do not affect synaptic dopamine levels are as effective as phencyclidine in reward function.

Drugs of abuse thus implicate several neurotransmitters in brain reward circuitry. Amphetamine and cocaine implicate dopamine: their reward-relevant receptor in the brain is the dopamine transporter and their reward-relevant action is the blockade of that transporter and thus the blockade of clearance of neuronally released dopamine. Nicotine implicates cholinergic circuitry: acetylcholine is the endogenous transmitter for the receptors at which nicotine triggers its habit-forming action. Opiates implicate their own endogenous counterparts, endomorphin-1, β-endorphin, and enkephalin. They also implicate GABA, acting to disinhibit the dopamine system by inhibiting a GABA system. Phencyclidine implicates glutamate, which is the primary endogenous transmitter for the NMDA receptor that phencyclidine blocks for its habit-forming actions. Other transmitter substances are also likely to be involved, as the classic transmitters – acetylcholine, glutamate, GABA, and dopamine – are each colocalized with peptide cotransmitters such as cholecystokinin, substance P neurotensin, and enkephalin.

KNOWN ELEMENTS IN REWARD CIRCUITRY

Diagrams of brain reward circuitry (Figure 1) invariably center on the mesolimbic dopamine system. The cell bodies of the mesolimbic system receive reward-associated cholinergic inputs from the pedunculopontine and dorsomedial tegmental nuclei, glutamatergic inputs from the frontal cortex and amygdala, and GABA-mediated inputs from the nucleus accumbens, ventral pallidum, and substantia nigra. The terminals of the mesolimbic system synapse on medium spiny neurons of nucleus accumbens. A nondopaminergic mesolimbic projection involves GABA-mediated ventral tegmental neurons that project to cholinergic interneurons of the nucleus accumbens, which, in turn,

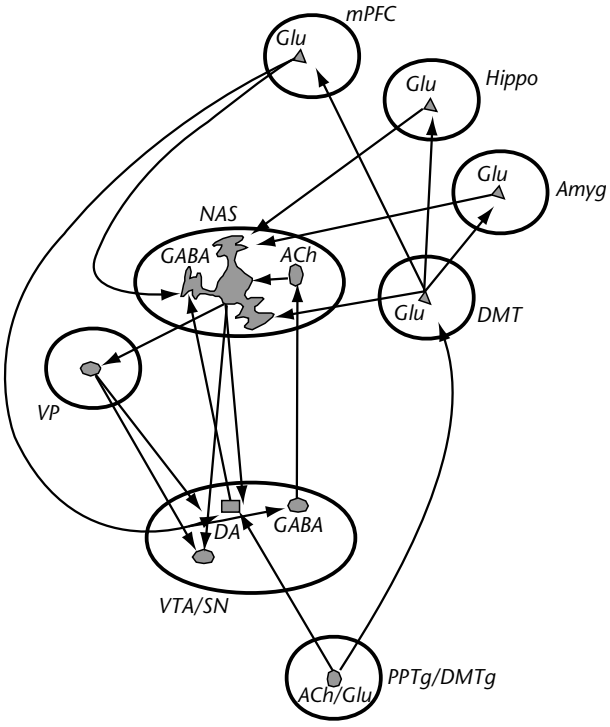

Figure 1. Some of the known complexity of brain reward circuitry. Subdivisions of the ventral tegmental area and nucleus accumbens are not shown because of uncertainties about the synaptic connections within them. Many related structures are not shown. Excitation, inhibition, and modulation are not differentiated. Colocalized peptide transmitters are not shown. Specific synaptic relations between afferents and efferents of each region are not shown in their known complexity. Receptor subtypes, sites of dendritic transmitter release, and sites of presynaptic (axon–axon) contacts are also not shown. Structures: Amyg, amygdala; DMT, dorsomedial thalamus; Hippo, hippocampus; mPFC, medial prefrontal cortex; NAS, nucleus accumbens; PPTg/DMTg, pedunculopontine and dorsomedial tegmental nuclei; VP, ventral pallidum; VTA/SN, ventral tegmental area and substantia nigra. Transmitters: ACh, acetylcholine; DA, dopamine; GABA, γ-aminobutyric acid; Glu, glutamate.

project to medium spiny neurons. The medium spiny neurons also receive glutamatergic input from the frontal cortex, amygdala, hippocampus, and dorsomedial thalamus. In large part, the system appears to parallel the extrapyramidal motor system with its dopaminergic link from the substantia nigra to the dorsal striatum.

Additional structures are clearly involved, as brain stimulation reward sites have been identified at all levels of the brain, from the sensory regions of the olfactory bulb and nucleus of the solitary tract, through the arousal systems of the brainstem and mesencephalon and the association areas of the diencephalon and telencephalon, to the region of the motor nucleus of the fifth cranial nerve. It is not clear to what degree these 25 or so reward sites connect to one another or converge on a common path, but while they have different sensitivities, none seems immune to modulation by dopaminergic drugs.

The role of dopamine in brain function is not well defined. The symptoms of schizophrenia, a mental disorder, are ameliorated by dopamine antagonists, and the symptoms of Parkinson disease, a movement disorder, are ameliorated by dopamine agonists. Extracellular dopamine levels are elevated not only by drug rewards, brain stimulation reward, sex, and food reward, but also by food deprivation. Stimulation at the lateral hypothalamic level of the medial forebrain bundle can serve not only as a reward but also as a drive. That is, rats will work for stimulation that makes them hungry; this is known as the drive–reward paradox. Dopaminergic neurons respond not only to reward-related stimuli but also to novel and painful stimuli and a variety of stressors. Thus brain dopamine and the circuitry in which it is embedded appear to play broad roles in some form or forms of arousal that are common to the range of stimuli that have behavioral significance for the animal. While the normal functioning of this circuitry is necessary for normally rewarding stimuli to exert their behavioral control, normal function of this circuitry is necessary for far more than simply reward function. Thus it should not be assumed that this circuitry is in any way 'specialized' for reward function.

When discussing the brain circuitry of reward it is frequently unconditioned rewards that are assumed: brain stimulation, addictive drugs, food, sex, and other biologically significant rewards. However, the cases of brain stimulation reward and injected drug reward make it clear that conditioned rewards must depend on this circuitry as well. In these two laboratory cases, there is no external incentive except the environmental stimuli that have been associated with unconditioned rewards in the experimental animal's reinforcement history. The stimuli that guide the animal's behaviors are the discriminative stimuli that signal reward availability and the incentive motivational stimuli and conditioned reinforcers that have been associated with the reward in question. In cases where the animal presses a lever for the drug or the stimulation, these include such stimuli as house lights, cue lights, the lever itself, and the noises that result from lever pressing. The drug itself (or the stimulation) does not present a sensory image, being delivered through an intravenous catheter. The drug is unexpected at first and subsequently signaled only by learned cues, and it is these cues – 'reinforced' by repeated association with the drug itself – that are present at the time the animal makes its habitual response. If we assume the rewarding impact of the drug to be experienced only when the drug elevates nucleus accumbens dopamine levels, the learned association may have to span minutes – a drug like cocaine, for example, must enter the bloodstream, move to the brain, cross the blood–brain barrier and bind to the dopamine transporter before a dopamine build-up will begin. Then dopamine cells must be stimulated to fire by other forces – cocaine itself, locally applied, actually decreases dopamine cell firing – before dopamine is released and allowed, by cocaine's action, to build up to significant levels. That learned associations are important is shown by the fact that an animal will press repeatedly for the drug-associated cue light alone. The fact that dopamine antagonists reduce responding for the cue light alone suggests that dopamine is important for conditioned as well as unconditioned reinforcement. Both nucleus accumbens and the central nucleus of the amygdala are important for the control of behavior by conditioned reinforcers.

Many of the elements of the brain circuitry of reward, and the way the various components of reward circuitry interact, remain to be characterized. Even the historically central element, the mesolimbic dopamine system, is not fully understood. Dopamine has important reward-relevant actions at both D1 and D2 type receptors in both nucleus accumbens and the ventral tegmental area. In the nucleus accumbens, D1 and D2 actions on medium spiny neurons are opposite (D1 action activates and D2 action inhibits the cyclic AMP second-messenger cascade in medium spiny neurons), while the behavioral actions are synergistic (neither selective D1 nor selective D2 agonists are rewarding, but the combination is). Dopamine in the nucleus accumbens seems to exert a

modulatory influence on glutamatergic activation of medium spiny neurons, but it also affects its own release from nerve terminals and acts on local interneurons and perhaps terminals. In the ventral tegmental area, dopamine acts at D2 receptors to limit the firing rate of its own neurons and acts at D1 receptors to inhibit glutamate and GABA release at incoming nerve terminals. Its D1-type actions in the ventral tegmental area are important for cocaine and probably other reward function.

The nucleus accumbens has complexities of its own. The shell subregion seems more important than the core subregion for phencyclidine and psychomotor stimulant reward, and shows greater dopamine elevations in response to drugs of abuse. The core region appears to have the more important role in opiate reward and conditioned reinforcement. Differences in the efferent connections of the two regions make this distinction a potentially important one.

Finally, the circuitry in which the ventral tegmental area and nucleus accumbens reside is complex. The dopamine-containing cells of the ventral tegmental area receive reward-related signals from the frontal cortex (as well as from drugs of abuse and from direct electrical stimulation) but so, apparently, do the GABA-containing cells of this region. While the dopamine release in nucleus accumbens has an important role in reward, it is not known what part the release of GABA plays. Dopamine is thought to inhibit the medium spiny output neurons of nucleus accumbens (both core and shell), while inputs from the frontal cortex, amygdala, hippocampus, and dorsomedial thalamus tend to excite these cells. One complication is thus that glutamate from frontal cortex not only directly excites the cells of nucleus accumbens but also excites the dopamine neurons that, in turn, inhibit the cells of nucleus accumbens. It also excites the ventral tegmental GABA cells which in turn inhibit cholinergic interneurons in nucleus accumbens, and may also contribute to GABA-mediated inhibition of the ventral tegmental dopamine neurons. Glutamate from frontal cortex projections also excites the pedunculopontine and dorsomedial tegmental pontine nuclei, which, in turn, excite the dopaminergic cells (and perhaps the GABA-containing cells) of the ventral tegmental area. As if this complexity on the input side of nucleus accumbens were not enough, some of the output cells of nucleus accumbens feed back to the ventral tegmental area, synapsing on dopaminergic or GABA-containing cells, or both. Other of the output cells of nucleus accumbens project to the GABA-containing cells of the ventral pallidum, which, in turn, project back to the ventral tegmental area, exciting the dopaminergic cells and perhaps others. Finally, the GABA-mediated output of the nearby substantia nigra and perhaps the ventral tegmental area projects to the pedunculopontine and dorsomedial tegmental nuclei and the dorsomedial thalamus.

CONCLUSION

The brain circuitry of reward is complex and as yet only partially understood. It involves many neurotransmitter substances, some of which are better known for their ability to alter the actions of other synaptic interactions than for exciting or inhibiting postsynaptic cells directly. The circuitry involves many anatomical links, with multiple opportunities for feedback and feedforward complications. It participates in multiple arousal functions, including arousal critical to response reinforcement as well as to reward anticipation and response initiation.

CONTENTS

Multisensory integration is the ability of the brain to combine information from different sense receptors to enhance the organism's perception of its environment.

INTRODUCTION

Multisensory integration refers to the brain's ability to pool information from different senses. It is a process that allows the brain to construct an accurate picture of the world and to guide motor acts. Because all perceptions and behaviors take place in an environment rich with stimuli that activate very different sensory receptors, the processes underlying multisensory integration are continuously in operation. They add depth to our sensory experiences and accuracy to our judgments of environmental events.

CROSS-MODAL PERCEPTION

Basketball players don't seem so tall when we see them from the cheap seats or watch them play on television. We know that this misimpression is a result of judging the players against one another, and this is confirmed at the end of the game when we see one or more of them interviewed by someone of average height. The apparent change in a player's height may be amusing, but it is rarely startling, because we have learned very early in life that visual judgments are not absolute, and can be easily manipulated by the clever use of contrast and perspective.

Indeed, many elementary-school children are delighted to draw innumerable versions of railroad tracks that seem to disappear in the far distance. We also find it obvious that sounds appear louder or softer than usual if heard after sounds of contrasting volume, and are not surprised to find that normal speech has become inaudible after a rock concert. The relativity of sensory impressions characterizes each of our senses (i.e. sensory modalities).

Nevertheless, the idea that this relativity extends across different sensory modalities is less obvious. It is difficult at first to believe that the presence of a brief, low-intensity sound can markedly change one's estimate of the brightness of a light – but it does. It is also true that vibrating one side of the neck can make a spot of light in an otherwise darkened room appear to move. Similarly, activation of receptors in the vestibular and proprioceptive systems by rotating the body can make it seem as if that horizontal illuminated line we are viewing in the dark is now tilted, and stimulation of receptors in the body by the powerful gravitational forces produced by high-speed takeoffs from aircraft carriers can temporarily disrupt a pilot's visual estimates. These are just a few of the many intersensory, or 'cross-modal', influences that determine our daily perceptual experiences and on which we base our judgments about the events around us.

The difficulty of divesting oneself of the idea that each sensory modality functions in its own unique realm, from which it cannot alter judgments in other sensory modalities, is likely to be because each modality has its unique subjective impressions, or 'qualia'. Color is unique to vision, pitch

to audition, tickle and itch to somatosensation, salty to gustation, and so on. It is for this reason that one cannot really describe the color blue to someone who is born blind. Such people have had no way of constructing an equivalent experience through their intact senses and it is anyone's guess what their imagined sensations are like. Despite the unique nature of their qualia, the different sensory modalities have evolved to work in concert.

Because we know our world through our senses, and this knowledge is essential for survival, evolution has favored the creation of multiple senses that coexist in the same individual. It has also devoted massive amounts of brain tissue to ensure that the sensory information received is effectively processed so that it can modify perception and behavior. Each sensory modality carries somewhat different information because each is tuned to a different form of physical energy. Although this discussion is limited largely to sight, sound, and touch, many organisms depend on somewhat more exotic senses that are tuned to such stimuli as reflected sound (e.g. the echolocation and sonar capabilities of bats and dolphins), electrical currents (some fish), infrared heat (pit vipers), and magnetic fields and/or polarized light (migrating birds). Having multiple sensory modalities increases the range of possible stimuli that an organism can use to detect an event, allows the senses to substitute for one another when necessary (touch, smell, and hearing can substitute for vision in the dark) and can reduce ambiguities that often occur when evaluating an event through only one sensory dimension (two events may sound alike but look different).

For these reasons alone, developing multiple sensory modalities would have been extremely useful, and would have had a significant impact on evolution. However, there is a consequence of this evolutionary development that goes well beyond the obvious assets associated with the simple addition of new systems, and that is the ability to use the information carried by different sensory modalities in an integrative fashion. This 'multisensory integration' is possible, in large part, because many areas of the brain serve as common targets for multiple sensory channels and contain neurons that are able to share and compare the cross-modal information they receive. The final product of these processes is the enhancement of signals in the brain that are linked to common events, and hence are meaningful in an operational sense, as well as the suppression of nonmeaningful, or distracting, signals. This is obviously useful in determining which events are to capture an organism's immediate attention and overt responses. The efficiency of this system could not be achieved with independent channels of sensory information, and the neural bases for this multisensory integration are explored in more detail below.

Even without modern neurophysiological studies, the existence of neural mechanisms capable of synthesizing cross-modal cues – and even some of the principles by which these mechanisms must function – can be readily surmised from perceptual experience. As noted earlier, cues in one sensory modality can alter judgments in another. These cross-modal phenomena have been noted for some time, and it has become evident that one can often create cross-modal illusions by introducing slight discrepancies into the normal relationship between the different sensory stimuli that ordinarily are derived from the same event. This has been exploited by entertainers who have mastered the ventriloquist's art. We know that the dummy is not speaking, but the movement of its lips (and sometimes its head and eyes) in rough synchrony with what we hear produces a compelling illusion that the sound is coming from its mouth.

Actually, the ventriloquist's trick is less a consequence of the entertainer's skill (though few of us could drink water while reciting a limerick) than of the manner in which our brains integrate the visual and auditory cues associated with speech. The spatial resolution of the visual system is extraordinary, and it is no accident that it is this sensory modality on which we depend most heavily for locating events in space. Hence, the spatial discrepancy between what is received by the ear and the eye is resolved by the brain, attributing the source of the speech to the more compelling visual stimulus – the dummy. The far more common form of this illusion is experienced whenever we watch a film or a television show. The sounds are linked to events on the screen regardless of their location, when in reality all the sounds are coming from the same source: the speakers in the cinema or in the television cabinet.

There are many cross-modal illusions that involve different combinations of unimodal cues. Some involve translocation of the apparent source of the stimulus, others involve apparent changes in the meaning of the stimuli. Yet each serves as another illustration of the fact that the brain readily combines information from different senses in order to construct a representation of the outside world. This is a normal functional process, and in most circumstances the multiple sensory cues derived from a single event are coincident in space

and time. Such cross-modal cues produce an enhanced perceptual and/or behavioral product that can exceed statistical predictions based on responses to the individual unimodal cues.

THE SUPERIOR COLLICULUS

A Model for Understanding the Neural Bases of Multisensory Integration

Information from different senses is brought together in the brain by the convergence of their various projections onto the same neurons (Figure 1). Whenever and wherever such convergence takes place there is the opportunity to synthesize information from the sensory modalities involved and, it is important to note, this sort of sensory convergence takes place at all levels of the neuraxis. Thus, it is a common event, and the sites involved are generally found outside the primary projection pathways (those pathways that carry information in its most direct route from the peripheral sensory organ to a primary sensory cortex). One of the best known and most closely studied of these multisensory sites is the superior colliculus (SC).

The superior colliculi look like a pair of bumps on the surface of the midbrain (Figure 2). Each SC uses visual, auditory, and somatosensory information to initiate attentive and orientation movements, and it produces these movements through its connections with structures in the brainstem and spinal cord which are in more direct contact with muscles. The sensory cues received by the SC are used both individually and together in order to orient the sensory organs towards an interesting object or event that occurs on the opposite side of the body (i.e. in contralateral space). While the SC is best known for initiating and controlling eye and head movements such as gaze, it is involved in coordinated behaviors in which various peripheral sensory organs (eyes, head, ears, limbs, whiskers, and mouth) are moved contralaterally toward the source of stimulation. Most relevant to this discussion are the observations that have been made about how individual neurons in this structure integrate their various sensory inputs in order to produce these behaviors.

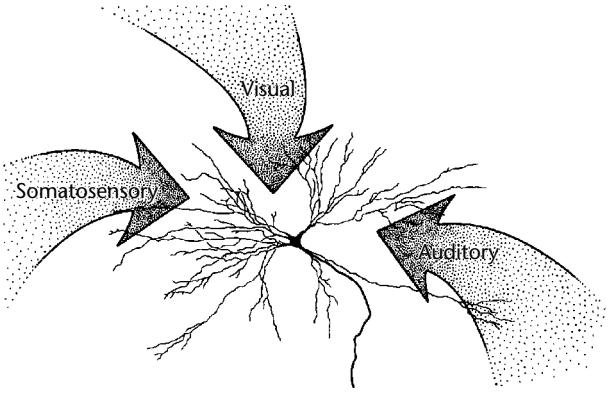

Figure 1. Visual, auditory, and somatosensory neurons often have converging projections onto other neurons, thereby rendering them multisensory. Adapted from Stein and Meredith (1993).

Spatial Register of Cross-modal Receptive Fields

The superior colliculus receives its visual, auditory, and somatosensory information via projections from many brain structures. However, all these projections terminate in the SC in a systematic manner, forming map-like or 'topographic' representations (Figure 3). These maps are composed of neurons, each of which responds to sensory cues only within a circumscribed region of space (its 'receptive field'). Although these inputs are considered sensory and confer sensory responsiveness onto SC neurons, it is important to emphasize that the maps they form are not based on the usual sensory referents that are found in structures more traditionally linked to the processing of unimodal visual, auditory, or somatosensory information. In these 'primary' sensory structures, the visual, auditory, and somatosensory topographies are linked to the retina, head, and body surface, respectively. In the SC, in contrast, each of the 'sensory' representations has been transformed from its own particular (and unimodal) reference frame to a common 'motor' frame of reference, a transformation that is critical for translating a sensory stimulus into a motor action.

The implications of this transformation for orienting can be illustrated by considering the problem of having to shift gaze to an interesting sensory stimulus, one of the primary functions of the SC, and one in which multisensory integration plays a critical role (see below).

Accordingly, there is a systematic arrangement of motor-related SC neurons. Each of these neurons is selective and is most active in association with the generation of a shift of gaze to a particular region of space. Neurons found in progressively more rearward positions of the (right) SC code progressively larger movements of the eyes and head (to the left), whereas neurons progressively further toward the midline code progressively more upward movements and those more lateral produce downward shifts of gaze. As a result, the

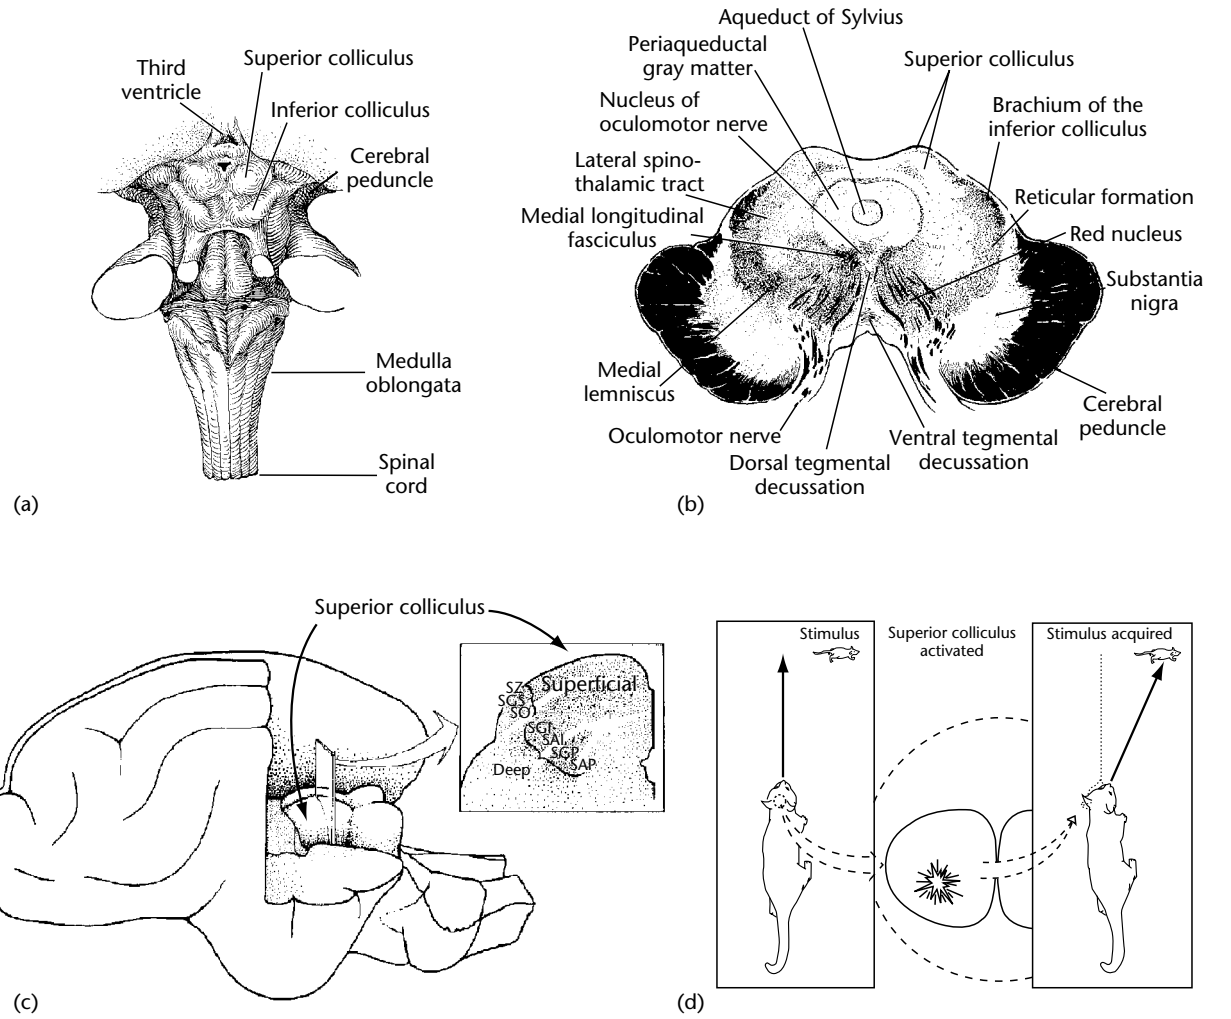

Figure 2. The structure and function of the superior colliculus (SC). (a) Dorsal view of the human brain, in which the overlying cortex and cerebellum have been removed. Note the location of the superior colliculi, which appear as a pair of bumps on the surface of the midbrain. (b) A transverse section through the human midbrain illustrates the location of the SC as well as subjacent tissue. (c) Cat brain, in which the caudal portion of the cerebral cortex has been removed to show the underlying midbrain and SC. A transverse section has been made through the middle of the structure. It is viewed from the front in the inset, and shows the highly laminated organization of the structure in which there are alternating darker (primarily cellular) and lighter (primarily fibrous) layers. The deeper layers are where multisensory neurons are located. SZ, stratum zonale; SGS, stratum griseum superficiale; SO, stratum opticum; SGI, stratum griseum intermediale; SAI, stratum album intermediale; SGP, stratum griseum profundum; SAP, stratum album profundum. (d) Role of the SC in orientation movements. In this example, the stimulus (a rodent) gives rise to a focus of neural activity within the SC's visual topographic map. This activity initiates promotor neural responses that are associated with the orientation of the animal's eyes, ears, and head toward the initiating stimulus. Parts (a) and (b) adapted from Chusid JG and McDonald JJ (1967) *Correlative Neuroanatomy and Functional Neurology*, 13th edn. Los Altos, CA: Lange Medical Publications; parts (c) and (d) adapted from Stein and Meredith (1993).

site of activity within the SC motor map dictates the size and direction of a gaze shift.

Returning to the problem of orienting gaze toward a sensory stimulus, it would seem an efficient coding strategy if the sensory and motor topographies were in register so that the site activated by a sensory stimulus would correspond exactly to the site at which motor-related activity would produce the shift of gaze necessary to look directly at that stimulus. So, for example, if one were looking directly ahead and an auditory stimulus were 10° to the right of midline, the activity it produces in the SC would be at the site at which the activity of motor-related neurons would produce a 10°

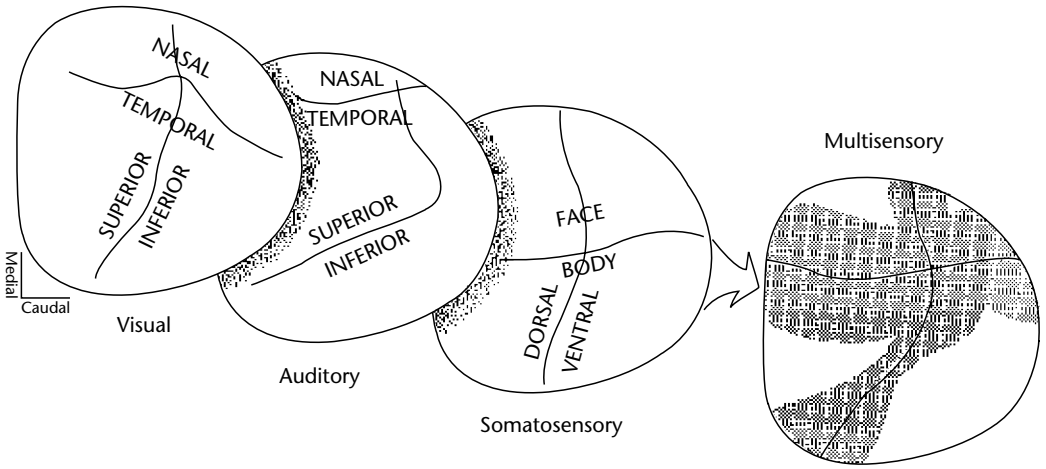

Figure 3. The superior colliculus is composed of maps of visual, auditory, and somatosensory space. These sensory maps have similar coordinate frames and involve many of the same multisensory neurons. Thus, these maps can be viewed as components of an integrated multisensory map. Adapted from Stein and Meredith (1993).

rightward shift of gaze. However, if the eyes happened to be pointed 10° to the left, a 20° rightward movement would be required to look at that same stimulus – a stimulus that has not changed in 'auditory' (head-centered) coordinates. The stimulus must now activate a different site in the SC motor map, one further rearwards in the SC. To ensure that any given auditory stimulus evokes activity at the SC site capable of producing the correct gaze shift, the auditory information has been transformed from a head-centered to an eye-centered frame of reference. The same logic can be applied for a tactile stimulus. Thus, insofar as orienting gaze is concerned, SC sensory topographies represent the position of stimuli with respect to current gaze position, not stimulus position in 'sensory space' as is more commonly done elsewhere in the central nervous system.

The presence of a common reference frame for representing sensory information has important consequences for multisensory integration. By definition, a multisensory neuron is responsive to stimuli from more than a single sensory modality. Accordingly, a multisensory neuron can be viewed as having multiple receptive fields, one for each modality to which it responds. Among SC multisensory neurons, 'bimodal' neurons are most common. These are, in order of incidence: visual–auditory, visual–somatosensory, and auditory–somatosensory. Trimodal (visual–auditory–somatosensory) neurons are also encountered, but they are comparatively rare. A common coordinate system for representing sensory information allows for topographic register among the modality-specific receptive fields, an important factor for the way in which these neurons integrate information.

The general alignment of the unimodal sensory representations has been demonstrated in studies carried out in animals with eyes, ears, head, and body facing forward so that the axes of visual (retina), auditory (head), and tactile (body) space are in approximate alignment with the direction of gaze. For each sensory modality, receptive fields shift systematically across space as one samples neurons in any given direction across the SC. For example, visual or auditory neurons in the front of the SC have their receptive fields in central space (consistent with sites in the motor map that produce small contralateral gaze shifts), whereas those located progressively further rearwards in the structure have their receptive fields shifted progressively more eccentrically into the peripheral aspects of contralateral space (in register with sites that produce larger contralateral gaze shifts). In short, when the animal is facing forwards, neurons in the front of the structure represent the space in front of the animal and those in the rear of the structure represent space in the periphery. The somatosensory representation corresponds to this organization in that neurons with receptive fields on the face are located rostrally (forwards) in the SC and those with receptive fields progressively further back on the body (towards the rump) are located progressively more caudally (rearwards). Neurons found towards the midline (medial in the structure) have receptive fields in upper space (or on the upper body) and laterally located neurons have receptive fields progressively lower in space (or lower on the body). The cross-modal

receptive field register among these neurons ensures that regardless of which sensory cues (visual, auditory, somatosensory) are derived from an event, they will activate the same neurons and thereby lead to activation of the same motor circuitry that is necessary to elicit an appropriate contralateral orientation response.

MULTISENSORY RESPONSE ENHANCEMENT AND DEPRESSION

Multisensory neurons do more than simply respond to cues in different sensory modalities: they are able to synthesize the unimodal inputs they receive into an integrated multisensory product. Operationally, multisensory integration has been defined as a statistically significant difference between the number of impulses evoked by a cross-modal combination of stimuli and the number evoked by the most effective of these stimuli alone. Multisensory integration can result in a response that is markedly enhanced, and that can exceed the arithmetic sum of the individual unimodal responses. It can also result in a response that is markedly depressed and sometimes eliminated. One of the most important determinants of this interaction is the spatial relationship among the cross-modal stimuli.

When stimuli are derived from the same event they also originate at approximately the same time and from the same location, thereby allowing them to stimulate their respective receptive fields of the same multisensory neurons. The two resultant excitatory signals interact in a synergistic fashion to enhance the neuron's response (Figure 4). The magnitude of this response enhancement is generally higher when the individual unimodal stimuli are weakly effective, suggesting that the benefits of multisensory enhancement are especially great when stimuli are difficult to detect individually. On the other hand, if these same stimuli are derived from different locations (e.g. they originate from different events), so that, for example, the visual stimulus falls inside the neuron's visual receptive field and the auditory stimulus falls outside the neuron's auditory receptive field, either response depression will occur, or there will be no interaction at all (Figure 4). These spatial relationships show how important it is to maintain the register among the receptive fields of multisensory neurons even if the peripheral sensory organs move relative to one another. If the register varied, the detection of important events might be compromised, and/or unrelated stimuli might gain preferential access to the circuitry of the SC.

Behavioral studies have shown that the principles that govern multisensory integration at the single neuron level in the SC also apply to SC-mediated overt behaviors. Specifically, cross-modal stimuli derived from the same location in space produce interactions that enhance behavioral responses (e.g. detection and orientation), whereas spatially disparate stimuli inhibit one another's effectiveness (Figure 5).

THE ROLE OF ASSOCIATION CORTEX

Although one might think that when cross-modal inputs converge on a particular neuron, the neuron would automatically be rendered capable of synthesizing these inputs, this is not correct. Some of the multisensory neurons in the SC are unable to synthesize the cross-modal inputs they receive, and nearly all of the others can do so only in the presence of influences from specific areas of association cortex. If these influences are eliminated by temporarily deactivating these areas of cortex, the SC neuron continues to respond to the individual unimodal inputs, but can no longer synthesize these inputs to produce the response enhancement that characterizes normal multisensory integration (Figure 6).

The importance of these cortical influences is also apparent behaviorally. Temporarily deactivating these association cortices has been shown to have no effect on an animal's ability to orient to a visual cue, but compromises its ability to use spatially coincident visual and auditory cues synergistically to enhance its performance (Figure 6). Similarly, the inhibitory effects of a spatially disparate auditory cue on its responses to the visual cue are significantly ameliorated. Thus, these 'association' areas of cortex produce at least some of their associative products via the SC and, in doing so, control some of the behaviors the SC mediates.

SUPERIOR COLLICULUS VERSUS MULTISENSORY CORTEX

Experiments like those described above in the SC have also been conducted in multisensory areas of cortex. Here, too, the different receptive fields of a multisensory neuron show the same sort of spatial register that typifies SC neurons. In addition, the same spatial principles of multisensory integration appear to apply (although the incidence of response depression is somewhat lower and it is less strong), and, as in the SC, the largest multisensory response enhancements are obtained with weakly effective unimodal cues. Lastly, the window

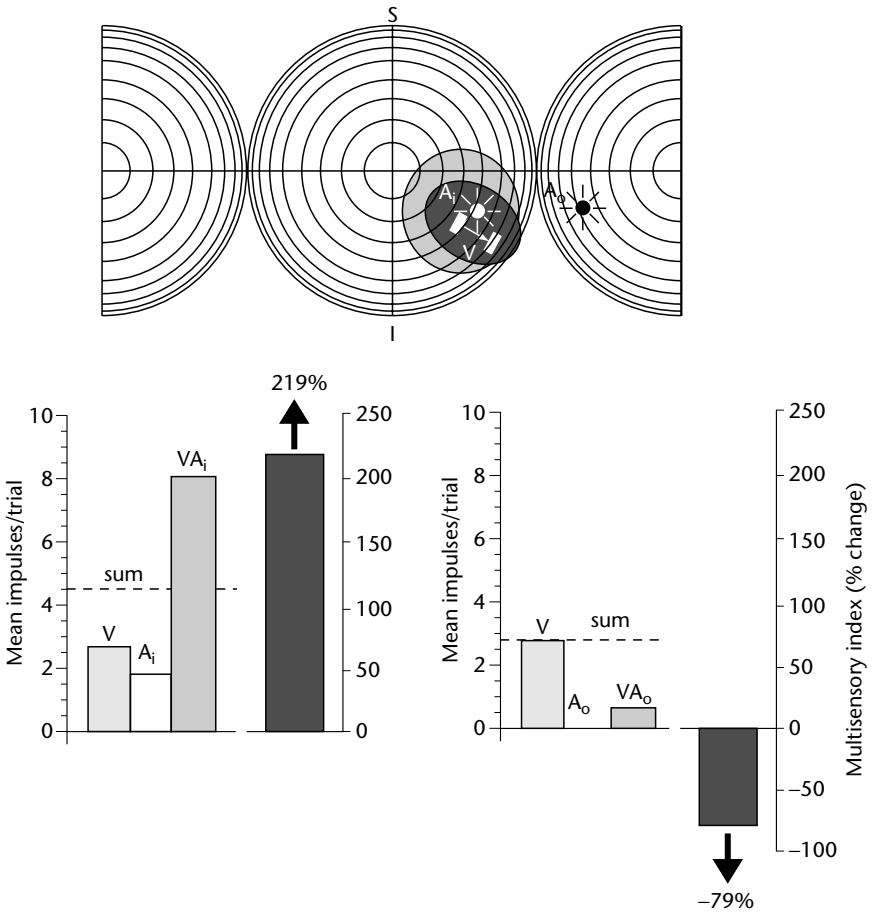

Figure 4. An example of the stimulus conditions that evoked multisensory response enhancement and multisensory response depression in a single SC neuron. At the top are shown the receptive fields (shaded) and locations of the stimuli presented (the visual stimulus is represented by the bar of light with arrow indicating direction of movement; the star represents the location of the auditory stimulus) for examining the multisensory responses of this visual-auditory neuron. The receptive fields are plotted onto a standardized representation of visual and auditory space in which the central 90° of space is depicted by the central sphere. Each concentric circle within the sphere represents 10°; the horizontal and vertical meridians are shown as straight lines. Auditory space extends around the animal, and its caudal aspect is depicted by the two hemispheres that have been split and folded forward. The bar graphs show the modality-specific and multisensory responses of this neuron to stimuli at two different configurations: when both the visual (V) and auditory (A_i) stimuli were within their respective receptive fields and, thus, at similar spatial locations (left), and when the auditory stimulus (A_o) was displaced from the visual and positioned outside its receptive field. The sum of the activity of the two modality-specific stimuli is indicated by the dashed line. Note the large multisensory response enhancement (VA_i) that resulted when both stimuli originated from a similar location, and the depression of the visual response (VA_o) when the auditory stimulus was moved outside its receptive field so that the two stimuli were spatially disparate. Dark shaded summary bar on the right illustrates the proportionate change induced by the stimulus combination (i.e. the multisensory index). This index is calculated by the following formula:

$$[(\mathrm{CM} - \mathrm{SM}_{\max})/(\mathrm{SM}_{\max})] \times 100 = \%\ \text{interaction}$$

where CM is the mean number of impulses evoked by the combined-modality stimulus and $\mathrm{SM}_{\max}$ is the mean number of impulses evoked by the most effective single-modality stimulus.

of time during which cross-modal stimuli can produce a multisensory interaction is similar to that seen in the SC. This parallel between the principles that govern multisensory integration in the midbrain and in the cortex is likely to reflect a more widespread condition that makes intuitive sense. A core of fundamental principles of multisensory integration operating across the brain would ensure that the salience of a given stimulus complex would be enhanced or degraded in the many

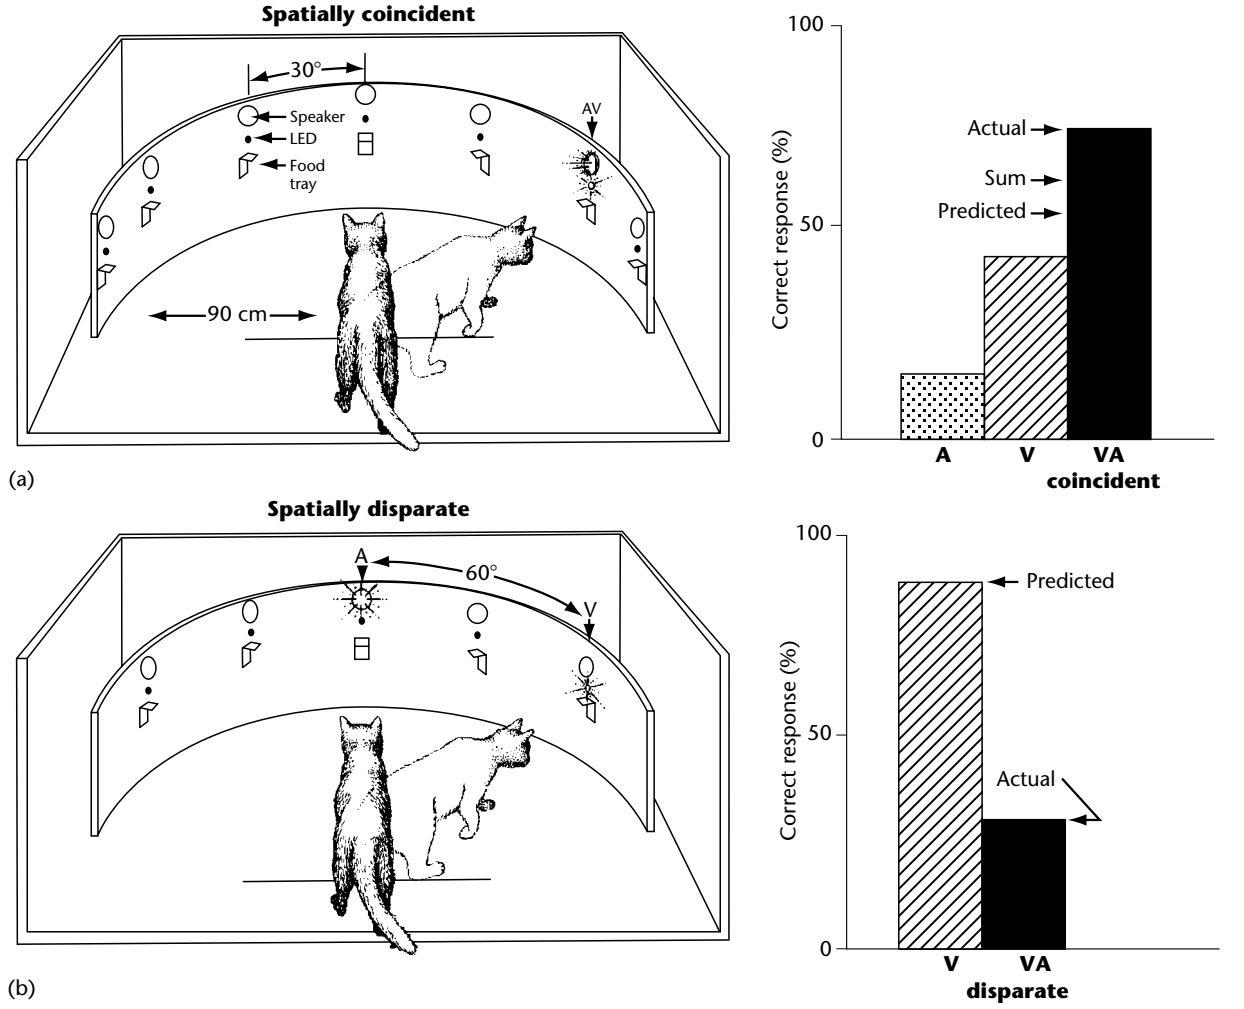

Figure 5. Conditions evoking multisensory response enhancement and multisensory response depression at the behavioral level. The animal is first trained, in the perimetry device shown, to orient to and approach a high-intensity visual stimulus provided by a light-emitting diode (LED). After learning, the intensity of the visual stimulus is decreased until the animal responds correctly on approximately 50% of the trials at each location within the perimetry (it is not trained to respond to the auditory stimulus). (a) Spatial coincidence: when the visual (V) and auditory (A) stimuli were presented at the same spatial location during testing, the cross-modal stimulus combination resulted in a significantly enhanced behavioral response. (b) Spatial disparity: in this case, the intensity of the visual stimulus was increased so that correct responses to the visual stimulus approximated 90%. The concurrent presentation of an auditory stimulus 60° disparate to the visual stimulus resulted in a significant behavioral depression. Adapted from Stein and Meredith (1993).

different brain regions that normally cooperate in producing a complex sensory experience and the behaviors that result from that experience.

Many of these same principles appear to be operative in very different species (e.g. carnivores, rodents, and nonhuman primates), and a number of studies have examined multisensory processes in the human cortex. Using techniques that can record electrical brain activity from the scalp, or that measure localized increases in blood flow by means of new imaging techniques, investigators have identified a number of multisensory areas of human cortex, including the right frontotemporal area, right insula-claustrum, left basal posterior temporal lobe, and the medial inferior parietal lobe. Furthermore, some of the same principles of multisensory integration that have been determined at the single neuron level in animals appear to apply to the activity of networks of neurons in human cortex.

It is not yet known whether the cross-species constancies in the fundamental principles governing multisensory integration that have been discussed here reflect a common origin or the convergent evolutionary pressures of ecological commonalities. Yet, however they came about,

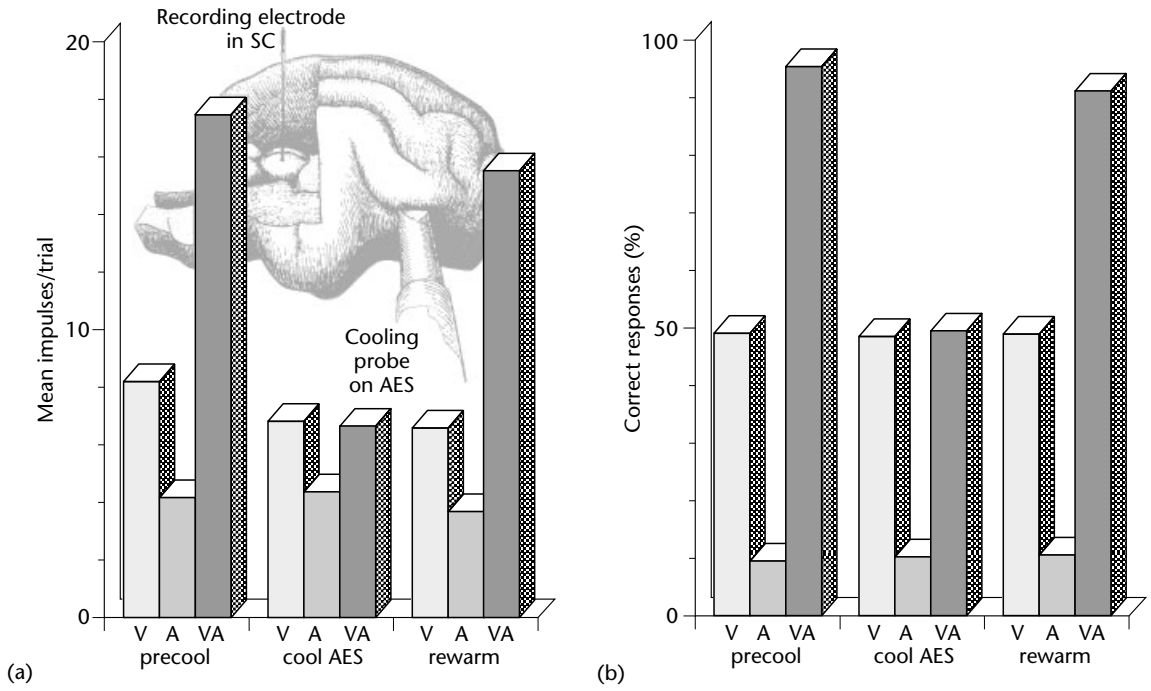

Figure 6. The cortex plays a critical role in mediated multisensory integration in the superior colliculus (SC). Neuronal (a) and behavioral (b) data illustrate the impact of deactivating the anterior ectosylvian sulcus (AES) on multisensory processes. Prior to cortical deactivation ('precool'), the response of the representative visual-auditory neuron to the combination (VA) of a visual stimulus (V) and an auditory stimulus (A) not only exceeded each individual modality-specific response (V or A), but it exceeded their arithmetic sum as well. This multisensory response enhancement was abolished during the deactivation of AES ('cool AES'). Now the response to the stimulus combination is no better than the response to the most effective modality-specific stimulus (V). Multisensory response enhancement returned when the AES was rewarmed ('rewarm'). Deactivation for the behavioral study was accomplished by means of small cooling coils implanted in the AES. Prior to cortical deactivation this animal showed a significant enhancement in correctly responding to the VA stimulus combination. However, deactivating AES eliminated this enhancement so that responses were no better than to the visual stimulus alone. Multisensory response enhancement was restored after cortical reactivation.

these principles appear to be capable of governing the integration of cross-modal information from several different senses. Although it may be reasonable to assume that these same principles are likely to govern the synthesis of information derived from even exotic sensory systems, a little caution may be in order. Because little is known about multisensory integration in systems other than the visual, auditory, and somatosensory systems, and comparatively few animal species have been examined thus far, it may be too soon to rule out the possibility that unique, species-specific principles of multisensory integration will be discovered.

Sex Differences in the Brain

Introductory article

Melissa M Holmes, University of British Columbia, Vancouver, Canada

CONTENTS

Differences between male and female nervous systems exist in a multitude of species. In the human brain, sexual dimorphism occurs in areas related to sexual and maternal behavior, and also to spatial abilities. Gonadal hormones may affect these differences at the developmental stage.

INTRODUCTION

Despite obvious anatomical and behavioral differences between males and females across mammalian species, the discovery of structural and functional differences in the brain was, and often still is, fascinating and controversial.

It is important to clarify that there are sex differences in the nervous systems of a multitude of species, ranging from invertebrates to mammals. Furthermore, a number of nervous system regions have been found to be sexually dimorphic with respect to both gross and microstructural morphology (e.g. the number of neurons, synapses, dendritic branching). A list of common sexual dimorphisms in the brain is given in Table 1. This article discusses the best-characterized dimorphisms of structure that have putative functional significance in human cognition and behavior, particularly the sexually dimorphic nuclei of the preoptic area (SDN-POA), the corpus callosum, anterior commissure, and hippocampus.

DISCOVERY OF THE SEXUALLY DIMORPHIC NUCLEI

The SDN-POA of the hypothalamus is approximately five times larger in the male than in the female in many species, including the human. This dimorphism is intriguing as the SDN-POA is located in the medial preoptic area (mPOA), a brain region that is essential for the expression of sexual behavior in male rats and maternal and sexual behaviors in female rats.

Research focusing on this brain region in humans has been somewhat controversial. In the human brain, there are four interstitial nuclei of the anterior hypothalamus (INAH-1 to INAH-4) and INAH-1 is thought to be equivalent to the SDN-POA. Roger Gorski and colleagues did not find a dimorphism in INAH-1, but they did report that INAH-2 and INAH-3 were significantly larger in human males. Interestingly, Simon LeVay reported that the size or volume of INAH-3 in homosexual men was similar to that of women. Owing to the correlational nature of these data, it is impossible to determine the direction of causality – that is, does the size of INAH-3 determine sexual orientation, or does orientation alter INAH-3 size?

Other sexual dimorphisms in the human brain focus on the connectivity between the left and right hemispheres. The corpus callosum (CC) is the major connective pathway between the two hemispheres and is essential for the communication of information between the left and right sides of the brain. It is thought that females have a larger CC relative to total brain size than males, although not all studies find this particular sex difference. An additional connective structure, the anterior commissure, is also sexually dimorphic, with women having a larger midsagittal area of this structure then men. Further, homosexual men tend to have a larger midsagittal area than either women or heterosexual men. Taken with the aforementioned data relating sexual orientation to INAH-3 size, this further supports a link between sexual orientation and brain structure, although again direction of causality remains elusive. The massa intermedia is an area that can connect the two thalami and is larger in females than in males. Ultimately, these sex differences in connectivity between the

Table 1. A partial list of sexually dimorphic regions in the mammalian central nervous system (CNS)[a]

Region of the CNS	*Sex difference*	*Gonadal hormone effects*
Bed nucleus of the stria terminalis		
MP volume	M > F	Developmental estradiol
MA volume	F > M	Developmental estradiol
Corpus callosum	F > M (humans)	?
	M > F (rats)	Developmental and adult levels of testosterone
Cortex		
Cortical thickness (right hemisphere)	M > F	Development levels of testosterone on left hemisphere
Frontal cortex (dendritic arborization)	M > F	?
Occipital cortex	M > F	Developmental and adult levels of testosterone
Parietal cortex (dendritic arborization)	M > F	?
Hippocampus		
Total volume	M > F	Developmental levels of testosterone
Dentate gyrus	M > F	Developmental levels of testosterone
CA3 (apical dendritic spines)	M > F	?
CA3 (basal dendrites)	F > M	?
CA1 (transmitter activity)	M > F	Developmental levels of testosterone
CA1 (dendritic spine density)	?	Adult levels of estradiol
Medial amygdala	M > F	Developmental and adult levels of testosterone (some controversy)
Hypothalamus		
Periventricular nucleus	F > M	Developmental levels of estradiol
SDN-POA	M > F	Developmental levels of estradiol via aromatization
Suprachiasmatic nucleus	M > F	Developmental levels of testosterone?
Ventromedial hypothalamus		
(total volume)	M > F	Developmental levels of testosterone
(cell nuclei)	F > M	Developmental levels of testosterone
Spinal nucleus bulbocavernosus	M > F	Developmental levels of testosterone

[a]It is important to note that differences can be in area, volume, neuron size or number, spine density, etc., and the reader is directed to the primary literature for more specific details concerning these dimorphisms. Also, these sexual dimorphisms may not be consistent across mammalian species.

hemispheres have fascinating implications for lateralization of cognitive function.

The final sexual dimorphism in the human brain to be discussed here is the hippocampus. Males tend to have larger hippocampal volumes than females in a variety of species and, on average, perform better on spatial tasks than females. The hippocampus is thought to be an important structure for spatial learning and memory. Studies in behavioral ecology have shown that species with a sex difference favoring males in hippocampal volume are also the same species in which males traverse larger territories and have better spatial ability. However, in species in which there is no sex difference in hippocampal volume there is often no sex difference in territory size or spatial ability. Interestingly, female cowbirds have a larger hippocampus than the males and, as brood parasites, are required to navigate more than males.

In adult human males but not females, the right hippocampal formation is larger than the left. This is particularly interesting as the right hemisphere is historically considered to govern spatial ability. Although the sexual dimorphisms in the hippocampus are not as large as in other structures, work with other species suggests that the hippocampus is particularly sensitive to sex differences in experience as well as endocrinological environment (discussed further below).

EARLY HORMONES AND CEREBRAL DIMORPHISMS

Conventional theory regarding hormones and sexual differentiation states that androgens, notably testosterone, are responsible for masculinizing an animal and that estrogens, notably estradiol, are responsible for feminization. Further convention states that hormones can have two types of effects: organizational and activational. Organizational effects are those that occur during a critical or sensitive period during development and have

permanent effects on the nervous system. Activational effects occur later in life and serve to cause transient alterations in behavior. While many exceptions to these two rules have been demonstrated, they remain a suitable framework for considering how hormones alter the development of sexually dimorphic regions of the mammalian nervous system.

The role of testosterone and estradiol in masculinization of the SDN-POA has been well established in rats. Castration of males early in postnatal development results in the development of a feminine SDN-POA, while administration of testosterone to females during development will induce a masculine SDN-POA. Adult hormone manipulations do not appear to have any effects on SDN-POA size, implying that hormone level early in development, during a critical period, is essential for differentiating this sexually dimorphic structure. Interestingly, masculinization of the SDN-POA is not accomplished directly by testosterone in rodents. Testosterone can be metabolized to estradiol through a process called 'aromatization'. In rats, aromatized estradiol causes the masculinization of the SDN-POA. However, research with human and nonhuman primates has suggested that aromatization is not involved in the masculinization of primate brains. This, combined with the difficulty of investigating the human brain, results in little being known about the endocrinological mechanisms that govern masculinization of the SDN-POA, or the relevant INAH, in humans.

Testosterone is involved in the masculinization of the rat CC. Blocking androgen receptors prenatally followed by postnatal castration results in a feminine CC, while administration of testosterone to females results in a masculine CC. Unlike differentiation of the SDN-POA, this appears to be via androgen receptors and not by aromatization to estrogen. However, it is essential to consider that, unlike humans (where females are thought to have greater total CC volume), male rats have greater total CC volume than females, so the endocrine mechanisms underlying differentiation of this structure may not be identical across species. In adult human males, the size of the posterior portion of the CC (which is some studies is larger in males) is positively correlated with adult testosterone concentration. This further implicates a relationship between testosterone level and CC morphology, although these data do not conclusively demonstrate direction of causality, nor confirm the developmental time point at which the hormone may be having its effects.

Gross differentiation of the hippocampus also appears to occur early in development of rats, as sex differences can be seen in prepubertal animals. However, many of the more subtle sex differences in cellular connections or electrophysiological properties can be altered by hormone manipulations in adulthood. This is particularly true for dendritic synapse number, which can be altered in adult female or male rats by manipulating estradiol levels. The hippocampus is remarkably altered by gonadal hormone level (testosterone and estradiol) as well as by behavioral experiences such as stress and enriched environments. Indeed, a number of studies have shown that these interactions can be remarkably different across the sexes: for example, exposure to stress appears to have more dramatic detrimental effects on the male hippocampus compared with the female hippocampus.

It is clear that both androgens and estrogens are essential for sexual differentiation of the mammalian nervous system both in development and adulthood. The reader is directed to work done by Marc Breedlove and colleagues on the sexually dimorphic spinal nucleus of the bulbocavernosus for an excellent demonstration of the complex relationships between endocrinology, a sexually dimorphic structure, and behavior. Owing to the limitations of studying humans, present knowledge of the role of hormones in sexual differentiation of the human brain must come from individuals with endocrinological disorders and generalization from other species.

FUNCTIONAL SIGNIFICANCE OF HUMAN SEXUAL DIMORPHISMS

Many cognitive abilities are sexually dimorphic and these abilities may also be linked to sexually dimorphic brain regions. Females, on average, tend to perform better on tasks of verbal ability, verbal memory, fine motor control, and perceptual speed, while males, on average, tend to perform better on spatial tasks and, in some instances, mathematical reasoning. Interestingly, performance on these cognitive tasks varies with adult levels of hormones. For example, better performance on 'female advantage' tasks is associated with high levels of estradiol, while better performance on 'male advantage' tasks is associated with low levels of estradiol across the menstrual cycle in females. Spatial abilities also vary in human males, with low levels of testosterone being associated with better spatial performance. It is unclear where the neural substrates for each of these abilities lie, but

there is certainly evidence that the areas believed to control each of these cognitive abilities have some degree of sexual dimorphism. For example, the temporal superior gyrus and its subdivisions, areas linked to language abilities, are more often larger in females than males. In addition, the larger CC and anterior commissure size in human females has been purported to result in female brains being less lateralized than males in both structure and function. Studies using functional magnetic resonance imaging (fMRI) to visualize a working brain show that language is less lateralized in women than in men. Interestingly, Elizabeth Hampson has found that dichotic listening (a test of lateralization) is also related to adult levels of hormones in women, with low levels of estrogens being associated with less lateralization.

It is generally agreed that the hippocampus is involved at least partially in spatial learning and memory. Studies using MRI technology have demonstrated that London cab drivers have larger right posterior hippocampi than controls and that the right posterior hippocampal size is positively correlated with amount of cab driving experience. (London cab drivers undergo extensive training to navigate through the labyrinth of streets.) Taken together, this suggests that the sexually dimorphic spatial ability in humans is related to the known sex differences in hippocampus size.

Sex differences in the hypothalamus, specifically in the SDN or the INAH, are likely to be involved in differential expression of sexual behavior. It is well documented in many species that, along with elevated gonadal hormone levels in adulthood, masculinization of the hypothalamus results in the expression of stereotypical masculine sexual behaviors, whereas feminization of the hypothalamus results in the expression of stereotypical feminine sexual behaviors. Although the extent to which this occurs in humans remains unclear, it is certainly plausible that both endocrine level and sexually dimorphic neural structures serve to mediate the expression of sexual behavior in adult humans.

CONCLUSION

It is clear that there are numerous sexual dimorphisms in the human brain and that these dimorphisms probably play an important role in governing sex differences in behavior. The role of androgens and estrogens in the development and maintenance of these dimorphic structures continues to be a prolific area of research. Undoubtedly, androgens and estrogens are also essential for the differentiation of the human nervous system and behaviors, although future research must determine the precise nature of these effects.

Single Neuron Recording

Intermediate article

Jeffrey S Taube, Dartmouth College, Hanover, New Hampshire, USA

CONTENTS

Single neuron recordings are the voltage or current responses monitored extracellularly or intracellularly from individual neurons over time.

INTRODUCTION

Brain functions are largely carried out by electrical activity arising in individual neurons and conveyed to other neurons. The pattern of electrical activity across many circuits within the brain gives rise to all our perceptions, feelings, and behaviors. Monitoring this electrical activity and understanding the neural information it encodes is a central theme of cognitive neuroscience.

In efforts aimed at exploring cortical localization of function, Richard Caton (1842–1926) was probably the first to record the spontaneous electrical activity of the brain (Finger, 1994). In 1875 he reported that an electrode placed on the surface of the skull recorded electrical activity that varied according to where on the skull he placed the electrode and the specific type of peripheral stimuli presented to the person being studied. (*See* **Electroencephalography (EEG)**)

Since these early experiments, many different techniques have been devised to record from populations of neurons in the brain, as well as from individual neurons. These techniques can be grouped into two general categories: intracellular and extracellular recording. Both techniques monitor neural activity by measuring voltage changes over time. This article focuses on recording from single neurons.

INTRACELLULAR RECORDING

Intracellular recording involves the placement of a small electrode (microelectrode) so that its tip is in contact with the inside of the cell. The electrode is then used to monitor changes in the cell's membrane potential over time, particularly the changes that occur during action potentials and postsynaptic events. Because neurons are small – a neuron's cell body (soma) is 10–50 μm in diameter – the tip of a microelectrode must be extremely small so that it can penetrate the cell without excessively damaging the plasma membrane and killing the cell. Although it is possible to record from inside a dendrite or axon, most intracellular recordings are made from the soma because it is the largest part of the neuron. The same microelectrode used to record from a neuron can also be used for passing electrical current or charged particles into the cell.

More recent techniques have used whole-cell patch clamping to record intracellularly. Patch clamping involves pressing a glass micropipette with a small opening against the cell's plasma membrane, as opposed to piercing it with a sharp electrode. If the pipette achieves sufficiently tight contact with the membrane, light suction can be applied so that the small patch of membrane circumscribed by the pipette is ruptured, providing access to the interior of the cell.

Because of the small size of neurons and the stability required for either of these manipulations, at present it is not possible to routinely make intracellular recordings from an awake, behaving animal. Thus, most intracellular recording is confined to neurons in anesthetized animal preparations, thin tissue slices, or tissue culture.

EXTRACELLULAR RECORDING

Extracellular recording monitors the electrical activity of a single neuron from an electrode positioned outside the cell. The electrical activity detected is composed of currents generated in the surrounding neuronal milieu by both action potentials and synaptic events. Extracellular recording from a single neuron (referred to as single unit recording) requires the electrode to be in close proximity to the cell; when the cell discharges, the magnitude of the extracellular current density generated decreases approximately as the square of the

distance from the cell. Single unit recording uses microelectrodes that are advanced into the tissue blindly with the hope that the electrode tip will terminate sufficiently close to a cell to enable detection of cell discharge. The chance of recording a single cell is increased by using multiple electrodes or microelectrodes that are moveable, usually along the dorsoventral axis. Thus, if there are no detectable cells at one location, the electrodes are advanced to a new location and each electrode is checked again to determine whether the waveform of an individual cell can be detected. This procedure is repeated until one of the electrodes can detect a neuron's waveform that is larger than the background electrical activity.

Before the recorded activity is displayed on an oscilloscope, the signal is usually amplified and filtered, so that frequencies below 300 Hz and above 10 000 Hz are significantly attenuated. The low-frequency filtering removes rhythmical brain activity that has higher voltage amplitudes than the single neurons the experimenter is trying to detect, while the high-frequency filtering removes electrical noise inherent in the recording equipment. The waveforms observed are usually biphasic, with the first phase being negative and the second phase positive with respect to ground. Occasionally the waveform is triphasic. The waveform's duration is about 1 ms, and although the peak-to-peak amplitude of the waveform is dependent on the distance between the recording electrode and the cell it is generally in the range 100–300 mV.

Frequently, more than one cell's waveform can be observed when recording with a single microelectrode. It therefore becomes important to distinguish the firing of one cell from another. Different methods have been developed to detect the occurrence of spike discharge. One of the more common techniques uses time–amplitude window discriminators, which detect the occurrence of signals passing through a range of voltages at specific times. Multiple windows in series are frequently used to detect biphasic and triphasic waveforms. More recent techniques use computers and employ template matching programs where the detected waveform must fall within a specified percentage of a 'master template'. Another method uses 'stereotrodes', which are two thin wires twisted together so that their tips are next to one another. Because they are close to one another, each wire usually detects the same nearby cells. However, the electrode that is closer to the cell will record a larger amplitude waveform than the second electrode. Graphs are constructed that plot the amplitude of the signal from one microelectrode against the amplitude of the similar signal recorded with the second microelectrode. Cluster analysis then distinguishes one recorded cell from another. To avoid the problem where multiple cells are simultaneously equidistant from both electrodes, bundles of four wires ('tetrodes') are used to distinguish the cells. Performing cluster analysis using stereotrodes or tetrodes is particularly helpful when recordings of single cells are desired from brain areas where cell density is high, such as the hippocampus.

Extracellular recordings are frequently used in conjunction with either electrical stimulation of afferent pathways or with natural occurring stimuli, such as a flash of light or brief sound. The responses observed are referred to as 'evoked responses'. Sometimes efferent pathways are stimulated and the experimenter is interested in monitoring the activity propagated back to the recording site. This type of activity is referred to as 'antidromic stimulation'.

SLICE RECORDING

Many of the methods devised to record from the brain are limited by the inability to visualize the placement of the electrode. Even when the electrode can be properly placed, the small size of neurons in a respiring animal with a heartbeat that continually produces small brain pulsations makes it difficult to maintain a recording of a single cell – even when the electrode is positioned extracellularly. To accomplish this task with an intracellular electrode requires an anesthetized preparation and considerable patience. Even then, the length of time a cell can be monitored is usually brief. The task of recording intracellularly in an awake, freely moving animal is impossible with current methodologies. However, many questions about neuronal functions and brain mechanisms can be answered only by using intracellular recordings. Thus, it is no wonder that our knowledge of how individual neurons function coincides with the development of the slice preparation.

The slice preparation involves the formation of thin brain slices (250–500 μm thick) from a larger piece of brain tissue using a vibrating tissue slicer or tissue chopper. The slices are placed on a fine mesh in a specialized chamber that warms, oxygenates, and bathes the tissue in a solution similar to the cerebrospinal fluid. Under such conditions, the slices remain reasonably healthy for more than 8 h. A microscope is positioned over the chamber and aids in the accurate placement of microelectrodes for recording and micropipettes for delivering

pharmacological agents into the slice. Thus, access to the tissue is excellent and the problems encountered *in vivo* are avoided. Depending on the plane in which the tissue is sliced, many brain regions retain a large portion of their afferent inputs, permitting the study of individual brain areas with most of their synaptic connections intact. The slice technique has therefore been of enormous benefit in exploring questions about ion channels, synaptic transmission, action potentials, microcircuitry and neuropharmacology.

SHARP AND PATCH ELECTRODES

Two types of electrodes have been used for recording: sharp microelectrodes made from glass micropipettes or fine metal wires, and patch electrodes made from glass micropipettes. Sharp electrodes were the first to be developed and are made from small glass (borosilicate) capillary tubes, known as micropipettes.

The electrodes are made by heating the capillary tube in the middle and slowly pulling the two ends apart. The resultant tip is sharp (1 μm or less for intracellular recording and 1–2 μm for extracellular recording) and in the case of intracellular recording can pierce the cell's plasma membrane with minimal damage. Despite the small tip size that results from the heat treatment, the capillary hole is preserved all the way to the tip. Thus, any solution contained in the capillary tube is in contact with the fluids outside the microelectrode. The shank of the glass micropipette is usually long (5–10 mm) in order to minimize tissue damage when the electrode is inserted into the brain, yet not so long that the shank becomes too brittle and breaks upon insertion into the tissue.

To facilitate filling of the micropipette, especially at the tip, capillary tubing is used that contains a small glass filament running the length of the pipette. This filament enhances the movement of fluid down to the tip through capillary action. The electrical resistance at the recording tip is usually 50–200 MΩ for an intracellular electrode and 5–10 MΩ for an extracellular electrode. A solution containing potassium chloride or potassium acetate is backfilled into the micropipette for intracellular recording, while a sodium chloride solution is used when recording extracellularly. With the electrode filled, a silver chloride coated wire connected to an amplifier is placed in contact with the salt solution. The silver chloride coating reduces potentials that form at the junction between the conductive solution and wire. Occasionally the solution contains a dye, which can be deposited into the cell or surrounding tissue by passing current through the electrode.

Another type of sharp electrode is the metal electrode, which is used almost solely for extracellular recording. These electrodes are constructed from fine metal wires made of tungsten, stainless steel, or nickel–chromium or platinum–iridium alloys. Except for the tip, the wires are insulated with epoxy. Irrespective of the metal used, it is important for the wire to be rigid enough to penetrate neural tissue without bending. Thus, some protocols use thick wires (about 1 mm) tapered at one end to a very fine point (0.5–3 μm). Other protocols, especially when multiple microelectrodes are used, pass several fine wires (each 15–25 μm in diameter) through a stainless-steel cannula that provides the rigidity. In these cases, the recording end protrudes 1–2 mm from the cannula. Sometimes a thin coat of an electrolyte is applied to the tips (e.g. gold plating) to reduce the electrode's impedance and thereby lower the noise characteristics of the electrode. Metal electrodes usually have resistances in the 2–10 MΩ range.

Patch clamp electrodes, like some types of sharp electrodes, are formed from small glass capillary tubes that are heated in the middle and the two halves slowly pulled apart. While the diameter of the opening at the end of the electrode is also small (about 1 μm), the shaft of the patch electrode tapers much more quickly than that of the sharp electrode, resulting in a much blunter tip. When the patch electrode is filled with a salt solution, its resistance is typically 1–5 MΩ. To record from a neuron, the patch electrode is placed next to the cell surface and mild suction is applied to the other end of the micropipette to form a tight, highly resistant seal (about 1 GΩ) between the fire-polished pipette tip and the cell membrane, so that no ions can pass through this junction. Additional suction is then applied and the membrane circumscribed by the electrode tip ruptures. The solution in the patch pipette is then in contact with the intracellular fluid and the cell's membrane potential can be measured over time.

An advantage of the whole-cell patch clamp technique over the sharp electrode technique is that the seal lowers the electronic noise and provides increased sensitivity, while the short, blunt electrode helps minimize the errors made in recording the magnitude and temporal changes in membrane potential.

REPRESENTING RESPONSES

Extracellular recording at the level of the single neuron is most often used when the goal is to

understand brain function in relation to the animal's behavior: experimenters record from single neurons and try to correlate the cell's activity with the animal's behavior. The ongoing behavior or sensory stimuli that best correlates with the unit's activity is referred to as the 'neuronal correlate' for that cell. Experiments using neuronal correlates have been applied to sensory, motor, regulatory, and cognitive systems. Although this is a useful and common technique for inferring the neural mechanisms underlying a particular behavior, the experimenter needs to be cautious because correlation does not imply causation. There are many examples where the activity of neurons in a particular brain area have correlated well with a particular behavior, only for researchers to discover later that lesioning the area has little effect on performance of a task that involves the purported function of the neurons. Thus, the neural mechanisms that underlie a particular behavior can be complex and the neuronal correlates thought to be involved can be redundant or not necessarily essential to the behavior in question. (*See* **Decoding Single Neuron Activity**; **Neurons, Representation in**)

The advantage of intracellular recording over extracellular recording is that it permits the recording of graded synaptic potentials that can lead to spike discharge. At the single cell level, extracellular recording can record the occurrence of spike discharge, but cannot detect the synaptic potentials or ionic currents from a single cell. The type of recording method selected depends upon the scientific issue under investigation and the kinds of measurements required to test a hypothesis. While an extracellular electrode can detect the discharge behavior of individual cells, it is not informative about what the population of cells in the circuit are doing or the nature of the underlying synaptic events that led to cell discharge. For example, the cell may have discharged because of excitatory events activating the neuron, or because of a decrease in inhibitory events impinging on the neuron. Intracellular recording can differentiate between these possibilities, but again, intracellular recording is not informative about population responses and it is nearly impossible to record intracellularly in the awake, behaving animal. Thus, all the different recording techniques have their own advantages and disadvantages, and are complementary. Therefore, in elucidating a particular neural process, several different techniques are often needed to bear on the problem. (*See* **Neural Inhibition**)

Sleep: Polyphasic

Introductory article

Claudio Stampi, Chronobiology Research Institute, Newton, Massachusetts, USA

CONTENTS

Polyphasic sleep describes the ubiquitous rest–activity pattern observed in nature, in which animals show bouts of activity and rest alternating several times per day.

INTRODUCTION

Humans are unique in that they mostly are monophasic sleepers, with a single consolidated sleep episode each night. Most other mammalian species are polyphasic sleepers, and some of them show ultra-short sleep–wake patterns, especially when living in dangerous natural environments. However, humans too have polyphasic patterns, such as in infancy, in sickness, or in around-the-clock operations. Especially in the latter conditions, when time available for sleep may be considerably reduced, and demands for human performance exceptionally high, polyphasic sleep appears to offer one of the most efficient strategies to minimize performance and cognitive impairment resulting from sleep reduction.

WHAT IS POLYPHASIC SLEEP?

The concept of *polyphasic sleep* was introduced for the first time in 1920 by Szymanski to describe the ubiquitous behavioral pattern observed in the animal kingdom, showing bouts of activity and rest alternating several times per day. Indeed, the majority (over 86 percent) of mammalian genera have typical polyphasic rest–activity patterns. The remaining species show a daily pattern of one consolidated period of sleep followed by a period of activity without any sleep, or with the intermission of a relatively brief rest–quiescence period. It appears that evolution led such minority of species to develop the ability to sustain wakefulness for relatively prolonged periods (about 16 hours), without apparent need for much intervening sleep. This is the monophasic activity pattern that is typical of, and well known for, the adult human.

Monophasic activity behavior appears therefore to be an exception to the ubiquitous and primordial behavior of the animal kingdom. However, are adult humans strictly monophasic, or is this just a variant of, or evolution from, an ancestral polyphasic behavior? In other words, do humans *need* to take sleep in one continuous, prolonged period, or can sleep be taken in several naps?

The question of whether we are irrevocably tied to a monophasic sleep pattern in order to function is becoming increasingly important in today's nonstop, around-the-clock society. Sleep occupies a substantial portion of our life span and its quality, duration, and pattern can dramatically affect wakeful functioning and performance. Insufficient or inappropriate rest has been the cause of, or a strong contributing factor to, several accidents that reached catastrophic proportions (e.g., Chernobyl, Three Mile Island, Space Challenger). Is polyphasic sleep then a suitable alternative to monophasic sleep when the latter is not an option?

NATURAL HISTORY OF POLYPHASIC SLEEP

Although the reasons why so many animal species are polyphasic (and – perhaps more importantly – why some of them *may not* be monophasic) are still open for speculation, the answers appear to be related to energy demands and exposure to risk. The negative correlation existing between body mass and metabolic rate is the reason why small mammals are forced to spend most of their waking time foraging. For example, species of shrew have to eat their own body weight of food each day to survive. Animals with such high

energy expenditure levels cannot afford to remain inactive or to sleep for prolonged periods: they must keep eating as often as possible. Indeed, owing to their high metabolic rates, some of these animals will not survive for more than a few hours if they are prevented from feeding.

When exposure to risk is examined, it appears that mammals living under dangerous or adverse conditions display highly polyphasic behavior. For instance, sleep is a particularly vulnerable state in the giraffe, an animal that takes 10 or more seconds to stand up. The giraffe lies down for periods between 3 and 75 minutes, three to eight times a night. Although most of this time is spent awake, it is assumed that the giraffe cumulates only 2 hours of (fragmented) sleep per 24 hours.

Polyphasic sleep naturally occurs in humans during certain situations or phases of the life span. Most typically, this is the natural sleep pattern during the first months of human life, where a 3- to 4-hour cycle in sleep–wake behavior is normally displayed. At the opposite end of the lifetime spectrum, nocturnal sleep is more fragmented in the elderly, and their daytime naps may become relatively frequent, even in healthy, alert individuals. Finally, it is well documented that adult humans do engage in more than one sleep episode per day when given the opportunity to do so.

If polyphasic sleep is then the primordial, ancestral pattern among animals, when in *Homo sapiens'* evolution did behavior become less polyphasic, and why did this happen? Anthropological studies suggest that one possible cause for change might have occurred as recently as circa 10 000 years ago, when the until then dominant hunter-gathering economy began to be gradually replaced by more settled and daytime-oriented agricultural societies. Support for this hypothesis comes from the partially polyphasic behaviors observed in a handful of hunter-gathering tribes that have survived isolated from modern civilization. Studies conducted on the Temiars and the Ibans of Malaysia indicate that their average nocturnal sleep is brief (4 to 6 hours) and that nighttime activities (fishing, cooking, watching over the fire, rituals) at any one time involve approximately 25 percent of the adult members. Daytime napping is widely practiced in both tribes: at almost any time of day, at least 10 percent of adults are asleep.

The next and most recent evolutionary milestone began with the Industrial Revolution and the invention of the light bulb. Having blurred the difference between day and night and dramatically extended the hours available to work, they eventually led to the so-called 24-hour society. Today, it is estimated that in industrialized societies, 20–25 percent of the workforce is involved in night- or shift-work, and this is indeed an important challenge to the practice of a monophasic, nocturnal sleep.

RHYTHMS OF SLEEP AND WAKEFULNESS

Are there any internal or external rhythms driving human sleep–wake and cognitive behaviors, in addition to the widely studied and prominent circadian (24-hour) light–dark cycle? Several have been described, and one of them is the circasemidian (12-hour) cycle. In humans and in most diurnal animals this is typically expressed by an increase in sleepiness in the early afternoon, and is also the explanation for the 'siesta' time observed in the many cultures that have grown to respect this biological drive.

The 90-minute ultradian REM/NREM sleep cycle represents the regular recurrence in sleep of REM (rapid eye movement) and non-REM sleep, two markedly different physiological states. The prominence of the REM/NREM cycle led to the speculation that this is the expression in sleep of a broader basic rest–activity cycle (BRAC), a never-ending beat which persists during both sleep *and* waking. A waking BRAC has been indeed observed for a variety of physiological and cognitive functions. In addition to the BRAC, a 4-hour ultradian periodicity has been observed in the multiple, spontaneous naps of subjects studied in isolation from time cues, in the rest–activity patterns of newborns, or in the pattern of involuntary daytime naps in narcoleptics.

The existence of the ultradian 4-hour cycle, and particularly of the BRAC, is one of the pillars supporting the theory that the ancestral sleep–wake pattern was polyphasic, which in turn helps to explain why humans appear to adapt to it. It is believed that one of the BRAC's functional values, or survival advantages, is to allow multiple transition opportunities, in the 24-hour continuum, from sleep to wake, or vice versa.

POLYPHASIC AND ULTRASHORT SLEEP RESEARCH: EFFECTS ON COGNITION AND PERFORMANCE

Is a polyphasic pattern a more effective solution when normal monophasic sleep is either disrupted, or especially when it is dramatically curtailed? Examples of possible applications range from the problems faced by parents attending the needs of

their newborns at night, to more extreme scenarios involving around-the-clock work, such as observed during emergency, survival, rescue or defense operations.

Two types of study have been conducted to answer these questions. One approach has been to *impose* a variety of polyphasic sleep scenarios in conditions of reduced sleep and then to compare the effects of such schedules to monophasic ones that allowed equivalent sleep time. A large number of field and laboratory sleep reduction studies conducted over the past three decades has shown that highly motivated individuals may be able to maintain acceptable levels of motor and cognitive performance if they sleep a minimum of 4.5 to 5.5 hours per day. Below that level, the effects of sleep deprivation invariably occur. For this reason, most studies comparing poly- versus monophasic sleep have chosen daily sleep quotas of 3 hours, thereby allowing the quantification of measurable decrements.

The most typical study design compared a polyphasic sleep schedule with 30 minutes of sleep every 4 hours to a monophasic sleep pattern allowing the same daily amount of sleep – 3 hours – in the middle of the night. Subjects had to follow each of these schedules under controlled laboratory environments for periods of about one month. These studies have shown that greater decrements in cognitive and psychomotor performance were observed when subjects adopted the monophasic pattern. That is, with only 3 hours' sleep per day, subjects under a polyphasic regimen performed significantly better than those with a monophasic pattern, albeit, as expected, both groups showed more errors than when performance was measured after 8 hours of normal nocturnal sleep.

SPONTANEOUS POLYPHASIC SLEEP DURING EXTREME PERFORMANCE

One of the first natural experiments with polyphasic sleep was apparently conducted as early as half a millennium ago. It has been claimed that Leonardo da Vinci would sleep 15 minutes out of every four hours, for a daily quota of only 1.5 hours' sleep per day. As one of the many unconfirmed yet intriguing enigmas surrounding Leonardo's life, if this were true it would certainly help explain the vastness of his productivity and legacy. More recently, the most compelling evidence of the potential effectiveness of polyphasic sleep came from studies of motivated individuals exposed to prolonged, extreme, and highly demanding around-the-clock work. When the fundamental need for sleep competes with an equally powerful call for staying awake 24 hours per day, will individuals spontaneously follow polyphasic patterns? If this is true, one may assume that they are adopting this behavior because it allows for a more effective waking performance.

Single-handed sailing races across the oceans offer the ideal field model to verify these hypotheses. Solo sailors are exposed for days and weeks to recurrent, and often extenuating demands to be awake, to adjust the yacht to varying conditions of sea and wind, to study complex weather data, and survey the tactics of competitors to obtain maximum speed. When asleep, autopilot yacht control may not be optimal, and risks of collision with other ships or obstacles (e.g., icebergs) increase. Motivation to win is extremely high and is incited by valuable prizes and sponsors' rewards.

Studies of over a hundred solo sailors conducted over the past 20 years, on races ranging from transatlantic (14 days minimum) to round-the-world non-stop (94 days), have confirmed that polyphasic sleep is the preferred strategy. Top competitors average 4.5 to 5.5 hours sleep per day, confirming the results of the sleep reduction studies mentioned earlier. Sailors' polyphasic behaviors showed some relationship with their circadian profile. Morning individuals tended to adopt shorter and more frequent naps, with up to 10 naps per day, averaging 25–30 minutes each. Evening-prone individuals, o the other hand, appeared to prefer fewer but longer sleep episodes. When the same sailors were studied in different races, as was the case with British Ellen MacArthur, the first and youngest woman to win the transatlantic race, it was found that their daily sleep amounts were reduced, and that sleep was more polyphasic, in the shorter races (transatlantic) compared to the longer ones (round-the-world).

CONCLUSION

Contrary to the common assumption that adult humans are dependent on a rigid, monophasic sleep–wake system, the issues briefly reviewed here point to the high level of plasticity of sleep regulatory mechanisms. Not only do adult humans adapt to polyphasic behaviors, but such strategies appear more advantageous during demanding conditions that involve dramatic sleep reduction. Such ability may represent the behavioral expression of the various underlying biological rhythms of sleep propensity. It also suggests that the recuperative value of sleep on performance and cognition is not linearly correlated with sleep duration.

Indeed, studies on polyphasic sleep have repeatedly indicated that short naps are responsible for remarkable recuperative effects, disproportionate to their duration. Rather, sleep recuperative power might be best represented by an exponential function, providing highest recuperative value at the beginning of sleep. As a result, under a restricted sleep regime, the strategy of choice is to recharge the sleep 'batteries' more often with short sleep episodes, and preferably prior to the occurrence of cognitive decrements.

Sleep Reduction, Cognitive Effects of

Introductory article

John PJ Pinel, University of British Columbia, Vancouver, British Columbia, Canada
Steven J Barnes, University of British Columbia, Vancouver, British Columbia, Canada

CONTENTS

Even minor sleep loss (e.g., 3 or 4 hours for one night) increases sleepiness, disturbs mood, and reduces vigilance. More complex cognitive and motor disturbances have been reported after sleep loss, but they have been proven to be less sensitive. Remarkably, the few studies of individuals who have adopted long programs of reduced sleep (e.g., 5.5 hours per night) suggest that their sleep gradually becomes more efficient, and their initial deficits diminish.

INTRODUCTION

Sleeping for fewer hours than one would ideally choose is commonly referred to as *sleep loss*. Identifying the adverse effects of sleep loss has been a major focus of research because it may provide insights into the function of sleep. The fact that all mammals and their evolutionary relatives spend a substantial proportion of their time sleeping suggests that sleep plays a critical role in maintaining normal function, but this role remains a mystery.

There are also practical reasons for determining the effects of sleep loss. Many individuals suffer from chronic sleep loss (e.g., medical interns, soldiers, mothers of young babies, or those suffering from sleep disorders), and it is important to understand their functional disabilities in order to counsel or treat them, or to design their environments in such a way as to limit the risk of mishaps.

THE NATURE OF SLEEP AND DIFFICULTIES IN ASSESSING SLEEP LOSS

Identifying the disruptive effects of sleep loss appears to be a simple matter. Virtually everyone has experienced the effects of sleep loss, and the debilitative effects seem to be compelling and obvious. However, there are several factors that complicate their identification.

One complicating factor is the fact that sleep is not a unitary phenomenon. Although it is commonly regarded as a single entity, it actually comprises distinct phases which may serve different functions. When one first falls asleep during a normal night's sleep, the cortical electroencephalogram (EEG) is characterized by a predominance of low-amplitude, short-duration waves. Then, as sleep ensues, the predominant waves gradually increase in amplitude and duration. For the purposes of analysis, this gradual progression from smallest to largest sleep EEG waves is artificially divided into four distinct phases, with the stage 1 sleep EEG being characterized by the highest density of the smallest, fastest sleep waves (theta waves), and the stage 4 sleep EEG being characterized by the highest density of the largest, slowest waves (delta waves). Although the average amplitude and duration of sleep EEG waves are the usual means of distinguishing between the various sleep stages, other differences exist. For example, sleep spindles (intermittent waxing and waning 1- to 2-second bursts of 12- to 14-Hz waves) tend to be restricted to stage 2 sleep.

Once a sleeping individual has progressed through sleep stages 1 to 4, the progression is reversed back through the stages. An entire cycle from stages 1 to 4 and back to 1 typically lasts about 90 minutes. Then the sleeper spends the rest of the night going back and forth through the sleep stages in a pendulum-like manner. However, an important change occurs as a typical night of sleep unfolds. The first half of a night's sleep contains much more slow-wave sleep, whereas the second half contains much more stage 1 and stage 2 sleep.

The initial stage 1 EEG episode is uneventful, but thereafter each period of stage 1 EEG tends to be accompanied by a variety of physiological changes, such as increased pulse and blood pressure, extreme relaxation of the muscles of the body core, irregularity of breathing, and a pattern of rapid eye movements (REMs). Accordingly, periods of stage 1 EEG sleep after the initial episode are typically referred to as *REM sleep*. The EEG of REM stage 1 differs slightly from the initial stage 1 EEG in several respects, the most obvious being the occasional appearance of bursts of slightly larger, slower, sharply pointed waves, which are termed *sawtooth waves* because of their appearance.

REM sleep is of particular interest because of its association with dreaming. When sleeping subjects are awakened during REM sleep, they tend to report that they have been dreaming, and they can recount the dream. However, although the relationship between REM and dreaming has been well documented, the association is not all or nothing in nature. On some occasions subjects who are awakened during REM sleep do not report dreams. On the other hand, on some occasions subjects who are awakened during slow-wave sleep (SWS) do report dreams. However, the psychological experiences associated with REM sleep tend to have more of a narrative quality than those that are associated with SWS. Because of the relationship between dreaming and REM, the fact that the proportion of SWS decreases and the proportion of REM sleep increases as the night progresses suggests that more dreaming occurs late in a night's sleep. In the present context, it is important to bear in mind that any detailed understanding of the effects of sleep loss must address the fact that SWS and REM sleep appear to serve different functions.

The following four factors also tend to complicate any interpretation of the effects of sleep loss. First, many situations in which there has been sleep loss also involve disturbances of circadian cycles, which themselves can produce physiological and behavioral disturbances. Secondly, when sleep loss occurs in natural situations, it has often been caused by stressful events (e.g., worry or an excessive workload), which themselves could have deleterious functional effects. Thirdly, there is often a surprising dissociation between the subjective feelings of sleep-deprived individuals and their actual abilities. Fourthly, the expectations of sleep-deprived individuals need to be taken into account.

Because of these problems with regard to interpreting the effects of sleep loss, efforts to identify those effects have relied on the results of controlled experiments. There are two fundamentally different types of sleep loss experiments (which will be discussed separately in the following two sections), namely short-term studies, which typically last for several days or less, and long-term studies, which typically last for several weeks or more.

EFFECTS OF SHORT-TERM SLEEP REDUCTION

Studies of short-term sleep reduction (those that involve sleep-reduction schedules of several days or less) can be divided into two distinct subcategories, namely those in which the deprivation is total (e.g., no sleep for 3 days) and those in which it is partial (e.g., 4 hours of sleep per night for 3 days). One of the early studies of short-term total sleep reduction was the classic 1922 study by Kleitman, who found that students were capable of staying awake continuously for several days with no major performance deficits that could not be attributed to their overwhelming tendency to fall asleep. Remarkably, the sleepiness of the participants did not develop monotonically. For the first 3 days they were much more sleepy during the night than during the day, with each successive day becoming more problematic than the one before. However, by the end of the third sleepless day, the circadian cycle of sleepiness became no more severe.

Unlike Kleitman's study, which was largely anecdotal, modern studies of sleep reduction have focused on the objective assessment of its effects. Effects of four different types have been widely investigated, namely physiological effects, deficits in motor performance, mood changes, and cognitive deficits. The implicit premise on which many of these studies have been based is that sleep serves a critical, albeit unknown survival function, and that it is maintained at a homeostatic level by unknown regulator mechanisms. The goal of these studies has been to document the adverse effects of disturbing this homeostasis. The fact that increases in negative mood and decreases in the time needed to fall asleep reliably occur after as little as 3 or 4 hours of sleep loss for one night is consistent with the idea that sleep is homeostatically regulated. However, the inconsistency of other effects of short-term sleep reduction has been less compatible with this view. For example, it has proven difficult to demonstrate adverse disturbances of physiological function or motor performance produced by sleep loss that are reliable from one study to another. For instance, various studies of up to 72 hours of sleep deprivation have not found reliable changes in muscle strength or

in cardiovascular or respiratory responses to heavy exercise. Although sleep-deprived individuals do feel that exercise requires more exertion, and they report exhaustion more quickly, these effects have not been confirmed by cardiovascular measures.

The effects of short-term sleep deprivation on cognitive abilities have been puzzling. Performance on complex demanding cognitive tests, which one would expect to be most sensitive to sleep loss, is sometimes unaffected. In contrast, simple tests of vigilance are consistently sensitive to sleep loss. For example, in one common test, sleep-deprived individuals listen to a series of tones and respond to those tones that are slightly shorter than the others. Loss of 3 or 4 hours of sleep on one night is sufficient to produce reliable deficits on this type of task, particularly if the task is lengthy.

It has been suggested that the cognitive deficits caused by sleep reduction are entirely attributable to microsleeps (3- or 4-second periods of sleep that commonly occur in sleep-deprived individuals, sometimes even when they are standing or sitting). According to this view, sleep-deprived people experience a powerful drive to sleep, which disrupts their performance, but while they are awake they perform normally. However, a careful analysis of the performance of sleep-deprived individuals does not support this interpretation. If it were correct, performance would be normal with occasional lapses in performance during the microsleeps, but this pattern has not been observed. For example, sleep-deprived people perform poorly on simple vigilance tasks even when they are not experiencing microsleeps; and on more complex cognitive tasks, sleep-deprived subjects often respond inappropriately, rather than just displaying occasional lapses of performance.

In 1997, Dinges and colleagues conducted a particularly thorough study of short-term sleep deprivation. The sleep of the participants was reduced to 5 hours per night for 7 days. As a result, they displayed deficits on several tests of sleepiness, mood, vigilance, and cognitive function. Of most interest was the finding that there was a gradual increase in the effects of sleep loss over the 7-day period, indicating that the effects of several nights of sleep reduction can accrue, at least in the short term.

In summary, studies of periods of partial or total sleep reduction lasting for several days or less have consistently shown that the loss of as little as 3 or 4 hours of sleep for one night increases sleepiness, disturbs mood, and decreases vigilance. In contrast, the performance of more challenging cognitive and sensorimotor tasks has proved to be less sensitive to sleep loss – deficits have tended to require more extreme sleep loss, and have been less consistently reported. In addition, various physiological changes have been reported following sleep loss (e.g., in the pattern of hormone release), but so far none of them has proved to be sufficiently large or reliable to suggest why sleep that is composed of both REM sleep and SWS has evolved in all mammals and birds.

EFFECTS OF LONG-TERM SLEEP REDUCTION

A second type of study of sleep reduction has focused on the effects of long-term programs of reduced sleep (e.g., 5.5 hours per night for 6 months). One method that has been used in these studies is to have the participants reduce their sleep gradually in small (e.g., 30-minute) increments until they reach the target level. These studies are particularly significant because they focus on an important point about sleep that is of major theoretical significance and is not addressed by studies of short-term sleep loss. This point is that once individuals begin to sleep less on a regular basis, their sleep seems to become progressively more efficient.

Several lines of evidence indicate that SWS is largely responsible for the restorative power of sleep in humans. For example, people who consistently sleep less tend to have sleep with a higher proportion of SWS, and they often get as much SWS as those who sleep much more. Moreover, following several nights of total sleep deprivation, there is a major increase in the proportion of SWS for the first few recovery nights, even though there is only a minor increase in total sleep.

What happens when people are placed on long-term restricted-sleep schedules? In one study, the eight participants gradually reduced their sleep time in 30-minute increments until they experienced prohibitive chronic fatigue. Two individuals reduced their sleep to 5.5 hours, four to 5 hours, and two to 4.5 hours. The participants were then required to sleep at their lowest level plus 30 minutes for the remainder of the experiment, which lasted 6 months. As the participants reduced their sleep, its efficiency increased. The proportion of SWS increased, the time needed to fall asleep decreased, and the number of night time awakenings decreased. A large battery of medical, personality, performance, mood, sleepiness, and cognitive tests (including a test of vigilance) failed to reveal any deficits. Indeed, when the participants were

revisited 12 months after the end of the study, all of them were sleeping 1 to 2.5 hours less per night than they had been doing before the study.

In a similar study, participants reduced their amount of sleep to 5.5 hours per night in one step, and then slept at that level for 2 months. They initially experienced daytime sleepiness and difficulty awakening from sleep in the morning, but as the efficiency of their sleep increased, these adverse effects disappeared. Again, a large battery of tests revealed no clear cognitive, performance, or mood deficits.

One currently active line of research on long-term sleep reduction involves polyphasic sleep schedules, in which the sleep of the participants is limited to several scheduled naps in each 24-hour period (e.g., 30 minutes every 4 hours). Naps have proved to be particularly effective in reducing the adverse effects of sleep loss. Consequently, individuals who learn to take all of their sleep in the form of naps can reduce their sleep to remarkably low levels in the absence of obvious dysfunction. (*See* **Sleep: Polyphasic**)

Despite the consistent results of studies of long-term sleep reduction and their provocative implications, these studies have one major weakness. They are rare, presumably because their duration is prohibitive for most researchers. Still, it seems likely that ultimate conclusions about the minimum requirements of sleep for effective cognitive functioning will of necessity rest on the results of these types of studies.

CONCLUSION

In the short term, even a few hours of sleep loss disturbs mood, increases sleepiness, and diminishes vigilance, and more extensive sleep loss can produce a variety of motor and cognitive deficits. It is important to appreciate the nature of these deficits because the demands of modern life impose short-term sleep loss on many people. Although there have been far fewer studies of long-term sleep reduction, their findings have been consistent and provocative. Most participants in long-term sleep reduction experiments have been successful in reducing their sleep to 5.5 hours per night or less. Initially they experience fatigue and other expected adverse effects, but if they persist, the efficiency of their sleep increases, and the obvious adverse effects of their new sleep regimen diminish.

CONTENTS

Somesthesis is the awareness of sensation from the skin, muscles, joints, and viscera, through specialized receptors in the skin and deep tissues.

INTRODUCTION

Somesthesis is the awareness of sensations from the skin, muscles, joints, and viscera. Its neural basis is the specialized receptors located in the skin and deep tissues that are selectively sensitive to mechanical stimuli of various kinds (e.g., pressure, vibration, body position, and movement), changes in skin temperature (warmth and cold), chemical stimuli of certain kinds (e.g., histamine, which activates itch receptors) and noxious stimuli. In order to convey the specificity of somesthesis, this discussion concentrates on the neural basis of discriminative tactile sensation from the human hand.

The human hand is a complex organ that is used to explore the world around us and to manipulate objects. We do so both directly and indirectly. In direct exploration and manipulation, information about surface features, object size, shape, and weight are communicated to the brain by specialized mechanoreceptive and proprioceptive receptors in the skin and muscles. The object's surface features and texture are signaled by one group of mechanoreceptors. Its shape is signaled by these mechanoreceptors together with proprioreceptors in the muscles and deep tissues. The proprioceptors also signal object weight, hand conformation, and finger location. Another group of mechanoreceptors in the skin provides feedback signals for grip control. Two groups of thermoreceptors signal object temperature: one group is selectively sensitive to warming, the other to cooling. In indirect exploration and manipulation we use tools or probes as extensions of our hands. Even though a probe or tool comes between our hands and the object of interest, we commonly perceive the object as though our fingers were present at the working surfaces of the tool or probe. This perception of distant events depends on (1) specialized mechanoreceptors in the hand which respond to minute vibrations created by interactions between the tool and the object being probed, and (2) other receptors that respond to reaction forces transmitted to the hand from the object.

Perception from the hand begins with the activation of 13 kinds of afferent fibers that receive information from receptors embedded in the skin and deep tissues. These afferents respond with a high degree of specificity to different kinds of internal and external stimuli. In everyday life all of the receptors (except the pain and itch receptors) are continuously active and send a constantly changing dynamic representation of the external world and the internal state of our tissues to the brain.

Four of the 13 afferent fiber types provide information about discriminative touch on the glabrous skin, and evidence discussed below suggests that these four kinds of mechanoreceptive afferents serve different sensory functions (for a detailed review see Johnson 2002). The slowly adapting type 1 (SA1) system, which terminates in Merkel receptors, provides the basis for the perception of local features (edges, corners, points) and the perception of surface form and texture. The rapidly adapting (RA) system, which terminates in Meissner corpuscles, provides the basis for the perception of low-frequency vibrations and provides feedback signals required for grip control. The Pacinian corpuscle (PC) system, which terminates in Pacinian corpuscles, provides the basis for the

perception of events distant from the hand signaled by minute vibrations. The slowly adapting type 2 (SA2) system provides information about hand conformation and about shear forces acting parallel to the skin surface (Edin, 1992).

SPATIAL DISCRIMINATION THRESHOLDS

There is much evidence that the threshold for spatial acuity is determined by the SA1 system. Three different psychophysical tasks – a gap detection task, a grating orientation task and a letter identification task – demonstrate that the threshold (element spacing that produces performance midway between chance and perfect discrimination) at the fingertip is about 1.0 mm (Figure 1; Johnson and Phillips, 1981). Acuity is not uniform across the body surface. It is highest at the lip and tongue (threshold about 0.5 mm; Van Boven and Johnson, 1994), lowest around the calf (about 30 mm; Stevens *et al*., 1996) and steadily decreases with age (threshold at the fingertip is about 3.0 mm for 80-year-old subjects; Stevens *et al*., 1996). Anatomical studies show that the performance at the fingertips is close to the theoretical limits imposed by the innervation densities of either the SA1 or RA and that it far exceeds the spatial capacity of the PC and SA2 afferent fibers. There are approximately 100 SA1 and 150 RA afferents per square centimeter (Johnson, 2002). These innervation densities correspond to mean spacings between individual fibers of about 1.0 mm and 0.82 mm respectively, which is similar to the limit of tactile spatial resolution at the fingertip. Evidence that acuity is determined by the SA1 system alone comes from neurophysiological studies in monkeys and humans demonstrating that only the SA1 afferent fibers are able to resolve spatial patterns with spatial feature separated by about 1.0 mm (Phillips and Johnson, 1981; Phillips *et al*., 1992).

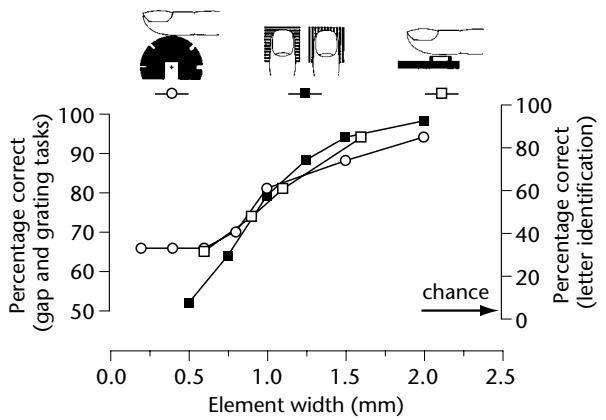

Figure 1. Human performance in gap detection (open circles), grating orientation discrimination (filled squares), and letter recognition (open squares). The abscissa represents the fundamental element width for each task: gap size for the gap detection task, bar width (half the grating period) for the grating orientation discrimination task, and the average bar and gap width within letters (approximately one-fifth of the letter height) for the letter recognition task. Threshold is defined as the element size producing performance midway between chance (50% correct for the gap and grating tasks, 1/26 for letter recognition) and perfect performance. Adapted from Johnson and Phillips (1981).

DISCRIMINATION OF COMPLEX SPATIAL PATTERNS

The perception of complex spatial patterns (e.g., Braille or embossed letters) is robust. It is relatively unaffected by contact force (over the range 16–128 grams; Loomis, 1985), by stimulus height (over the range 0.24–1.92 mm; Loomis, 1985), by scanning velocity (over the range 20–80 mm s^{-1}; Vega-Bermudez *et al*., 1991), by stimulus orientation (medial–lateral discrimination is the same as proximal–distal; Craig, 1999), whether patterns are scanned actively or scanned across the passively restrained hand (Vega-Bermudez *et al*., 1991), and whether the pattern is scanned or indented into the skin without horizontal movement (Phillips *et al*., 1983).

Humans discriminate surface curvature well. When a single finger pad is used, the threshold for discriminating a flat surface from a concave or convex surface is about 5 m^{-1} (radius 200 mm; Goodwin *et al*., 1991). People also discriminate very small changes in curvature accurately (e.g. 144 m^{-1} versus 158 m^{-1}). Goodwin and his colleagues have shown that only the SA1 mechanoreceptors can account for this perceptual capacity (Goodwin *et al*., 1995). When several fingers are used, the discrimination thresholds for flat surfaces decrease to around 0.5 m^{-1}; i.e. using three fingers we can distinguish a flat surface from one with a 2 m radius (Pont *et al*., 1997).

Slowly adapting type 1 afferents are sensitive to negative as well as positive surface curvature and provide the central nervous system with an isomorphic representation of the local two-dimensional and three-dimensional structure of stimuli on the skin (Figure 2). The neural responses of these afferents are only moderately affected by changes in contact force and scanning velocity (see Figure 2).

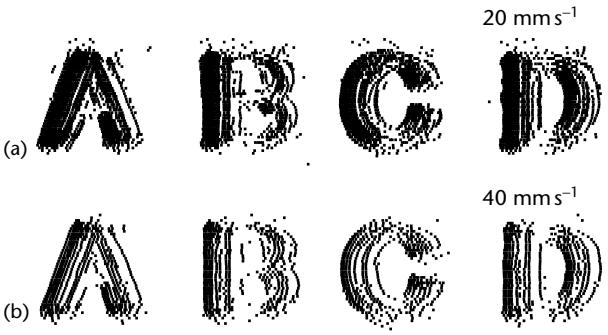

Figure 2. Spatial event plots from a representative slowly adapting type 1 (SA1) afferent fiber. Each tick represents the occurrence of an action potential evoked by the embossed letters A, B, and C (6.0 mm high) which were repeatedly scanned across the neuron's receptive field. After each scan, the embossed letter was shifted 200 μm in the vertical direction and the scan repeated. The plots show the responses after about 70 scans of the letter across the receptive field at two different scanning velocities – (a) 20 mm s^{-1} and (b) 40 mm s^{-1} – demonstrating that peripheral SA1 afferents provide an isomorphic representation of the letter (independent of scan velocity) to the central nervous system.

TEXTURE PERCEPTION

Multidimensional scaling studies show that texture perception is composed of two main dimensions (smooth–rough and soft–hard) and, possibly, a weaker third dimension that is not well understood (Hollins *et al*., 1993). Roughness, like form perception, is only mildly affected by contact force and scanning velocity. Studies using raised gratings as stimuli show that roughness increases as groove width increases and decreases as ridge width increases (Lederman, 1983). Studies using raised dot patterns show that roughness perception increases as the dot spacings increase to about 3 mm and decreases as spacings increase beyond 3 mm (Connor *et al*., 1990). Neurophysiological studies demonstrate that roughness, like form, is conveyed by the SA1 afferents, and perceived roughness is based on the variation in firing rates between groups of SA1 afferents (Yoshioka *et al*., 2001).

Experimentally, people are good at discriminating subtle differences in the softness of objects with deformable surfaces with and without active touch (Srinivasan and LaMotte, 1996). The essence of softness is progressive conformation to the contours of the fingers and hand in proportion to contact force. The degree of softness is signaled by the rate of growth of contact area with contact force and by the uniformity of pressure across the contact area. Conversely, the essence of hardness is invariance of object form with changes in contact force (Johnson, 2002). The ability of SA1 afferents to signal the spatial pattern of skin indentation suggests that they are responsible for softness perception (for a discussion see Johnson, 2002).

PERCEPTION OF MOTION AND VIBRATION

Rapidly adapting afferents are responsible for perceptual functions related to the detection of minute skin motion. This hypothesis is supported by two lines of evidence. The first is the demonstration that only RA afferents account for the detection of low-frequency vibrations (threshold of about 10 μm at 30 Hz; Mountcastle *et al*., 1972). The second is the demonstration that RA afferents are responsible for the detection of minute slips that occur between the object and skin when an object is lifted (Johansson and Westling, 1984). Rapid slip detection is needed for the minute adjustments in grip forces necessary to hold objects securely.

Numerous studies demonstrate that only PC afferents account for the detection of high-frequency vibrations (Mountcastle *et al*., 1972; Brisben *et al*., 1999). Humans can detect vibrations as small as 10 nm at 200 Hz and this is accounted for by the responses of the most sensitive PC afferents (Brisben *et al*., 1999). Studies of the detection of complex vibratory stimuli show that humans are sensitive to the temporal structure of high-frequency stimuli that activate only PC afferents (Formby *et al*., 1992), suggesting that PC afferents are responsible for the ability to perceive vibratory events at the working surfaces of tools held in the hand (Johnson *et al*., 2000).

ROLE OF ATTENTION IN HAPTIC PERCEPTION

Attention plays a critical role in haptic perception (Hsiao and Vega-Bermudez, 2001). Try consciously shifting your attention from one body location to another: notice how the other body locations disappear from your consciousness and how the location attended to dominates it. The degree to which attention can be focused is addressed in experiments in which the participants' ability to ignore distracting stimuli is tested. People asked to discriminate a vibratory stimulus presented to one finger (which depends on information conveyed by the RA system) can ignore distracting stimuli applied to the opposite hand, but not stimuli applied to other fingers on the same hand (Craig, 1985). However, a more recent study has shown that people

can make texture judgments (which depend on the SA1 system) with one finger and completely ignore distracting textures applied to adjacent fingers (Dorsch *et al*., 2001). This suggests that the ability to focus attention may differ between receptor systems – that we can focus attention narrowly when we rely on the system responsible for spatial information (the SA1 system) but not when we rely on the system responsible for the detection of motion on the skin (the RA system).

The psychophysical studies of attention are paralleled by neurophysiological studies in nonhuman primates and imaging studies in humans showing that the responses of neurons in both primary and secondary somatosensory cortex are modified by the attentional state (Hsiao *et al*., 1993; Burton and Sinclair, 2000). The modifications are of two kinds: one is a change in the firing rates of neurons processing information from the body part being attended to; the other is a change in the temporal firing patterns of the action potentials in these same neurons so they become more or less synchronous between neurons. The effect of enhanced firing rates and increased synchrony is enhancement of the saliency of the message conveyed by those neurons (Steinmetz *et al*., 2000).

CONCLUSION

Evidence from psychophysical and neurophysiological research indicates that the different aspects of tactile perception are based on different afferent fiber types. As in the visual system, one afferent system (SA1) appears to be specialized for form and texture perception and another (the RA system) for the detection of motion (Hsiao, 1998). The PC system, like neurons in the auditory system, is specialized to perceive vibratory events at a distance. Research is needed to determine whether modality specificity is preserved in the central processing pathways, and to identify the role and mechanisms of selective attention.

CONTENTS

The neural signals responsible for the control of spatial attention are presumed to stem from activity in specific cortical and subcortical networks and are transmitted via feedback projections to sensory cortex where they exert their modulatory effects.

INTRODUCTION

Suppose you are looking for a folder on the desktop of your computer. You might shift your eyes to different locations or, if the folders are close together, merely shift attention without moving your eyes while looking for the target. When you find a likely candidate you might examine the label carefully to make sure it is correct. When you move your eyes between locations or shift attention between words on the label, you employ a specific network of neural areas that operate to enhance the priority given to information from the selected location in comparison to other places in the visual field. While the acuity of the visual system is relatively fixed by the wiring between retina and primary visual cortex, the priority can be shifted at will to different places in the visual field. Once attention has moved to a new location, the location that had been previously attended appears to be slightly inhibited (inhibition of return), encouraging search of novel areas.

Experiments involving relatively empty visual fields often cue attention to a location by providing a marker at the location where the target might arrive, or by a central or symbolic cue informing the person of the target location. Performance in processing the target can then be compared with performance in the absence of cues providing information about target location. The improvement in reaction time (RT) and detection thresholds with a valid cue over a neutral condition is often slight; however, if the cue indicates a wrong location, the cost in performance is much larger. This illustrates the fact that, if not already engaged, attention can be rapidly summoned to the presentation of a target by luminance, motion or other cues that occur when a target is presented. For this reason a cue prior to the target produces only a small benefit. However, if attention is already engaged in processing a visual stimulus, costs due to disengaging and moving attention to the new location can be considerable.

When the visual field is cluttered with many objects, attention can be moved from location to location in a systematic fashion, or it may be guided by knowledge of the target properties (guided search). In addition, a new target can efficiently summon attention by luminance or motion cues. However, if these cues are artificially removed, the critical role of attention becomes clear. Powerful alterations of the meaning of objects in the field can be made without the viewer being aware of them as long as they are outside the current focus of attention. Thus the strong belief that we are attending to the entire visual field is not a correct one. In fact our attention is limited, but its ability to shift to a target that provides proper cues is impressive.

Visual spatial attention is closely related to the process of making eye movements. Indeed, one of the primary functions of spatial attention may be to identify locations in the visual field that contain pertinent information and to help the oculomotor system guide the eyes to those locations. Saccadic eye movements are preceded by an increase in spatial attention at the location to which the gaze will move. Although the exact correspondence between the network of brain areas responsible for visual spatial attention and that

responsible for planning and executing eye movements remains open to debate, it is clear from recent neuroimaging studies that there is considerable overlap between them.

Visual spatial attention is only one network of the attention system. However, because of its close relation to eye movements and the similarity of its operation between humans and other primates, the neural systems and pathways involved have been better analyzed than for other networks and it serves as a model for linking attention to neural systems.

PATHWAYS OF ORIENTING

Directing spatial attention to a location produces a modulation of the processing of sensory information. These are the sites on which attention operates and they can be distinguished from the sources that guide and control the spatial allocation of attention. The neural signals responsible for the control of spatial attention are presumed to stem from activity in higher cortical areas and are transmitted via feedback projections to sensory cortex where they exert their modulatory effects.

At a simple level, orienting can be viewed in terms of more elementary operations (such as disengage, move and engage) involved in the allocation of attention to locations or objects. Each operation is thought to be mediated by activity in different cortical or subcortical regions. The first two operations, disengaging and moving attention from the current location or object, involve the functioning of the parietal cortex together with the superior colliculus. Engaging attention at the relevant object or location seems to involve the pulvinar nucleus of the thalamus. The view that attentional control is mediated by a distributed network of brain areas is consistent with studies of people with brain damage who show impairments in their ability to direct attention spatially following localized lesions to a variety of brain regions. Different forms of deficit have been described in patients with damage to the temporoparietal junction, portions of frontal cortex, the anterior cingulate cortex, the basal ganglia, and the thalamus (in particular the pulvinar nucleus).

In recent years functional neuroimaging studies, using both position emission tomography (PET) and functional magnetic resonance imaging (fMRI), have played an important part in further investigating the sources of attentional control signals in the human brain. Using a variety of paradigms in which participants covertly direct attention to peripheral visual stimuli, a number of studies have reported activations within a common frontoparietal network of brain areas that seem to be recruited during directed spatial attention. These brain regions include the superior parietal lobe (SPL), temporal parietal junction, the frontal eye fields (FEF) and the supplementary eye fields (SEF), extending into the anterior cingulate cortex. An fMRI study by Kastner and colleagues compared activations in SPL, FEF and SEF in the presence and absence of visual stimulation. During the stimulus expectancy period (i.e. prior to delivery of the visual stimulus) there was an increase in activity within these frontoparietal areas that was greater than that observed in visual cortex. The sustained activity during the expectation period provides compelling evidence that the SPL, FEF and SEF areas were the sources of the signals producing attentional modulation of sensory activity seen in visual cortex.

One important characteristic of many directed attention tasks is the need for participants to hold in working memory information about the attended location in anticipation of stimuli to be presented at that location. Accordingly, it has been proposed that the signals controlling the deliberate allocation of spatial attention share neural mechanisms with those involved in spatial working memory. Consistent with this view is the finding that neurons in the lateral intraparietal sulcus (area LIP) of the monkey display elevated background firing rates when the animal performs a spatial working memory task as well as a spatial attention task. This functional link between spatial working memory signals and attentional control signals is further supported by human neuroimaging. Specifically, a number of neuroimaging experiments requiring the storage of spatial information in working memory have reported activations in posterior parietal and lateral frontal regions largely overlapping with those activated during spatial attention tasks.

The visual cortex in primates (including humans) and many other species is divided into a number of specialized regions that are organized in a hierarchical fashion. Visual information from the retina is relayed through the thalamus to the primary visual cortex (also called area V1), which is the first stage of cortical processing. The receptive fields (areas of space within which a stimulus will drive a cell) of V1 cells are small. From area V1, visual information propagates to successively higher areas including areas V2, V4, IT and MT. The structure of this hierarchical system is complex and it may contain over 35 separate areas specialized for visual processing. Among the characteristics that distinguish

one visual area from another are the type of stimuli to which each area responds and the size of receptive fields for individual cells in each area. Areas that are higher in the visual cortical hierarchy tend to respond to progressively more complex types of stimuli and have larger receptive fields.

Attention effects tend to become larger at higher levels of visual processing. These effects in primary visual cortex tend to be small: experiments in both monkeys and humans have shown that these responses become larger in area V2 and even larger in area V4.

One function of spatial attention is to bias the competition between visual objects when two or more objects are within the same receptive field. (*See* **Attention, Neural Basis of**)

One might imagine that attention could work by enhancing neural signals associated with the objects or spatial locations to which one's attention was directed, or by inhibiting the processing of nonattended items or locations. In fact, there is evidence that both types of mechanism – enhancement and suppression – are at work. Imaging studies in humans have shown that areas of visual cortex corresponding to the attended region of visual space show increased levels of activation not only when an object is present but also in the period between an attention-directing cue and the actual appearance of the object. This 'prestimulus' effect has been described in monkeys also in areas V2 and V4. In addition to areas of increased activity corresponding to attended regions, there is evidence for suppression of activity in nonattended regions.

Although orienting to visual stimuli has been most researched, there is increasing interest in orientation to information in other sensory modalities. Many of the mechanisms involved in vision are also used in orienting to both auditory and tactile modalities. There is evidence that orienting to one side of space can enhance information arising from different modalities at that location, even when the participant is not expecting a stimulus in that modality. The sensory sites at which attention operates can be very different, depending on the modality of the target. Whereas cueing to spatial locations dominates visual selection, auditory cueing of frequency of the target is more efficient than spatial cueing, perhaps because of the nature of cortical maps in the two modalities. Many of the sources of orienting effects are similar to those discussed for purely visual orienting. For example, the superior colliculus, superior parietal lobe, frontal eye fields and other eye movement structures are important to spatial orienting when the target information is not visual. Many areas of the parietal lobe are multimodal and may be involved both in integrating information across modalities and in orchestrating shifts of attention to novel stimuli. However, it is not yet understood how these areas are involved in the preattentive integration of information to form multimodal objects and in attentional orienting to the resulting objects.

FRONTAL CONTROL SYSTEMS

While spatial attention has a distinct anatomy, it can also act as part of a more general attention system that involves several other frontal areas and subcortical areas. When targets require difficult discriminations to separate them from nontarget events a network of frontal areas including the anterior cingulate gyrus, lateral frontal areas and sometimes the basal ganglia and cerebellum are active. These areas are involved in dealing with events in absence, in mediating conflict between targets and in generating novel responses. The exact function of each area is still unclear. A popular current view proposes that the medial frontal areas, including the anterior cingulate, may be involved in monitoring for cognitive and emotional conflict. Lateral frontal areas may serve to hold items on-line (working memory) and provide priority for selected information. The basal ganglia are often thought to be involved in switching between tasks. Orienting can have close ties to this more general frontal network, as when attention is drawn to places of interest during solving a problem or as indicated by a narrative. Because of this feature orienting is frequently used by cognitive studies to develop the time course of information processing during complex tasks.

Spatial Disorders

Introductory article

Giuseppe Vallar, University of Milan–Bicocca, Milan, Italy

CONTENTS

Cerebral lesions may impair a person's ability to perceive and remember objects, and to orient and navigate in the surrounding space. These neuropsychological disorders may be highly selective, suggesting that the internal anatomofunctional representation of space is multicomponential, although our phenomenal experience of it is largely unitary.

INTRODUCTION

Human beings, and other animals, live in a complex environment. They receive and process information concerning objects in space, and the spatial position of their body, through different sensory modalities (visual, auditory, somatosensory, vestibular); they continuously move, and are able to keep track of the position of their body, and of the location of objects in the space around them. These complex skills, essential to survival, comprise the perceptual processing of different sensory inputs from a continuously changing environment, and the programming and execution of motor acts. These include pointing to and reaching for objects through grasping, and locomotion. Sensory and motor information give rise to an internal representations of the body in space, and of the space around us. Our phenomenal experience of space is unitary. This is based, however, on the operation of multiple representations of different aspects of space. These may be selectively impaired by lesions of the brain, giving rise to specific disorders of spatial cognition.

MULTIPLE REPRESENTATIONS OF SPACE

The processing of sensory inputs first gives rise to representations of the stimulus specific to each sensory modality – retinotopic in vision, somatotopic in the tactile domain. Brain damage disrupting these levels of representation brings about primary sensory disorders, such as visual field defects (e.g. hemianopia) or impairments of tactile perception (e.g. hemianesthesia). The integration of visual, auditory, and somatosensory information with signals (eye position, vestibular, proprioceptive) concerned with the position of the body and of body parts in space results in two fundamental classes of representations of objects in space, including the subject's own body: egocentric and allocentric. In egocentric coordinate frames the position of the object is coded with reference to the subject's whole body or body parts, giving rise to representations, which may be head-centered (in the visual domain, resulting from the combination of the retinotopic map with information about eye position), trunk-centered (based also on information about the position of the head and about posture), arm-centered, and so forth (Figure 1). In allocentric coordinate frames, objects are primarily coded with reference to their spatial and configurational properties, such as the relationships between their component parts, and among different objects present in the environment. Egocentric representations may be used for the organization of goal-directed movements such as reaching a target or avoiding a harmful stimulus. Allocentric representations, encoding the configurational properties of objects and the relationships among them, may be useful for their identification and for navigation in space. In ecological conditions, objects are typically perceived from a variety of egocentric (observer-based) perspectives, suggesting a close interaction between these two frames of reference.

SPATIAL DISORDERS

Unilateral Spatial Neglect

Lesions to one cerebral hemisphere may severely impair the person's ability to detect and report sensory stimuli presented in portions of space contralateral to the side of the lesion (contralesional),

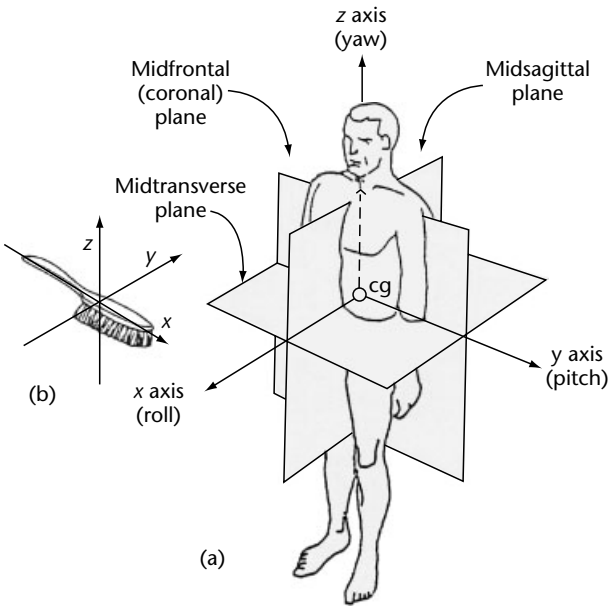

Figure 1. (a) The midsagittal plane of the body, which divides the extrapersonal space and the body into left and right sides, and other body coordinate systems and axes of rotation; cg: centre of gravity. (b) An object with its intrinsic axes. Adapted from Howard IP and Templeton WB (1966) *Human Spatial Orientation*. Chichester: John Wiley, with permission from John Wiley.

and to explore, through pointing or reaching movements or locomotion, that side of space. Neglect is a higher-order cognitive disorder, which can occur independently of primary sensory (e.g. hemianopia, hemianesthesia, deafness) or motor (e.g. hemiplegia) disorders. In humans, unilateral neglect is definitely more frequent and severe after damage to the right cerebral hemisphere, and concerns therefore the left side of space.

The spectrum of spatial neglect

Neglect of contralesional stimuli may occur in different sensory modalities – visual, auditory, tactile, or olfactory. Figures 2 and 3 show examples of left visuospatial unilateral neglect. The deficit may also concern the contralesional side of images evoked from long-term memory. Patients with this disorder, in an experiment requiring them to recall a familiar landscape (such as the Piazza del Duomo in Milan) from a given vantage point, failed to report landmarks on the left side. When, however, the vantage point was reversed, the neglected items became those that were left-sided with reference to the new perspective (Figure 4). This imaginal manifestation of neglect shows unambiguously that the disorder cannot be explained in terms of defective sensory input. In all these examples spatial neglect

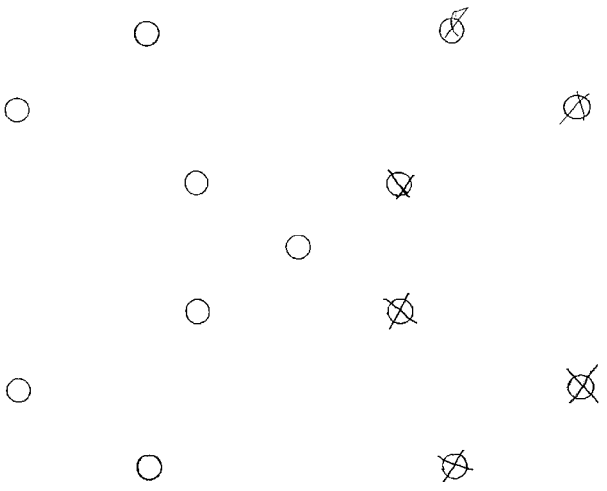

Figure 2. Spatial unilateral neglect. In a circle cancellation task a person with right-sided brain damage, who used his unaffected right hand, omitted to cross out circles on the left side.

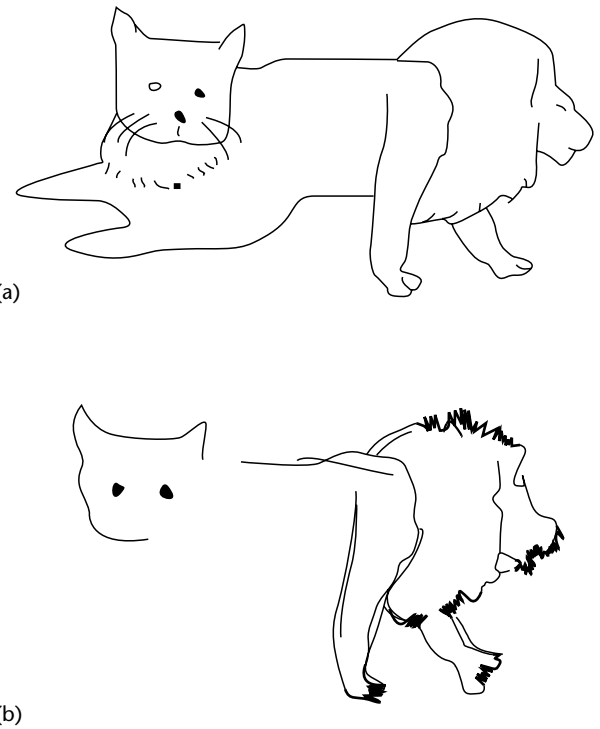

Figure 3. Patients with right brain damage and left unilateral neglect typically omit left-sided details in copying tasks. This cat–lion chimera (a) was identified by the patient as a lion on the basis of its right side (b). is defined with respect to an egocentric reference frame, such as the midsagittal plane of the body.

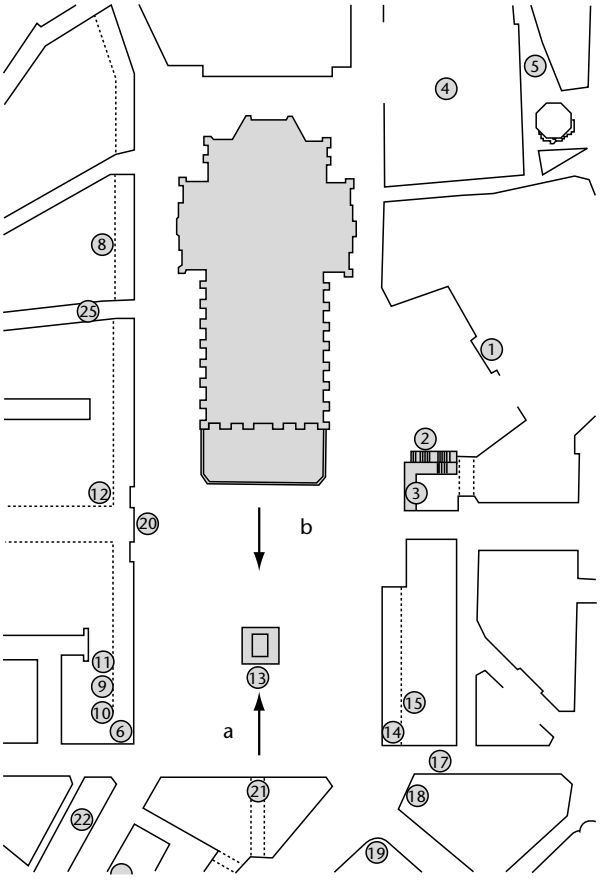

Figure 4. The Piazza del Duomo, Milan, Italy. Imagining the piazza from perspective (a) (looking at the cathedral with the steps in front of them), patients with left neglect fail to recollect left-sided details such as the front of the Galleria (20) or the Via San Raffaele (25), but not right-sided details such as the Royal Palace (1) or the Arengario (3). From the opposite perspective (b) (from the front doors of the cathedral) the deficit is reversed. From Bisiach E and Luzzatti C (1978) Unilateral neglect of representational space. *Cortex* **14**: 129–133, with permission from Masson.

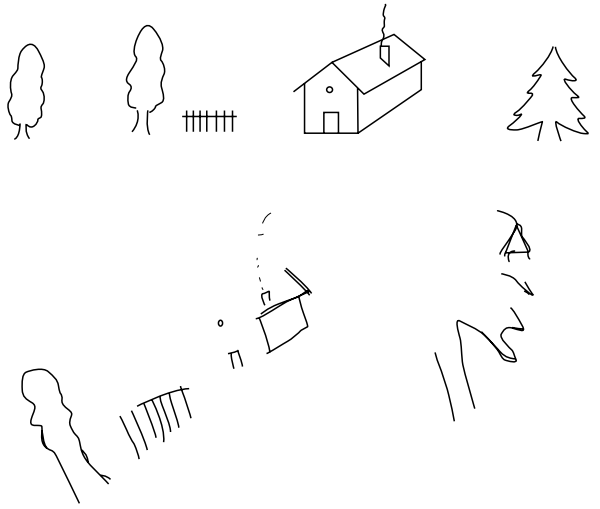

Figure 5. Object-based neglect. The patient copied many elements of the model, not only on the right but also on the left side of the sheet, but left unfinished the left half of various elements (the house and the fir tree). Reprinted from Gainotti G, Messerli P and Tissot R (1972) Qualitative analysis of unilateral spatial neglect in relation to laterality of cerebral lesions. *Journal of Neurology, Neurosurgery, and Psychiatry* **35**: 545–550, with permission from BMJ Publishing Group.

Within the space around us (extrapersonal) the disorder may be confined to specific sectors of it, such as 'near' (within hand-reach) and 'far' space. It may be also confined to specific types of objects (words, faces). Finally, although the lateral (left–right) dimension of neglect is the most frequently observed, the disorder may also manifest in other dimensions (e.g. altitudinal).

Spatial neglect may affect the contralesional left side of individual objects, rather than the left side of the whole field of perception (Figure 5). In a reading task, neglect may disrupt processing of the contralesional letters with reference to a canonical (e.g. horizontal, left to right, in a language such as English) representation of the word, independent of its physical presentation (vertical, mirror-reversed). These manifestations of neglect indicate that the disrupted level of representation concerns primarily an allocentric (object-centered or object-based) rather than an egocentric spatial reference frame.

These manifestations of neglect may reflect defective perception, impaired programming of movements towards the contralesional side of space, or both input and output factors. Patients with neglect may show evidence of entirely preserved processing of objects in the neglected side, up to the semantic level, provided such a knowledge is assessed by paradigms not entailing perceptual awareness (e.g. electrophysiological indexes, priming). Seen in this perspective, neglect is a case of defective access to conscious experience.

Neglect may affect the contralesional side of the body of the patient, who may be unaware of the presence of the left hand or arm, failing to reach them with the right hand (hemiasomatognosia). Patients may be selectively unaware of neurological disorders which affect their left side (anosognosia for hemiplegia, hemianopia, hemianesthesia) and actively deny the presence of a contralesional neurological deficit. They may develop delusional views about the contralesional side of their body (somatoparaphrenia). For instance,

patients might obdurately assert that their left arm is in fact their niece's arm, with this belief being resistant to persuasion. Anosognosia and somatoparaphrenia provide insights into the mechanisms of aware monitoring of function and of sense of ownership and personal identity.

In many patients these different manifestations of neglect coexist. However, empirical evidence has accumulated to show that each of these forms of neglect may occur in isolation, independent of the others. These dissociations of symptoms and signs provide a strong argument towards a view of the clinical syndrome of spatial unilateral neglect as a multicomponent deficit, and of spatial cognition as based on the integrated operation of multiple representational systems. These manifold manifestations of spatial neglect may be temporarily improved by a number of lateralized sensory inputs, including vestibular, proprioceptive–somatosensory, and visual stimulations. The observations that these modulatory effects concern virtually all manifestations of neglect, ranging from extrapersonal visuospatial neglect to somatoparaphrenia, suggest the existence of a common spatial representational medium, shared by different, more specific, representations.

Anatomic and functional basis

Unilateral spatial neglect is caused by a variety of cortical and subcortical lesions, which most frequently involve the right cerebral hemisphere, particularly in the parietal lobe. In the cortex, the inferior–posterior parietal region, at the temporoparietal junction, and the frontal premotor cortex (Brodmann's areas 6 and 44) represent main anatomical correlates (Figure 6). Damage to subcortical structures, such as the thalamus, the basal ganglia, and some white-matter fiber tracts, may also bring about neglect, suggesting that the disruption of a cortico-subcortical circuitry may be the pathological underpinning of the disorder. Damage confined to the primary sensory and motor cortices does not cause neglect, confirming the higher-order, cognitive character of the disorder.

The hemispheric asymmetry that characterizes neglect in humans may be explained by the hypothesis that both cerebral hemispheres include spatial representational and attentional systems devoted to perceptual processing and motor programming in the contralateral side of space. This organization replicates the general crossed anatomofunctional architecture of sensorimotor systems, whereby each hemisphere is mainly concerned with the contralateral side. In the case of spatial cognition, however, an hemispheric asymmetry is present.

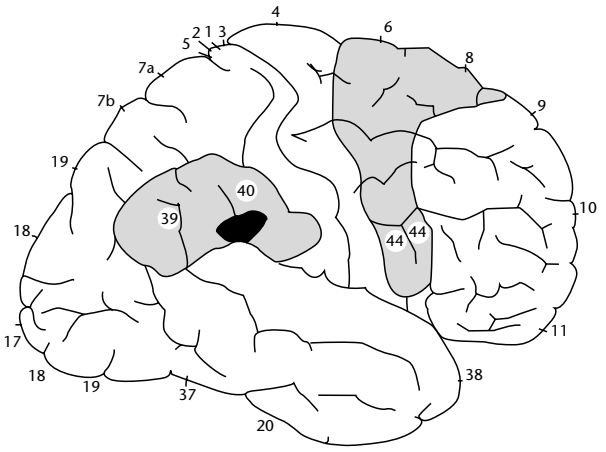

Figure 6. The anatomical basis of extrapersonal visual unilateral neglect (shaded area). Numbers are Brodmann areas. In the majority of patients the lesion involves the inferior parietal lobule, at the temporoparietal junction (black area), in the right hemisphere. Unilateral neglect after right frontal damage is less frequent and is usually associated with dorsolateral lesions of the premotor cortex. From Bisiach E and Vallar G *Unilateral Neglect in Humans*, Handbook of Neuropsychology, 2nd edn, vol. 1, pp. 459–502, with permission from Elsevier Science.

Only the right hemisphere is able to deploy spatial attention to both the left and the right sides of space, and has a complete lateral representation of it. The left hemisphere, by contrast, is mainly concerned with the contralateral right side of space. Accordingly, damage to the right hemisphere brings about a left-sided deficit, which cannot be compensated for by left-hemisphere neural networks. This hemispheric difference in the neuronal machinery subserving spatial representation and attention is likely to be a matter of degree. The difference between the 'neglected' and the 'preserved' sides of space, in a given reference frame, should be conceived as a contralateral–ipsilateral gradient, rather than a sharp divide.

Disorders of Spatial Perception and Reaching

Unilateral hemispheric damage may impair the patient's ability to localize visual and auditory stimuli, and to perceive the orientation of lines, in the visual and tactile modality. In general, the deficit is much more severe after damage to the right cerebral hemisphere. Patients with cerebral damage may be selectively impaired in reaching for visual objects with their arm (optic or visuomotor ataxia). The responsible deficit involves the spatial egocentric reference coordinates including

the representation of the position of the target with respect to the body and the reaching effector (e.g. the arm and hand). Allocentric reference frames are not involved, since these patients can correctly localize objects with respect to each other. Optic ataxia is associated with posterior parietal lesions, with a critical role of damage to the interparietal sulcus and the superior parietal lobule. The association of optic ataxia with 'gaze apraxia' (the inability to shift gaze, in order to bring peripheral visual stimuli into fixation), together with an extreme narrowing of the attentional field preventing the perception of more than one object at a time, and with defective estimation of distance and depth, constitutes the Bálint–Holmes syndrome. This symptom complex is usually caused by a bilateral parietooccipital lesion.

Disorders of Spatial Memory

A broad distinction within memory systems is between components concerned with the retention of a limited amount of material for short periods (seconds) (short-term memory) and components involved in the longer-lasting acquisition and retention of information (long-term memory). Unlike neglect, these spatial disorders do not show any lateral or altitudinal gradient.

Deficits of spatial short-term memory

Short-term memory for spatial locations is selectively disrupted by damage to the posterior, parietooccipital regions of both the left and right cerebral hemispheres, although the role of the latter appears to be more relevant. These patients show a selective deficit of immediate retention of short sequences of spatial locations, as assessed by a block-tapping task (a spatial analogue of digit span). The impaired retention of spatial locations cannot be accounted for in terms of visuoperceptual or response-related disorders (e.g. unilateral spatial neglect or misreaching). These patients may show no evidence of topographical disorientation or impairment in long-term learning of visuospatial information such as the path of a visual maze, suggesting a complete independence of short-term and long-term memory systems concerned with spatial locations.

Deficits of spatial long-term memory and topographical disorientation

Right hemispheric lesions involving the medial temporal regions in the limbic lobe and the posterior parietal areas impair learning and retention of the spatial position of objects and of pathways. Patients show a selective and disproportionate impairment in navigating in the environment, and are unable to find familiar routes, to learn new ones, to

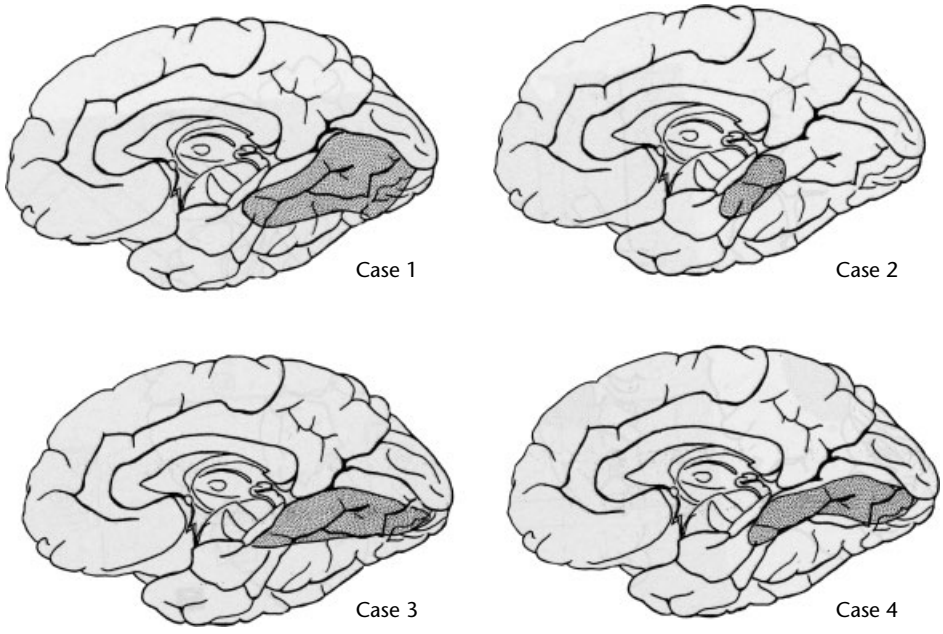

Figure 7. Lesions involving the right parahippocampal gyrus in four patients with pure topographical disorientation (medial view of the right hemisphere). From Habib M and Sirigu A (1987) Pure topographical disorientation: a definition and anatomical basis. *Cortex* **23**: 73–85, with permission from Masson.

draw a map, or to describe the path to reach one place from another (topographical amnesia). These patients are unable to draw or describe verbally the map of the Piazza del Duomo in Figure 4, or to walk from one place to another. Topographical disorientation, unlike unilateral neglect, does not exhibit a lateral gradient of impairment. These patients can recognize familiar landmarks but cannot give them any localizing value, being unable to recall their relationships. The disorder concerns mainly allocentric coordinate frames. The lesion responsible for purely topographical amnesia involves the medial temporal regions of the right hemisphere, with a main role of damage to the parahippocampal gyrus (Figure 7).

CONCLUSION

Neuropsychological investigations in people with brain damage suggest that spatial cognition, far from being monolithic, is articulated into a number of discrete systems, with specific neural correlates, which may be selectively impaired. These disorders include deficits characterized by a gradient of impairment, along a specific spatial axis (the syndrome of unilateral spatial neglect), disorders of reaching (optic ataxia), of spatial perception, and impairments of short-term and long-term spatial memory (topographical amnesia or disorientation). The neural correlates of spatial cognition, and of its neuropsychological disorders, are mainly based in the right hemisphere, including the premotor frontal, posterior parietal, and medial temporal regions. These spatial impairments may be qualified with respect to the deficit of a specific coordinate frame or representation, the main distinction being between egocentric and allocentric dimensions.

Split-brain Research

Introductory article

Maryse Lassonde, University of Montreal, Montreal, Quebec, Canada

CONTENTS

Split-brain research has led to an understanding of the role of the two hemispheres in perceptual and cognitive processes, and has raised important questions with regard to human consciousness and self-awareness.

INTRODUCTION

The corpus callosum, which has an estimated 600 million fibers, constitutes the largest communication pathway between the two cerebral hemispheres (Figure 1). The surgical division of the pathway which allows the two hemispheres of the brain to communicate with each other (the 'split brain') is performed for therapeutic purposes in cases of intractable epilepsy. For over 40 years this procedure has allowed testing of the specific cognitive and perceptual abilities of each cerebral hemisphere, thereby enhancing our knowledge of hemispheric specialization which, prior to the 1960s, had been derived mainly from brain lesion studies. However, whereas the effects of cerebral lesions could be obscured by many factors, including individual variability, the split-brain studies allowed researchers to investigate for the first time the abilities of each hemisphere *within the same individual*.

HISTORY OF SPLIT-BRAIN STUDIES AND THEIR SIGNIFICANCE

The interest in and mystery surrounding the role of this gigantic bundle of fibers have a long history in the field of neurosciences. In the eighteenth century, just as Descartes had proposed the pineal gland as the site where body and mind interact, Giovanni Lancisi, an Italian physician, proclaimed that the corpus callosum, because it was both unique and situated in the middle of the brain, was the seat of the soul.

In the nineteenth century, when questions were raised about the double nature of the brain (it is composed of two hemispheres that appear to be largely symmetrical), the corpus callosum was regarded as a structure that could reconcile this duality, thereby providing unity of consciousness and preventing the development of a 'double personality'. However, several cases were found in which no mental impairments could be observed in the absence of the corpus callosum. The notion of the callosal structure as an essential link to consciousness was therefore abandoned, and its exact role remained the subject of debate.

This situation was further complicated by reports published in the 1940s. Following the observation that, in animals, sectioning of the corpus callosum ('callosotomy') could prevent the spread of epileptic seizures from one hemisphere to the other, neurosurgeons decided to apply this operative technique to patients who had drug-resistant epilepsy. The psychologist Andrew Akelaitis, who conducted extensive behavioral studies in these first split-brain patients, failed to demonstrate any specific pattern of disconnection between the two hemispheres with regard to behavior, emotion or cognition. These negative findings prompted scientists such as Warren McCulloch to claim that the unique role of the corpus callosum was the propagation of epileptic seizures from one hemisphere to the other, or perhaps, as was facetiously proposed by Karl Lashley, its function was simply to hold the two hemispheres together!

Fortunately, a brilliant student of Karl Lashley, namely Nobel Laureate Roger Sperry, together with his colleague Ronald Myers, decided to investigate the role of this anatomically important

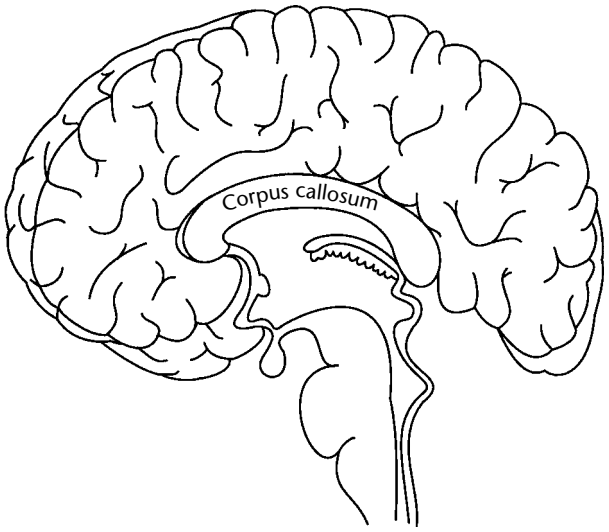

Figure 1. Midsagittal view of the brain, showing the internal portion of the disconnected right hemisphere. The corpus callosum is the large fiber tract that interconnects the two hemispheres.

structure further. They surgically divided the brain of cats by cutting the corpus callosum. They also sectioned another pathway – the optic chiasm – such that visual information from one eye would reach only the ipsilateral hemisphere. They then trained the animal to learn a simple visual discrimination task while one of the eyes was occluded. Once the animal had mastered the problem, the same task was presented to the untrained eye (and hemisphere) while the trained eye was occluded. Extraordinarily, the cat seemed to have no recollection of the task. It had to learn the task all over again with the other half of the brain. In fact, the animal behaved as if the section of the corpus callosum had produced two independent minds within its head, whereas outside the testing situation, nothing in its behavior had changed or distinguished it from its normal cage mates.

Soon afterwards, two Californian neurosurgeons, Philip Vogel and Joseph Bogen, decided to apply the surgical procedure used in the 1940s to patients with severe intractable epilepsy. Having heard about Sperry's work with cats and monkeys, Bogen invited Sperry and one of his colleagues, Michael Gazzaniga, to study these split-brain patients. Like the split-brain animals, these patients displayed normal behavior in their everyday lives, but under special testing conditions they behaved as if they had two distinct types of conscious awareness, one in each hemisphere. These results confirmed the animal research and contributed to a new understanding of the functions of the corpus callosum which eventually opened up a new era in the study of the relationships between brain and mind.

THE ROLE OF THE CORPUS CALLOSUM AND THE TWO HEMISPHERES IN COGNITION

Methodological Issues

In contrast to the situation in animals, the corpus callosum in humans joins two functionally different hemispheres. Sectioning of the corpus callosum thus allows the functions of each hemisphere in isolation to be studied. Callosotomy disrupts all of the direct connections between the left and right hemispheres, including the connections between the regions responsible for the motor and sensory control of each hand and those that interconnect the left and right visual fields. However, under normal circumstances the division of functions between the two hemispheres cannot be easily observed, due to the bilateral 'wiring' of the brain and the use of various strategies by the patients. This is one of the reasons why Akelaitis failed to observe any disconnection signs in the earlier series of split-brain patients that he studied. Sperry and his collaborators, on the other hand, devised specific testing procedures that restricted processing of sensory and motor information to a single hemisphere. An example of these procedures is shown in Figure 2.

Somatosensory and Motor Control

Following callosotomy, tactile information processed by one hand remains largely lateralized to the opposite hemisphere. Thus split-brain patients cannot compare two objects manipulated with one in each hand, although they are aware of holding something in each hand. However, noxious information from each hand, such as intense heat or pain, is conveyed to both hemispheres and is consciously perceived by each half of the brain as an unpleasant sensation.

The movements of each hand are also controlled by the opposite hemisphere. Early research indicates that split-brain patients experience difficulty in performing asynchronous, simultaneous movements with their two hands. In rare instances, split-brain patients perform conflicting actions with their hands (e.g. pouring water with one hand while taking away the glass with the other).

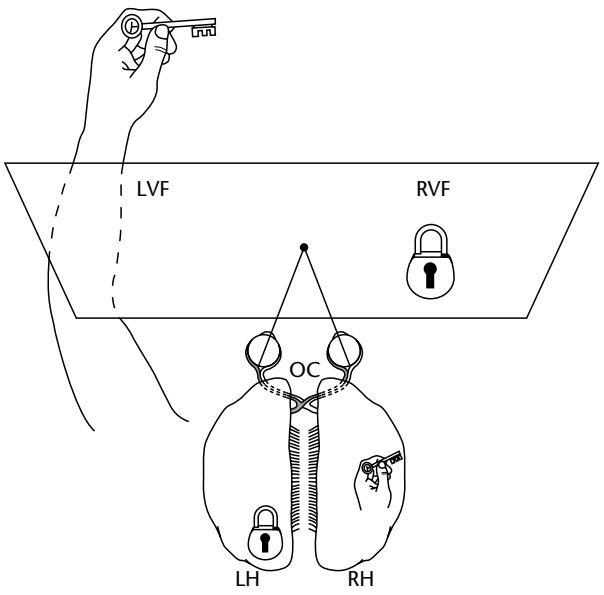

Figure 2. An example of the type of procedure used with split-brain patients. Visual information is lateralized to the right or left hemisphere by presenting it to the left or right side, respectively, of a central fixation point for a very short time in order to prevent eye-tracking and hence bilateral visual representation. Tactile information is kept within one hemisphere by asking the subject to feel an object out of view. In this set-up, the split-brain subject is incapable of comparing an object (key) held by the left hand (right hemisphere) with the visual stimulus flashed in the right visual field (left hemisphere). Moreover, only the object processed by the left hemisphere (key) can be named by the subject. RVF, right visual field; LVF, left visual field; OC, optic chiasm; LH, left hemisphere; RH, right hemisphere.

Patients who present with this so-called *diagonistic apraxia* act as if each hemisphere wanted to take control of the environment.

Language and Speech

Split-brain studies have consistently shown a marked left-hemisphere superiority for verbal processing, and this applies not only to right-handed subjects whose left hemisphere is dominant for motor control, but also to the majority of left-handed individuals. Although split-brain patients can readily name objects held in the right hand or presented in the right visual field (and hence projecting to the left hemisphere), they are unable to do so when the stimuli are processed by the right hemisphere, because the latter does not possess the mechanisms of speech. Patients may even deny having seen anything when the images are flashed in the left visual field, and some will report that their left hand has 'lost its sensitivity'. However, it appears that the patients have a full knowledge of the stimuli, even though they cannot name them, because when prompted they are able to retrieve with their left hand (connected to the right hemisphere) the corresponding object from an array of objects, or point to the picture that has been presented in their left visual field.

Although the disconnected right hemisphere has problems in producing speech, it does have some linguistic abilities. Thus many studies have shown that the right hemisphere possesses a lexicon, that it can make judgments about grammaticality, and that it can even sometimes develop expressive speech abilities, allowing the patient to report verbally sensations and perceptions experienced in their previously mute right hemisphere. In fact, research with split-brain patients has shown that there is enormous inter-individual variability in the linguistic abilities of the isolated right hemisphere.

Visuospatial Processing and Perception

There is a general consensus that the right hemisphere is superior with regard to processing spatial information. For example, split-brain patients – even right-handed ones – succeed better on the block design subtest of the Wechsler intelligence scale when using their left hand. This test, which involves reproducing a visual pattern using red and white blocks, is strongly correlated with the non-verbal intellectual quotient (performance IQ), suggesting that the right hemisphere has some specific higher-order cognitive abilities. Right hemisphere superiority has been found for other types of spatial abilities, such as perceiving the shape of a partially occluded object, deciding whether two visual images are identical or mirror-reversed, judging spatial relationships or recognizing faces. Drawings are also better accomplished by the left hand, which may sometimes even try to take over the right-hand execution (Figure 3).

Memory and Learning

Split-brain patients sometimes complain of memory problems following surgery, and indeed early reports indicated deficits in short-term memory in these patients. However, subsequent studies have reported improvements in memory following callosotomy. The most important difference between the earlier and later series of patients is the preservation of the anterior commissure in

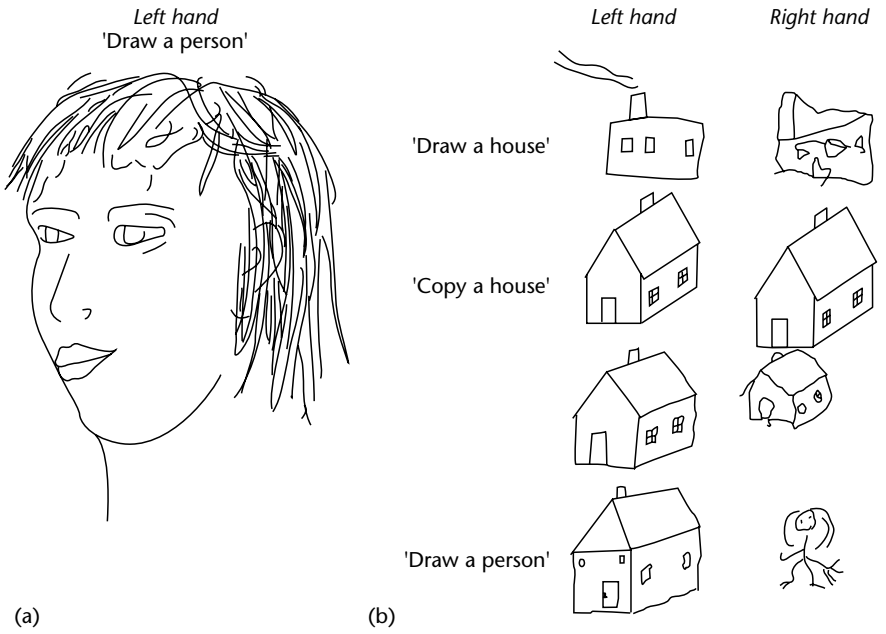

Figure 3. Drawings produced by one of our split-brain patients examined pre- and post-surgically. (a) Prior to surgery (pre-callosotomy), this left-handed patient used to draw as a hobby. (b) Following the operation (post-callosotomy), he can still produce drawings with his left hand (and thus his right hemisphere), although his spontaneous productions represent simplified versions of objects. Using his right hand, his spontaneous reproductions are rudimentary and often unrecognizable. In this particular instance, when the patient used his right hand to copy a house, the left hand tried to take over the copy but was stopped by the experimenter. When the patient was subsequently asked to draw a person with his left hand, the 'frustrated' right hemisphere produced a well-executed house. However, the patient complained verbally about the production, stating 'This is not a person'. The right hand (left hemisphere) then tried to draw a person, but with only limited success.

the latter, which is known to link areas in both hemispheres that mediate memory. More recent research suggests that in some cases callosotomy may interfere with the encoding of new information, but without affecting recognition of the previously learned material. Furthermore, consistent with previous results reported for unilateral brain lesions, the disconnected left hemisphere has been found to be more proficient in encoding verbal material (e.g. words), whereas the right hemisphere is superior with regard to remembering visual information (e.g. images and faces).

With regard to procedural memory, each hemisphere is capable of learning a routine or procedure, but the memory engram that results from this learning is not necessarily transferred to the other hemisphere. Furthermore, split-brain patients experience difficulties in implicitly (automatically) learning a routine that involves the simultaneous use of both hands, although they can explicitly (or consciously) describe all of the steps of the procedure. In fact, they show a dissociation between implicit (unconscious) and explicit (conscious) learning, which may explain the apparent unity in overt behavior in the presence of two cognitive systems that operate largely independently from one another.

Attention

Normal individuals can only attend to one visuospatial location at a time. However, studies in split-brain patients have shown that each of the two hemispheres is able to direct its attention to its own visual field. Thus the divided hemispheres can independently and concurrently scan their corresponding visual fields during visual search such that it takes a split-brain patient half the time to scan a given number of pictures when they are presented on either side of the midline compared with when they are viewed on only one side. In fact, because of the 'division of labor' between the two hemispheres, split-brain patients can outperform normal individuals in a test of visual retention when the information is distributed between the two visual half-fields.

IMPLICATIONS FOR PHILOSOPHY OF MIND AND SELF

Split-brain studies have thus shown that each disconnected hemisphere has its own set of percepts and cognitive abilities that have been variously described in terms of a number of dichotomies (e.g. verbal/visuospatial, analytic/holistic, propositional/appositional, global/local, rational/intuitive, or even intellectual/artistic). For several years now these distinctions have captured the attention of the general public, leading to popular (mis)interpretations. For example, it has been suggested that one could exercise one's right hemisphere in order to develop intuitive faculties or become more artistic (e.g. Betty Edward's 1980 book entitled *Drawing on the Right Side of the Brain*). Such popular beliefs fail to take into account the fact that the normal brain does possess a corpus callosum, which ensures that there is constant 'cross-talk' between the two hemispheres.

Apart from its impact on our knowledge of hemispheric specialization, split-brain research has also raised important questions about the nature and substrate of mind and conscious awareness. Transection of the corpus callosum apparently produces a division of the mind, since most conscious experience that is generated by one hemisphere appears to be inaccessible to the other. If this is the case, what does it signify about the unity of the conscious self in the normal intact brain?

One approach maintains that the mind and self remain unified because of the predominant control of the language hemisphere. The right hemisphere is viewed as subordinate, possessing few if any higher cognitive abilities and acting almost as an unconscious automaton. The intellectually superior left hemisphere, which alone is capable of verbal expression in most individuals, constantly formulates hypotheses and generates explanations about the environment and one's self. The interpretations given by the left hemisphere (labeled the 'Interpreter' by Gazzaniga) would thus provide the sensation of a unified mind even in the absence of available information from the right hemisphere.

Another view has emerged lately. Some recent research indicates that the right hemisphere may preferentially process self-face recognition, which has been regarded as an indicator of higher-order self-consciousness. Recognition of self (e.g. in a mirror) is indeed a predominantly human attribute that can be associated with other self-related tasks such as introspection and hence self-awareness. Interestingly, early reports indicated that split-brain patients displayed alexithymia (a difficulty in expressing feelings verbally). This would suggest that the verbal left hemisphere is unable to access emotions experienced by the (introspective?) right hemisphere. Such a theory would predict that division of the brain may disrupt the sense of self-awareness because an important part of the person's inner life cannot be conveyed explicitly by verbal means. However, as yet there have been no reports of a loss of personal identity or self-awareness in split-brain patients.

A more intermediate approach to the 'duality of mind', first expounded by Hughlings Jackson and endorsed by Sperry, views the mind as normally single and unified, with the two specialized hemispheres working in synchrony through the commissures, and functioning as an integrated whole rather than as a double or divided system. In fact, Sperry has proposed that this integrated activity leads to an emergent property whereby the combined activity of the two hemispheres is greater than the sum of each hemisphere functioning separately. He maintains that even in the split brain, where the cognitive processes of each hemisphere are largely separate, other aspects of consciousness are not necessarily divided. This is because, just like Siamese twins, the two surgically isolated hemispheres are exposed to the same experience. In the brain, this is achieved through bilateral distribution at several levels of sensory and motor pathways, as well as through behavioral means of compensation, such as explorative movements of the body and eyes which allow both hemispheres to be concurrently aware of a percept or sensation. However, whether the subsequent treatment of this information, either through the formulation of hypotheses or by introspection, can ultimately lead to the same high-level unified self-concept as exists in the undivided brain is still a matter of debate.

CONTENTS

Stressful events impose a very important set of demands on the body, and this is reflected by changes in cognitive function.

STRESS HORMONES AND COGNITIVE FUNCTION: OVERVIEW

Stress that occurs in the form of an actual or threatened insult produces states of increased emotional arousal which alter neuroendocrine function in a manner that is of obvious importance to an individual facing adversity. One way to appreciate the logic of these adaptive responses is simply to imagine the demands placed on the individual during virtually any form of stress. First, there are metabolic demands that arise from the increased level of cellular activity in tissues such as lung, liver, heart and brain. The organism meets these demands by mobilizing energy substrates (e.g. fats and sugars) from macromolecular storage sites and by increasing blood flow (and thus the distribution of energy substrates) through enhanced cardiovascular tone. These responses are produced as a result of increases in sympathoadrenal activity, resulting in increased levels of stress hormones, such as the highly catabolic glucocorticoids and the catecholamines, adrenaline and noradrenaline, which directly regulate lipolysis, gluconeogenesis and cardiovascular activity. These same hormones also influence learning and memory for information related to the stressful events, as well as the ability of the individual to process information that is not related to the stressor.

The release of these stress hormones occurs in response to signals from the hypothalamus as well as extrahypothalamic sites that assess the salience of the threat and regulate the release of stress hormone from sympathetic and adrenal sources. The most important of these regions are the basolateral regions of the amygdala, the hippocampus and the orbitofrontal cortex (or the medial prefrontal cortex in rodents). In addition, cognitive demands are placed on the individual that relate to coping with the immediate challenge and learning to avoid the same conditions in the future. During or immediately following a period of stress, cognitive function is focused on the events associated with the stress response. Not surprisingly, there is a price to pay for this. Thus the processing of information that is not related to the stressor is impaired, and this appears to be the case for both storage and retrieval of information.

Many of the adaptive, cognitive processes that occur during stress involve these same brain regions and are regulated by the same stress hormones. Thus glucocorticoids and catecholamines mediate stress-induced changes in attention, as well as learning and memory, through their effects on neuronal populations in the hippocampus and amygdala. In large measure, the effects of stress hormones on learning and memory can be understood in terms of the timing of the stressful event. The increase in emotional arousal that is associated with stressful events enhances learning and memory for those events. Thus the elevated levels of both glucocorticoids and catecholamines that are provoked by the stressor enhance memory storage. In contrast, these same hormones will impair storage of information that is related to events which follow the stressor, or the retrieval of information that is not related to the stressor. These effects may in part be explained by the effects of glucocorticoids and catecholamines on the hippocampus and amygdala.

THE PRINCIPAL STRESS HORMONES

The hypothalamic–pituitary–adrenal (HPA) axis is the primary endocrine branch of the stress response (de Kloet *et al*., 1998). Activation of the HPA axis results in increased adrenal release of glucocorticoids into the circulation. Under most conditions, the HPA axis is under the dominion of specific releasing factors that are secreted by neurons located in the paraventricular nucleus (PVNh) of the hypothalamus, notably corticotropin-releasing factor (CRF) and vasopressin. Neurons of the PVNh project extensively to the median eminence, providing a potent excitatory signal for the synthesis and release of adrenocorticotropin (ACTH) from the anterior pituitary, and thus the means whereby neural activity associated with the stressor is transduced into endocrine signals (de Kloet *et al*., 1998). Elevated ACTH levels in turn increase the synthesis and release of glucocorticoids from the adrenal gland (in primates, the primary glucocorticoid is cortisol, whereas in rodents it is corticosterone).

A second, neural branch of the stress response involves a projection from the PVNh, the central nucleus of the amygdala and the bed nucleus of the stria terminalis to midbrain regions, such as the noradrenergic cell bodies of the locus coeruleus (Valentino *et al*., 1998). Interestingly, this projection uses CRF as its primary neurotransmitter signal, resulting in the activation of noradrenergic neurons and the release of noradrenaline in multiple target regions in the cortex and limbic system. The locus coeruleus as well as neighboring CRF target sites such as the nucleus of the solitary tract are part of the midbrain structures that have classically been associated with emotional arousal. Thus activation of this amygdala–locus coeruleus pathway corresponds to the emotional states of fear and apprehension. Not surprisingly, increased activity in this pathway is associated with anxiety disorders, and consequently these structures have emerged as primary targets for anxiolytic drugs. Activation of these noradrenergic projections to regions such as the amygdala and hippocampus also influences learning and memory.

STRESS HORMONES AND COGNITIVE FUNCTION: THE AMYGDALA

Learning and memory are enhanced under conditions where an event is perceived by the organism as being highly aversive. The emotional state which occurs in response to the cognitive–perceptual processing of the stressor then influences the nature of subsequent cognitive events, including the strength of learning and memory, as well as the nature of what is learned. For example, rats acquire a conditioned fear response to a cue that predicts footshock after only one trial. The neural processes that underlie such emotional learning and memory and the relevant actions of stress hormones have been well described in the rat using various models of fear conditioning (Davis *et al*., 1994; Cahill and McGaugh, 1998; LeDoux, 2000). Information about the aversive properties of stimuli is transmitted from sensory pathways through cortical and subcortical structures such as the thalamus and the parabrachial nucleus to the basolateral complex of the amygdala, which consists of the basolateral, lateral and anterior basal nuclei. While debate continues as to whether the amygdala is the actual locus for the relevant memory, there is unanimity about the importance of the amygdala in the acquisition and expression of fear conditioning. Activity within the basolateral complex of the amygdala is essential for learning/memory that concerns aversive events, while activity within the medial portion of the central nucleus of the amygdala is associated with the expression of fear-like states, but not with learning/memory *per se*.

These sites are also primary targets for the enhancing effects of noradrenergic and dopaminergic projections on fear conditioning. Glutamatergic inputs into the basolateral complex of the amygdala are a critical feature of amygdaloid learning/memory, possibly involving long-term potentiation processes comparable to those of the hippocampus (see below). Thus glutamate-receptor antagonists block fear conditioning as well as fear-potentiated startle. Interestingly, glucocorticoids block glutamate reuptake by glial cells and thus increase the magnitude of an extracellular glutamate signal. In Pavlovian fear conditioning, the sensory information that is associated with the predictive stimuli as well as the nocioceptive information associated with pain converge on the basolateral complex of the amygdala to produce fear conditioning to the predictive stimuli. In contextual fear conditioning, information about context emerges from the ventral hippocampus and involves projections to the basolateral complex of the amygdala. Projections from the basolateral complex to the cental nucleus activate the expression of the fear response through the extensive projection from the central nucleus, including CRF projections, to regions that mediate autonomic, emotional and behavioral responses to stress, such as the locus coeruleus.

Similarly, in humans, emotionally adverse stimuli activate the human amygdala (Cahill and

McGaugh, 1998). Indeed, the degree of amygdaloid activation is highly correlated ($r = +0.93$) with recall of emotionally disturbing (but not neutral) material. With high-temporal-resolution functional magnetic resonance imaging (fMRI) techniques, LaBar *et al*. (1998) found increased amygdala activity during the acquisition phase of fear conditioning, and patients with amygdala damage show profound deficits in fear conditioning. Interestingly, individual differences in the degree of amygdaloid activation during fear conditioning were highly correlated with the strength of a conditioned autonomic fear response.

The enhanced learning and memory that are associated with a stressor are a result of the effects of the stress hormones on the amygdaloid complex. The infusion of a glucocorticoid-receptor agonist directly into the basolateral region of the amygdala facilitates learning. Drugs that activate β-adrenoreceptors in the amygdala have the same effect. In both human and non-human subjects, β-adrenoreceptor blockers attenuate emotional learning and memory. The glucocorticoids act in synergy with noradrenaline to activate hepatic and cardiovascular systems during periods of stress. Essentially the primary effect of the glucocorticoids is to increase tissue sensitivity to noradrenaline. A comparable pharmacological interaction appears to underlie the effects of the stress hormones on the amygdala. Thus the infusion of a β-adrenoreceptor blocker into the amygdala blocks the memory-enhancing effects of glucocorticoids. It is critically important to note here that in each case these effects are obtained with pharmacological treatments that follow learning and memory training. This protocol maps on to the real world, since the elevated levels of stress hormones that facilitate learning and memory occur during and after the stressful event. Increases in the levels of stress hormones prior to an experience have the opposite effect, namely to impair learning and memory (see below).

In general, treatments that decrease the excitability of neurons in the basolateral complex of the amygdala, such as increased γ-aminobutyric acid (GABA) transmission, retard fear conditioning. Drugs such as the benzodiazepines, which serve to dampen the emotional and endocrine response to a stressor, impair learning and memory for information associated with the stressor. The effects of the benzodiazepines are mediated by the ability of these compounds to enhance the effects of GABA at the $GABA_A$-receptor site. There are a variety of intrinsic and extrinsic GABA-ergic amygdaloid projections which can constrain the acquisition (i.e. an 'amnesic' effect) and expression (i.e. an 'anxiolytic' effect) of conditioned fear responses. Thus infusion of $GABA_A$-receptor agonists into the amygdala impairs emotional learning and memory, while $GABA_A$-receptor blockers have exactly the opposite effect.

Whether or not one views the amygdala as the actual location of the memory trace is a matter of debate. What is not contested is the idea that amygdaloid stimulation enhances information storage. This appears to be the case even in learning paradigms that do not normally involve amygdaloid activation. Thus under normal circumstances spatial learning and memory are not dependent on amygdaloid function. However, amygdaloid stimulation facilitates spatial as well as procedural learning. Probably the best way to understand these effects is to assume that stressors activate the amygdala and that this activation can then serve to mediate certain forms of learning and memory, such as fear conditioning, as well as to facilitate other forms of learning.

CHRONIC STRESS AND AMYGDALOID FUNCTION

It should come as no surprise to learn that chronic stress enhances amygdaloid function. We are probably more familiar with this effect in the form of increased feelings of 'anxiety' and 'irritability'. First, chronic stress increases CRF gene expression in the amygdala, an effect that is mediated by adrenal glucocorticoids. CRF, of course, serves to enhance fear conditioning, and this effect is in part due to effects on ascending noradrenergic systems arising from structures such as the locus coeruleus. Secondly, there is also increased activity or 'sensitization' at the level of the noradrenergic neurons of the locus coeruleus. Repeated exposure to a stressor results in an enhanced noradrenergic response to any new form of stress – an effect that derives from the sensitization of the locus coeruleus neurons. The same is true for the HPA axis, and thus chronic stress substantially increases stress hormone responses to new forms of stress appearing on the horizon. Oddly enough, to the best of our knowledge the effects of chronic stress on emotional learning and memory have never been extensively examined. However, the activation of stress hormones in response to emotionally aversive stimuli is enhanced at every level during chronic stress. It would be surprising, therefore, if chronic stress did not serve to further enhance emotional learning and memory. Clearly this topic merits attention.

STRESS HORMONES AND COGNITIVE FUNCTION: THE HIPPOCAMPUS

In order to appreciate the effects of stress hormones on hippocampal function, it is critical to understand the timing of the stress hormone release and the emotional valence of the information (Figure 1). In the real world, the presence of a stressor diverts attention towards the stressor and away from unrelated information. This is the reality of cognitive function under duress. Two factors contribute to this state – first, the activation of the state of emotional arousal which corresponds to amygdaloid activity, and secondly, the increased levels of noradrenaline and glucocorticoids acting at multiple sites in the brain.

Activation of glucocorticoid receptors as a result of the high levels of glucocorticoids released by a stressful event enhances learning and memory for the stressful event. A common behavioral test for learning and memory in the rat is the Morris water maze, in which the animal is placed in a 'pool' of water and must find an escape platform located about 2 cm beneath the water level. Normally rats are proficient but reluctant swimmers, so the task is mildly aversive. Since the platform is not visible, the animal must rely on spatial cues in order to locate it. The administration of glucocorticoid-receptor antagonists following training in the Morris water maze facilitates the learning of escape routes. Similar findings have been obtained using other tests that are aversively motivated, such as the Porsholt swim test. However, the presence of elevated levels of glucocorticoids before the occurrence of an emotionally neutral or mildly stressful event can disrupt information processing. Thus the infusion of glucocorticoid-receptor agonists into the hippocampus prior to training in the Morris water maze disrupts learning and memory. The precise mechanisms underlying these actions of glucocorticoids are not entirely clear, but both effects involve glucocorticoid action at the level of the hippocampus. It has been proposed that the memory-impairing effects may also involve glucocorticoid action at the level of the frontal cortex, and may be associated with impaired working memory rather than information storage *per se*. Overall, the evidence both for facilitation of learning by stress hormones following an emotional aversive event and for the memory-impairing effects of stress hormones preceding an emotionally mild or neutral event is remarkably strong. The timing of the increase in stress hormone levels in relation to the event is critical (Figure 1).

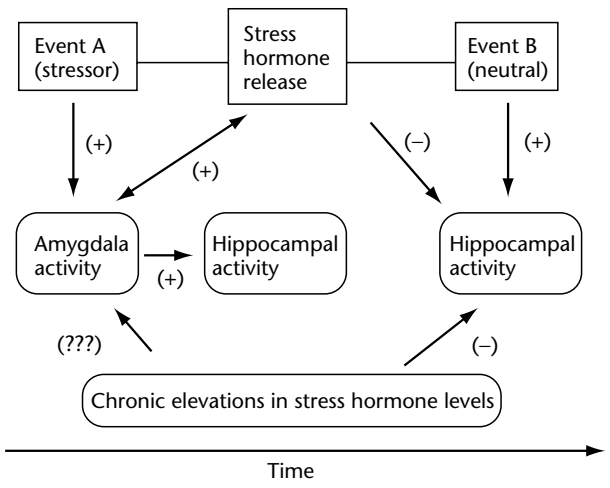

Figure 1. Timing and anatomical distribution of stress hormone release as a function of the emotional valence of stressful events.

The memory-impairing effects of exposure to stress or to elevated levels of glucocorticoids prior to learning and memory are reflected in the results of studies of hippocampal long-term potentiation (LTP). Hippocampal LTP is a model of synaptic plasticity induced by brief tetanic stimulation of glutaminergic afferents to either the CA1 or dentate gyrus region of the hippocampus, and is defined by the enhanced synaptic response to subsequent stimulation. Such LTP is thought to model the processes of synaptic plasticity that mediate learning. Stress or elevated levels of glucocorticoids prior to LTP induction significantly reduce the strength of LTP in the hippocampus. Glucocorticoids regulate the excitability of hippocampal neurons, and more recent studies using models of LTP have clarified the relevant mechanisms of action. High levels of glucocorticoids that result in glucocorticoid-receptor activation suppress LTP. The mechanism underlying this effect involves corticosteroid regulation of intracellular Ca^{2+} concentrations. Following a prolonged sequence of stimulation, hippocampal neurons exhibit a slow, enduring after-hyperpolarization (AHP) that is mediated by a slow Ca^{2+}-dependent K^{+}-conductance, serving to decrease hippocampal excitability. Ca^{2+} influx through voltage-gated channels, and thus the strength of AHP, is substantially increased with the occupation of glucocorticoid receptors. Interestingly, there are also several models of hippocampal synaptic sprouting, and in each case increased levels of glucocorticoids inhibit synapse formation (McEwen, 1999). Unfortunately, in all of these studies the emphasis has been on the effects of glucocorticoids applied prior to stimulation.

As a consequence, we know much more about the mechanisms associated with glucocorticoid-induced impairment of learning and memory than we do about how glucocorticoids act at the level of the hippocampus to enhance learning and memory.

The memory-impairing effects of glucocorticoids administered prior to cognitive testing have been well established in human populations. For example, the oral administration of 10 mg of hydrocortisone leads to a significant decrease in declarative and non-declarative memory performance as tested 60 minutes after hydrocortisone intake. This is of interest in view of the fact that studies report that the hippocampus is essential for a specific type of memory, notably declarative memory, while it is not essential for non-declarative memory. Declarative memory refers to the conscious or voluntary recollection of previous information, whereas non-declarative memory refers to the fact that experience changes the facility for recollection of previous information without affording conscious access to it (priming). Thus this somewhat specialized role of the hippocampus serves as the basis for specific hypotheses about the effects of acute administration of corticosteroids on human cognition (Lupien *et al*., 1998). The results demonstrated that subjects who received hydrocortisone treatment showed impaired performance on the declarative memory task but not on the non-declarative memory task. This suggests that cortisol interacts with hippocampal neurons to induce cognitive deficits.

Although most of the effects of exogenous administration of glucocorticoids on human psychophysical and cognitive processing have been investigated using hydrocortisone, some other studies have used other compounds and reached different conclusions. Poor performance (e.g. errors of commission, incorrectly identifying distractors as targets) on verbal memory tasks occurs in normal volunteers following the administration of prednisone (80 mg/day for 5 days). The general cognitive deficit described in this study involved the relative inability to discriminate previously presented relevant information (target) from irrelevant information (distractors) in a test of recognition memory. The authors concluded that exogenous administration of corticosteroids may reduce the encoding of meaningful stimuli and impair selective attention (i.e. reduce the ability to discriminate between relevant and irrelevant information) (Wolkowitz *et al*., 1990).

It appears that medium to high levels of circulating glucocorticoids may first affect the process of selective attention, thus impairing further explicit acquisition of information, while high or very high circulating levels of corticosteroids may affect explicit memory. This theory has recently been confirmed by a dose–response hydrocortisone infusion study in young normal controls in which infusion of a modest dose of hydrocortisone impaired selective attention capacity, while infusion of a higher dose impaired both selective attention and explicit memory. Interestingly, glucocorticoids also impair the retrieval of information from memory, and indeed these effects may have been confounded in studies where corticosteroids were applied prior to cognitive training, since these steroids will persist in the circulation for periods of up to 1 hour or more. Thus in subjects who had been trained in a declarative memory task, glucocorticoid treatment prior to recall testing impaired performance.

CHRONIC STRESS AND HIPPOCAMPAL FUNCTION

Acute increases in stress hormone levels can serve to enhance or impair learning and memory depending on the timing and emotional impact of the events. The effects of chronic stress have been studied generally within a much more limited set of test conditions. Chronic exposure to elevated levels of stress hormones markedly impairs learning and memory for emotionally neutral information, and the effects can be so severe as to mimic conditions of dementia (Lupien *et al*., 1998; McEwen, 1999).

It has been known for some time that corticosteroid treatment can induce a reversible psychotic condition (so-called 'steroid psychosis') in certain individuals. This condition also includes cognitive disturbances, such as loss of memory, attentional deficits, and problems with logical thinking. A 'dementia-like' syndrome (including attentional deficits and memory impairments) was found to occur frequently in a group of patients who were given high doses of corticosteroids for disorders not related to the central nervous system and who did not show prior evidence of psychosis. These findings are consistent with studies of Cushing's patients, in whom cortisol levels are markedly elevated. Cushing's patients consistently display attentional deficits and memory impairments, and the magnitude of those impairments correlates with plasma cortisol levels. Interestingly, the older subjects (> 45 years) were more seriously affected – they showed significantly greater memory impairments than did younger subjects. Importantly, these deficits were reversible, such that surgical intervention to correct the hypercortisolemic state

resulted in normalized cortisol levels and improved cognitive performance. Moreover, a recent study of Cushing's patients revealed that surgical treatment of hypercortisolism in Cushing's patients leads to a reversal of the glucocorticoid-induced hippocampal atrophy reported to occur in this population, with an average volume increase of 3.2%, and variations up to 10% in some patients (Starkman *et al*., 1999).

In addition, cognitive impairments (including attentional deficits and verbal and visual memory impairments) are often associated with clinical depression and are correlated with increased cortisol levels (Lupien *et al*., 1999). Again, both the increase in plasma cortisol levels and the magnitude of the cognitive disturbances are more severe in elderly patients, often resulting in a condition of so-called 'pseudodementia'. Importantly, in hypercortisolemic patients the cognitive disturbances are more pronounced. It is interesting that depression is also associated with hippocampal atrophy (McEwen, 1999). Considering the evidence for hippocampal atrophy in this population, it is tempting to speculate about the potential involvement of hippocampus dysfunction as a source of the cognitive dysfunction that is associated with the hypercorticoid state.

The results of these studies suggest that in humans, as in rodents, elevated glucocorticoid levels compromise hippocampal function and promote cognitive impairment. In a population of elderly but generally healthy human subjects, cognitive function was related to individual differences in HPA activity and hippocampal integrity (Lupien *et al*., 1998; McEwen, 1999). Cortisol levels were inversely correlated with performance on tests of episodic memory as well as with hippocampal volume. Predictably, the cognitive impairments (including deficits in spatial learning and memory) were associated with the degree of hippocampal atrophy (Lupien *et al*., 1998). These findings are consistent with data obtained for rodent populations, where prolonged exposure to elevated glucocorticoid levels can also compromise hippocampal integrity and certain forms of learning and memory. There is an impressive level of functional equivalence between the rodent and human models of hippocampal aging, and the apparent role of corticosteroids in promoting degeneration.

The assumption that was made on the basis of the earlier rodent studies was that all of this is entirely irreversible. However, more recent studies have emphasized the role of dendritic atrophy as a major component of the loss of hippocampal volume associated with prolonged exposure to elevated corticosteroid levels. Adaptive neuron loss may be a more minor component of the earlier phases of hippocampal degeneration than was originally thought. Instead, the primary effect of prolonged exposure to elevated stress or glucocorticoid levels is that of neuronal atrophy subsequent to dendritic culling. Exposure to chronically elevated glucocorticoid levels compromises hippocampal function to the point of endangering neuronal integrity and survival (McEwen, 1999). Once again the focus is at least in part on corticosteroid effects on Ca^{2+} homeostasis. Chronic stress in rodents and primates produces a reversible regression of apical dendrites. This effect is mimicked by high doses of corticosterone, and is blocked by inhibition of corticosterone synthesis or by Ca^{2+}-channel blockers. Interestingly, these effects parallel changes in the expression of a hippocampal-derived neurotrophic factor, namely brain-derived neurotrophic factor (BDNF) (McEwen, 1999). Chronic stress or chronically elevated corticosterone levels decrease BDNF mRNA expression as well as that of trkB, the BDNF receptor. In essence, the risk is associated with damaging levels of Ca^{2+} as well as with the withdrawal of trophic support, with the decreased production of factors such as BDNF.

SUMMARY

Stressful events impose a very important set of demands on the body, and this is reflected by changes in cognitive function. Although the mechanisms that underlie these effects are still incompletely understood, the existing data appear to provide strong support for the following conclusions. (1) Stress hormones mediate the enhanced learning and memory for emotionally salient information during and following periods of stress. (2) The exact nature of the effects of stress hormones on learning and memory depends on both timing and context. (3) Elevated levels of glucocorticoids following a period of stress can impair learning, consolidation and retrieval of emotionally neutral information, and such effects appear to involve the hippocampus. (4) Chronic stress and thus prolonged exposure to elevated glucocorticoid levels can produce severe impairment in both attention and memory.

Stroke

Introductory article

Fernando Gonzales-Portillo, University of Arizona, Tucson, Arizona, USA
Bruce M Coull, University of Arizona, Tucson, Arizona, USA

CONTENTS

Stroke is a general term for loss of brain function (persisting for more than 24 h) caused by loss of blood supply to the brain, or by hemorrhage within or around the brain.

INTRODUCTION

Stroke is a broad, generic term that encompasses a vast number of causes for loss of brain function due to vascular dysfunction. It is defined as the abrupt onset of focal or global neurologic symptoms caused by a loss of blood supply to the brain (or spinal cord) or hemorrhage within or around the brain that is a result of diseases of the cerebral blood vessels, the heart or blood elements. Although some strokes are 'silent', stroke is commonly distinguished from other neurologic disorders by the sudden development of symptoms that almost always start with a focal loss of neurological function, such as paralysis, loss of speech, vision, or balance and coordination. Sometimes the symptoms of stroke resolve quickly, and if the focal neurological deficit lasts less than 24 h the episode is termed a 'transient ischemic attack' (TIA). It is important to recognize TIAs since they are a harbinger of future strokes that might be disabling. By clinical convention, if the neurologic symptoms due to vascular causes continue for more than 24 h then the event is diagnosed as a stroke.

Stroke is a major public health problem worldwide. It is the third leading cause of death and the leading cause of major disability in the elderly in the USA. The annual incidence of stroke is estimated to be approximately 750 000. Stroke is the most common neurologic disorder of adults in the USA. More often disabling than fatal, stroke has enormous economic, social and psychological costs, measured in terms of both healthcare expenses and loss of productivity. Major strides have been made in understanding the epidemiology, etiology and pathogenesis of stroke and have led to new approaches to diagnosis and treatment.

Strokes can be classified into two principal categories based upon whether the stroke is caused by a blocked blood vessel (ischemic stroke) or a ruptured blood vessel (hemorrhagic stroke). Hemorrhagic strokes are further divided into categories based on the site and origin of the blood: subarachnoid hemorrhage, when the bleeding originates in the subarachnoid spaces surrounding the brain, and intracerebral hemorrhage, when the bleeding is into the brain parenchyma. Ischemic strokes are classified according to the mechanism or cause of the vascular occlusion.

RISK FACTORS

Although stroke is an illness that mostly affects the elderly, a stroke can occur at any age. The risk of stroke increases with age and in the presence of certain risk factors for stroke. African–Americans are more likely than white Americans to experience stroke. Modifiable risk factors for ischemic stroke include the following:

- hypertension
- cardiac disease (atrial fibrillation, myocardial infarction)
- diabetes mellitus
- cigarette smoking
- hypercholesterolemia
- heavy alcohol use
- TIA
- hyperhomocysteinemia
- carotid stenosis.

Nonmodifiable risk factors include:

- age
- male gender
- hereditary or familial factors

Table 1. Incidence of ischemic stroke in people at high risk

Risk factor	*Stroke rate (%) per year*
General population aged 70 years	0.6
Prior MI	1.5
Asymptomatic bruit	1.5
Asymptomatic carotid stenosis	2.0
Nonvalvular AF	5.0
Nonvalvular AF with TIA or stroke	12.0
TIA	6.0
TIA with > 70% carotid stenosis	13.0
Prior ischemic stroke	12.0 (first year after initial stroke)

AF, atrial fibrillation; MI, myocardial infarction; TIA, transient ischemic attack.

- race or ethnicity (e.g. stroke is more common in African–Americans)
- geographic location (southeastern USA is known as the 'stroke belt').

Risk factors for hemorrhagic stroke differ somewhat from those for ischemic stroke and include female gender, hypertension, cigarette smoking and increasing age.

Some risk factors for stroke increase the chance of stroke more than others (Table 1). Combinations of risk factors have an additive or multiplicative effect on risk. For example, a woman with hypertension and atrial fibrillation who is over 75 years old may have more than 15 times the risk of stroke compared with a woman of the same age without these risk factors.

ISCHEMIC STROKE

Ischemic strokes account for 80–85% of all strokes. A cerebral artery that supplies part of the brain is suddenly occluded, with an immediate loss of the function of the affected brain region. The onset of symptoms is immediate because the brain cells cannot effectively store metabolic energy sources and depend upon a continuous supply of oxygen and glucose in order to function. If the vascular occlusion persists for more than a few minutes the brain tissue begins to die, leading to a permanent neurologic deficit.

Ischemic strokes are usually divided into five subtypes based on the mechanism or cause of the vascular occlusion:

1. Primary thrombotic occlusion of a large cerebral artery occurs in 15–40% of ischemic strokes, usually in a vessel already partially occluded by atherosclerosis, for instance the carotid artery or the basilar artery.
2. Occlusion of a small artery or arteriole (lacunar infarct) occurs in 15–30% of cases. It is characterized by hyaline thickening of small penetrating arteries of the brain (lipohyalinosis) and is most commonly seen in people with diabetes mellitus and hypertension. The occlusion of these vessels results in small, deep, often cystic infarcts, appearing as holes (lacunae). These infarcts are often asymptomatic but may cause certain clinical syndromes, such as pure motor hemiparesis, pure sensory stroke, clumsy hand–dysarthria, ataxia hemiparesis, and others. Not infrequently the arteries may also be the target of embolism, and at times the occlusion is due to atherosclerotic plaque in the large vessel from which it arises.
3. Occlusion of a cerebral vessel by a clot that arises from a distant source, usually the heart (cardioembolism), occurs in 15–30% of cases. The heart is the most common source of the embolic material (mural thrombus formation in the setting of atrial fibrillation or myocardial infarction, patent foramen ovale, prosthetic valves, septic endocarditis, etc.). Less commonly embolism arises from ulcerated rupture of atherosclerotic plaques in the aortic arch or at the origin of the great vessels.
4. Uncommon causes of ischemic stroke include cerebral vein thrombosis, inflammation of the blood vessel (vasculitis), paradoxical embolism, polycythemia vera, subclavian steal, sickle cell anemia, and cocaine abuse, among others.
5. Undetermined cause may account for as many as 40% of cases.

HEMORRHAGIC STROKE

Hemorrhagic stroke (subarachnoid and intracerebral) accounts for 15–20% of all strokes, but this figure depends on race and geography, with greater relative frequencies of hemorrhagic stroke observed in China and Japan than in the USA. Bleeding damages the brain by cutting off connecting pathways and by causing localized or generalized pressure injury to brain tissue.

Subarachnoid hemorrhage is most commonly caused by leakage of blood from a ruptured cerebral (berry) aneurysm. This condition is a common, life-threatening medical and surgical emergency and is potentially curable. The signs and symptoms of aneurysm rupture vary according to the severity of the bleed and location of the aneurysm. The classical presentation is an abrupt onset of the worst headache of one's life followed by altered consciousness, meningismus, photophobia, nausea and vomiting.

Intracerebral hemorrhage is characterized by bleeding into the brain parenchyma, usually from

a small penetrating artery. Hypertension has been implicated as the cause of weakening in the arteriole walls and the formation of microaneurysm. Among elderly, nonhypertensive patients with recurrent lobar hemorrhages, amyloid angiopathy has been implicated as an important cause. Other causes include arteriovenous malformations, bleeding disorders, excessive anticoagulation, trauma, tumors, moyamoya disease, cavernous malformations and illicit drug use. The most common sites are the putamen, caudate, pons, cerebellum, thalamus or deep white matter.

The clinical picture depends on the location and size of the hematoma. Headache, vomiting and evolution of motor or sensory signs characterize the usual clinical presentation over minutes to hours. Consciousness is sometimes impaired at the start, and this often becomes a prominent feature in the first 24–48 h with moderate to large hematomas.

PRIMARY SYMPTOMS OF STROKE

The clinical presentation of stroke is diverse and depends upon the type of stroke and the region of the brain affected. Most patients who suffer a stroke develop an obvious loss of motor or sensory function on one side of the body. The motor symptoms may appear as a profound weakness, paresis, or a loss of coordination termed ataxia. Any sensory system may be involved in stroke, but the somatosensory and visual systems are most commonly affected, with sparing of smell, taste and hearing. People with hemorrhagic strokes frequently complain of severe headache, and may vomit, experience seizures or have an altered mental status, including coma.

COGNITIVE CONSEQUENCES

Cognitive and related higher cortical functions including language are often impaired by stroke, especially when the stroke is large and affects the cerebral cortex. Overall, about 30% of stroke survivors will develop dementia within 3 years. This is more likely to occur in elderly individuals, and in those with previous 'silent strokes', cerebral atrophy or diabetes mellitus. Among individuals with dementia, in about 25% the dementia is due to an underlying vascular cause. The loss in cognitive abilities after a stroke can be obvious, as with aphasia, characterized by an inability to produce and/or understand language including reading and writing. Lesions that disconnect or isolate motor areas can produce apraxias in which voluntary movements are impaired despite an intact motor output function. Such individuals often can perform complex involuntary movements such as scratching the nose, despite an inability to perform the same movement to command. Strokes that affect the prefrontal areas can produce impulsive behavior, poor planning, and disinhibition of emotional control with outbursts of crying or inappropriate laughter. Such behavior can be disruptive to family and caregivers and may impair rehabilitation efforts. Individuals with widespread multifocal small strokes often develop 'sundowning' – the manifestation of agitation, delirium with hallucinations and confusion towards nightfall. Some patients with nondominant parietal lobe lesions deny the existence of illness, paralysis or dysfunction even when severe, or fail to recognize their own body parts: these are forms of agnosia.

One important consequence of stroke that is frequently overlooked by both caregivers and healthcare providers after stroke is depression. The onset of depressed mood and flat affect is often mistaken as a reaction to the neurological deficit produced by the stroke rather than an intrinsic depression. Within 18 months of stroke, up 45% of persons recovering from stroke will experience depression. In about half of these, the depression is considered serious enough to affect outcome or quality of life.

OUTCOME

Outcome after a stroke depends upon the type and severity of stroke. About 25–30% of individuals with ischemic stroke recover with minimal or no deficit and roughly 15% will die within a year. Unfortunately, over 50% of stroke survivors will have a permanent severe deficit. The immediate period after ischemic stroke (the first 30 days) carries the greatest risk of death, with fatality rates ranging from 8% to 12%, and the greatest risk of recurrence, with a range from 3% to 10%. Death is more likely to be caused by cardiopulmonary complications than by the stroke itself. For stroke survivors, recurrent stroke within 2 years is the most frequent occurrence and is responsible for subsequent major stroke morbidity and mortality. The hemorrhagic strokes have worse case fatalities and overall prognosis, mortality ranging from 30% to 80% for intracerebral hemorrhage and 20% to 50% for subarachnoid hemorrhage.

TREATMENT

Stroke prevention is the mainstay of treatment since it is far better to keep a stroke from happening than to effect a cure once it has happened. Most primary

preventive strategies focus on treatment of modifiable risk factors such as hypertension, diabetes and smoking, and on dietary and habit interventions to improve general cardiovascular risk. Anticoagulant drugs such as warfarin are useful in certain high-risk patients with atrial fibrillation. With effective control of stroke risk factors, up to two-thirds of strokes could be prevented annually. The use of low-dose aspirin and related antiaggregate treatments, estrogen replacement in postmenopausal women and the application of carotid endarterectomy to asymptomatic individuals remain somewhat uncertain or controversial.

Ischemic Stroke

Acute medical treatment for stroke is designed to prevent or minimize ischemic brain infarction, to optimize functional recovery and to avert stroke recurrence. The current treatment for acute ischemic stroke is largely based on the results of the National Institute of Neurological Disease and Stroke (NINDS) tissue plasminogen activator (tPA) trial published in 1995, demonstrating a beneficial effect of tPA given within 3 h of symptom onset for some individuals; stroke has thus become a neurological emergency. The NINDS results indicate that patients who receive tPA are 30% more likely to have a full recovery or minimal neurological deficit at 3 months after stroke. However, the administration of this thrombolytic therapy does carry a significant 10-fold increase in risk of brain hemorrhage. In order to decrease the incidence of hemorrhagic conversion after tPA, the treatment protocol has to be followed strictly.

In patients who are not eligible for tPA therapy, a variety of treatments including antithrombotic agents can be considered. Several anticoagulant and antiplatelet drugs have been evaluated in clinical trials. The use of antithrombotic agents in an attempt to reduce the risk of stroke progression is complicated by the existence of different stroke etiologic subtypes. The therapeutic approach to the acute ischemic stroke should take into account the underlying pathophysiologic mechanism, but unfortunately, in the early hours of presentation, this is often unknown.

Platelet antiaggregation agents have been shown to prevent recurrent strokes. Aspirin is the most widely studied of these agents, and until recently was the only drug used broadly for this purpose. Results of clinical trials indicate that ticlopidine, clopidogrel, and dipyridamole in combination with low-dose aspirin, are also effective for stroke prevention. Anticoagulant therapy substantially reduces the risk of cardiac embolism, but the evidence supporting the use of it in patients with acute cardioembolic stroke is based upon limited data. Studies of anticoagulants for acute stroke therapy have failed to show a significant reduction in stroke progression, mortality, risk of stroke recurrence, or favorable outcomes. There have been several studies with neuroprotective agents, but unfortunately none of these drugs has shown any benefit in stroke reduction, morbidity and mortality.

Hemorrhagic Stroke

Hemorrhagic strokes are treated according to the cause of the hemorrhage. For intracerebral hemorrhage the medical treatment is supportive and directed at controlling elevated intracranial pressure and maintaining respiratory and other vital functions. In some instances, such as cerebellar or large intracerebral hemorrhages, surgical decompression is required. Surgical evacuation of a hematoma is considered for a lobar or subcortical white-matter hemorrhage if the patient is neurologically deteriorating. In subarachnoid hemorrhage due to a ruptured aneurysm, surgical extirpation and clipping or endovascular coiling of the aneurysm is indicated in order to prevent recurrent bleeding.

CONTENTS

Synapses are specialized structures in neuronal circuits where signals are transmitted from one nerve cell to the next. Synaptic plasticity, involving changes in the efficiency of signal transmission and rearrangement of connections between nerve cells, is thought to underlie brain learning and memory.

INTRODUCTION

Information entering the nervous system through the sense organs is processed by vast arrays of neural circuits where it is progressively transformed into the coordinated muscle movements that make up behavior. At the same time, memory traces are laid down within these same circuits allowing animals to modify their behavior based on past experience. The function of these circuits depends on specific patterns of neuronal connections made by synapses and it is their properties and organization that lie at the heart of nervous system function.

The concept of the synapse was introduced at the end of the nineteenth century by the English physiologist Charles Sherrington, and was based on a combination of ideas from physiology and anatomy. Crucial in its inception was Sherrington's observation that reflex activity in the spinal cord always travels from the sensory fibers to the motor nerves and never in the reverse direction. This suggested the existence of a valve-like function somewhere within the reflex circuit that guaranteed the unidirectional transfer of excitation. Another key insight came from the Spanish anatomist Santiago Ramón y Cajal who argued persuasively that neuronal circuits are not continuous, as had been previously widely thought, but are composed of individual nerve cells whose axonal processes terminate in 'free' endings that are in close contact with the dendrites of other neurons. It was the combination of Ramón y Cajal's histological observations and his own physiological data, both pointing to a unidirectional mode of signal transmission in neuronal circuits, that led Sherrington to propose a specific structure at the point of contact – the synapse – that embodied these properties. It took more than fifty years, and the development of the electron microscope with the power to resolve structures on the scale of nanometers, to confirm the existence of such structures, but when they were finally visualized, they were seen to embody precisely the principles of operation that Sherrington had predicted (Figure 1).

FUNCTIONAL PROPERTIES OF SYNAPSES

Synapses of the kind Sherrington envisaged, which transmit signals between neurons using a chemical 'neurotransmitter' substance, dominate signal transmission in vertebrate nervous systems. A second type of 'electrical' synapse, which operates by direct passage of charged ions through minute pores between two neurons, is less common and will not be dealt with here.

Chemical synapses typically consist of two distinct components: a presynaptic terminal or bouton, which releases the neurotransmitter in response to the arrival of a nerve impulse, and a postsynaptic element where specialized receptor proteins on the neuronal surface detect the neurotransmitter and convert it into a signal inside the second cell (Figure 1). It is this differentiation into pre- and postsynaptic elements that provides the chemical synapse with its distinctive property of transmitting information in only one direction: from the presynaptic terminal where the neurotransmitter is released, to the postsynaptic element where it is detected. One important consequence of this arrangement is that it provides for progression, guaranteeing that signals flow from the sense

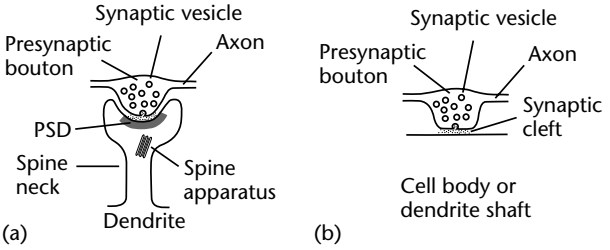

Figure 1. Excitatory and inhibitory synapses. (a) The excitatory synapse is made onto a dendritic spine with a prominent postsynaptic density (PSD) attached to the postsynaptic membrane in the region of the synaptic junction. (b) Inhibitory synapses are typically made directly onto cell bodies or dendrite shafts and lack a prominent postsynaptic membrane specialization. The synaptic cleft is where neurotransmitter molecules (dots) are released from the presynaptic bouton to interact with receptors embedded in the postsynaptic membrane. In both cases presynaptically released neurotransmitter activates postsynaptically located receptors, guaranteeing that signal transmission is unidirectional (from presynaptic to postsynaptic).

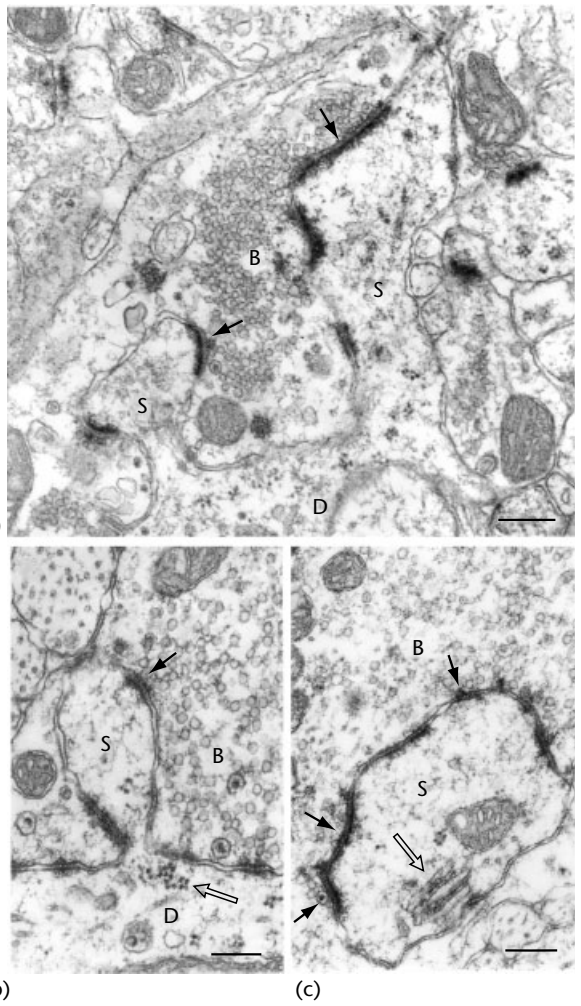

Figure 2. Three examples of giant boutons (B) formed by excitatory mossy fiber axons in the hippocampus which establish asymmetric synaptic contacts (arrows) with large dendritic spines (S). The dendritic shafts (D) are indicated in (a) and (b). The open arrow in (b) indicates ribosomes at the base of the spine, while the open arrow in (c) points to a spine apparatus. Bar, (a), (c) 0.25 μm; (b) 0.2 μm.

organs into the central nervous system and ultimately reemerge from the spinal cord to reach the muscles. It also provides for a wide range of logical operations, such as signal feedback and convergence, which would operate inefficiently or not at all in a bidirectionally transmitting network. These operations are used repeatedly in neuronal circuits throughout the brain and are crucial to their analytical and integrative capabilities.

An important feature of most chemical synapses is that the presynaptic and postsynaptic elements are closely joined by a specialized intercellular junction (marked by arrows in Figures 2 and 3), which provides for specificity of signal transfer within a compact and complex network of axons, dendrites, and synapses. The extent of this problem can be appreciated by considering that 1 mm^3 of gray matter in the cat visual cortex contains in the region of 300 million synapses and estimates for the human cortex range up to one billion synapses per mm^3 (Shepherd and Koch, 1998). With such an enormous density of synapses simultaneously chattering to one another it is crucial that the specificity of transmission be maintained, and it is difficult to imagine a better means of doing so than by 'gluing' the transmitting and receiving elements to one another via an intercellular junction.

Despite this morphological specialization, the small neurotransmitter molecules that convey the signal across the synaptic junction diffuse readily, raising the possibility that they will inadvertently reach and stimulate receptors at other synapses. To avoid this, the neurotransmitter is released into a narrow gap – the synaptic cleft – between the pre- and postsynaptic elements, and its action is rapidly terminated by active reuptake into the neuron or into processes of the glial cells which surround the synapse. Even so, it is thought that spillover of neurotransmitter from one synapse to another may lead to 'cross-talk' between synapses and influence signal processing in the dense central nervous system neuropil (Rusakov *et al*., 1999). Indeed, the presynaptic terminals of axons

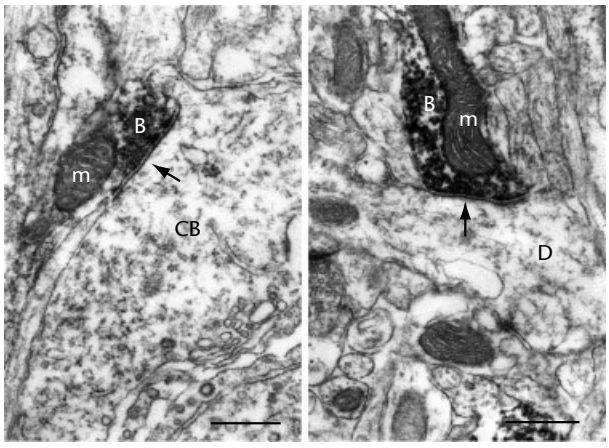

Figure 3. Two examples of inhibitory synapses, identified as such by immunoreactive staining (dark precipitate) in their presynaptic boutons (B) for glutamate decarboxylase, the enzyme synthesizing the inhibitory neurotransmitter γ-aminobutyric acid. The two boutons establish symmetric synaptic contacts (arrows) with a neuronal cell body (CB) in example (a) and a dendritic shaft (D) in (b). Mitochondria (m) are commonly found in axonal boutons. Bar, 0.25 μm.

releasing neurotransmitters such as noradrenaline (norepinephrine), which have a modulatory influence on dendrites spread over wide target areas, seem in general not to make point-to-point contacts.

TYPES OF SYNAPSE

It is also important to recall that while small, focal synaptic contacts of the kind shown in Figure 1 are the rule for the vast majority of neurons in the central nervous system, many other arrangements also occur. Often these are morphologically specialized in ways that are plainly tailored to their function. Examples include giant synapses with multiple independent sites of neurotransmitter release and reception, such as the calyx of Held synapses in the medial nucleus of the trapezoid body, where this reduplication is thought to impart reliability to a circuit whose function is to transmit auditory information with high fidelity. Another example is the giant mossy fiber synapse in the hippocampus, illustrated in Figure 2. Furthermore, whereas in most cases the presynaptic component is part of an axon and the postsynaptic component is part of a dendrite, other arrangements, including axoaxonic and dendodendritic synapses, such as those formed between the dendrites of mitral and granule cell neurons in the olfactory bulb, also occur as solutions to specific processing needs.

Excitatory and Inhibitory Synapses

Major distinctions exist between excitatory synapses, whose activity increases the likelihood of a cell firing by depolarizing the postsynaptic membrane, and inhibitory synapses, which do the opposite. The most salient difference between the two lies in the types of neurotransmitters and neurotransmitter receptors they use. For the vast majority of excitatory synapses in the central nervous system the neurotransmitter is the amino acid glutamate, whereas the corresponding major neurotransmitter for inhibitory synapses is γ-aminobutyric acid (GABA) or, in the spinal cord and brainstem, glycine. At both excitatory and inhibitory synapses, two principal types of neurotransmitter receptors can be distinguished: ligand-gated ion channels serving fast synaptic transmission, and receptors coupled to guanine nucleotide-binding regulatory protein (G protein), whose activation leads to a delayed response in the postsynaptic cell.

The pharmacological distinction between excitatory and inhibitory synapses is accompanied by significant structural differences (Figures 2 and 3). One of these occurs at the synaptic junction, which at excitatory synapses (Figure 1(b)) is marked by a prominent disk-shaped structure, the postsynaptic density (PSD), embedded in the postsynaptic junctional membrane. This postsynaptic specialization is far less prominent at inhibitory synapses, where instead the presynaptic and postsynaptic membrane specializations are of similar thickness (Figure 3). Because of this, inhibitory contacts have been referred to as *symmetric synapses*, whereas excitatory synapses, with their postsynaptic density being more prominent than the presynaptic membrane specialization (Figure 2), have been described as *asymmetric contacts*. The two types are still often referred to as Gray type I (asymmetric synapses) and type II (symmetric synapses), based on their original description by the British electron-microscopist George Gray. The presynaptic boutons illustrated in Figure 3 may be identified as terminals of inhibitory neurons, not only by the symmetric contacts they form but also by their immunostaining for glutamate decarboxylase, the synthesizing enzyme for the inhibitory neurotransmitter GABA. The morphological distinction between asymmetric (excitatory) and symmetric (inhibitory) synapses is correlated with molecular differences, including the virtual absence from

inhibitory synapses of a complex enzyme, calcium–calmodulin kinase II, which is the major protein component of the PSDs of excitatory synapses where it has been postulated to have a role in memory formation (see below).

Advances in molecular biological techniques have led to the identification of a growing number of molecular components that make up these junctional structures, particularly at excitatory synapses. On the presynaptic side, giant modular proteins interact through multiple binding sites with different specificities to build up an active zone which defines the site where synaptic vesicles dock and fuse with the presynaptic membrane to release neurotransmitter in response to an action potential. Postsynaptically, the PSD structure is assembled from a wide range of modular proteins whose binding sites marshal together neurotransmitter receptors and ion channels and couple them to other active components, including other proteins that modulate their function. Much effort is being put into understanding how these pre- and postsynaptic molecular arrays are assembled during development, and how their arrangement and functional state may be modifed in response to activity to modulate the efficiency of synaptic transmission (Sheng, 2001). Rearrangements within these multimolecular complexes, triggered by alterations in neuronal firing rates, may represent an intermediate step in changes of circuit connectivity that underlie learning and memory.

Levels of Organization and Signal Integration

Excitatory and inhibitory synapses differ also in where and how they contact the dendrite of the postsynaptic cell. Excitatory synaptic contacts are concentrated on dendrites and occur far away from as well as close to the cell body. As a result, their influence on the cell's overall state of excitation, and on the rate at which action potentials are generated at the cell body, may be influenced by their location. In contrast, inhibitory synapses are more prominent close to and on the cell body (Figure 3(a)) where their membrane hyperpolarizing influence can act as a 'choke' on action potential generation. This arrangement is particularly important in functions such as surround inhibition, where collateral inhibitory transmission triggered by an active neuron suppresses the firing of its neighbors, thus increasing signal salience relative to background activity. Even the intimacy of the contact made by the two types differs significantly.

Whereas inhibitory synapses are formed directly onto cell bodies (Figure 3(a)) and shafts of dendrites (Figure 3(b)), the vast majority of excitatory synapses, estimated at approximately 90% of those in the brain, are made onto dendritic spines – tiny protrusions, about 1 μm long, from the dendrite surface (Figure 2). Typically a dendritic spine consists of an expanded head, where contact with the presynaptic axonal bouton is made, connected to the dendrite shaft by a narrow neck (Figure 2(a), (c)). Synaptic transmission occurs at the tip of the head (Figure 1(a)), so that in effect the rest of the spine forms a separate compartment interposed between the axon terminal and the dendrite shaft. This compartment often contains what is called a *spine apparatus* (Figures 1(a) and 2(c)), an organelle thought to be involved in sequestering calcium ions. Imaging studies on living neurons using Ca^{2+}-sensitive fluorescent dyes have shown that postsynaptic calcium ion fluxes elicited by low levels of afferent stimulation remain restricted to the spine itself, whereas the larger ion flows produced by higher levels of stimulation can invade the dendrite shaft and neighboring dendritic spines.

Many neurons in the central nervous system receive thousands of synaptic inputs onto dendritic spines, arising from diverse sources, with the figure increasing to tens of thousands for large pyramidal neurons in the cerebral cortex and ranging up to 200 000 on the dendrites of giant Purkinje cells in the cerebellar cortex. The ability of these large numbers of dendritic spines on a single neuron to regulate the access of postsynaptic signaling molecules to the dendrite shaft is widely thought to play a major part in integrating the multiple synaptic signals impinging on a dendrite from different sources.

COMPUTATION IN DENDRITES

Precisely how synaptic signals are integrated to modulate neuronal firing rates is the subject of intensive research that has benefited from increasingly detailed biophysical analyses of electrical activity in dendrites (Hausser *et al*., 2000). These studies have shown that the active properties of dendrites vary as a function of distance from the cell body, so that distant synapses may have a disproportionately large influence on the level of membrane polarization at the cell body, which determines the rate of cell firing. The source of this enhanced efficacy of distal synapses is not yet clear, but may involve higher densities of postsynaptic

neurotransmitter receptors at these sites compared with synapses closer to the cell body.

Another important emerging concept in dendrite function concerns the possibility that the dendritic trees of large neurons are partitioned into discrete zones that can either integrate synaptic inputs independently or combine to give a different, more global output. This has been investigated in large apical dendrites of pyramidal neurons in layer 5 of the cerebral cortex, where synaptic activity in the terminal tuft of dendritic branches in upper layers of the cortex may operate independently of electrical activity in lower levels proximal to the cell body. In this way synaptic influences impinging on basal and proximal dendrite branches may be processed differently from those arriving distally, suggesting that different forms of neuronal computation may occur in different layers of the cortex. Particularly significant is that upper layers of the cortex are rich in long-distance intrinsic connections between pyramidal neurons. This marks a significant shift in thinking from a traditional model of neuronal processing in which the summation of synaptic inputs acts by determining the firing rates of individual neurons, to one in which data-processing operations are carried out by the integrated activity of vast arrays of synapses scattered over the dendrites of many cells. If shown to be a general property of cortical circuits, such a model of 'subthreshold' processing could have significant implications for the processing of multimodal data between widely separated cortical areas.

A further insight from these new data on dendrite function is that the action of distal and proximal dendritic processing may be coupled by calcium-based action potentials within the dendrite itself. Improved techniques for measuring electrical signals in individual dendrites have shown the existence of back-propagating action potentials that originate in the cell body and invade the dendrite. Whether such coupling occurs depends on the relative timing of distal and proximal synaptic events within a timescale of milliseconds. Because of its precisions and association with long-distance intracortical connections, this time-sensitive coupling between cortical layers provides a potential means of synchronizing activities in different cortical regions, a cellular mechanism with obvious implications for cognitive coupling at the psychological level.

SYNAPTIC PLASTICITY

Perhaps the major outstanding question regarding synaptic function is what events mediate the storage of information underlying learning and memory, about which – despite intense efforts – little is known. The most widely investigated memory-related phenomenon is long-term potentiation (LTP), in which an episode of high-frequency stimulation (a tetanus) or the delivery of paired stimuli leads to a long-lasting increase in the synaptic response to a subsequent test stimulus. Conversely, repetitive stimulation at low frequencies can give rise to a long-lasting lowering of synaptic responses known as long-term depression (LTD). In contrast to transitory forms of synaptic plasticity such as post-tetanic potentiation (a short-lived facilitation of synaptic responsiveness that occurs directly following a tetanus), LTP is accompanied by changes in protein synthesis. It has been suggested that this may occur locally at dendritic spines because groups of ribosomes (polyribosomes), the organelles on which proteins are synthesized, are frequently observed at the base of a spine (Figure 2(b)).

Behavioral testing in several sensory systems has associated LTP and LTD with learning and memory and with the adaptation of animals to novel environments (Martin *et al.*, 2000). Various cellular mechanisms have been discussed that might underlie these long-lasting changes. For example, alterations in the amount of neurotransmitter released from presynaptic terminals in response to a standard action potential is one obvious way in which synaptic efficacy might be modulated in response to prior activity. Alternatively, changes in the number or activity of neurotransmitter receptor molecules at postsynaptic sites could alter the level of current elicited in dendrites during synaptic transmission. A considerable body of evidence now exists supporting the existence of such activity-induced changes in postsynaptic receptors, which is particularly marked during synapse development. Experimental evidence suggests that both the insertion of receptors into synaptic junctions and their biochemical modification may be important in the changes in synaptic strength that accompany LTP.

A second general category of potential memory-related adaptation involves changes in synaptic morphology. The shapes of dendritic spines have excited interest over many years as a possible morphological substrate of functional diversity among excitatory synapses that might be linked to learning and memory. Experiments in which animals as diverse as bees, fish, and mice have been raised under conditions of sensory enrichment or deprivation indicate that spine shape and number can vary as a function of brain activity, encouraging

the belief that anatomical plasticity may provide a means of tailoring synaptic throughput to match circuit activity. A link to human cognition is suggested by the observation in many studies that various forms of learning disability are associated with abnormalities in dendritic spine structure.

Based on morphological criteria, three distinct categories of spines are conventionally recognized: 'mushroom', with a thin neck and expanded head; 'thin', with a long neck and less prominent head; and 'stubby', where the neck is absent. These variations might influence synaptic transmission in a variety of ways. For example, differences in the length of the spine neck appear to influence the spread of postsynaptic calcium fluxes from the spine neck into the dendrite. It is also becoming increasingly clear that the expression of functional molecules such as neurotransmitter receptors (both the number and the type of receptor) is closely coupled to the synaptic geometry. A striking example of this principle has emerged from recent experiments showing that α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) subtype of glutamate receptor is closely associated with mushroom spines (Matsuzaki *et al*., 2001).

Such morphology-dependent functional parameters would be expected to be strongly influenced by changes in synaptic geometry, and the recent advent of methods for visualizing synaptic structure in living neurons now allows this hypothesis to be tested. Results of initial studies not only confirm that dendritic spines can change shape but show them to be remarkably morphologically plastic. Time-lapse recordings show that spines are rapidly motile, undergoing spontaneous changes in shape over a time course of seconds which can be regulated by the activation of postsynaptic neurotransmitter receptors. Over longer periods, a variety of other modifications have been described, ranging from the growth of new spines over periods of the order of an hour following the induction of LTP, to their regression and eventual disappearance when synaptic transmission is blocked for a period of days. These phenomena have obvious implications for activity-dependent modulation of neuronal connectivity in central nervous system circuits which are now being explored using *in vitro* cell culture models and, with the aid of new techniques such as two-photon microscopy, in the living brain, where developmentally regulated changes in dendritic spine motility related to sensory stimulation have been described (Lendvai *et al*., 2000).

This structural plasticity depends on the presence in dendritic spines of a specialized cytoskeletal structure consisting of a dynamic meshwork of actin filaments which drives the morphological changes (Matus, 2000). Two kinds of experimental observations lend support to the hypothesis that actin-based motility is an important factor in cognitive function. First, electrophysiological experiments on brain slices have shown that drugs that block actin dynamics interfere with the development and maintenance of LTP, suggesting that actin-dependent changes in dendritic spine shape might be required for memory formation. Second, volatile anesthetic agents such as chloroform and halothane, when applied to cultured neurons at concentrations that are clinically effective, have been shown to block actin dynamics and changes in dendritic spine shape, suggesting that spine motility may contribute to global brain function.

Many of the different molecular mechanisms described as playing a part in synaptic plasticity are susceptible to genetic techniques that allow them to be manipulated in the brains of mutant mice. Applied to glutamate receptor subtypes, this approach has already revealed unexpected subtleties in the relationship of synaptic plasticity to spatial learning (Zamanillo *et al*., 1999). Future experiments of this type should dramatically improve our understanding of the roles that synaptic molecules play in cognitive function.

CONTENTS

Literally billions upon billions of connections between neurons (synapses) exist in the brain. These connections are not static, but wax and wane in strength as we learn, remember and forget.

INTRODUCTION

The brain is composed of perhaps a trillion (1×10^{12}) individual nerve cells called neurons; some estimates are an order of magnitude lower. Neurons communicate with one another using chemical messengers at synapses. Neurons receive information via synapses on their dendrites and cell bodies, and transmit information to other neurons via their axons. A synapse consists of the terminal portion of a presynaptic axonal process, a postsynaptic specialization, and the tiny space separating these. Any given neuron might form several thousand synapses, so the human brain has trillions of synapses. Since each of these synapses can be active or inactive, the number of possible synaptic states is unimaginably large (all of the atomic particles in the known universe total a smaller number). Just these numbers and considerations demonstrate that the brain has immense computational power, but there is more. While synapses can be active or inactive, the strength of the coupling between pre- and postsynaptic neurons can wax or wane for any of a number of reasons (e.g. learning-related or injury-induced changes in inputs). It is such changes in 'synaptic weights', or correlations between pre- and postsynaptic neuron activity, that are the essence of neural plasticity at a system-wide level.

MANIFESTATIONS OF NEURAL PLASTICITY

Changes in the synaptic weights of connections between neurons arise when the inputs impinging on the circuit are altered. Alterations in the pattern of inputs can be due to experience- or injury-induced processes. The most obvious examples of experience-dependent changes in synaptic weights are learning and memory; the former can be thought to involve the identification of the relevant neural circuit, while the latter involves changes in synaptic weights in the connections between the neurons making up the circuit.

Learning can be defined as a change in an organism's behavior as a function of experience. The maintenance of these modifications of behavior is memory. A given memory might be essentially permanent, with its duration defined by the lifetime of the organism, or brief, reflecting moment-to-moment behavioral adjustments to immediate events. Further, learning can occur in response to a single environmental stimulus, or it can involve the formation of associations between two or more stimuli. In any case, the behavioral changes must have a neural correlate in the central nervous system, the organ of behavior.

Nonassociative learning involves a change in behavior in response to a single stimulus. There are two sorts of nonassociative learning: habituation and sensitization. In habituation, the response to a stimulus attenuates with repeated presentations of the stimulus. Loosely speaking, one could say the organism learns to ignore the stimulus. When a rat is presented with an unexpected loud sound, it will reflexively 'freeze', a primary fear response in rats. If the sound is presented a number of times, the magnitude of the startle response will progressively decline, and eventually disappear. The systematic exposure to the unexpected loud sound might occur during a brief period, leading to short-term habituation; if a long period passes during which the sound is not presented, a subsequent presentation will elicit a startle reflex indistinguishable from that produced from the first presentation. Alternatively, if the sound is made a part of the rat's day-to-day experience, the habituation will be retained. The same process occurs in humans; the smell of a

paper mill is obvious to individuals passing by, but the people who live nearby do not notice it. Similarly, people living under a flight path serving a major airport eventually habituate to the sounds of aeroplanes taking off or landing, while for visitors to these people's homes the same level of noise is quite intrusive.

Sensitization represents a different outcome, in which the delivery of one stimulus potentiates responsiveness to other, unrelated, stimuli. For example, if you walk past a cemetery at 2 a.m., a snapping twig will elicit a response of much greater magnitude that it would at 2 p.m. The first stimulus (the cemetery) has potentiated responsiveness to the second. Like habituation, sensitization can be of short or long duration. Habituation reduces synaptic weights, making a postsynaptic response less likely, whereas sensitization increases synaptic weights, increasing the probability of a postsynaptic response to an input. Clearly, the neural mechanisms responsible for short-term versus long-term habituation or sensitization must differ, as the former reflect transient changes in synaptic weights while the latter reflect more permanent changes.

PUTATIVE MECHANISMS OF NEURAL PLASTICITY

Short-term Habituation

An early, elegant set of experiments aimed at elucidating the neural mechanisms of habituation used the marine mollusk, *Aplysia*. The gills of these animals are located on their backs, and as they move around, they spread their gills and extend a siphon that draws in water so that it can be circulated over the gills. A jet of water directed at the gill, or a touch delivered to the siphon, elicits a reflexive retraction of the gill. Continued presentations of either of these stimuli produces habituation of the gill withdrawal reflex. Might this happen because of muscle fatigue, or a reduction in the strength of the neuromuscular synapse? No: direct stimulation of the motor neuron innervating the muscle responsible for gill withdrawal produces muscle contractions of comparable amplitudes before and after habituation. Might the amplitude of the sensory neuron's response to the stimulus (e.g. touch to the siphon) diminish with repeated stimulus presentations so that its activating influence on the motor neuron declines? No: there is no change in the sensory neuron's response to the stimulus during habituation. The neural change upon which this habituation depends must, therefore, exist at the synaptic interface between the sensory and motor neurons.

To understand the mechanism that was eventually revealed, it is necessary first to discuss synaptic transmission in greater detail. The sensory neuron communicates with the motor neuron chemically. When activated, the sensory neuron discharges neurotransmitter molecules that are recognized by specialized proteins embedded in the membrane of the motor neuron. Prior to their release, these neurochemical molecules are sequestered in small, spherical structures called synaptic vesicles. As this 'packaging' occurs in the sensory neuron, roughly equal numbers of transmitter molecules are stored in each vesicle. The amplitude of the response of the motor neuron to activation of the sensory neuron is directly related to the number of synaptic vesicles that are released by the sensory neuron. Moreover, a motor neuron's response amplitude increases in a stepwise fashion, with each step due to the release of a single additional synaptic vesicle. Thus, there is a 'quantum response' to a 'quantum of neurotransmitter release', with the latter being isomorphic with vesicle number. The researchers found that the amplitude of the postsynaptic response of the motor neuron decreased in a stepwise fashion during habituation training, indicating a stepwise decrease in the number of synaptic vesicles released by the sensory neuron. The number of vesicles released by the sensory neuron is determined, at least in large part, by the magnitude of influx of calcium ions as the nerve impulse invades its axon terminals. This influx of calcium ions is triggered by the voltage transition experienced in the axon terminal as the neural impulse in the sensory neuron arrives. During habituation, the influx of calcium ions into the axon terminals of the sensory neuron declines; thus, the quantal release of synaptic vesicles diminishes, as does the resulting postsynaptic response of the motor neuron (Figure 1).

Short-term Sensitization

Aplysia has also proved to be a particularly useful subject for the study of sensitization. Delivery of a noxious stimulus to the animal's tail strengthens synaptic transmission at several sites in the circuit mediating the gill withdrawal reflex. The stimulus delivered to the tail activates sensory neurons that synapse upon facilitator interneurons; these facilitator interneurons, in turn, form synapses on the terminals of sensory neurons responsive to stimulation of the siphon. When the tail is stimulated, the activation of the facilitator interneurons

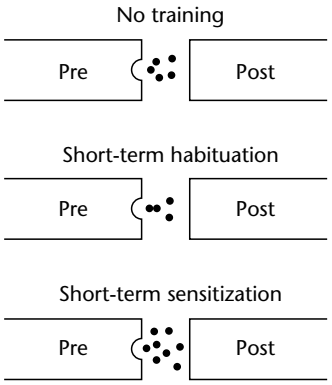

Figure 1. Changes in synaptic weights with short-term habituation and short-term sensitization. Represented are presynaptic terminals of sensory neurons and postsynaptic receptor sites on motor neurons. The black circles in the synaptic space illustrate the level of presynaptic neurotransmitter release. With short-term habituation, the strength of the synaptic connection is decreased owing to a reduction in presynaptic neurotransmitter release. With short-term sensitization the synaptic connection is strengthened owing to an increase in presynaptic neurotransmitter release. Pre, presynaptic terminal of sensory neurons; Post, postsynaptic receptor sites on motor neurons.

potentiates the motor response to siphon stimulation by increasing neurotransmitter release by the siphon sensory neurons. The increased ('sensitized') release of neurotransmitter by the siphon sensory neurons is due to several cascades of events within the presynaptic nerve terminal of the siphon sensory neuron that are initiated with the binding of the neurotransmitter used by the facilitator interneurons with receptors on the siphon sensory neurons. One cascade culminates in a change in potassium ion channels such that potassium ions are impeded in their outward flow across the cell membrane. This serves to prolong the duration of the neural impulse arising from siphon stimulation, and thus, to increase the influx of calcium ions, which in turn increases vesicular release. A second cascade mobilizes mechanisms that act to move vesicles closer to release point, increasing the likelihood that the calcium ion influx will trigger their release. A third cascade leads to the opening of another set of calcium ion channels, and this additional calcium influx also acts to increase neurotransmitter release.

Long-term Habituation and Sensitization

The delivery of 10 tactile stimuli to the siphon in a single training session produces habituation that lasts for minutes. Similarly, a single shock to the tail produces a sensitized response to siphon stimulation that lasts for minutes. On the other hand, four habituation training sessions separated by as much as a day lead to retention of the habituated response that can last several weeks, and five or more shocks to the tail produce sensitization that lasts for days or weeks. These longer-lasting manifestations of habituation and sensitization obviously begin in the same way as their short-term analogs, but just as obviously must involve additional mechanisms that sustain the experience-dependent changes in synaptic weights. Experiments have shown that these additional mechanisms actually alter the morphology of the connections between the siphon sensory neurons and the dendrites of the motor neurons. With long-term habituation, there is a reduction in the number of synaptic connections between sensory and motor neurons in the gill-withdrawal reflex circuit; with long-term sensitization, the number of synaptic connections is increased (Figure 2).

Long-term sensitization has received most of the research attention. Short-term and long-term sensitization both involve a strengthening in connections between sensory and motor neurons due to an increase in neurotransmitter release. Moreover, cyclic adenosine monophosphate (cAMP) and protein kinase A (PKA) are intimately involved in both. The sensitizing stimulus (the tail shock) provokes the release of modulatory neurotransmitters from facilitator interneurons that bind to postsynaptic receptors on sensory neurons. This transmitter–receptor binding initiates the production of cAMP, which in turn activates PKA. Together with some other molecules, PKA acts to phosphorylate (add a phosphate group to, and thus change the function of) several proteins. The phosphorylation

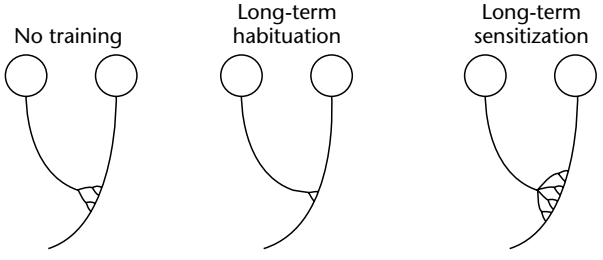

Figure 2. Morphological changes associated with long-term habituation and sensitization. The small triangles represent synaptic connections. Their numbers are decreased with long-term habituation and increased with long-term sensitization. Adapted from Bailey and Chen (1983).

of these proteins leads to an increase in neurotransmitter release from the sensitized sensory neuron (representing the siphon), provoking an enhanced motor response. The transition from short-term to long-term sensitization involves a process referred to as consolidation: the establishment of a more permanent record of experience. When you move to a new town and acquire a new home phone number, some effort is involved in storing that new number in memory for retrieval on demand. Initially one might rehearse the number over and over, and ultimately the number finds its way to long-term memory. Similarly, as one moves from short-term to long-term sensitization, the repeated presentation of the sensitizing stimulus serves the function of rehearsal, and the sensitized responsiveness acquires a less transient representation in the nervous system. With long-term sensitization in *Aplysia* this transition is due to the activation of another kinase by the accumulating PKA. Together, these two kinases migrate to the nucleus of the sensory neuron where they initiate a sequence of genetic processes that result in two significant effects: the activation of molecules that stabilize the PKA (acting to maintain the increase in neurotransmitter release initiated by the initial sensitizing stimulus), and the activation of a gene product required for the growth necessary for the creation of new synaptic connections (thereby augmenting the increased presynaptic neurotransmitter release). Thus, modifications in the efficacy of existing synapses can support the more transient short-term 'memories', while changes in synapse number due to changes in gene expression provide the means to consolidate the short-term memories into longer-lasting memories.

CONCLUSION

While the work discussed here, involving simple forms of learning in an invertebrate model, illustrates nicely how experience can affect synaptic weights, many questions remain. The means by which stimuli reduce calcium ion influx into presynaptic terminals during short-term habituation training remain speculative. The presumptive genetically regulated cascade that results in long-term habituation has received little research attention. Certainly, it is the case that 'positive' changes in synaptic strength (as with sensitization) appear to have greater relevance for learning and memory, but it is reasonable to expect that mechanisms leading to the weakening of connections are equally important. Most significantly, even with these very simple models of learning, the 'decision' mechanisms that act to consolidate short-term to long-term memories of the sensitizing or habituating stimuli are unknown. When is enough enough? How can a presynaptic nerve terminal in the reflex circuit 'know' its history of activation? Perhaps by monitoring free intracellular Ca^{2+} levels. How can it know whether to activate gene-regulated changes in morphology? Perhaps by precisely measuring free intracellular Ca^{2+} levels. Thus, increased (or decreased) intracellular Ca^{2+} levels stimulate locally regulated mechanisms act to increase (or decrease) neurotransmitter release. The larger (or smaller) postsynaptic response then tends the synaptic connection toward sensitization (or habituation).

Perhaps. However, we must not lose sight of the fact that the 'long-term' plasticity discussed here has been shown to last only days to weeks. There are many things that you know that do not require monthly rehearsal regimens – such as an ability to recite the alphabet. Clearly, additional factors (activated by completely unknown mechanisms) are responsible for consolidation as we know it (i.e. the 'permanent' storage of memory). Finally, this review has focused on two forms of nonassociative learning, but associative learning accounts for a much greater proportion of any human's memory store, and neural mechanisms that might support associative forms of learning have been extensively studied. An example of this is long-term potentiation.

Syntax and Semantics, Neural Basis of

Intermediate article

Lewis P Shapiro, San Diego State University, San Diego, California, USA

CONTENTS

Based on evidence from aphasia and neuroimaging studies, elements of syntax and semantics appear to be neurologically isolable and have distinct time courses.

INTRODUCTION

The neurology of syntax and semantics begins with a broad description of these two general areas of language. Syntax includes (a) phrasal geometry – the way in which lexical categories such as noun and verb project hierarchically to form phrasal categories such as noun phrases and verb phrases; (b) the 'dislocation' property of language whereby phrases that are pronounced, heard, or read in one position, are interpreted in a different, nonadjacent position; (c) lexical properties that have structural effects (e.g. the number and type of logical arguments or thematic roles a verb or noun entails); (d) binding relations – the distribution of pronouns, reflexives, and their antecedents (the noun phrases to which they co-refer); and (e) inflectional morphology and agreement. Syntax, then, is essentially about structure-building, from the word to the sentence. Semantics includes (a) the meanings or senses of words (known as lexical-semantics; more formally this may include lexical-conceptual structure); and (b) the meaning of the entire sentence, including its truth-value and logical form. Sometimes semantics also includes how the meaning of a sentence fits into the discourse of multiple sentences. (*See* **Binding Theory**; **Construction Grammar**)

Linguistic theory is concerned with characterizing a mental grammar – the set of abstract categories, rules and principles that underlies language. Accordingly, it has been suggested that a theory of a mentally represented grammar must be accountable to neurological data. The theory can be used as a set of 'discovery procedures', seeking whether elements of syntax and semantics are neurologically isolable. It is also often assumed that linguistic theory is directly relevant to the computational activity of the language processor, the latter being concerned with the study of the mental operations that compute, activate, and integrate linguistic information types. The neurology of language, therefore, involves concepts and methods from linguistics, cognitive psychology, neuropsychology, computer sciences, the neurosciences, and communicative disorders. (*See* **Language and Brain**)

There are two general methods in the study of the neurology of syntax and semantics and in the study of brain–language relations: behavioral studies and functional imaging. Behavioral studies typically use aphasia (that is, lesion studies) as a window into the normal system. Functional imaging techniques could be argued to be more directly aligned with neurology, and are designed to measure the localization of, and in some cases temporal unfolding of, aspects of language. These techniques include positron emission tomography (PET), functional magnetic resonance imaging (fMRI) and magnetoencephalography (MEG), and the measurement of event-related potentials (ERPs) using electroencephalography. Though functional imaging has begun to bear empirical fruit, the study of brain–language relations has, as its bedrock, studies of language pathology subsequent to brain damage. (*See* **Aphasia**; **Electroencephalography (EEG)**)

EARLY LESION STUDIES

Syntactic and semantic analyses of aphasia have evolved from a theory of the localization of 'language as activities' as exemplified by the work of Wernicke, Lichtheim, and Geschwind. This theory focused on the dissociation of production and

comprehension: the former was considered to be disrupted by left inferior frontal lesions involving motor association cortex (Broca aphasia) (Figure 1), the latter by left superior posterior temporal lobe lesions involving auditory association cortex (Wernicke aphasia) (Figure 1). From these findings it was assumed that language production depended upon principles of motor system organization and that comprehension depended upon principles of auditory perception. (*See* **Wernicke–Geschwind Model**; **Broca, Paul**)

Following Chomsky's groundbreaking work in theoretical linguistics, psycholinguists in the 1960s and 1970s began investigating brain–language relations in terms of abstract grammatical categories. In people with Broca aphasia, comprehension limitations were discovered that seemed to parallel production deficits: just as these patients tended to omit grammatical morphemes when speaking, so, too, were they unable to use them for the purpose of comprehension. Also in line with their syntactically simplified output, they were unable to carry out normal syntactic analyses on input strings, their comprehension at the sentence level thereby being abnormally reliant on semantic and plausibility cues. Taken together these findings suggested that damage to left inferior frontal cortex produced an overarching syntactic limitation, even as it spared the capacity to carry out semantic inference (Figure 1). In contrast, people with Wernicke aphasia did not show a normal capacity for semantic inference at the sentence level. Since these patients also tended to produce semantically empty speech in the context of what seemed to be normal syntax, it seemed reasonable to assign this cortical area the role of an amodal semantic center (Figure 1). (*See* **Government–Binding Theory**)

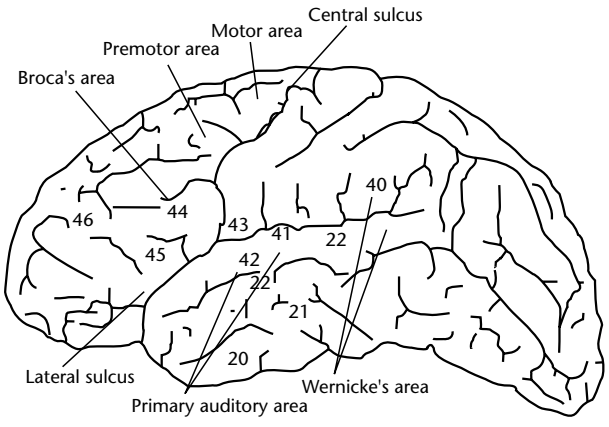

Figure 1. Lateral view of the left cerebral cortex, showing the cytoarchitectural boundaries and Brodmann's areas.

On further analyses in the 1980s and beyond, both functional distinctions (production–comprehension, and syntax–semantics) harvested some support from lesion studies. In what follows, the focus is primarily on comprehension. The language parts and the neurology are considered separately, beginning with an introduction to current psycholinguistic theories of normal language processing, those that are relevant to the study of brain–language relations.

MAJOR PSYCHOLINGUISTIC THEORIES

Just as a linguistic theory should be neurologically defensible, so, too, should hypothesitical processing operations be accountable to data gathered from both normal and language-impaired individuals. Current psycholinguistic theories (mostly concerned with comprehension) can be divided into two competing sets of accounts. Serial, form-driven accounts have a modular architecture and claim that syntactic processing proceeds initially independently from semantic and pragmatic considerations (e.g. Frazier and Clifton, 1996). One such account claims that a first-pass analysis of a sentence includes only placing the incoming lexical items into lexical categories, and, perhaps, activating lexical properties that have immediate structural implications (for example, whether a verb licenses one, two, or three arguments). Lexical categories are then set into phrases via simplicity heuristics: for example, 'build the smallest number of nodes'; 'attach the next lexical item to an already existing phrase'. Thus, only one possible parse is attempted at any given time. The second-pass analysis (or reanalysis if the first parse fails) uses contextual semantic and pragmatic information to identify the correct interpretation for the input. To complicate matters, there are also form-driven accounts that allow multiple syntactic parses in the case of syntactic ambiguities. (*See* **Language Comprehension**; **Psycholinguistics**; **Sentence Processing**; **Sentence Processing: Mechanisms**)

Unlike such form-driven accounts, highly interactive accounts claim that various processes (including syntax and semantics) interact continuously during comprehension. Syntax is considered mostly to be a second-order description for what are really concatenated lexical activation processes (e.g. MacDonald *et al*., 1994). One critical difference between the two accounts, then, is the initial influence of contextual, semantic and pragmatic influences: a form-driven account claims that initial processing is not influenced by such extrasyntactic

information, whereas a highly interactive account claims that processing is continuously affected by multiple sources of information (with different types of information having different degrees of influence). Note that the highly interactive account has some intuitive appeal; after all, it is unarguable that all types of information interact to yield an interpretable sentence. However, the issue is not if information interacts during language processing, but when particular types of information are activated and integrated into the temporal unfolding of language processing. (*See* **Constraint-based Processing**)

To this end, psycholinguistic investigations sometimes make a distinction between offline and online tasks. Offline tasks are useful in studying coarse-grained characteristics of language processing; they are designed to collect data at the endpoints of processing after conscious reflection has occurred. Typical offline methods are untimed, and include sentence–picture matching tasks, grammaticality judgments, answering questions about a sentence, or paraphrasing that sentence. Online tasks collect 'processing time' data moment by moment as input is being analyzed; in particular, they are claimed to be sensitive to rapid, 'reflexive' and unconscious operations. Online tasks include crossmodal lexical priming techniques and word-by-word reading and eye-tracking.

Normal Lexical Processing

The battleground for the form-driven and highly interactive processing accounts has typically involved lexical (and also structural) ambiguities, as well as the dislocation property of sentences. Lexical ambiguities concern the processing of lexical items that have more than one meaning, and the subsequent resolution toward one of those meanings. For example, consider:

> The man saw several spiders, roaches and other bugs [1] in the corner [2] of his room.

The word 'bugs' is lexically ambiguous (ignore for the moment the effect of sentence context); it has (at least) two distinct meanings – 'insect' and 'listening device or hidden microphone'. Given the presentation of a sentence containing a noun (or any lexical item) that has multiple senses attached to one phonological or orthographic form, are one or all of the meanings activated, and when during the time course of sentence comprehension does that activation take place? The answer to these questions seems to indicate that at the point where the phonological/orthographic form of the ambiguous item is recognized, multiple senses are activated. Interestingly, these multiple senses are initially activated even in sentence contexts that appear to be biased toward one particular sense. So, given the example above, at probe position 1 – in the immediate temporal vicinity of the target 'bugs' – the 'insect' sense and 'hidden microphone' sense are both momentarily activated; it is only downstream from the target (position 2, roughly 750 ms later) that the contextually relevant meaning (that is, 'insect') remains active and the inappropriate meaning is suppressed. (*See* **Lexical Ambiguity Resolution**)

These results suggest that lexical access is initially form-driven; context effects and those based on real-world knowledge are seen to take place only subsequent to lexical access. Similar immediate, form-driven effects have been found for the activation of a verb's argument structure (the number of participants/noun phrases entailed by a verb).

Normal Syntactic Processing

The processing of dislocation ('discontinuous dependencies') has likewise reflected on the form-driven nature of initial language operations. Consider:

> The policeman saw the boy who the crowd at the party [1] accused _____ [2] of the crime.

Note that this complex sentence contains two underlying propositions: 'The policeman saw the boy' and 'The crowd at the party accused the boy of the crime'. Each underlying proposition suggests a subject–verb–object order (which is canonical in English). So, in the surface form of the complex sentence, the direct object of the verb 'accused' (that is, 'the boy') occurs prior to the verb, in a noncanonical position. Linguistic theories have various ways for dealing with such dislocation. For example, in a transformational framework the underlying direct object noun phrase (NP), 'the boy', has moved to a noncanonical position, leaving behind a trace or copy of itself at the post-verb position (signified by the gap). In psycholinguistic terminology, the moved NP (or the NP that is heard during auditory presentation) is called the 'filler', and the position from where it moved and where it is interpreted is called the 'gap'.

Presented with such structures, normal listeners indeed appear to interpret the dislocated NP at its canonical, postverb position (position 2 above), yet interpretation does not occur just prior to this position (at 1 above). Thus, the dislocated NP is reaccessed (see, for example, Love and Swinney, 1996). Like the lexical ambiguity work, gap-filling also appears to be a form-driven, automatic, reflexive

operation, even when biasing semantic and contextual information is added. Consider:

> Everyone watched the enormous heavyweight boxer who the small 12-year-old boy on the corner had [1] beaten ____ [2] so brutally.

Even though real-world plausibility strongly suggests that 'the enormous heavyweight boxer' is not a plausible direct object for the verb 'beaten', 'boxer' is activated at the gap position (2), but not at the pregap position (1). This interesting property of language processing is also observed with other complex constructions, and it has been argued that lexical entailments and even probabilistic information do not seem to affect such automatic, initial processing routines.

LESION STUDIES: AN UPDATE

In the 1990s the lesion-localizing value of Broca and Wernicke aphasias continued to dominate the investigative landscape. Though lesion extent is often variable, the neurological damage underlying these two types of aphasia appears to be quite distinct: Broca aphasia involves cortical tissues which include the left frontal operculum (Broca's area) and insula, as well as subjacent white matter; Wernicke aphasia involves tissue that lies more posteriorly, in the left temporoparietal region inferior to the sylvian fissure (Figure 1). What, then, are the behavioral manifestations tied to these profiles that involve linguistic information types and their processing routines?

One influential set of accounts – the trace deletion hypothesis – has claimed that individuals with agrammatic Broca aphasia have a restricted syntactic deficit that disallows the normal representation of traces or copies of moved NPs. This deficit (essentially, a description cast in terms of linguistic theory) behaviorally manifests as an inability to comprehend only certain sentence structures (e.g. passives, object relatives and object clefts), while sparing others (e.g. actives, subject relatives and subject clefts). The empirical support for this account has come primarily from patterns of sparing and loss seen on offline tasks such as sentence–picture matching and grammaticality judgments. Thus, the claim is that the neural tissue implicated in Broca aphasia is used to support the computation underlying dislocation – of transformational relations between moved NPs and their extraction sites – and is not used for any other 'syntactic' or lexical activity (Grodzinsky, 2000). Unlike the interpretable sentence comprehension patterns evinced in Broca aphasia, Wernicke aphasia results in variable, often uninterpretable behavior. When these behaviors are interpretable, however, they suggest a lexical-semantic deficit that does not overlap to any significant extent with syntax or with that of Broca aphasia. There is also considerable online evidence for a distinction between Broca aphasia and Wernicke aphasia, related grossly to the syntax–semantics partition. Zurif and colleagues in a series of online examinations found that people with Broca aphasia do not reaccess fillers at their gap site. Processing a sentence continues without the normal link established between the NP and its extraction site, resulting in offline comprehension difficulties (e.g. Zurif *et al.*, 1993). Individuals with Wernicke aphasia show normal, on-time reaccess effects. Furthermore, though it has also been claimed that lexical deficits cause the syntactic limitations in Broca aphasia, the activation of lexical properties (specifically, verb–argument structure) is intact in Broca – and not Wernicke – aphasia, and therefore independent from observed syntactic limitations (e.g. Shapiro *et al.*, 1993). These online data also suggest that it may not be syntactic processing that is served by Broca's area and surrounding tissue, but rather that this brain region may provide the resources necessary for carrying out fast-acting, reflexive operations that happen to underlie structural processing.

Other Ways to Cut the Language Pie

The interpretation that either (a) a restricted syntactic deficit underlies Broca aphasia while people with Wernicke aphasia evince a lexical-semantic deficit, or (b) reflexive, automatic processing routines are disrupted in Broca aphasia, has not gone unchallenged. The relevant opposing claim is that attempting to generalize sentence comprehension patterns to individuals with Broca aphasia is misguided because of the heterogeneous nature of the behavioral patterns observed in these individuals, and because of the wide-ranging cortical and subcortical damage associated with Broca aphasia. This claim suggests a more 'holistic' approach to language representation and processing in the brain; on this account the apparent linguistic-specific deficits are more likely to be explained by deficits in general cognitive abilities, though these 'abilities' (e.g. working memory, attentional resources) remain relatively undefined.

It would seem, then, that this domain-general account of language deficits is at complete odds with a localizationist, language-specific account. Certainly the underlying assumptions are at odds: the linguistic distinction account suggests that

brain regions are specialized for particular language operations, while the holistic account claims that language emerges from the conjoint activity of spatially discontinuous and widely distributed brain regions. The evidence from neuroimaging might help to resolve some of these issues; indeed, this evidence suggests that the lesion studies have been on the right track – that syntactic and semantic operations recruit different neuroanatomical regions, and, critically, have distinct time courses.

FUNCTIONAL NEUROIMAGING AND EVOKED-POTENTIAL STUDIES

Recent technological advances have demonstrated that neuroimaging and electrophysiological examinations have important potential. Each technique has its limitations: PET has fair spatial resolution (10 mm or more) but poor temporal resolution (approximately 30 s); fMRI has excellent spatial resolution (less than 5 mm) but temporal resolution is moderate (approximately 1 s). Evoked potentials have excellent temporal resolution (in ms), but comparatively poor ability to locate the neural generators of electrical activity in the brain (within about 20 mm).

Positron Emission Tomography

Positron emission tomography involves taking images of regional cerebral blood flow after injection of a radiopharmaceutical tracer such as water labeled with oxygen-15. It thus can be used to see which areas of the brain 'light up' during overall sentence interpretation. Caplan and colleagues have produced a series of such studies, examining sentence structures like right-branching subject gaps (e.g. 'the child spilled the juice that stained the rug') and center-embedded object gaps (e.g. 'the juice that the child spilled stained the rug'). These studies show that the left perisylvian cortex (pars opercularis of Broca's area) is activated in complex (object gap) structures, while Wernicke's area is not (see, for example, Caplan *et al*., 2000).

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging exploits the local magnetic properties of brain tissue. When the person to be investigated is placed in a magnetic field, the proton nuclei of hydrogen atoms align themselves within the field and move about in random orientation to one another. A brief electromagnetic pulse is introduced which disturbs the nuclei and results in their coherent orientation. This coherence is detected as a radio signal and is formed into an image. Blood can be used as an endogenous contrast agent which allows the measurement of the hemodynamic response to event-related (that is, stimulus presentation) activities. Taken as a whole, fMRI studies indicate that different neural regions appear to support different linguistic information types.

Event-related Brain Potentials

Event-related brain potentials record the electrical activity of the brain time-locked to an external event (in the present case, time-locked to word or sentence input). Like many of the neuroimaging techniques, it is common practice to use the detection of different types of linguistic errors, and the resultant ERPs are measured in terms of their amplitude, latency and (in some cases) distribution. The ERP has been extensively used to study language processing. The N400 – a negative waveform occurring approximately 400 ms after presentation of relevant stimulus – is typically used as a marker for semantic processing, following the groundbreaking work of Kutas, Hillyard and their colleagues (Kutas and Hillyard, 1983). It is likely that the N400 is elicited in response to the semantic or pragmatic expectation of a given word in a particular sentence context, with large N400s found when the word is semantically anomalous. (*See* **Event-related Potentials and Mental Chronometry**)

Syntactic processing has been associated with two distinct waveforms, a late and large positive wave shift (the P600), and a left anterior negative (LAN) wave. The P600 has been found with various types of syntactic violations, such as phrase structure and agreement errors, and appears to be associated with second-pass reanalysis routines. Friederici and colleagues (e.g. Friederici, 1995) have specifically tied their work to models of normal sentence processing. They have suggested a two-stage serial processor whereby first-pass parsing routines are highly automatic and reflexive, and are reflected by an early LAN wave, and that controlled, second-pass reanalysis routines are reflected by the P600.

Magnetoencephalography

A newer electrophysiological technique, magnetoencephalography, has similarly good temporal resolution, and significantly better spatial resolution than ERPs, but is limited by only detecting signals from areas of cortex that lie perpendicular to the scalp. Thus far, MEG has been used mostly to examine phonetic and acoustic variables (the

latter has been directly compared, favorably, to the detailed data obtained from invasive electrode recordings in other animals).

Summary of Aphasia and Neuroimaging Data

Though neuroimaging and electrophysiological techniques have yielded important information about brain–language relations, it could be argued that the fuel for these studies has been investigations of language processing in both normal and brain-damaged individuals. To be sure, there are limitations to both methods. Evidence from brain damage is, by its nature, imprecise. Theoretical differences, stimulus characteristics, task considerations, subject selection, and perhaps individual variation, combine to sometimes yield conflicting data. Neuroimaging has attempted to provide greater precision regarding localization of function, but it turns out that there is considerable variability regarding strict localization of syntactic and semantic processing here as well, and localization of semantic processing is typically computed by reference to semantic anomalies or simple lexical access, which are at best rough attempts at semantics.

Nevertheless, by combining lesion studies with neuroimaging techniques, scientists have begun to unravel the temporal and spatial characteristics of language representation in the brain (Figure 1). These characteristics may include:

- acoustic information that is analyzed in the auditory cortex within 100 ms of stimulus onset;
- identification of phonological word forms and phonological sequencing, which recruits left planum temporale and also involves the upper and posterior parts of Broca's area;
- lexical category formation that occurs within 200 ms of onset, and moves from Wernicke's area (Brodmann's area 40) to the inferior part of Broca's area (Brodmann's area 44), the latter supporting initial structure-building – including dislocation processing;
- lexical-semantic activation and integration, which involves the temporal language region (Brodmann's areas 22 and 21) and occurs within 300–500 ms of onset;
- reanalysis of input (if necessary), which occurs within approximately 600–1000 ms of onset and probably recruits areas involved in working memory (e.g. Brodmann's area 46) and regions including the right hemisphere as well (see Friederici, 1995).

RECOVERY, TREATMENT AND NEUROIMAGING

Recovery from brain damage is just beginning to be seriously studied by scientists interested in brain–language relations. The issues confronting these investigations are particularly thorny, since brain organization, learning or relearning, and several facets of language are involved. In particular, careful attention has to be paid to the research designs and methods that yield and measure learning over time. Although there are many published studies on the treatment of language disorders through the fields of communicative disorders and the neuropsychology of language, very little of this work has been concerned with the sorts of specific syntactic and semantic deficits observed in the aphasias (but see, for example, Thompson *et al*., 1997). Fewer still have exploited neuroimaging techniques to map the purported recovery process. One broad issue is whether perilesional tissue or right hemisphere homologs (of, for example, Broca's and Wernicke's areas) appear to be active during good or poor recovery from aphasia. The evidence is equivocal, and is limited by the large differences in methods and participant selection.

SYNTACTIC PRODUCTION

Most of this discussion has been on how comprehension – normal and disordered – reflects on the neurology of syntax and semantics. There have been few similar efforts in syntactic production, even though the hallmark of Broca aphasia has always been effortful, halting and syntactically impoverished speech. The most recent work in production deficits in Broca aphasia from a linguistic framework suggests that phrasal geometry and its relation to abstract inflection features of language may be involved in a description of the deficit. Within that part of syntactic theory that deals with the phrase structure tree (which describes the structural configuration of sentences), lexical categories such as noun, verb, preposition and so on are said to 'project' upwards in the tree to maximal projections (e.g. noun phrases, verb phrases, prepositional phrases and so on). Careful analyses of agrammatic speech have yielded a circumscribed syntactic deficit: the sentence structures do not project to the topmost part of the tree, resulting in a production impairment of some sentence constructions in English (e.g. *wh*-questions, tenseless verbs), while different constructions that rely on the same part of the tree in other languages are affected (e.g. Friedmann, 2002). These sentence production results highlight the apparent importance of Broca's area for the normal functioning of syntactic abilities that are quite distinct in production versus comprehension; thus far, a description encompassing an overarching syntactic deficit has not been satisfactorily proposed.

CONCLUSION

The study of brain–language relations has benefited greatly from work in theoretical linguistics, psycholinguistics, lesion studies, and functional neuroimaging. Elements of syntax and semantics – the former more specified than the latter – appear to recruit different brain regions as well as distinct time courses, although some overlap has been observed. This localizationist hypothesis in one form or another has been with us in the modern era for at least 150 years (as has been its counterpart, the holist approach); we are now beginning to fill in some of its details.

Temporal Cortex

Intermediate article

Elisabeth A Murray, National Institute of Mental Health, Bethesda, Maryland, USA

CONTENTS

The temporal cortex is named for the portion of the cranial bone under which it lies. In human and macaque brains, the temporal cortex lies beneath the lateral sulcus and consists of three main parts: the superior temporal cortex, the inferior temporal cortex, and the paralimbic cortex.

INTRODUCTION

Because 'temporal cortex' is a descriptive term, derived from this tissue's physical proximity to the temporal bone of the cranium, the boundaries of this structure are fuzzy and subject to debate. In general, the temporal cortex can be divided into three main parts: the superior temporal cortex, the inferior temporal cortex, and the paralimbic cortex. The superior temporal cortex, including cortex on the superior temporal gyrus as well as cortex lying on the lower bank of the lateral sulcus, processes auditory information, but much of it has a multimodal (polysensory) function involving both auditory and visual inputs. The inferior temporal cortex, including cortex on the middle and inferior temporal gyri, processes mainly visual information. In monkeys the inferior temporal gyrus abuts the paralimbic cortex; indeed, the paralimbic cortex actually extends onto the gyrus. In contrast, humans possess additional cortex on the ventral surface of the brain (mainly on the fusiform gyrus), located between the inferior temporal gyrus and paralimbic cortex, which is also part of the inferior temporal cortex. The paralimbic cortex, which includes much of the cortex on the temporal pole, receives an array of unimodal and multimodal sensory inputs and is thought to play a part in integrating information from the different sensory modalities.

For obvious ethical reasons, human brains are rarely the subject of detailed scientific study at the single-cell level, nor are they available *in vivo* for tracer studies of neuronal connectivity. Accordingly, much of the available information about the temporal cortex comes from the study of nonhuman animals, especially macaque monkeys. For example, insights into temporal cortex function have emerged from the study of activity of neurons in awake, freely moving monkeys. In addition, neuroanatomical studies have been carried out to help define how the various parts of the temporal cortex communicate with each other and with other brain regions. Finally, the behavioral effects of selective cortical lesions have been characterized to a degree that is clearly impossible in humans. These approaches provide complementary sets of information that together provide a picture of the functional organization of the temporal cortex. A noninvasive technique for localizing function in the human brain has now been developed. This functional imaging technique uses sophisticated methods to measure local rates of blood flow and other hemodynamic events in people who are exposed to specific sensory stimuli, or while they engage in a behavioral task. Local physiological activity in a population of cells and synapses contributes to the hemodynamic changes, measures that collectively are called 'activations'.

INFERIOR TEMPORAL CORTEX

The inferior temporal cortex subserves vision, especially what is known as higher-order vision. Higher vision can be distinguished from lower vision along the same lines as perception can be distinguished from sensation. Anatomical and physiological studies have identified at least 30 separate areas with visual functions in the cortex of monkeys, and there could be an even greater number of visual areas in the cortex of humans. One view of the division of labor among the visual areas holds that there are two main processing systems, one devoted to identifying what an object is, and the other devoted to identifying where an object is (Ungerleider and Mishkin, 1982). According this view, the temporal cortex is mainly the province of the former system, known as the ventral stream because of the idea that visual information 'flows',

in some sense, from occipital cortex forwards and ventrally toward the temporal cortex (Figure 1). The other system, known as the dorsal stream because information is held to flow from the occipital to the parietal cortex, is thought to have a role in either spatial perception, as noted above, or in the guidance of movements to spatial targets (Milner and Goodale, 1996). Part of the evidence in support of two separate processing streams is that the inferior temporal areas can continue to function even though the parietal areas have been damaged. In Balint syndrome or optic ataxia, people with damage to the parietal cortex are good at naming and identifying objects, but show profound disabilities in reaching towards those same objects. Conversely, patients with damage to the inferior temporal cortex may be unable to identify objects, but at the same time are able to navigate around them and to reach accurately towards them. (*See* **What and Where/How Systems**)

Anatomy of the Inferior Temporal Cortex

In macaque monkeys, the occipitotemporal or ventral stream pathway begins with the projections from the striate cortex (the primary visual cortex, V1, also known as area 17) to the second and third visual areas, V2 and V3, which in turn project to area V4 (Figure 1). These prestriate visual fields are arranged in adjacent cortical belts that nearly surround the striate cortex. One output of these prestriate regions is to the inferior temporal cortex, comprising areas TE and TEO. (The labels 'TE' and 'TEO' are derived from cytoarchitectonics: the parcellation of cortical fields based on cell size, type and staining intensity, laminar organization, and other structural features that together can be used to differentiate one region from another. The T stands for temporal, the E designates the fifth of a group of fields, classified by anatomists as A to E, and the O in TEO stands for occipital, meaning the subdivision of TE nearest the occipital lobe.) The inferior temporal cortex is in receipt of highly processed visual information arising not only from lower-order visual areas, but also from subcortical structures including the thalamus and basal ganglia.

Inferior Temporal Cortex Function in Monkeys

Neurons in the visual cortex 'see', or represent, pieces of our visual world. The amount of visual space that a neuron represents, or is responsive to, is termed the 'visual receptive field'. In striate and prestriate areas the representation in the cortex is map-like or visuotopic: that is, nearby parts of visual space are represented in nearby parts of a cortical area in a systematic mapping. In area TEO of the inferior temporal cortex, this visuotopic organization seems to be coarser than that in earlier fields; in area TE it may be nonexistent. In area TE, unlike other visual fields, neurons have large

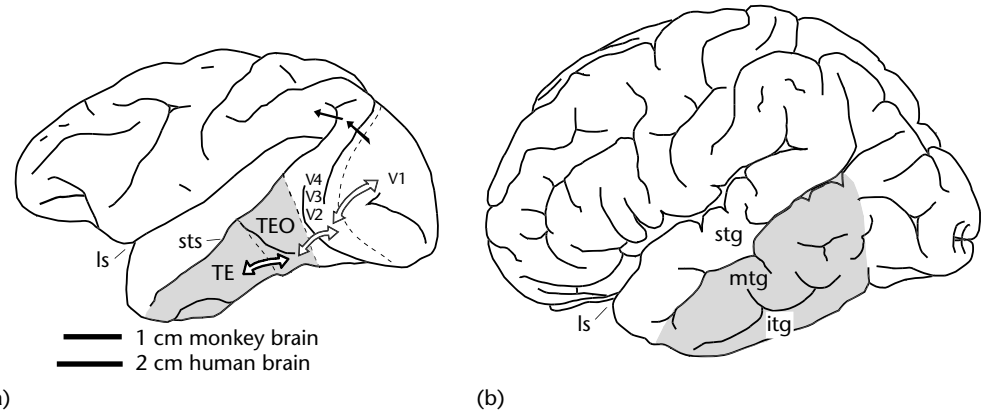

Figure 1. Location of inferior temporal cortex (shaded region) in (a) macaque monkey and (b) human brains, shown on a lateral view of the brain. In monkeys, the inferior temporal cortical fields related to vision are areas TE and TEO, which occupy all of the middle temporal gyrus and much of the inferior temporal gyrus. White arrows indicate flow of information from striate cortex (V1) to prestriate (V2, V3, V4) areas into inferior temporal cortex, together constituting the ventral visual stream. Black arrows suggest flow of information from striate to prestriate to parietal cortex, the dorsal stream. itg, inferior temporal gyrus; ls, lateral sulcus (sylvian fissure); mtg, middle temporal gyrus; stg, superior temporal gyrus; sts, superior temporal sulcus.

receptive fields that often cross the midline. Thus, neurons in area TE can 'see' an object regardless of its position in the visual field.

Neurons in the inferior temporal cortex are sensitive to one or more aspects of the stimulus qualities that we perceive. For example, neurons represent color, texture, direction of motion, size and orientation, and binocular disparity. Because neurons in inferior temporal cortex receive visual information from the earlier stages, it appears that the inferior temporal cortex neuronal responses are built up from those in earlier areas. For example, neurons in caudal visual fields respond well to oriented bars and simple gratings; in contrast, neurons in anterior and ventral portions of inferior temporal cortex respond better to complex visual stimuli. Although single neurons may respond selectively to objects, it seems likely that individual objects are represented by a population of neurons, as opposed to single neurons.

Damage to the inferior temporal cortex leads to deficits in the identification of objects through vision. Behavioral tasks designed to test visual abilities in monkeys indicate that inferior temporal cortical damage produces difficulties in discriminating and in matching objects on the basis of vision. At the same time, objects can be discriminated by touch. Because basic sensory capacities such as acuity and color vision are largely intact after inferior temporal cortical damage, the difficulty is considered to be one of higher-order vision. The nature of the impairment caused by inferior temporal cortex lesions is controversial. One idea is that damage to this region results in a loss of the ability to represent features, in such a way that the greater the damage, the fewer the visual features that can be represented. Another idea is that it is not the ability to represent features that is lost, but rather the ability to represent conjunctions of features. Both these ideas emphasize the role of inferior temporal cortex in visual perception: that is, its role in representing visual features. On either view, damage to inferior temporal cortex will lead to disruption of stored representations of features, resulting in a loss of long-term visual memory. At the same time, this damage would result in an impaired ability to represent features, a perceptual deficit. Thus, it appears that neurons in the inferior temporal cortex contribute to both perception and memory, and that perceptual and mnemonic functions are anatomically inseparable in this part of the brain. (*See* **Object Perception, Neural Basis of**; **Vision: Object Recognition**)

Also in the temporal cortex are two areas involved in processing motion vision, the middle temporal and middle-superior temporal areas, abbreviated as MT and MST, respectively (not illustrated). These areas are located in the depths of the superior temporal sulcus, near the temporal-parietal-occipital junction. Often considered a third visual stream, contrasting motion vision with the object vision of the ventral stream and the spatial vision of the dorsal stream, these visual areas have been the best characterized in terms of their neurophysiological mechanisms. Neurons in MT and MST reflect precisely the judgments reported by monkeys about the direction in which a field of light spots is, on average, moving. Further, exciting cells by passing electrical current through an electrode near them affects the monkey's perceptual judgment in a systematic manner. For example, if a group of neurons represents upward motion, then stimulating these cells during a period when the light spots are tending to move to the left will induce the illusion that they are moving slightly upwards as well as to the left.

Inferior Temporal Cortex Function in Humans

The general pattern of visual information processing appears to be similar in monkeys and humans (Figure 1), and many of the cortical fields identified in monkeys have probable homologues in humans (Wandell, 1999). As in monkeys, there are visual areas devoted to processing object features, and others, buried deep in the posterior portion of the superior temporal sulcus, devoted to processing motion.

Damage to the inferior temporal cortex in humans – which may follow stroke, herpes encephalitis, degenerative disorders such as Alzheimer disease, or surgical intervention to excise a brain tumor – results in a class of deficits termed 'visual agnosia'. Depending on the location and extent of the brain damage, deficits range from severe impairments in shape discrimination, in which patients are impaired in identifying, matching, copying or discriminating simple visual stimuli, to milder deficits characterized by difficulty in naming objects on visual confrontation. Between these extremes are patients who, although able to identify objects presented singly, have difficulty when several objects are present, or when they must describe the contents of complex pictures. Not surprisingly, these patients also have difficulty reading. Yet other patients display remarkably selective visual deficits; for instance, some are unable to identify faces of familiar persons or family members through vision, although they are able

to visually identify other types of objects and to identify familiar people upon hearing their voices (Farah, 1990).

Damage to more rostral portions of the inferior temporal cortex is characterized by intact visual matching abilities but deficient retrieval of information related to familiar objects. The study of patients with semantic dementia, in particular, has helped provide a picture of rostral inferior temporal cortex function. Patients with semantic dementia sustain a progressive loss of neurons in the inferior temporal cortex. The defining characteristic of these patients is a loss of semantic knowledge, that is, a loss of factual information about the world. This loss of knowledge affects both verbal and nonverbal aspects of knowledge. For example, such patients have difficulty naming familiar objects, generating a definition of objects, matching object pictures to their names, selecting appropriate colors for objects, and drawing objects from memory (Hodges *et al*., 1992). As was the case for monkeys with inferior temporal cortex damage, the impairments described above cannot be reduced to simple visual perceptual deficits; in all cases, the deficits appear despite intact acuity, brightness discrimination, and color vision.

Functional imaging studies in humans have been able to identify regions within the inferior temporal cortex that respond selectively when the person views pictures of objects in different categories, including animals, faces, tools, houses, and chairs. In general, the representations of different object categories within the inferior temporal cortex are topographically organized; that is, the spatial arrangement of the locations of the peak activations for tools, houses, etc. are consistent across subjects and tasks. At the same time, the representations are distributed and overlapping. They can be said to be distributed because the region of activation is not focal, but rather is typically a complex pattern spread over an expanse of cortex; they can be said to be overlapping, because even if the locations of the peak activations for two categories differ, there may be overlapping zones of activation as well. This pattern of results has led to the idea that the ventral and lateral temporal cortex contains a kind of feature space in which stored information about objects, especially shape information, is represented (Martin and Chao, 2001).

Similar patterns of activation are found when people are asked either to view or to imagine objects from different object categories. In addition, the same temporal cortical regions are activated when participants recognize, name, read about and answer questions about particular objects. These findings are consistent with the idea that these areas store information about objects, representing object-specific features and attributes.

The regions described so far appear to represent object categories, in that groups of neurons respond not to unique entities, but to almost any item in a given category. This leaves open the question of how individual objects are represented. In humans, the most commonly studied unique item has been photographs of famous faces. Interestingly, such studies usually find activations in the anterior middle temporal gyrus and temporal pole. Based on this and other information, the idea has arisen that more anterior regions of the temporal cortex are important for retrieving information about unique items.

As we have seen, the inferior temporal cortical areas of monkeys and humans share many functional properties. Indeed, taken together, the studies of monkey and human inferior temporal cortex provide converging evidence that this region is important for storing information about the visual world. So far, however, we have ignored potential differences between monkeys and humans in the organization of inferior temporal cortex. First, it should be noted that the regions that are important for representing color and form, while located in the most anterior portions of inferior temporal cortex in monkeys, are located in more caudal and ventral portions of inferior temporal cortex in humans. This leaves relatively uncharted a large expanse of anterior inferior temporal cortex in humans, which may be devoted to language-related processing. Second, in humans there is a division of labor between the left and right temporal lobes such that the left is predominately involved in language-related functions and the right predominately involved in processing complex geometric figures, such as abstract designs. This division is not absolute, as even damage to the right temporal lobe can affect linguistic processing, and furthermore, deficits that occur after damage to inferior temporal cortex in both hemispheres tend to be more severe than those that occur after damage to inferior temporal cortex in one hemisphere.

SUPERIOR TEMPORAL CORTEX

Much of the auditory sensory processing in primates takes place within the superior temporal cortex. Anatomical and physiological evidence from monkeys indicates that there are at least 12 separate cortical fields serving audition. As was the case for visual sensory processing, auditory sensory processing appears to proceed through a

series of stages. In primates, there are three primary or primary-like auditory cortical fields, often referred to collectively as the core region, located on the lower bank of the lateral sulcus (also known as the superior temporal plane), hidden by the overlying parietal cortex (Figure 2). These regions project to a belt region consisting of about seven additional cortical fields. The belt regions, in turn, project to a parabelt area, which occupies much of the superior temporal gyrus (Kaas *et al*., 1999).

Superior Temporal Cortex Function in Monkeys

All of the primary fields and many of the belt fields are cochleotopically organized: that is, different neurons in these regions represent different frequencies of sound, with a systematic shift from low to high frequency as one moves across the cortical field. The activity of neurons in the core and belt regions often reflects not only frequency, but also the temporal features and spatial location of an auditory stimulus. Whereas neurons in the core region are more active in relation to pure tones than to complex sounds (narrow-band noise), neurons in the belt areas show the opposite pattern. Thus, as in visual sensory processing, for auditory sensory processing there are multiple cortical fields containing representations of the auditory world, and there appears to be convergence of inputs from primary areas to higher-order areas.

In addition to primary and nonprimary auditory areas, the superior temporal cortex contains many polysensory fields, primarily related to combined processing of auditory and visual information (not illustrated). These lie largely in the depths of the superior temporal sulcus, in a position between the auditory cortical areas and the visual areas.

Superior Temporal Cortex Function in Humans

Primary auditory cortex in humans is located on the first temporal transverse gyrus (also known as the transverse gyrus of Heschl). There is some evidence to suggest that there is more than one cochleotopically organized field in this region. In addition, preliminary evidence suggests that there are several auditory cortical fields in this general region, many of which might be homologues to the fields identified in monkeys (Melcher *et al*., 1999). It has been proposed that auditory sensory processing, like visual sensory processing, may involve two main pathways, one for interfacing speech with object representations, and another for interfacing sensory with motor processes (Hickok and Poeppel, 2000). This view is in line with a division of ventral (temporal cortex) versus dorsal (parietal cortex) function in terms of perception and visuomotor control, respectively. However, it is possible that the two systems involved in speech processing both interact with parts of the ventral stream,

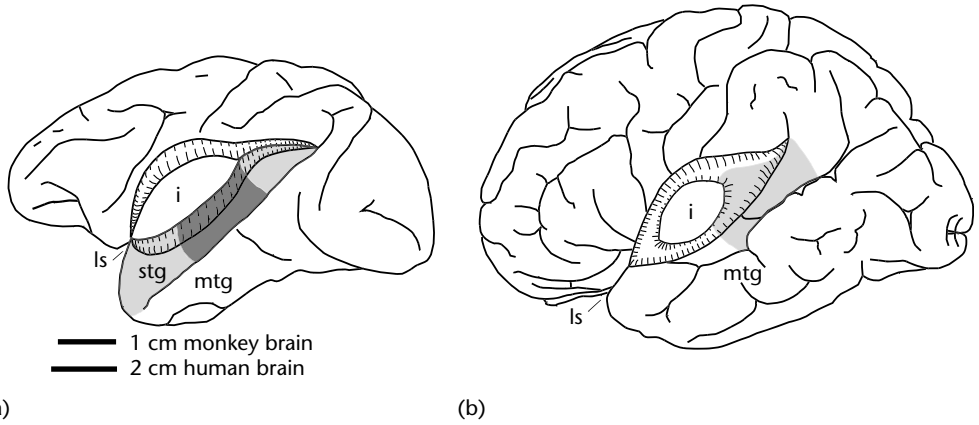

Figure 2. Location of temporal cortical areas (shaded regions) related to auditory processing in (a) macaque monkey and (b) human brains. The lateral sulcus has been opened to reveal cortex on the insula, and on the lower bank of the lateral sulcus, regions that are normally hidden from view. In the monkey brain, the dark shading shows the approximate location of the core, belt, and parabelt fields of auditory cortex. The lighter shading shows other auditory-related areas. In the human brain the shaded region includes both core and other auditory-related areas. Adapted from (a) Kaas *et al*. (1999) and (b) Hickok and Poeppel (2000). i, insula; ls, lateral sulcus; mtg, middle temporal gyrus; stg, superior temporal gyrus.

which, in turn, functions in both visual perception and visuomotor control.

Based on studies of patients with brain damage and on functional imaging studies, sound-based representations of speech are thought to be located bilaterally. After the initial analysis of speech sounds, regions in the temporal-parietal-occipital junction are thought to help interface the sound representations with other semantic and conceptual representations. Patients with bilateral damage in the region of the posterior superior temporal lobe exhibit profound speech perception deficits; although they may display normal pure tone thresholds, they are incapable of understanding auditorily presented words. This constitutes a type of aphasia, usually referred to as Wernicke aphasia. However, numerous subtypes of aphasia have been distinguished, and the term refers generally to a variety of deficits in either expressing or comprehending speech. (*See* **Audition, Neural Basis of**)

There are some differences in left and right hemispheric contributions to speech perception. The left hemisphere is more important than the right for the processing of fine-grained temporal events. Conversely, the right hemisphere may be more important than the left for the processing of spectral information. In addition, evidence from brain-damaged patients and from functional imaging studies suggests that auditory cortex in the left hemisphere may contribute to aspects of speech production.

PARALIMBIC CORTEX

Three cortical fields in the ventromedial aspect of the temporal lobe make up the paralimbic cortex: the entorhinal cortex, the perirhinal cortex, and the parahippocampal cortex (Figure 3). These regions have also been referred to collectively as the 'parahippocampal region', because of their proximity to, and anatomical relations with, the hippocampal formation: all three are six-layered cortical fields that have reciprocal anatomical connections with parts of the hippocampus and with each other.

The paralimbic cortical fields receive not only visual and auditory sensory inputs, but also an array of inputs from other sensory modalities. Indeed, they have long been recognized as a site of convergence of information arising from all the sensory systems. These fields receive anatomical connections from high-order modality-specific fields such as TE (for vision), regions on the superior temporal gyrus (for audition), areas in the caudal insula (for somatic sensation), as well as from areas that process visuospatial information, such as the retrosplenial cortex and posterior parietal cortex. Olfactory inputs also reach the paralimbic cortical

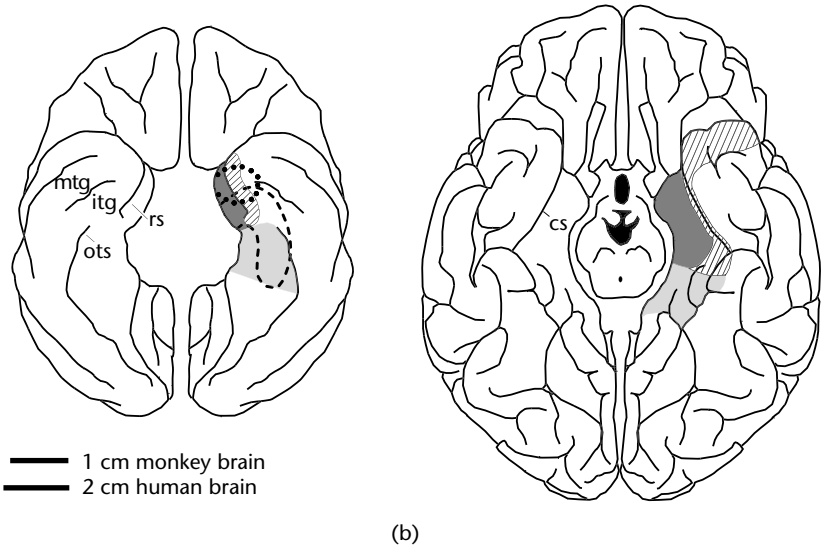

Figure 3. Locations of paralimbic cortex (shaded areas), shown on the ventral surface of (a) macaque monkey and (b) human brains. Dark gray shading represents the entorhinal cortex, oblique hatching shows the perirhinal cortex, and light gray shading represents the parahippocampal cortex. In the schematic of the monkey brain, heavy dotted and dashed lines show approximate locations of the amygdala and hippocampus, respectively. Schematic of human brain adapted from Burwell *et al.* (1996). cs, collateral sulcus; itg, inferior temporal gyrus; mtg, middle temporal gyrus; rs, rhinal sulcus; ots, occipitotemporal sulcus.

fields. Thus, these regions are in a position to bring together disparate pieces of information about objects, including their associated attributes. (*See* **Sensory Integration, Neural Basis of**)

Paralimbic Cortex Function in Monkeys

Although the paralimbic cortical fields have been delineated on anatomical grounds for nearly a century, until recently little was known about the functions of these regions. Historically it has been difficult to separate the functions of the paralimbic cortex from those of the adjacent hippocampus and amygdala, structures that lie deep to the paralimbic region (Figure 3). However, development of methods for making selective lesions has helped resolve this difficulty.

Of the cortical fields composing the paralimbic region, much more is known about the entorhinal and perirhinal cortex than about the more caudally located parahippocampal cortex. Unlike monkeys with damage to the inferior temporal cortex, who have extreme difficulty distinguishing between objects on the basis of vision, monkeys with damage to the paralimbic cortical fields can, for the most part, identify and select objects accurately. Damage to the entorhinal and perirhinal cortical fields produces a characteristic pattern of behavioral impairments including a deficient ability to judge whether an object has been seen or touched before (i.e. a deficit in both visual and tactual recognition memory); an inability to link together in memory items or other sensory inputs that have occurred together repeatedly (stimulus–stimulus associative memory); an impairment in remembering items that were familiar before the brain damage occurred (retrograde memory); and difficulty in certain other types of visual tasks (Murray, 2000). The activity of neurons in the entorhinal and perirhinal cortex mirrors these key functions. For example, single neurons in the paralimbic cortex carry information about whether an item has been seen before, about what other visual items or sensory inputs might have occurred in close proximity (temporally or spatially), and about where those items might have appeared. Preliminary data suggest that the parahippocampal cortex, in particular, may be important for certain aspects of spatial memory.

Although the primary function of the paralimbic region is generally accepted as mnemonic, and although its diverse anatomical relations set it apart from the other types of temporal cortex we have discussed, it is clear that many of the functions of perirhinal cortex are similar to those already described for the inferior temporal cortex. Indeed, neurons in both entorhinal and perirhinal cortex have many of the same properties as neurons in TE. (*See* **Amnesia**; **Neural Basis of Memory: Systems Level**)

For example, neurons in all three regions respond to complex visual stimuli and also carry signals reflecting whether items have been seen before. In addition, the magnitude of impairments on many visual tasks is graded in relation to the extent of combined damage to inferior temporal cortex, perirhinal cortex, and even entorhinal cortex, indicating that all these cortical fields are contributing to performance. For these and other reasons, it seems likely that the paralimbic cortex, especially the perirhinal cortex, is important not only for memory, as described above, but also is operating as an extension of the ventral visual stream. In the latter role, the perirhinal cortex is held to represent complex conjunctions of visual features, thereby extending the notion of the hierarchical organization of visual representations in the ventral visual pathway from inferior temporal cortex into the paralimbic cortex. Thus, the inferior temporal and paralimbic cortical fields together appear to make up a system devoted to the identification of objects.

Paralimbic Cortex Function in Humans

Knowledge of the functions of the paralimbic cortex in humans is sorely lacking. In humans, as in monkeys, damage to the medial temporal lobe that includes the perirhinal cortex yields deficits in visual recognition memory. As already indicated, more extensive damage that involves the inferior temporal cortex disrupts semantic memory as well. Damage to the parahippocampal cortex appears to yield deficits on spatial memory tasks, including difficulty in navigating in large environments.

Functional imaging studies report activations in the ventromedial region in relation to processing of object and word meaning, regardless of how the meaning is accessed (verbally, by Braille, or by pictures). Other studies suggest a role for parahippocampal cortex in representing the spatial layout of scenes and in navigating through space. Precisely how the perirhinal, entorhinal, and parahippocampal fields contribute to these cognitive functions in humans, how the contributions of the regions differ from those of the neighboring visual areas in the inferior temporal cortex, and whether the 'object' and 'spatial' related zones identified in human cortex are homologous with any of the identified paralimbic cortical fields in monkeys, is unknown.

Thalamocortical Interactions and Binding

Introductory article

Antti Revonsuo, University of Turku, Turku, Finland

CONTENTS

Thalamocortical interactions are synchronous neural activities in bidirectional thalamocortical loops. They may serve as the neural mechanism of binding, or perceptual integration and the unity of consciousness.

INTRODUCTION

We experience the world around us as a holistic, subjective reality. The objects we perceive appear to us as coherent bundles of different perceptual features such as color, three-dimensional shape and motion. How is the unity of perception achieved by the cognitive and neural mechanisms in the brain? Elementary sensory features have to be bound together to form coherent perceptual objects, and the individual objects we perceive have to be bound to a common spatial framework so as to appear to us as parts of one globally unified perceptual world. The term 'binding' refers to the process or mechanism of this integration.

It has been suggested that synchronous neural oscillation could be the mechanism that binds together distributed neural elements to form representations of coherent perceptual wholes. The thalamocortical system can be regarded as a unified oscillatory machine, and the abundant bidirectional thalamocortical interactions could therefore have an important role in perceptual binding and the unity of consciousness.

THE BINDING PROBLEM

The binding problem appears in several different formulations in the different branches of cognitive science.

In neuroscience, the binding problem is the problem of the integration of single neuron activity into functional neuronal groups and assemblies. For example, neuroscientists interested in the neural mechanisms of vision formulate the problem in the following way: how do the thousands of anatomically separated neurons, responding to different parts or features of the same visual stimulus, integrate their activity into a neural representation of one single object?

In cognitive psychology, the binding problem is formulated in terms of information processing and representation. According to the modularity hypothesis, the input processing of perceptual information is handled by a multitude of isolated, specialized, mandatory, fast, nonconscious, neurologically specific modules. In a cognitive architecture like this, the binding problem is: how does the information initially processed by a multitude of independent modular input systems become integrated into coherent representations for perception, memory, and action?

The core of the problem is the fact that, at the level of conscious perception, there is an undeniable experiential unity. In subjective visual perception, objects appear as unified perceptual wholes located in one unified perceptual world. This phenomenal unity of subjective experience connects the modern binding problem to the classical philosophical problem of the unity of consciousness.

Immanuel Kant (1724–1804) was preoccupied with this problem. He thought that the world we experience is above all a world of perceived objects, and in order for the mind to produce such a complex and unified representation, the mind has to have some way to relate the different things it experiences to one another. He called it 'synthesis'; we now call it 'binding'. Kant distinguished between two levels of synthesis. Apperception is the process of synthesizing individual objects of awareness, such as binding the form, color and movement of a butterfly to a single coherent representation. In cognitive science, it is called 'feature binding' or 'feature integration'. Transcendental

apperception is the process that constructs the overall unity of consciousness: the representation of one single perceptual world where all the currently perceived objects are simultaneously present.

In experimental psychology, Gestalt psychologists dealt with the binding problem during the first half of the twentieth century. They described sensory organization in terms of perceptual units that are formed in the subjective perceptual field when the contents of particular areas are experienced to 'belong together'. They described these effects in terms of their famous 'Gestalt laws' of perception, and tried to explain them by referring to holistic fields in perception and in the brain. A modern formulation of the binding problem appears in Treisman's feature integration theory, which postulates specialized feature maps for basic visual features, a master map of locations that relates the features to specific locations in the visual field, and a scalable window of attention that scans the master map of locations. Scanning selects all the features that are currently at that location and binds them together into one coherent representation or temporary object file. This theory is formulated at the cognitive level of description and for the time being its neurophysiological basis remains unclear.

In neuroscience, the binding problem is closely related to the problem of neural coding. How is the environment represented in neural firing patterns? There are three competing hypotheses: the 'grandmother cell' theory; population or assembly coding; and temporal coding. The 'grandmother cell' theory assumes that every distinct perceptual element and every possible combination of elements – such as the perception of your grandmother – is represented by a distinct, dedicated neuron; this idea is nowadays regarded as implausible in the light of what we know about the neural basis of perception. The population or assembly coding theory says that the representation of a stimulus such as a visual object consists of a pattern of activity in a large group of neurons. This theory faces the 'superposition' problem: how is more than one stimulus entity coded at a time? The hypothesis of temporal coding addresses this problem by postulating that a cell assembly is distinguished from the other ones by the synchronicity of firing in all the members belonging to the same assembly. Different but simultaneously active assemblies can be distinguished from each other by the timing of their activity. Synchronous activity may constitute a recurrent regular pattern or oscillatory rhythm having a characteristic frequency of simultaneous neuronal discharges.

There is a growing body of theoretical and empirical evidence indicating that the synchronization of neural activity at high frequencies (especially gamma-band or 20–80 Hz synchronization) is associated with the processing of stimulus unity, such as the overall shape or the coherent gestalt of the stimulus. Francis Crick and Christof Koch were the first to explicitly connect neural synchronization with a theory of binding and consciousness. Their hypothesis is that binding involves an attentional mechanism that temporarily binds the relevant neurons together by synchronizing their spikes in 40 Hz oscillations. Subsequently, Wolfgang Singer proposed that only neural activation patterns that are sufficiently organized or coherent can reach the threshold of consciousness, and Andreas Engel further developed this coherence hypothesis by postulating that neural synchronization is necessary for access to visual awareness.

There is now ample evidence that, at the cortical level, synchronous neural activity is related to stimulus unity and to the unity of conscious visual perception. However, these studies are concerned with neural synchronization as a cortical phenomenon. Nevertheless, thalamocortical interaction probably has an important role in the generation of the unity of conscious perception.

PUTATIVE ROLE OF THE THALAMUS IN BINDING

The thalamus is a group of subcortical nuclei anatomically located in the very center of the brain. The thalamus has remarkable connections with virtually every region of the cortex. It has been traditionally regarded as the 'gateway to the cortex' or the brain's 'relay station', because all sensory inputs (apart from olfactory stimuli) make synaptic relays in the thalamus before reaching the sensory receiving areas in the cortex.

This traditional concept is an oversimplification, for the cerebral cortex receives input not only from the sense-specific nuclei, but also from the nonspecific thalamic nuclei that have multimodal connections to the cortex and other parts of the brain. The most remarkable feature of thalamocortical connectivity, however, is its bidirectionality. Thalamic nuclei receive reciprocal pathways from the same cortical areas that they project to. In fact, the number of corticothalamic fibers is significantly greater than the number of thalamocortical axons. These reciprocal thalamocortical connections create bidirectional neuronal loops between the thalamus and the cortex. Hence, the distributed neural representations of simultaneous perceptual features or

events could be related to each other within the thalamocortical system so as to bind input from different sensory modalities into a single perceptual event. Therefore, the thalamocortical system is a plausible candidate for a role in the binding or integration of multiple distributed representations to a coherent perceptual world.

THALAMOCORTICAL INTERACTIONS IN BINDING

The most detailed model of thalamocortical interactions and binding has been presented by the neuroscientist Rodolfo Llinás and his group. They base their model on two facts: first, there are abundant reciprocal thalamocortical connections that establish constant large-scale reverberating activity between the thalamus and cortex; and second, some cortical and thalamic neurons are capable of generating intrinsic 40 Hz oscillations. This leads to the view that the thalamocortical network can generate global oscillatory states on its own, even in the absence of sensory input. When we perceive an external stimulus, the intrinsic activity of the thalamocortical network is modulated by sensory input which thereby becomes incorporated into the functional state of the brain. In accordance with this view, magnetoencephalographic recordings have revealed continuous 40 Hz oscillations over large areas of the surface of the head both in the awake state and during rapid eye movement (REM) sleep. In the awake state, sensory stimulation is consciously perceived and causes a reset of the 40 Hz activity, but in REM sleep the stimulus neither resets the 40 Hz activity nor enters consciousness.

Llinás and Paré argue that there must be a mechanism that is capable of producing and maintaining the synchronized pattern of activity in remote groups of neurons and that this mechanism must have extensive projections to the cerebral cortex. They propose that the reticular thalamic nucleus cells could be responsible for the synchronization of the 40 Hz oscillations in distant thalamic and cortical territories. This mechanism involves two thalamocortical resonant loops: the specific thalamocortical loop and the intralaminar, nonspecific thalamocortical loop. The 40 Hz oscillation in the specific thalamic nuclei can establish a resonating thalamocortical loop through the projections to the cortical layer IV. The oscillation can be fed back to the thalamus via cortical layer VI pyramidal cells. The second thalamocortical loop is between the intralaminar nonspecific nuclei which project to cortical layer I and reenter via cortical layers V and VI pyramidal systems to the thalamus. The reticular nucleus of the thalamus is in interaction with both of these loops and could thus synchronize the activity in both of them.

This model of thalamocortical interaction can be directly related to two different types of binding. The specific thalamocortical loop is assumed to be responsible for the binding of distributed sensory fragments into single coherent objects of awareness (Kant's 'apperception' and Treisman's 'feature integration'). The nonspecific thalamocortical loop is assumed to provide the overall context or functional conscious state where the individual objects of awareness are related to each other within one globally coherent representation (Kant's 'transcendental unity of apperception'). Consistent with this model, lesions of specific thalamic nuclei abolish modality-specific contents of consciousness whereas lesions of nonspecific thalamus (especially the intralaminar nuclei) abolish the global background state of consciousness, resulting in coma. Thus, the interaction of these two thalamocortical loops through synchronous oscillatory activity around 40 Hz is hypothesized to take care of the binding of perceptual content into a single coherent experience.

Other theories of the mechanisms of binding have been less explicit about the role of thalamocortical interactions. The theory presented by Wolfgang Singer's group describes the cortical mechanisms of synchronization in detail, but only mentions in passing that attention could function as an internal synchronizing mechanism through thalamocortical connections. Empirical evidence suggests that the neocortex and thalamus engage in a permanent dialogue and form a unified oscillatory machine, but direct empirical evidence relating thalamocortical interactions to the unity of conscious perception is hard to come by. However, corticothalamic feedback connections from the visual cortex to the lateral geniculate nucleus (the modality-specific visual nucleus in the thalamus) in fact synchronize the responses of the thalamic cells projecting to the visual cortex. Further experimental evidence will be necessary to confirm the hypothesis about thalamocortical resonating loops and their role in binding.

CONCLUSION

The binding problem is a set of related problems that can be formulated at different levels of description, as concerning the integration of neural activity, the integration of modular cognitive processing, or the classical problem of the unity of consciousness. Empirical evidence supports the

view that synchronization could be the neural mechanism of at least some types of perceptual binding. Evidence also suggests that thalamocortical loops are involved in at least some of the synchronous neural activities related to perception. Furthermore, the physiological properties of thalamocortical connections make them intriguing candidates for having a central role in many types of binding.

The most detailed model describing the thalamocortical system as a possible binding mechanism is by Rodolfo Llinás and his group. The correctness of their model remains to be confirmed by direct experimental evidence. Most experiments on humans are capable of measuring cortical synchrony only. For methodological reasons, it will be difficult to design experiments that directly test the role of thalamocortical loops in the integration of perception in humans.

It may be that the unity of consciousness is created in the thalamocortical system, as Llinás and Paré speculate, but for the time being it remains a fascinating hypothesis rather than an established empirical fact.

Chariklia Malapani, Columbia University and New York State Psychiatric Institute, New York, USA

CONTENTS

INTRODUCTION

Timing is everything – whether in making shots, in making love or in making dinner. Indeed, it is difficult to conceive of an action that does not require temporal control. Modern humans have invented mechanical clocks that tell them the time accurately, but our hunter-gatherer forebears did not enjoy this temporal precision, and relied on their endogenous sense of elapsed time. In this respect, our forebears were in exactly the same position as animal foragers, estimating the rate of return in a given patch in order to know when to travel to another area. For mobile organisms, virtually any movement at all is timed, often sequenced in complex ways and temporally coordinated (e.g. in the approach-and-capture sequences of predators and the mating rituals displayed by many species). Exquisite temporal coordination is exemplified in the performances of skilled athletes and musicians, but even walking, driving a car or washing one's hands involves temporal sequencing of coordinated activities.

In addition to coordinating complex sequences, timing serves a very basic function that has long been recognized as a fundamental aspect of the learning process in animals, namely anticipation or prediction. Sometimes important events are associated with exteroceptive cues (e.g. a rustle in the grass, the cast of a shadow, or a whiff of smoke) that function as conditioned stimuli, triggering sympathetic reactions. In other cases the only signal is the temporal regularity of the event itself, as occurs in temporal conditioning. Evolution has selected for neurobehavioral mechanisms that anticipate events as well as react to them, making animals do the right thing at the right time. Whereas the 'origin' for time may be in the future (anticipatory timing), or it may be set by a pattern of responses (coordinated timing), animals are often under the control of the time that has elapsed since some prior marker, known as interval timings as opposed to periodic-oscillatory timing.

The last decade has seen a growing interest in quantitative analysis of timing behavior, and also in new theoretical developments that integrate models of timing with insights from areas of behavioral analysis and neurobiology. In previous decades, the idea that animals can represent time was resisted, partly because it was difficult to imagine a plausible physiological basis for this representational capacity. However, research revealed that multicellular organisms possess endogenous oscillators whose periods range from less than a second to minutes, hours, days, weeks or even a year. When a system contains within itself oscillations with widely differing periods, it can represent the time when an event occurred by recording the momentary phases of these oscillatory processes. The endogenous oscillators provide a physiological foundation for the capacity to represent time – the so-called *internal clock*.

PROPERTIES OF TIMING SYSTEMS

There are two basic forms of mechanisms or processes that make possible the recording of moments in time and the determination of temporal intervals, namely oscillatory processes and non-oscillatory decay or accumulation processes.

Periodic-oscillatory Timing

Life evolved in a cyclic environment caused by the relative movements of the earth, sun and moon. Biological clocks are generally thought to have

evolved as adaptations to these geophysical cycles. When studying biological rhythms, researchers actually look at the rhythmic processes (daily, lunar, monthly or annually periodic lengths) and make inferences about the biological clock itself. However, the biological clock is separate from the behavioral rhythms that it drives. Processes become rhythmic when they are coupled to the biological clock.

A defining property of clock-controlled rhythms is that cycles continue in the absence of environmental cues such as light–dark and temperature cycles. However, in the constant conditions of the laboratory, the period of the rhythm is rarely exactly what it was in nature – that is, it becomes slightly longer or shorter. The assumption is made that the period length is a reflection of the rate at which the clock is running. This point is emphasized by describing the circadian (close to 24-hour) period length in constant conditions as free-running, implying that it is no longer manipulated by environmental cues. Although the period length of biological rhythms is typically 'circa' in the constant conditions of the laboratory, in nature each period length matches that of its geophysical cycle, because the clock is 'entrained' to (i.e. locked on to) its corresponding environmental cycle. The 'entrainment' principle is illustrated by the response of a marcher to the beat of a drum. If the marcher hears the timing signal after his foot has struck the ground, he slows his step, so that his next footfall coincides more closely with the timing signal. If he hears the timing signal before his foot has struck the ground, he accelerates his next step, which again makes the next footfall coincide more closely with the drumbeat. The marcher's response to the timing signal – whether it involves decelerating or accelerating his step – depends on where in his stepping cycle he hears the drum (before or after the fall of his foot).

Interval Timing

As life flows inexorably onward, an animal's hold on its past requires memory for events, their times and the relationships between them. Only timing systems that are capable of starting and stopping at will and covering a very broad range of times can manage these key functions. Such interval timing systems must be extremely flexible, and this flexibility is achieved at the cost of precision (the precision of interval timing systems can vary from 5% to about 60% of the interval being timed, in contrast to circadian timing, which show variability as low as 1% for the 24-hour cycle).

During the past two decades, different theories have emerged aimed at elucidating the psychophysical properties of interval timing and/or providing better tools for the quantitative analysis of mechanisms that living organisms use to time intervals. The *scalar expectancy theory* (SET) remains the most prominent of the theoretical accounts. It originated from reliable findings of cross-species similarities in the psychophysical properties of timing from a variety of different paradigms utilizing the time sense. Figure 1 illustrates two main properties of interval timing, namely *flexible accuracy* and *scalar variability*, which are evident in a variety of time perception as well as production tasks, and in different time ranges.

Figure 1a shows the mean time between taps by subjects synchronizing tapping with a metronome at various inter-stimulus intervals. Subjects are very nearly veridical in their average tapping rate over an order of magnitude, often within 1 millisecond of the target interval. In the same graph, the standard deviation of the inter-tap intervals (right ordinate), although small, increases almost proportionally with the size of the target interval. This finding is known as the *scalar property*. Figure 1b shows data from college students estimating three intervals. Subjects were asked to remember a target time presented as the duration of a visual signal. In subsequent trials, the signal was turned on, and subjects reproduced the time by responding on the space bar just before they thought the target time had elapsed, and stopping just after it. What is shown is the relative frequency distribution of the estimates around the target intervals. The three distributions (shown in the left panel, Figure 1b) superpose when rescaled relative to their target size (right panel, Figure 1b), providing a more complete example of the scalar property. Both flexible accuracy and scalar variability are also evident in time perception tasks. Figure 1c shows data from a perceptual timing task in which subjects are asked to remember two anchor times – a short time and a long time. They are then probed at intermediate values and asked to respond 'short' or 'long', depending on their perceived relationship to the anchors. The judgments are quite accurate. The proportion of 'long' reports increases from about 0 at the short anchor to about 1.0 at the long one. As the short–long pairs are further separated, the functions show decreasing slopes. This decrease again reflects the scalar property, illustrated when the data are replotted (right panel) relative to the point of subjective equality (PSE) (i.e. the point where subjects are maximally uncertain whether to categorize the stimulus as closer to the long or short anchor).

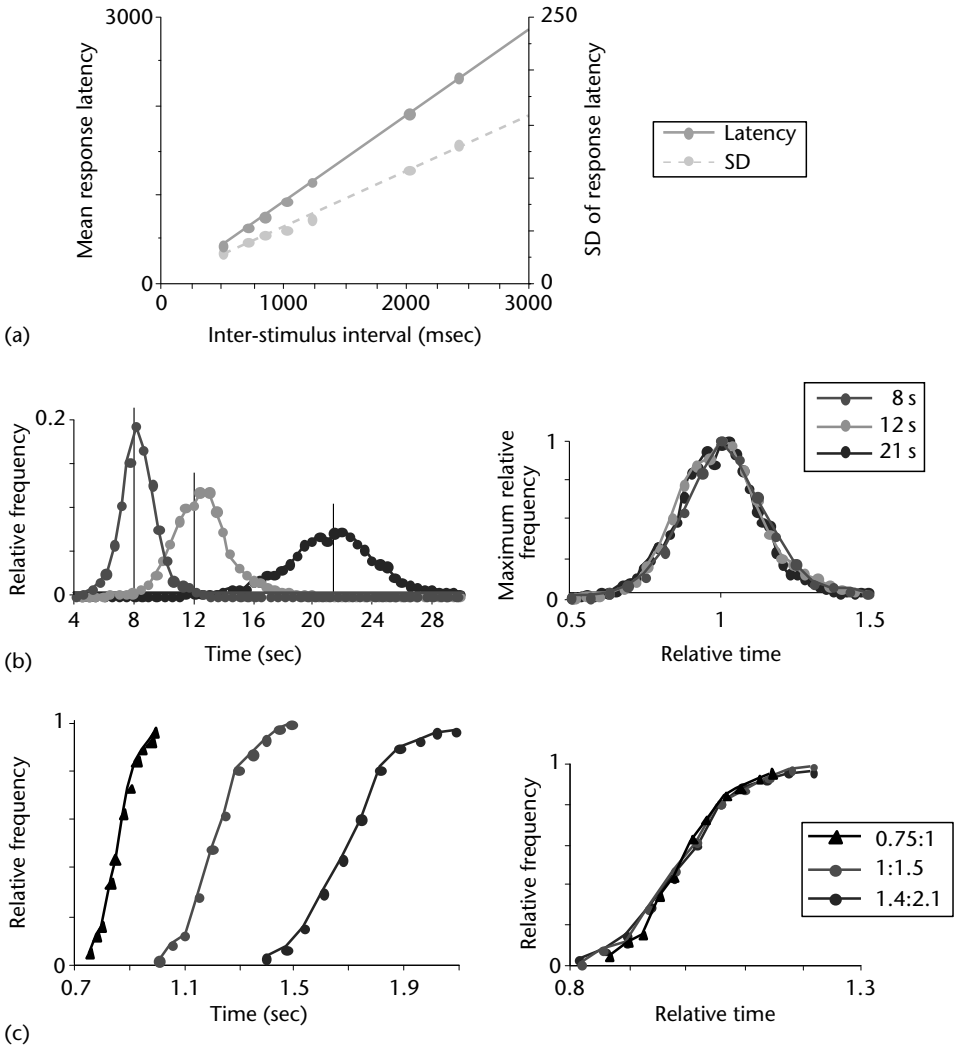

Figure 1. Flexible accuracy and scalar variability of time estimates. Flexible accuracy: subjects are very accurate in their mean reproduction of a known time, which may be an arbitrary value over several orders of magnitude. Scalar variability: subjects in a variety of temporally controlled tasks show error rates that are proportional to the absolute value of the times being estimated. This multiplicative increase implies that essentially one timing distribution is used which is then re-scaled to any arbitrary target time. (a) Tapping data. (b) Peak interval data. (c) Bisection data.

The scalar expectancy theory deals elegantly with yet another psychophysical property of interval timing, which together with flexible accuracy and scalar variability puts important constraints on any mechanism that is purported to underlie timing behavior. That is the *ratio decision*. The comparison process for generating responses involves a ratio of remembered time to current time. Consider for example, the classical conditioning that permits prediction of important events – the unconditioned stimulus (US) – with a formerly 'neutral' stimulus, such as a tone or a light – the conditioned stimulus (CS). After several such pairings, subjects respond to the neutral signal in a similar way to that in which they respond to the important event itself. Significantly, for our purposes, the CS (the neutral signal) is a better predictor than anything else in the environment for the delivery of the US (the important event). That is, the signal must be proximal to the event and not, for example, present continuously or for a long time prior to the event. Pavlov noted that after training his dogs by pairing the sound of a bell and the delivery of meat powder, they would salivate when he entered the laboratory. However, they did not respond for long. It was only his sudden appearance that induced this effect. Thus a very long CS only appeared to have an effect at its onset, and its continued presence no longer elicited the conditioned response. Recently, attention has focused on the relationship between

the duration of the signal and the duration of the time between signaled episodes. This relationship is a relative one. It is the ratio of the trial duration to the inter-trial duration that matters. The ratio – not the difference – controls the speed with which subjects learn about the CS. Subjects acquire similarly to CS of 10 seconds spaced 100 seconds apart and CS of 5 seconds spaced 50 seconds apart. Moreover, the variability of acquisition scores is approximately constant at a given ratio, and decreases roughly proportionally to increasing ratios (another example of the scalar property).

Using the scalar expectancy theory, a quantitative description of the patterns of temporal data is linked to different psychological constructs (clock, memory and comparison/decision mechanisms), as illustrated in Figure 2.

NEURAL BASIS OF TIMING SYSTEMS

Despite the major advances that have been made during the last decade, there is continuing debate about the exact nature of the neural systems and/or brain networks that underlie the functions of timing systems.

Circadian Timing

There is compelling evidence that biological clocks exist in single cells, and that there may be many such clocks in a single individual. The suprachiasmatic nucleus (SCN) in the hypothalamus is widely recognized as the primary clock in circadian timing, but its 'master' role in regulating different rhythms is still debated. Its role may depend on whether information is transmitted through chemical or neural influx within the nucleus itself or its different targets. Figure 3 summarizes the current consensus about circadian organization in mammals.

Time Perception and Timing

Some advances have been made with regard to specifying the brain systems involved in interval timing systems (mainly the basal ganglia and the cerebellum), and links have been established between the cognitive processes underlying timing and specific pharmacological and physiological manipulations. However, there is still controversy about the way in which neural networks involving these structures, either independently or in conjunction, influence timing capacities.

Animal research has mainly emphasized the role of dopaminergic brain systems and the striatofrontal circuitry in timing behavior. Specifically, dopaminergic neurons that originate in the substantia nigra pars compacta (SNc) and project to the striatum are thought to represent the 'pacemaker'

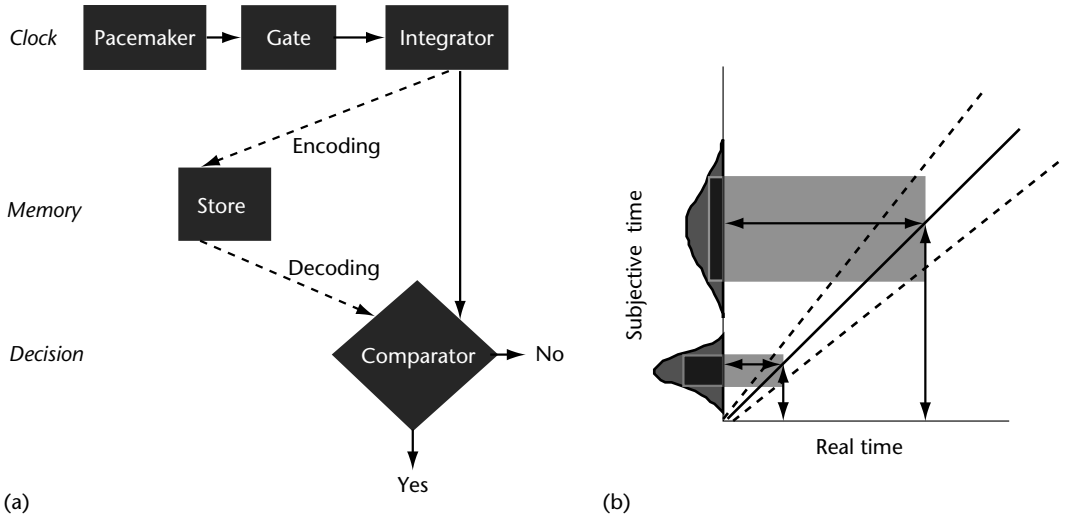

Figure 2. (a) Information-processing components of the scalar timing model. An internal pacemaker/integrator monitors the passage of time (clock stage). Accumulated subjective time is occasionally an important (reinforced) time, and these time records are transferred (encoded) to memory (memory stage) for later comparison (decision stage) with the passage of current time. The decision stage compares current time with time retrieved from memory and identifies an appropriate response outcome. Scalar variance may enter in the clock or memory stage, or through threshold variance in decision. (b) Subjective time increasing linearly with real time. Variation in the rate of the subjective integration (broken lines) generates subjective time distributions for real time (on the ordinate), which are scale transforms of each other (the scalar property shown on the abscissa).

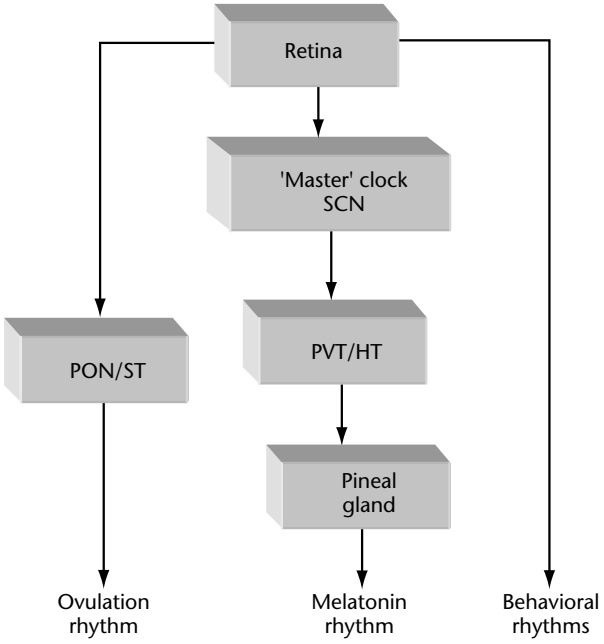

Figure 3. Neural correlates schematic of circadian organization in mammals. The circadian system in birds seems to contain three interacting clocks: the pineal gland, the suprachiasmatic nuclei (SCN) of the hypothalamus, and the eyes. This system of interacting clocks controls other clocks in the body through the pineal gland's rhythmic output of the hormone melatonin. The photoreceptors for entrainment in mammals are the eyes. The information reaches the SCN via the retinohypothalamic neural tract. Whereas some signals from the SCN are sent via neural pathways, others are sent by small diffusible molecules. The assumption is that the SCN is the 'master' clock for certain rhythms, but not for others. The SCN has at least two neural output pathways that affect rhythms – one to the preoptic nucleus of the hypothalamus (rhythm in ovulation): and a second pathway that leads to the paraventricular nucleus in the hypothalamus and then to the pineal gland. Finally activity rhythms are thought to be caused by the SCN's release of a chemical signal to other parts of the brain without the help of neural connections. Chemical control of rhythms by the SCN seems to be unique to behavioral rhythms such as activity and drinking. Reproductive responses to daylength, which depend on melatonin from the pineal gland, and endocrine rhythms require neural connections. PON/ST, paraventricular nucleus in the hypothalamus; PVT/HT, paraventricular nucleus in the hypothalamus.

(clock) in interval timing. However, the striatum is also believed to serve as the 'accumulator' that integrates the action potentials of dopaminergic pacemaker cells. Consistent with this hypothesis, striatal lesions eliminate timing in rats, and timing does not recover after administration of L-Dopa to the lesioned striata. However, L-Dopa does restore timing in animals with damage to the SNc, which suggests that pacemaker-dopaminergic cells that survive the lesion can act effectively again under L-Dopa supplementation. Research also suggests that whereas the pacemaker's speed in emitting pulses would depend on the integrity of the striato-nigral dopaminergic system and the striatum itself, the acetylcholine systems modulate both short- and long-term memory for time. Moreover, short-term memory specifically depends on hippocampal integrity, while long-term memory depends on the integrity of the frontal cortex. A few studies suggest that lesions in the cerebellar cortex impair animal timing behavior in both perceptual timing tasks and temporal conditioning.

Most human timing research has also focused on the basal ganglia, the frontal cortex and the cerebellum as the brain areas that are most likely to be involved in timing and time perception. For example, imaging studies have found activity during both perception and production timing tasks in the basal ganglia and the cerebellum, as well as in their cortical target areas. Moreover, patients with damage to the basal ganglia or the cerebellum are impaired with regard to both time perception and production tasks. Taken together, these findings provide clear evidence that lesions of the basal ganglia and frontal cortex – but not of the cerebellum – impair accuracy, while dysfunction in either area increases variability in timing and time perception. Although increased variability is the norm, it is still unclear whether this effect stems from dysfunction(s) in clock and/or memory, or decision mechanisms.

More recently, clinical studies have provided compelling evidence that distinct neural brain mechanisms are related to specific distortions of the three psychophysical properties of timing defined above. For example, increased overall variability that remains scalar without accuracy distortions is associated with lesions in the lateral cerebellar cortex and the cerebellar nuclei. However, basal ganglia damage is associated with distortions in accuracy, in the form of either under- or over-estimation, together with violation of the scalar rules on variability during both perceptual and reproduction timing tasks. Moreover, dopaminergic deficiency in Parkinson's disease results in accuracy distortions which differ depending on whether information is being encoded to or decoded from temporal memory. While encoding different time intervals in Parkinson's disease, distortions of subjective time reveal linear (unidirectional) overestimation of all intervals. In contrast, while retrieving the trace of two or

more different time intervals normally encoded in previous training, patients with Parkinson's disease show a 'coupling' of remembered values such that the values appear to be more similar to each other. In addition to this coupling phenomenon, decoding deficits in Parkinson's disease are accompanied by a violation of the scalar variability rules, whereas this psychophysical property holds with the unidirectional shifts (i.e. lengthening of subjective time) that are observed during learning.

Although similarities between the findings of animal and clinical studies point to specific brain areas as being involved in timing and time perception, important differences between animal and human data must be noted. For instance, timing distortions in human basal ganglia diseases involve primarily temporal memory and/or decision processes, whereas animal research has provided evidence that timing deficits caused by damage to the striatum result from dysfunctional monitoring of current time. Moreover, bidirectional shifts in accuracy and non-scalar variability induced by dopamine-dependent distortions in the retrieval of traces from temporal memory have not been previously reported in animals. The question of whether these discrepancies reflect species differences can only be answered by future research.

SUMMARY

Our current understanding of the psychophysics of temporal processing far exceeds our understanding of the neural substrates involved. There are also major psychophysical findings that are not well understood, in particular the sources of non-scalar variability and plausible differential transformations that may occur while encoding and/or decoding temporal memories. These unresolved issues await new theoretical developments in the modeling of interval timing and time perception.

Tourette Syndrome

Introductory article

Thomas M Hyde, National Institute of Mental Health, Bethesda, Maryland, USA

CONTENTS

Tourette syndrome is a movement disorder that begins in childhood and is characterized by chronic motor and vocal tics. Clinical features span the disciplines of neurology and psychiatry. Effective pharmacological therapy is now available.

INTRODUCTION

Gilles de la Tourette syndrome (TS) is a movement disorder that crosses the boundary separating neurology from psychiatry. It is defined by chronic motor and vocal tics that begin in childhood, but psychiatric comorbidity also is an important feature. Motor tics – repetitive, involuntary stereotyped movements – most often involve the head and neck, but may involve any muscle group. Motor tics can be simple, such as forceful eye blinking, or complex, such as tugging on clothing. Vocal tics – repetitive, involuntary stereotyped vocalizations – are usually unintelligible sounds, such as sniffing or grunting, but can also be complex, involving words or even whole phrases. Other interesting complex phenomena, occurring less commonly, include coprolalia (involuntary and affectively inappropriate swearing), copropraxia (involuntary and affectively inappropriate use of obscene gestures), echolalia (involuntary repetition of the speech of others), echopraxia (involuntary imitation of the actions of others) and palilalia (involuntary repetition of parts of the individual's own speech). Tics come and go, even remitting completely for extended periods. Among psychiatric symptoms, TS is often associated with obsessive–compulsive traits such as repetitive hand-washing or checking rituals, and attention deficit hyperactivity disorder (ADHD), although these are not part of the current diagnostic criteria. While tics are the hallmark of TS, they also can be seen with other neurological disorders and as a side effect of medications.

The first description of a syndrome of motor and vocal tics was reported by the nineteenth-century French neurologist Jean-Marc Itard. His patient, the Marquise de Dampierre, a French noblewoman, developed motor tics in childhood and shortly thereafter developed involuntary vocalizations consisting of screams and piercing cries. Several years later she developed coprolalia and echolalia. On account of these problems this unfortunate woman was forced to live in seclusion, continuing her involuntary cursing until death at age 85. Some fifty years after Itard's report, Georges Gilles de la Tourette produced a detailed account of several patients with a similar condition, among them the Marquise in her later years. This account was the first case series that clearly established tic disorders as an important and distinct clinical entity. Jean Martin Charcot, a leading French neurologist of the nineteenth century and Gilles de la Tourette's mentor at the Salpêtrière, attached his pupil's name to this syndrome.

For most of the past century, TS was classified as a psychiatric disorder and treated by psychiatrists with a variety of therapies. The tics were thought to represent underlying psychopathology. This confusion was understandable, as the tics could be suppressed voluntarily, at least transiently, stress often led to an acute exacerbation, and many tics looked extremely bizarre. More recently, as the biological basis of TS and allied conditions has become apparent, including the efficacy of medications and the heritability of the disorder, TS appropriately has been reclassified within neurology as a movement disorder. With this change in perspective, the psychiatric comorbidity common in TS patients has been relegated to the sidelines, despite its importance. The syndrome has prominent behavioral as well as motor manifestations, and occupies a niche that spans neurology and psychiatry.

Tourette syndrome usually develops in childhood, with a median age at onset of 7 years. For many patients the disorder is lifelong. The prevalence is 0.3–0.5 per 1000. The syndrome is three to

four times more common in men than in women, and up to nine times more common in boys than in girls. Although in most cases the tics persist throughout life, there is often a decline in the severity of symptoms after puberty.

GENETICS

Tourette syndrome is the most severe form of the tic disorders, disorders that probably share a common genetic basis. There is a spectrum of severity, ranging from transient motor and vocal tic disorders to full-blown TS. The differentiation of these subtypes of tic disorders primarily depends upon the duration, number and type of tics (Table 1). The character of the tics themselves, however, is similar throughout the spectrum of tic disorders. Many of the genetic studies of tic disorders also have suggested a common genetic aetiology for tics and obsessive–compulsive disorder (OCD), which is common in many TS family trees. Obsessive–compulsive disorder is much less common in sporadic cases of TS than in cases with a strong family history.

In some pedigrees, TS and chronic tic disorders follow an autosomal dominant pattern of inheritance, with variable penetrance. Some have contested this mode of transmission. Segregation analysis in large families has shown that penetrance is gender-related. For males, penetrance is nearly complete when all tic disorders are included. For females, penetrance increases from 56% for tic disorders to 70% when OCD is included as part of the phenotypic expression of the TS gene or genes. This observation, and the familial association of OCD and TS, have led to the theory that OCD is a clinical variant in the expression of the TS genetic defect. In fact, obsessive–compulsive symptoms are common in TS patients, although only a minority meet the full diagnostic criteria for OCD. Despite intensive investigation with a number of techniques and patient cohorts, no specific gene has yet been linked to TS.

Nature Versus Nurture: Interactions Between Genes and Environment in TS

Genes and environment appear to interact in determining the clinical expression of the TS gene or genes. Two separate twin studies have reported concordance rates of about 50% for TS in monozygotic (identical) twins but less than 10% in

Table 1. Diagnostic categories for tic disorders

Tourette syndrome
- Multiple motor AND one or more vocal tics occur concurrently at some time during the course of the illness
- Tics occur daily, or nearly daily, intermittently over the course of at least a year
- Anatomic location, number, frequency, complexity or severity of tics changes over time
- Onset is before age 21 years
- There is no concurrent medical or neurologic condition that could explain the tics (e.g. stimulant exposure or Huntington disease)

Chronic multiple motor tic or phonic tic disorder
- Either multiple motor OR vocal tics, but NOT both, have been present at some time during the illness
- Tics occur daily, or nearly daily, intermittently over the course of at least a year
- Anatomic location, number, frequency, complexity or severity of tics changes over time
- Onset is before age 21 years
- There is no concurrent medical or neurologic conditions that could explain the tics (e.g. stimulant exposure or Huntington disease)

Chronic single tic disorder
- Criteria are the same as above except the patient has only a single motor or vocal tic for at least a year

Transient tic disorder
- There are single or multiple motor AND/OR vocal tics
- Tics occur nearly every day for at least 2 weeks but for no longer than 12 consecutive months
- There is no previous history of Tourette syndrome or chronic motor or vocal tic disorder
- Anatomic location, number, frequency, complexity or severity of tics changes over time
- Onset is before age 21 years
- There is no concurrent medical or neurologic condition that could explain the tics (e.g. stimulant exposure or Huntington disease)

Adapted from the Tourette Syndrome Classification Study Group.

dizygotic (fraternal) twins. When all tic disorders are considered, the concordance rate rises to nearly 80% in monozygotic (MZ) twins and about 25% in dizygotic (DZ) twins. While these results suggest a strong genetic contribution to TS, they also indicate that nongenetic factors must also have an important role, since only about half of the MZ twins are concordant for full-blown TS. This fact is illustrated by studies of identical twins, where the twins exhibit significant differences in the frequency, intensity and bodily distribution of tics, despite their identical genetic endowment.

Since TS is much more common in males than in females, sex-specific hormones probably play an important role. Testosterone, present in higher levels in males than females, might enhance tic production; alternatively, oestrogen and/or progesterone, present in higher levels in females than males, might suppress tics. In addition, a number of medications, including stimulants (such as amphetamines) and neuroleptics (such as haloperidol), can produce tics in people with no known genetic predisposition. Stimulants in particular may also aggravate preexisting tic disorders.

Since MZ twins have an identical genes and similar but not identical environmental experiences, twin studies are ideal for examining the relative contribution of genetic and environmental factors. One study of six MZ twin pairs discordant for TS found that the twin with TS consistently had a lower birthweight than the unaffected co-twin. A second study found that in 12 of 13 MZ twin pairs differing in birthweight, the twin with the lower birthweight had a more severe tic disorder than the other. Moreover, the size of the difference in birthweight strongly predicted the difference in the intrapair tic score difference in late childhood.

These findings suggest that crucial environmental events occurring during fetal development subsequently affect the clinical expression of TS. Possible factors *in utero* include such elements as the quality and location of the placenta, the position of the fetus within the uterus and (in the case of twins) intrauterine crowding. Abnormalities in fetal and placental blood vessels can produce decreased blood flow to one twin, resulting in differing degrees of oxygen and nutrient delivery to the developing brain. The basal ganglia are a group of structures deep within the brain. Abnormalities in the basal ganglia may be the cause of TS as well as most other movement disorders. Interestingly, the basal ganglia are especially vulnerable to injury induced by a lack of oxygen and nutrients.

Performance on neuropsychologic tests (nonmotor measures of cerebral function) also illustrates gene–environment interactions in studies of MZ twins with tic disorders. Tic severity and neuropsychologic performance tend to covary. Overall performance on a battery of neuropsychological tests was found to be significantly worse in the MZ twin with the more severe tics. These differences are most notable on tests of attention, visuospatial perception and motor function. This pattern is consistent with the neuropsychologic profile of TS observed in singletons as well as in MZ twins. Interestingly, the overall level of performance on neuropsychological tests in patients with TS is usually within normal limits. Nevertheless, the data on MZ twins illustrate that nongenetic factors influence not only tic severity, but also cognitive function. The behavioral associations and cognitive profile of TS have aroused suspicion that neural systems beyond the basal ganglia are abnormal in individuals with TS. Nevertheless, because of the pivotal role of the basal ganglia in integrating and relaying information from the cortex, it is not necessary to invoke widespread cerebral dysfunction in TS.

PATHOLOGICAL BASIS OF TS

The neuropathologic basis of TS is unknown. Traditionally in clinical neurology, involuntary movement disorders have been associated with basal ganglia dysfunction. Moreover, tics often occur in well-defined basal ganglia disorders such as Huntington disease and postencephalitic parkinsonism (encephalitis lethargica). Medications that stimulate the dopamine system, such as amphetamines, can aggravate tic disorders. Finally, medications that block the dopamine type 2 receptor are effective tic suppressants, and this receptor is most densely expressed in the basal ganglia. Taken together, these observations have led most investigators to focus on the basal ganglia as a likely site of pathology in TS. However, relatively few brains have been donated for research, so comparatively little postmortem analysis has been done. Classical neuropathologic analyses have been published on only two brains, with conflicting findings of basal ganglia (striatal) pathology. A small number of cases revealed possible abnormalities in dopamine and endogenous opioid neurotransmitter systems within the basal ganglia. As more brains are collected from individuals with well-characterized TS, more investigations will be undertaken.

Neuroimaging Studies

In vivo neuroimaging studies have provided some clues about the brain regions involved in TS.

Focusing on the basal ganglia, such studies have found evidence of subtle structural abnormalities in this region. Three quantitative analyses of magnetic resonance imaging scans have been conducted on separate patient populations with TS. The first, in a cohort of singleton TS patients, demonstrated reductions in regional basal ganglia volumes in these patients. The second, also in single TS patients, was more equivocal. In a study of 10 sets of MZ twins, a statistically significant 7% reduction in right caudate nucleus volume was observed in the more severely affected twins compared with the less severely affected ones. More consistent deviations in normal cerebral asymmetries of ventricles and basal ganglia have been reported in studies of both single patients and twins.

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) imaging, which offer insight into regional neurochemistry and cerebral function, have provided evidence of changes in activity of basal ganglia and prefrontal cortex, but the data are not consistent. These imaging techniques can be used to define regional cerebral blood flow and hence the activity level of brain structures. Such studies have revealed a widely distributed network of abnormalities, primarily in the frontal and cingulate regions. *In vivo* neurochemistry data can be derived from SPECT and PET studies as well. One group has found abnormalities in TS patients in dopamine-mediated neurotransmission in the caudate nucleus. Other studies also have found abnormalities in basal ganglia dopamine-mediated neurotransmission. Additional studies are needed to more clearly define the neurochemical basis of TS and related disorders.

TREATMENT

Clinical management depends upon the identification of target symptoms. While often the most obvious and most dramatic manifestation of pathology in TS, tics may not be the most disabling symptom. Concurrent OCD, ADHD, impulse control disorders and depression may be more problematic than the tics. Tics respond most consistently to low doses of dopamine type 2 receptor antagonists such as haloperidol or risperidone. Clonidine and guanfacine, which are agonists at the α_2-adrenergic receptor, offer some benefit, although they are less effective than dopamine antagonists. Some patients respond to benzodiazepines. Particularly as they get older, many patients learn to voluntarily suppress their tics without medication. Family counselling and psychotherapy may help with adjustment problems associated with the social stigma common in more severe cases. In addition, the physician may have to interact with the school system to explain the nature of the tic disorder, and occasionally to clarify the special needs of such children, such as untimed testing. Psychiatric comorbidity can be more disabling than the tics themselves. For those individuals, pharmacotherapy, such as the use of serotonin reuptake inhibitors (e.g. fluoxetine) for OCD or depression, can be an important intervention. For most patients with TS or tic disorders, the clinical course is benign and the outcome is good.

CONCLUSION

Tourette Syndrome is a disorder in which genetic and environmental factors interact to produce a complex neuropsychiatric syndrome. The clinical presentation and course of TS, like many disorders with a primary genetic basis, are influenced by extragenetic factors. Defining the genetic basis of this disorder, however, may lead to more definitive treatments and more focused pharmacological therapies.

Visual Imagery, Neural Basis of

Intermediate article

Sharon L Thompson-Schill, University of Pennsylvania, Philadelphia, Pennsylvania, USA

CONTENTS

Visual imagery is the process of seeing with the 'mind's eye'. The neural bases of visual imagery have been investigated using physiological recordings of normal brain activity and behavioral measurements in people with brain damage.

INTRODUCTION

Try to answer each of these questions: Do bears have rounded ears? Is a bath towel square in shape? Are roses smaller than a fist? Is a saw's blade narrower near the handle? As you think about the answer to each question, you may feel as if you are seeing each object in your 'mind's eye'. Cognitive psychologists call this phenomenon 'mental imagery'. Although one could speak of imagery in any modality – how does sandpaper feel? how does a ringing telephone sound? – most of the research into the neural bases of mental imagery has focused on the visual modality. Thus, the term 'imagery' will be used here to refer specifically to visual imagery. In addition, this discussion is limited to studies of explicit image generation; related topics such as illusory contour perception are discussed elsewhere. (*See* **Vision: Occlusion, Illusory Contours and 'Filling-in'**)

SIMILARITY BETWEEN VISUAL IMAGERY AND VISUAL PERCEPTION

How similar are the processes of thinking about the shape of a bear's ears and actually looking at a bear's ears? In other words, is visual imagery more closely related to verbal thought, or to perception? This question has driven research in cognitive neuroscience for decades. On one side of the imagery debate are those who believe that mental images have a spatial format and share representations with those used during perception (e.g., Kosslyn, 1980); on the other side are those who maintain that mental images are propositional or symbolic, like language, and therefore do not share representations with perception (e.g., Pylyshyn, 1981). Despite all the behavioral experiments that have been conducted to address this question, there is no unequivocal conclusion. For example, one could point to data illustrating a relationship between the amount of time it takes a person to scan a mental image and the amount of time it takes to scan an actual percept; however, these data have been attributed to the person's response to the experimenter's expectations. Thus, after a quarter-century of active research by psychologists on this topic, the debate is still far from settled.

An alternative way to investigate the extent to which imagery and perception share common representations or processes is to turn to the brain. An enormous amount is known about the neural substrates of perception and the structures of the brain that are responsible for visual perception. Considerably less is known about the neural substrates of mental imagery, because investigators are limited to neuroscientific methods that can be safely used with humans who can be instructed to form mental images. However, there are some physiological data from normal individuals and behavioral data from people with brain damage that provide a useful basis for the comparison between perception and imagery.

Physiological Responses to Visual Imagery

Event-related potentials (ERPs) have been used to address the relationship between visual imagery and visual perception in several ways. One approach is to try to isolate the evoked response to mental imagery and examine its topography, in relation to what is known about visual processing areas. In one such study, imagery and nonimagery conditions of a task were compared in order to yield a relatively pure measure of the evoked response to mental imagery (e.g., Farah *et al.*, 1989): the responses to mental imagery were located

over areas of cortex associated with vision. Furthermore, the magnitude of the ERP during imagery was related to the degree of vividness that the person reported in the images. A second approach is to examine the effects of imagery on early perceptual processing. Mental imagery, performed concurrently with perception, alters an early visual evoked response, termed the N1 component, that is observed 200 ms after a visual stimulus is presented (Farah *et al*., 1988). This response is thought to originate from extrastriate cortex (i.e., secondary visual processing areas). These findings indicate that mental imagery involves – at least in part – neural structures crucial for early visual perception.

The spatial resolution of ERP recordings is limited, so with the advent of new metabolic and hemodynamic imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), the ability to examine the similarity between the neural structures engaged by visual perception and those engaged by mental imagery has substantially improved. A number of neuroimaging studies have confirmed that mental imagery activates visual processing areas. For example, imagining a walk through a familiar neighborhood, imagining block letters, imagining flashing patterns, and imagining objects all activate regions of visual cortex. Furthermore, images of different sizes produce different patterns of activation, consistent with what is known about the retinotopic mapping of visual cortex (Kosslyn *et al*., 1993). Researchers disagree as to whether the activation is confined to higher-order visual association cortex or whether it includes primary visual cortex. However, there is almost unanimous agreement that visual imagery activates some retinotopically organized cortical regions, which supports the hypothesis that mental images have a spatial format and that imagery and perception have common representations. (*See* **Pattern Vision, Neural Basis of**)

Effects of Brain Damage on Mental Imagery

The strongest test of the assertion that imagery and perception have a shared neural substrate comes from the examination of people who, as a result of brain damage, have impairments in one or both of these processes. If mental imagery requires the same representations and neural structures as does perception, then it follows that a person who has selective impairments in visual perception should also exhibit impairments in visual imagery. Parallel deficits in perception and imagery have been reported in many cases. For example, people with impairments in color vision are unable to report the color of common objects from memory, and people with impairments in object recognition (visual agnosia) are unable to describe the appearance of objects from memory. An agnosic patient studied by Farah *et al*. (1988) was unable to report which animals had long or short tails, what color common objects were, and which US states were similar in shape.

People with damage to small regions of primary visual cortex do not have a complete loss of vision; rather, some portions of their visual field are normal and other portions are impaired. For example, a right occipital lobe lesion will produce a left visual field cut called a hemianopia. In such a person visual processing can still occur, but it takes place in a more restricted field of view. If visual imagery shares representations with visual perception, one might expect to see the effects of a restricted field of view in the 'mind's eye' in people with hemianopia. Farah and colleagues investigated this in a patient scheduled for a right occipital lobe resection as a treatment for her epilepsy (Farah *et al*., 1992). The patient was instructed to imagine walking towards a familiar object and to report how far away she would have to be from the object to 'see' it in its entirety. For example, prior to the operation she might have said that she could be 5 m away from a horse before the image overflowed the visual field of her mind's eye. After the surgery, her estimation would have changed to 10 m – that is, after her occipital resection, the visual field of her mind's eye was restricted just as was her visual field in perception.

DIFFERENCES BETWEEN VISUAL IMAGERY AND VISUAL PERCEPTION

Despite the evidence that visual imagery and visual perception share representations, there are data that point to differences between these processes: in other words, imagery and perception are not exactly the same thing. As briefly mentioned above, there is some disagreement as to whether mental imagery activates primary visual cortex in neuroimaging studies. The earliest neuroimaging study of mental imagery used a 'mental walk' paradigm, and reported activation in visual regions of the parietal and temporal lobes but not the occipital lobe. This result could illustrate a difference between the neural substrates of imagery and perception. However, many subsequent studies have reported early visual cortex activation. Kosslyn *et al*. (2000) suggested that activation of the earliest

visual areas might be observed only in studies that required the generation of high-resolution images. The neuropsychological literature also contains data that suggest differences between imagery and perception. For example, patients with occipital lesions have been described who are unable to perform some, but not all, imagery tasks. Likewise, some agnosic patients with clear impairments in perception of objects demonstrate normal imagery of objects. The implications of these dissociations are discussed by Farah (2000).

MULTIPLE TYPES OF IMAGERY

Another question in study of mental imagery is whether there is a difference between visual imagery and spatial imagery. Spatial representations can be based on visual information but can also be based on information derived from other modalities, such as touch. In contrast, some visual representations, such as color, can only be derived from the visual modality. Many of the tasks used to study mental imagery do not distinguish between visual representations and spatial representations. For example, one of the classic visual scanning tasks requires the participant to image a capital letter F, and then to scan around the letter and report the location of each corner as it is encountered. This visual task clearly requires spatial knowledge, and could be performed without any visual information (e.g., a blind person could use tactile imagery to traverse the letter). Kosslyn *et al*. (2000) have proposed three distinct types of imagery: (1) spatial imagery, which may not require visual representations at all; (2) figural imagery, which may require only low-resolution visual representations, such as those found in the temporal lobe which subserve object recognition; and (3) depictive imagery, which would require the highest-resolution images and which most directly corresponds to the notion of 'seeing with the mind's eye'. Some evidence for these distinctions comes from the neuroimaging literature: imagining a mental walk results in parietal activation, thinking about familiar objects results in inferior temporal activation, and comparing the width of stripes in memory results in medial occipital activation.

Some people with a disorder of spatial processing called 'hemispatial neglect' may have impairments in spatial imagery that parallel their perceptual deficits. These patients show an inability to attend to objects in the left side of space as a result of a right parietal lesion. A group of Milanese patients with hemispatial neglect were asked to imagine the well-known Piazza del Duomo in Milan (Bisiach and Luzzatti, 1978) – first, they were asked to imagine that they standing at the south end of the square, facing north towards the cathedral. When asked to report all the landmarks in the piazza, the patients tended to name landmarks on the east (to the patient's imagined right) side of the square and omit landmarks on the west (to the patient's imagined left) side. Later, the patients were asked to imagine that they were standing at the north end of the square, with their backs to the cathedral. Now, the patients tended to name landmarks on the west (to the patient's imagined right) side and omit landmarks on the east (to the patient's imagined left) side. In other words, they observed hemispatial neglect of imagined scenes.

The strongest evidence for multiple forms of imagery is the double dissociation between spatial and figural imagery impairments. In perception, there is considerable evidence for a dissociation between perception of object location and perception of object identity (i.e., the ventral 'what' pathway and the dorsal 'where' pathway). A parallel dissociation has also been observed during mental imagery (Levine *et al*., 1985). One patient with a dorsal lesion was unable to localize visual stimuli in space but could identify objects; this is the classic 'where' pathway deficit. This patient was able to describe the appearance of familiar objects from memory but was unable to describe the locations of familiar landmarks from memory. In contrast, a second patient with a ventral ('what' pathway) lesion was unable to identify objects or to describe the appearance of familiar objects from memory; this patient was unimpaired on spatial localization, from both perception and memory. In other words, these two patients demonstrate a double dissociation between imagery of spatial location and imagery of object identity that parallels their selective deficits in perception.

Wernicke–Geschwind model

Intermediate article

Andrew Kertesz, St Joseph's Hospital, University of Western Ontario, London, Ontario, Canada

CONTENTS

The Wernicke–Geschwind model is the basis for an aphasia classification system that is favored by many clinicians. It is also a model for language organization of the brain.

INTRODUCTION

Carl Wernicke described *der aphasische Symptomenkomplex* in a series of case reports emphasizing the disturbance of comprehension of language (Wernicke, 1874). These cases ranged from sensory aphasia – what we now call Wernicke aphasia – to global aphasia, where both comprehension and expression were severely disturbed. Wernicke's classification was solidly based on the input–output dichotomy and the division of the brain into sensory and motor systems. It was Wernicke's mentor, Meynert, professor of neurology in Vienna, who advanced this dichotomy based on anatomical and lesion studies, at that time representing a revolutionary advance in our knowledge of the brain. Wernicke extended these observations to language. Although Wernicke's original diagrams contained centers for sensory images of the words connected to motor images, he is very clear in his description of the results of disconnection between these centers. He predicted conduction aphasia would result from sensorimotor disconnection, even though he did not describe such a case himself.

Many of Wernicke's ideas were systematically summarized by Lichtheim (1885), based on the associationist theoretical framework of the nineteenth century. The Wernicke–Lichtheim model distinguished between subcortical motor, motor, subcortical sensory, sensory, conduction, transcortical motor and transcortical sensory aphasias (Figure 1). This diagram, dubbed 'Lichtheim's house', contains the essential pathways and their disruptions, each of which could result in a specific type of aphasia. The schema became accepted and used by many clinicians. Aphasia is not only caused by a focal lesion in an area considered the center for a particular function, but can also result from the disconnection between the centers. Conduction aphasia remains one of the prime examples of the disconnection syndromes, although it is still debated vigorously whether or not it is the insular cortex lesion that produces the deficits, or the disconnection of the temporal lobe from the frontal lobe, known as the arcuate fasciculus lesion.

Eighty years later, Norman Geschwind described the disconnection syndromes and resurrected the Wernicke–Lichtheim model of aphasias (Geschwind, 1965). This has become the basis of a number of current clinical classifications. Geschwind added a considerable degree of sophistication to the model, based on more modern physiological and anatomical knowledge. He also revived some of the syndromes outside the oral language system, specifically the one that was originally described by Dejerine involving the dissociation of visual recognition of words and the writing system: this results in alexia without agraphia, one of the best-known examples of disconnection syndrome.

THE WERNICKE–GESCHWIND MODEL AS IT STANDS TODAY

Sound stimulus is the basis of much animal and human communication. The human brain is particularly sensitive to human speech frequencies; much of this acoustic discrimination occurs in the temporal operculum, or lip of the temporal lobe in the depth of the sylvian fissure separating the temporal from the parietal lobes. Although elementary sound discrimination is processed tonotopically in Heschl's gyrus, the discrimination of speech sounds is elaborated in a much wider association area bilaterally. Geschwind believed that the planum temporale or the area behind Heschl's gyrus played a particular role in language. He used anatomical studies, cutting the brain in the plane of extension of the sylvian fissure, to show that the planum is normally larger on the left side, in the language-dominant hemisphere. The auditory

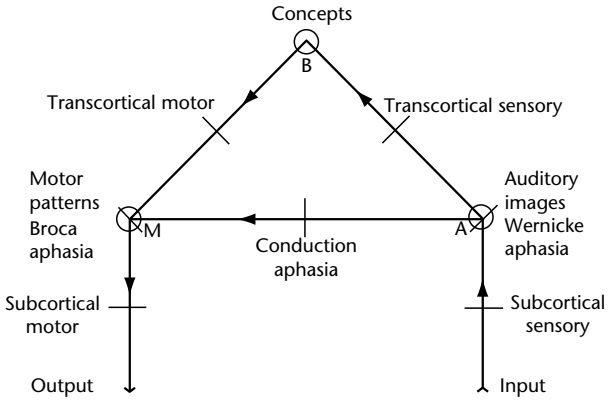

Figure 1. Lichtheim's house. (A = Auditory center, M = Motor center, B = Begriffen)

association area occupies the superior temporal gyrus on the outside, as well as the planum temporale in the inside of the lip of the sylvian fissure, and is distinguished cytoarchitectonically. The columnar organization of this neocortex resembles raindrops on a windowpane. Wernicke himself thought that auditory word images resided in the neurons of this area, now called Wernicke's area. The exact area is debated, although most people agree that both the outside posterior third of the superior temporal gyrus and the planum temporale are essential for the processing of verbal input, and lesions of this area if sufficiently large result in serious and persisting difficulties in comprehension. Wernicke's area also includes the inferior parietal lobule surrounding the end of the sylvian fissure.

Wernicke thought that if subcortical neural elements were damaged then impulses entering this area would be cut off, resulting in a subcortical sensory aphasia, better known as 'pure word deafness'. He reasoned that if the auditory association area itself were damaged then the result would be not only a comprehension deficit, as seen in pure word deafness, but also a disturbed output, since the auditory verbal images are not available to generate appropriate output. Wernicke also anticipated the idea of audiology feedback or monitoring the output system from the auditory area, long before computer systems were applied to theoretical modeling. His concept was that the auditory image area would perceive 'inner speech' before it was vocalized. During this process appropriate corrections could be made, and if damage was present, speech errors would occur.

Destruction of auditory engrams could result in several kinds of deficit and a variety of abnormal output. When a word is substituted, verbal paraphasia, when a phonemic error occurs phonological paraphasia results. When a word was completely replaced by erroneous phonology, unintelligible sequences or jargon would manifest. A combination of these deficits, generally a significant comprehension deficit with phonological and semantic paraphasias, is called 'Wernicke aphasia'.

Once auditory images are appropriately processed and selected, afferent or incoming phonological components would be associated with (or mapped onto) motor images of phonology. Those in Wernicke's time were called motor engrams, and in more recent terminology 'logogens'. Motor engrams would presumably be localized in or around Broca's area, since destruction of the posterior frontal inferior gyrus or the foot of F3, also called Broca's area, often results in output disturbances with well-preserved comprehension, because the auditory system is still operational. The phonological output system (the phonological buffer in the computer analogy) would be impaired, bringing about phonological articulatory errors. Impaired articulation, repetitive stuttering utterances, and distinctive phonological paraphasias affecting initial consonants, or literal paraphasias where only one phoneme or letter would be exchanged, would predominate. In some cases the motor errors are so prominent that Liepmann, one of Wernicke's students, suggested the term 'apraxia of speech', which was later added to the model. Others used the term 'verbal apraxia', which has become popular, especially in North America.

Wernicke and Lichtheim thought if the disturbance was peripheral or distal in the flow of processing motor images, then subcortical motor aphasia or pure motor aphasia would result with articular disturbance as the predominant feature, but relatively preserved comprehension, grammar, and writing, also known as 'pure word dumbness' or aphemia. This latter term has been resurrected in many contexts, and at times it is separated from aphasic disturbances as anathria, a pure motor phenomenon.

Broca aphasia is characterized by effortful speech output, a great deal of word-finding difficulty, and in some languages agrammatism with lack of grammatical words or small words. The idea of agrammatism and paragrammatism was first discussed by Pick, and its modern formulation was developed by Goodglass and his many students; it was not part of the original Wernicke–Lichtheim model. Syntax is much studied in modern aphasiology. It is closely associated with phonology experimentally and physiologically and it can be

dissociated from semantic and articulatory processing in clinical syndromes.

Wernicke predicted there would be cases where auditory images and motor engrams would be preserved, but connections between them would be disrupted, resulting in failed repetition and faulty paraphasic speech. *Leitungsaphasie* was translated as 'conduction aphasia', and cases conforming to this were described subsequently by Kleist and by Goldstein (1948). These patients have relatively well-preserved comprehension and fairly fluent output, which is at times disturbed by phonological paraphasias and at times by repetitive phonemic approximations of the target (*conduit d'approche*). The hallmark of conduction aphasia is the inability to repeat because of the disconnection of auditory images and motor mechanisms. Spontaneous speech therefore is still produced, but the otherwise automatic process of repetition cannot be carried out because of disconnection. A repetition deficit in conduction aphasia has also been viewed as a disturbance in short-term verbal memory or a disorganized execution of a phonological encoding program related to the auditory feedback, going beyond the simple idea of disconnection.

The concept of transcortical aphasias also originated from the Wernicke–Lichtheim model. Transcortical motor aphasia is the disruption of the pathway between word concepts and motor engrams; it is characterized by poor output and poor initiation of speech, but excellent comprehension and, above all, preserved repetition – in other words, the automatic transfer of language from auditory images is undisturbed, but the interrupted transcortical transfer from concepts and nonverbal association prevents the patient from initiating output. Transcortical sensory aphasia, on the other hand, represents a disconnection between sensory input and concepts, and shares preserved repetition with the other transcortical pattern. These patients can repeat, but they do not understand because the sensory images are not connected with their meaningful representation. Mixed transcortical aphasia results from both sensory and motor engrams being disconnected from transcortical associations and the only language function that remains is repetition without comprehension or spontaneous speech, a condition also called 'isolation of the speech area'.

Clinicians have devised systems of examination using the Wernicke–Geschwind model to allow the scoring of auditory comprehension of words, sentences, and grammar, and to assess output mechanisms through the scoring of spontaneous speech, repetition and naming. Repetition is useful, for instance to test the connection of the input and output systems, and it is essential for diagnosing conduction aphasia where the two systems are disconnected. It is also important to demonstrate the preservation of the central core system of auditory input and verbal output in case of transcortical aphasias where transcortical associations are impaired. Without testing repetition, the model cannot be validated. The model also allows the explanation of lexical access and disturbances of naming and the integration of auditory and visual images to account for naming on visual stimulation. Subsequent interpretation of the model suggests that temporal auditory associations and their integration with tactile and visual mechanism are important for lexical storage, selection and access.

The emphasis placed on comprehension by Wernicke was adapted by many subsequent investigators, even those who were detractors of the model. Most aphasiologists consider impaired comprehension the *sine qua non* of aphasic disturbance, while others claim that lexical access disturbance may be present even in cases where comprehension is not impaired. Most agree both are necessary to explain aphasic phenomena, and disturbance of either occurs to a certain degree in clinical aphasia. An account for both processes is necessary to explain normal language processing.

Modality-specific language disorders were also part of the original Wernicke–Geschwind model and were considered to be input and output problems. However, this was further developed by looking at the linguistic aspects of the phenomena. In France, 'aphemia' or 'pure motor aphasia' became known as 'phonetic disintegration disturbance'. Another group of investigators emphasized the complex motor aspects of speech, conceptualized as apraxia by Liepmann. Verbal apraxia is used for many of the motor and articulatory deficits, and older terms for this, such as anathria and aphemia, are resurrected from time to time. Subcortical sensory aphasia was further elaborated as pure word deafness to auditory agnosia for nonverbal sounds, and both were also called cortical deafness. Other subdivisions included sentence deafness, auditory disturbance for syntax, and word meaning deafness, which overlaps semantic aphasia or the loss of meaning, representing a two-way disturbance of comprehension and naming of words. These elaborations on the model have been succeeded by linguistic models, fractionated at a different theoretical level. Modality-specific anomia is exemplified by the specific difficulty of naming visually while other modalities such as tactile naming were preserved, and was called

'optic aphasia'. Other recognized examples are difficulty in naming fingers and discriminating right from left in the Gerstmann syndrome, associated with agraphia.

The Wernicke–Geschwind model provides the first account of the nature of internal representations of concepts. Wernicke's postulation of auditory verbal images does not explain the phenomena of mental imagery, the superior memory performance for pictures rather than for words. However, Wernicke's concept center was not explicitly stated to be restricted to words and was not meant to be located to any particular part of the brain, even though Wernicke's diagram placed it somewhere in the parietal area of the right hemisphere.

Many classifications of aphasia try to fit one model or another. A purely modality-oriented model fails to account for all the clinical phenomena. Adding the transcortical portion of the model represented a significant contribution and provided an adequate explanation for the majority of the cases. When an aphasia test is used that covers input and output modalities as well as repetition, most cases can be classified according to the Wernicke–Geschwind model. Although many clinicians are satisfied with impressions of unmeasured performance and aphasic profiles are constructed on the basis of such impressions, efforts have been made to support the model with classification based on test scores. Numerical taxonomy and discriminant function statistics have been used in attempts to achieve objective classification (Kertesz, 1979).

More recently category-specific naming deficits, showing dissociation between categories of items

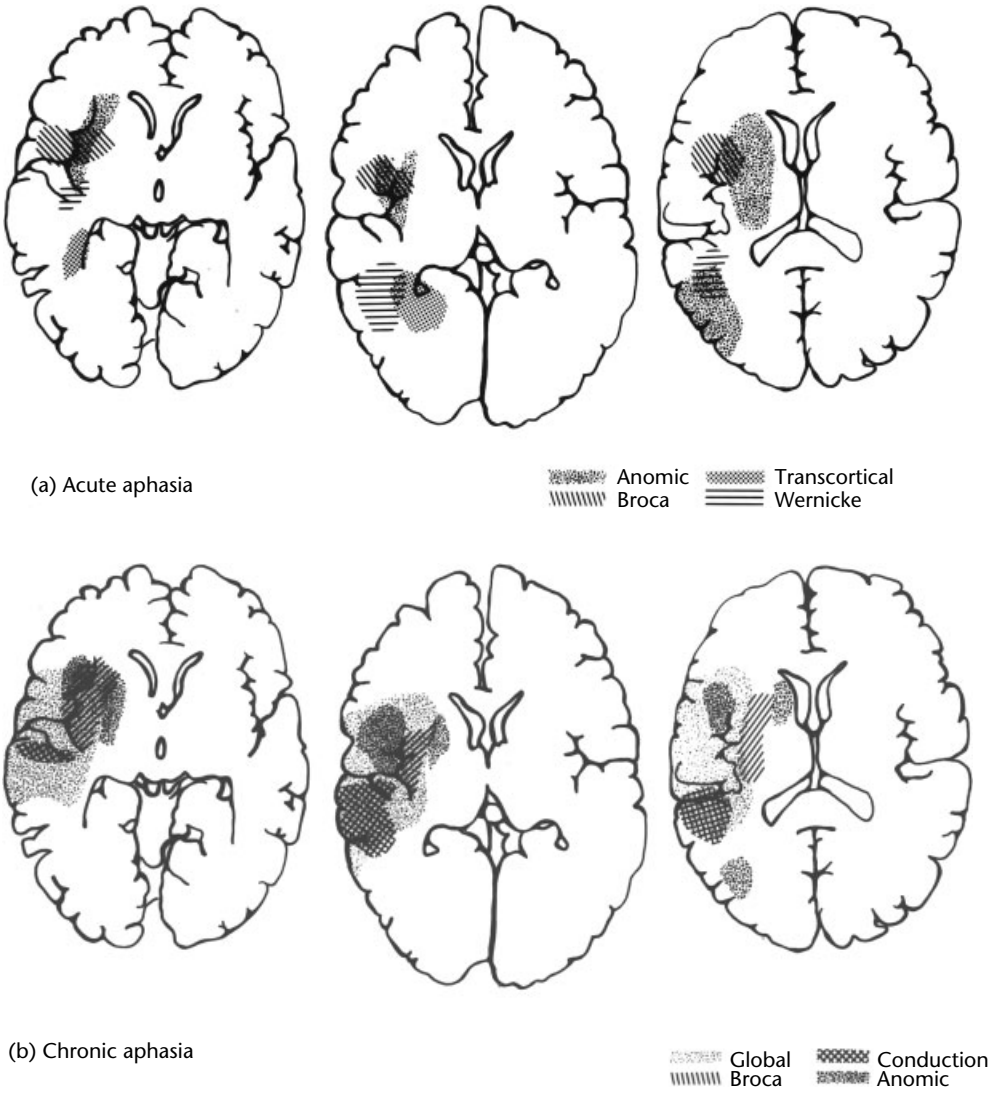

Figure 2. Brain changes following stroke. (a) Acute aphasia; (b) Chronic aphasia.

such as fruits versus vegetables or animate versus inanimate, have been described. None of these can be fitted into the Wernicke–Geschwind model and represent modern developments in aphasiology and linguistics. They tend to occur in temporal lesions secondary to herpes encephalitis or progressive semantic aphasia with Pick disease. The Wernicke–Geschwind model accounts best for discrete stroke and neoplastic lesions affecting nodes of processing or the connectivity between them.

The durability and usefulness of the Wernicke–Geschwind model is related to its reproducible anatomical basis. The model originated from anatomical observations of lesions in patients in combination with the theoretical consideration of the function of the structures involved. It has been confirmed by successive generations of localization techniques beginning with a compilation of autopsy records associated with clinical observations that continues to this day to be an important contribution. Recovery, reorganization and compensation complicates the relationship of the deficit to the structural change, and limits the conclusions about brain function. Changing or unstable lesions, such as growing tumors with all too brief cross-sectional observations, are even more challenging. In stroke lesions scanning images of the brain over a period show different overlaps corresponding to changes in the syndrome as the patient recovers (Figure 2) (Kertesz, 1979).

Functional localization has produced new pieces of information that were not predicted by the Wernicke–Geschwind model, although these are few in number compared with those that were confirmatory. One of these is the persistent appearance of activation in the dominant prefrontal region when semantic associations are made in normal individuals. Although this area is known to be part of the executive system including short-term memory and integration of external and internal stimuli, even planning and judgment, it was connected with language only in an indirect fashion. However, functional language studies persistently show activation of this area. The prefrontal area is active in many experimental paradigms, representing the executive function required for instance in the effort of producing verbs in associations.

When methods other than subtracting elementary auditory from language processes are used, it is evident that the structures involved in the Wernicke–Geschwind model are also activated. The superior temporal gyrus, the posterior frontal region, inferior parietal lobule and the supplementary motor area, which are involved in the lesions producing aphasia, are also activated in various experiments with functional activation of language (Petersen *et al*., 1988; Demonet *et al*., 1992).

What and Where/How Systems

Intermediate article

Hendrik Christiaan Dijkerman, University of Utrecht, Utrecht, The Netherlands

CONTENTS

What and where/how systems are the two main processing streams along which visual information is processed in the primate cerebral cortex.

INTRODUCTION

A large part of the primate cerebral cortex is involved in processing visual input. Indeed, within the monkey brain, more than 30 visual cortical areas have been identified so far. The work of Ungerleider and Mishkin has been highly influential in establishing the neuroanatomical structure of the visual areas and their putative function. In their seminal paper 'Two cortical visual systems', they argue that, after reaching the primary visual cortex (V1), input is further processed along two different routes (Ungerleider and Mishkin, 1982). One route is situated more dorsally and terminates in the posterior parietal lobe, whereas the other projects more ventrally to the inferotemporal cortex (Figure 1). We now know that the ventral stream proceeds from V1 through the more lateral and anterior visual cortical areas V2, V3 and V4 into the posterior part of the inferotemporal cortex. The dorsal stream also involves V2 and V3, which project to the middle temporal area, V3A and the parieto-occipital area, terminating in several areas including the medial superior temporal area, ventral intraparietal area, lateral intraparietal area, 7a, and the anterior intraparietal area. The anatomical separation in ventral and dorsal streams has been confirmed, although there may be more interconnections between the two streams than originally was thought.

EXPERIMENTAL EVIDENCE

Functional Characteristics of the Visual Ventral Stream

Many of the early studies on the functional characteristics of the two visual streams were performed with monkeys. Early lesion studies suggested impairments in visual discrimination performance after bilateral inferotemporal lesions (Gross, 1973). The visual abilities affected included not only hue and brightness, but also two-dimensional pattern and three-dimensional shape discrimination. In addition, single-cell recordings in monkeys showed that neurons in the ventral extrastriate cortex responded to intrinsic object properties such as shape, color, texture and orientation. Input into the ventral stream comes almost exclusively from V1, as evidenced by the lack of responsiveness in ventral neurons after ablation of this area. Evidence for the involvement of temporal areas in visual perception and object recognition in humans came originally from studies of people with brain damage. Impairments in the recognition of objects, in the absence of elementary visual deficits, are usually associated with temporal lobe lesions. More recent functional imaging studies have provided further evidence that the human inferotemporal cortex is involved in visual perception and recognition.

Functional Characteristics of the Visual Dorsal Stream

The posterior parietal lobe has been linked with many different functions, only two of which are discussed here: visuospatial localization, and visual control of movements. Important evidence for the involvement of the dorsal stream in visuospatial function again comes from monkey ablation studies. After lesions to the parietal lobe, monkeys were impaired in their ability to choose which of two food wells was closer to a visual landmark (Pohl, 1973). Other ablation studies found that monkeys had problems on a variety of other visual spatial tasks including the stylus maze task, cage finding and route following (Milner and Dijkerman, 1998). Furthermore, humans with right parietal lesions often show impairments on a

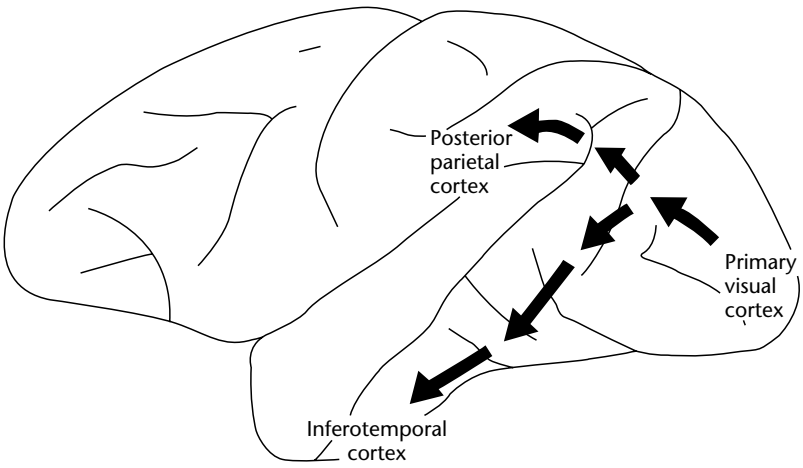

Figure 1. The visual dorsal and ventral streams in the monkey cortex. Reproduced from Milner and Goodale (1995) *The Visual Brain in Action* by permission of Oxford University Press.

variety of spatial tasks including matching of line orientation, estimating distance and discrimination of position (Von Cramon and Kerkhoff, 1993). However, visuospatial deficits do not exclusively follow parietal lesions. Temporal lesions in humans also result in impairments on several spatial tasks, suggesting that at least some spatial processes require an intact ventral stream (Maguire *et al*., 1996). These tasks included distance judgments, route knowledge and map reading, suggesting possible ventral stream involvement in environment-relative coding. Functional imaging studies also indicate activation of the parietal lobe during visuospatial processing. Activation of the posterior parietal lobe has been found in a range of tasks including spatial working memory, spatial long-term memory and spatial matching.

It is well established that lesions of the parietal lobe result in impairments in the visual guidance of movements in monkeys (Ettlinger and Kalsbeck, 1962). The impairment often affected only one arm, ruling out a purely visual deficit, and the monkey was generally able to put food with the affected arm into its mouth, excluding a purely motor impairment. In humans, a similar visuomotor impairment as a result of parietal lesions was first described by Balint (1909). Although the deficits of Balint's patient were assumed to reflect primarily a spatial disorder, it is now clear that nonspatial aspects of visuomotor behavior, such as adjusting the hand opening to the size of the object to be grasped, can also be impaired after parietal lesions. Indeed, there are probably several separate visuomotor channels within the dorsal stream. For example, single-cell recordings show that the responsiveness of neurons in the monkey posterior parietal lobe to visual stimuli may depend on the type of motor response required (Mountcastle *et al*., 1975). Thus, some neurons may only be active when a saccade occurs, while others respond only during the grasp of a certain object. Functional imaging studies also indicate a separation between the posterior parietal areas involved in visually guided saccades and reaching movements (Kawashima *et al*., 1996).

DISCUSSION

Ungerleider and Mishkin proposed not only an anatomical subdivision but also a functional separation between the two processing streams. They suggested that the ventral stream was concerned with visual processing of stimulus characteristics important for object identification (what a stimulus is), whereas the parietal lobe subserved spatial vision (where a stimulus is). This idea has been influential not only within the neuroscience of vision research, but also with respect to philosophical, cognitive, and computational models of the organization of the visual system.

Modifications to this proposal suggest a division between perceptual identification 'what' and visual guidance of goal-directed action 'how' (Milner and Goodale, 1995). Rather than focusing on the visual input characteristics, this view emphasizes the task requirements (what the visual information is processed for). Support for this modification comes from two sources: first, single-cell recordings showed that certain neurons in the monkey parietal cortex responded to intrinsic object characteristics such as shape of the stimulus and/or a grasping movement towards it, and not to its spatial location

(Sakata *et al*., 1995); second, neuropsychological studies of an agnosic patient, D. F., found that while she was unable to recognize the size or orientation of an object she could adjust her visuomotor responses towards this object on the basis of these stimulus characteristics. Although her brain damage was diffuse, it most severely affected the lateral prestriate areas, resulting in a selective disconnection between V1 and the inferotemporal cortex (seen on functional imaging).

A related model was proposed by Jeannerod (1997), who argued for separate object representations within the brain. Activation of a particular representation would depend on the task requirements. Two main representations were distinguished: the pragmatic representation contains parameters relevant for action and could be used to generate the corresponding motor response; in contrast, a semantic mode operates for identification purposes, during which object attributes are bound together. A consequence of this distinction is that object attributes should not be classified according to their putative anatomical channel, but to the requirement of the object-oriented behavior. Jeannerod emphasized that both representations can be used to guide different types of goal-directed action.

Although there is general agreement on the object recognition role for the ventral stream, the visual functions attributed to the dorsal stream differ. There may be several possible explanations for this apparent disagreement. First, many motor responses are based on visuospatial information, while many visuospatial tasks can assumed to require more oculomotor activity than does perceptual identification of foveated objects (Milner and Goodale, 1995). Thus, the requirements for visuomotor and visuospatial tasks may overlap considerably. However, there are some visuomotor tasks for which impairments are found after posterior parietal lesions which may not have a spatial component (e.g. grasping). Similarly, not all visuospatial impairments can be accounted for by deficits in visually guided movements. A second possible explanation for the discrepancy in the hypothetical dorsal stream function is that visuomotor processing and visuospatial representations may depend on different structures within the parietal lobe. The primate posterior parietal lobe can be divided into superior and inferior regions. Evidence from patient studies suggests that the superior part of the posterior parietal lobe is involved in immediate goal-directed visuomotor action, whereas the inferior parietal cortex is involved in spatial cognition. Thus, the common site of lesions in people with optic ataxia is superior to the area typically associated with visuospatial neglect (Perenin, 1997). The inferior parietal lobe regions that are commonly associated with neglect seem to be involved in a supramodal representation of space and receive input predominantly from the ventral stream.

INTERRELATIONS BETWEEN THE TWO VISUAL CORTICAL STREAMS

Whether a distinction is made between 'what' and 'where', or between 'what' and 'how', it is clear that the two visual streams need to work closely together to produce effective and coherent behavior in everyday life. Neuroanatomical studies in monkeys show that there are considerable interconnections between the two systems (Felleman and Van Essen, 1991). The superior temporal sulcus may be especially important in linking the two processing streams. Furthermore, the pattern of ventral and dorsal stream projections to the frontal lobe suggest that the final motor output area, the primary motor cortex (M1), can be influenced by either stream (Rossetti and Pisella, 2002), although its connections with the parietal lobe are more direct.

At a behavioral level, several interactions between the two visual streams are possible, depending on the functions ascribed to them. One important dorsal–ventral interaction is binding the object's spatial position with its identity. Evidence from neurological patients suggests that the medial temporal lobe is involved in retrieval of object–location associations (Milner *et al*., 1997), whereas the parietal lobe may have a role in encoding these associations. The interrelation between the ventral and dorsal streams is also important for interactions between conscious perceptual (semantic) representations and visuomotor (pragmatic) action. An example of such interaction comes from studies of people with selective lesions to the dorsal stream. Such people have been found to compensate for their impaired visual guidance of movements by relying on stored semantic or perceptual information processed within the intact ventral stream (Jeannerod, 1997; Milner *et al*., 2001). The opposite pattern has been observed in patient D. F., whose ability to use visual information for the guidance of arm and eye movements deteriorated when asked to use memorized perceptual target information (Milner and Goodale, 1995).

RELATION TO CONSCIOUSNESS

Studies with both healthy and neurologically impaired human participants indicate that

considerable neural processing of visual input occurs without it reaching awareness. Within the framework of the two visual systems, it has been suggested that only ventral stream processing could lead to conscious visual experience (Milner and Goodale, 1995). Indeed, perturbation studies in normal participants and evidence from neurological patients suggest that the visual guidance of action can occur without conscious awareness of the relevant stimulus features. However, ventral stream processing alone may not be sufficient for visual awareness. The signal additionally needs to be amplified by the kind of neuronal gating associated with selective attention mechanisms (Milner and Goodale, 1995). Neuroimaging studies confirm that although activity in the ventral visual cortex is necessary, it is not sufficient for conscious perceptual experience. Experiments on binocular rivalry and bistable figures (such as the Necker cube) in both healthy and neurologically impaired people indicate that superior parietal areas, in addition to frontal areas, make important contributions (Rees, 2001). These parietal areas are similar to those involved in directing spatial attention.

Working Memory, Neural Basis of

Introductory article

John Jonides, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

Working memory is the memory system used by humans and other animals to store small amounts of information for brief periods in the service of reasoning, thinking, problem-solving and the like.

INTRODUCTION

Consider this: you are driving, and stop to ask a passer-by for directions to a store. She tells you to proceed three blocks, make a left at the drugstore, make a right at the first light, go one mile, then find the store on the right. You do not write down the directions but are able to negotiate the route and find the store with little difficulty. Clearly, this task requires what has been called 'working memory', which has several important characteristics, all of which are illustrated by this example.

One is that it cannot store a great deal of information. Had the directions been much lengthier, the chances are that you would have forgotten a step. Another characteristic is that it remains active for only a short period, even if there is no interference. If you were distracted by a conversation with a passenger, you might have forgotten part of the directions, even if they were not complicated. A third characteristic is that the information stored in working memory is easy to retrieve. Finally, working memory is not a passive storage system; you can manipulate the contents of working memory in the service of some task. For example, you might transform the information from the verbal directions of the helpful passer-by to a visual image of a route map and then trace your way mentally along the map to reach your destination. Limited capacity, limited duration, easy accessibility, and provision for manipulating the contents are the hallmarks of working memory in humans.

Working memory is fundamental to many cognitive processes. It is used routinely in complicated problem-solving or reasoning tasks because any sort of mental problem requires information to be stored and manipulated. Also, it is claimed that working memory is essential to the comprehension of spoken language; storing the beginning of a sentence in working memory permits you to interpret the words at the end of that sentence properly. In fact, working memory ability correlates with overall performance on many measures of intelligence, showing that it is a fundamental component of cognition. For these reasons, it is important to understand the psychological and neurological mechanisms of working memory in humans.

A BRIEF HISTORY OF WORKING MEMORY

Working memory is not a new concept in psychological research. Over a century ago William James included a cogent discussion of working memory (which he called 'primary memory') in his classic work, *Principles of Psychology*. Like working memory, James's primary memory had a small capacity, short duration, and immediacy, in the sense of conscious experience. In fact, the alliance of working memory with consciousness has a long history in the study of this topic, a history which James helped to instigate.

Beyond James's introspective reflections, substantial behavioral research has helped to characterize working memory, largely carried out in the second half of the last century. Much of this research concentrated on the short duration and limited capacity of the memory system (then referred to as 'short-term' memory, a concept that focuses more on its storage characteristics and less on its usefulness in conducting the work of cognition; hence the change to the current term, 'working' memory). Based on some of this research, the capacity of working memory is often cited as 7 ± 2 items, where the definition of an

item can vary: it might be a word in a list of words, a letter in a list of letters, and so on. Also, many experiments were devoted to investigating the causes of forgetting from working memory: do new items interfere, or do memory representations simply decay with time? While the answer to this is still unresolved, there appears to be good reason to suspect that both decay and interference play a substantial role. Another issue that has been of concern is whether working memory can be differentiated from long-term memory behaviorally, as James differentiated it from what he called 'secondary memory'. Indeed, there are several reasons to suppose that it can be so differentiated. Of interest also has been research on how material is retrieved from working memory. Initial results suggested that items of information were retrieved one at a time, but more recent data suggest that there may be simultaneous access to several items.

The earlier concept of short-term memory gradually evolved into the concept of working memory because of the inclusion of the important idea captured by the term 'working'. Working memory includes a short-term storage system, one that is used in the service of other cognitive tasks. So, working memory studies have gone beyond the duration of the memory trace and the limited capacity of storage, to focus on how stored information is used by higher cognitive functions (such as comprehending directions, as illustrated above).

COMPONENTS OF WORKING MEMORY

Working memory is not singular in character; rather, it appears to have several components. Perhaps the most influential theory of the componential nature of working memory is due to Alan Baddeley and his colleagues. Baddeley has proposed a model that includes two fundamentally different components. One is a set of storage buffers that are responsible for holding a limited amount of information for a brief period. What differentiates the buffers is the kind of information they store. Baddeley's original conception of them included two types of information: verbal and visuospatial. We now know that the types of information that can be differentiated in working memory are more numerous than this, including working memory for objects that cannot easily be named; there may be other types as well. We also know that the different types of working memory storage are not simply a function of the modality of input. For example, working memory for verbal information appears to make use of the same neural machinery whether the words are presented by ear or by eye.

Because information in the storage buffers decays with time and interfering information, there is a need for a rehearsal mechanism that refreshes the contents of the buffers to keep the contents active. Rehearsal is conceptualized as a kind of inner speech in the case of verbal information, and as an inner spotlight of attention that moves among mental locations for spatial information. Studies of rehearsal for other types of information are lacking.

The second component of Baddeley's model of working memory has to do with the manipulation of information stored in the buffers. Baddeley called this the 'central executive' component, but it is perhaps more apt to refer to a set of 'executive processes'. Discussions of executive processes have focused on three sorts. There are attentional processes that allow one to focus on some particular information in the buffers. There are also processes that inhibit attention from irrelevant information, so that one can concentrate on what is relevant. The third type are processes that allow one to switch successfully between two tasks being performed at the same time (e.g., driving and participating in a conversation with a passenger). This may not exhaust the list of executive processes, but it gives a flavor of what the functions of executive processes are.

DIFFERENT VIEWS OF WORKING MEMORY

Baddeley's view of executive and storage components of working memory has been the most productive in stimulating research on the topic. However, it is not the only view available. One influential alternative comes from the work of Nelson Cowan. According to this view, there are three sorts of memory representations that need to be considered.

The largest and most comprehensive is long-term memory, the enduring repository of information that a person might store. At any moment, most of this information resides in a passive state, ready for retrieval. A small portion of the information, however, can be in an activated state because it has been the recent focus of attention, because it has been recently presented, because it is novel, or for other reasons. Within the temporarily activated information, furthermore, a subset of it might be the focus of attention, and this would correspond to the information that might be in consciousness at any time. All information that

resides in long-term memory is potentially available for activation. The information that is currently activated is akin to what others have called working memory in that it is limited in amount, it is readily accessible, its active state will wane over time or as other information is activated, and it is available to participate in other cognitive processes. Within the body of activated information, a small subset will be the subject of consciousness by virtue of its having been attended to.

Perhaps an intermediate position between that of Baddeley and that of Cowan is reflected in the research of Randall Engle and his colleagues. Like Cowan, they see working memory as the temporarily activated portion of long-term memory. However, they emphasize the importance of mental procedures such as rehearsal that are specific to working memory. In addition, like Baddeley and Cowan, they emphasize the importance of selective attention processes that control the contents of working memory. Unlike Cowan but like Baddeley, Engle and his colleagues also recognize the distinction among different codes of information, such as phonological or spatial. Indeed, the neuroanatomical data on this issue, reviewed below, make this distinction quite persuasive. What Engle emphasizes in his view more than the others is the importance of individual differences in attentional control over the contents of working memory. Such differences lead to differences in fluid intelligence which is important in reasoning and problem-solving. Furthermore, these individual differences are also reflected in how effectively people can maintain information in working memory in the face of interference and distraction. Indeed, research by Lynn Hasher, Rose Zacks and their colleagues has pinpointed the importance of attentional control in excluding unwanted information from working memory while allowing the person to concentrate on information of interest.

While there is no current resolution among the different views of working memory, it is worth highlighting some important features that have been contributed by each.

One is the idea that the contents of working memory are temporarily activated representations in long-term memory. Another is that the information in working memory needs to be refreshed and attended to in order to remain there, and this is controlled by executive processes that turn attention to relevant information and turn it away from irrelevant information. Yet another is that different sorts of information may have different representations in working memory. Add to this that there are now well-documented differences among individuals in working memory, and that these differences have important implications for intelligence and reasoning, and we see that the working memory system, however conceived, has a central role in cognition.

NEUROANATOMICAL BASIS OF WORKING MEMORY

The study of cognition has been greatly aided by studies of brain anatomy and function in both humans and other animals. This is true of working memory as it is of many other cognitive functions. One important set of findings about working memory has to do with which parts of the brain mediate the various components of working memory and what networks of brain areas are involved in working memory tasks. Knowledge about the localization of processes in the brain has permitted us to predict the nature of working memory impairment that a person would suffer with damage to one or another of these brain structures. Another important contribution of this research has been to test various psychological theories of working memory. For example, the view that working memory is not unitary in character, but is composed of subsystems responsible for different types of information, has been confirmed by testing patients with damage to different regions of the brain and by scanning normal individuals who are engaged in working memory tasks with different materials.

There are three important sources of information about the neuroanatomical basis of working memory. One comes from the study of animals who are challenged with working memory tasks when they are given selective lesions or when the activity of individual neurons is recorded. A second comes from the study of patients with localized lesions who offer the opportunity to study what aspects of working memory are compromised with damage to a specific region of the brain. The third comes from the recent use of neuroimaging tools, especially positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), to study normal individuals performing working memory tasks.

Studies of Working Memory in Animals

Beginning with the seminal work of Jacobsen in the 1930s, there has been a succession of important studies of working memory in animals, most notably monkeys. Many of these studies have used various versions of the delayed response

task, in which a stimulus is presented to an animal and must be retained in the animal's memory for a short interval, typically several seconds; the animal is then given choices among stimuli and must produce a response that indicates it has retained a memory of the original stimulus.

A spatial version of the delayed response task has been popular for studying working memory in animals, especially in recent studies by Goldman-Rakic and her colleagues. In this task an animal is trained to fixate a central location on a screen while a brief stimulus is illuminated in the periphery. The animal maintains fixation during the delay interval, and afterwards it is given a cue to shift its gaze to the location that it was storing in memory. Many experiments have shown that lesions of the dorsolateral prefrontal cortex produce a marked deficit of performance on this task. Interestingly, if the animal's task is to maintain not spatial information but information about an object's shape, the crucial lesion that produces a deficit is in a region just inferior to the one that is implicated in spatial working memory, suggesting a difference in working memory representations depending on the type of information stored.

Studies of animals performing a delayed response task while neural responses are recorded from individual cells in dorsolateral prefrontal cortex confirm the studies using lesions in animals: many of these cells are responsive to specific stimuli (e.g., specific spatial locations or specific object shapes) during the delay interval of the delayed response task. It therefore appears certain that even individual cells of the dorsolateral prefrontal cortex have working memory capability. Other studies suggest that the superior parietal cortex, certain subcortical structures, and the hippocampal region in monkeys are involved in the delayed response task as well. There is persuasive evidence of a network of highly interconnected posterior and anterior structures that mediate working memory.

Disorders of Working Memory Following Brain Lesions

Studies of patients with brain damage have also offered important insights about working memory. One of the most salient findings is a clear dissociation between spatial and verbal working memory based on the side of the brain that is damaged. This is supported by numerous studies of patients with deficits in verbal working memory, and by selected cases of patients with deficits in spatial working memory. In one review of patients with verbal working memory deficits, 17 of the 18 patients who were described had lesions of the left hemisphere. These lesions included inferior parts of the parietal lobe. Patients with lesions in this region, for example, have very poor digit spans, a standard test of the storage component of working memory. One well-studied case of this sort is patient K. F., described by Warrington and Shallice, who had a head injury affecting primarily the left parietal-occipital cortex, in the region of the inferior parietal lobe. This patient had great difficulty with repetition tasks, and his digit span was reduced to two. Similar cases confirm that posterior, left-hemisphere lesions seem to be selective for verbal as opposed to spatial working memory.

In contrast, the few cases of deficits in spatial working memory that have been reported suggest that it is the right hemisphere that is involved, not the left. The clearest case of this is patient E. L. D, described by Hanley and colleagues, a right-handed woman who had suffered an aneurysm in the right hemisphere which damaged tissue around the sylvian fissure. When tested on the Corsi Blocks Test, a spatial analog to digit span, she scored noticeably worse than normal; yet her performance on verbal working memory tasks was comparable with that of normal controls. The contrast between patient E. L. D. and patients with left hemisphere lesions suggests that different circuitries are responsible for verbal and spatial working memory.

Studies of patients with brain lesions have revealed yet more about the nature of verbal and spatial working memory systems. For example, the model of verbal working memory proposed by Baddeley and colleagues includes a storage buffer to retain material and a rehearsal system to recycle the material in the storage buffer so that it does not decay quickly. The rehearsal subcomponent has been likened to the activation of the speech system, albeit silently. Yet studies of patients with working memory deficits have often revealed that they have normal or nearly normal speech patterns. So, if the speech system is indeed involved in rehearsal, it must be an aspect of that system that is tied to internal recycling of information and not to overt speech.

The storage of spatial information in working memory has been thought to use the same neural machinery as that for the generation and manipulation of visual images. This idea has been tested by examining patients such as M. G., who had clear deficits on tests of mental imagery that required her to rotate or scan an imagined object, yet her spatial working memory was largely intact. Beyond this, researchers have found that asking people to

engage in a secondary task such as spatial tapping or arm movement while completing a spatial working memory task hinders performance on the memory task, but has little if any effect on visual imagery tasks. It thus appears that spatial working memory and mental imagery involve somewhat different mental machinery.

Studies of patients with brain lesions have furthered our understanding of the neural basis of working memory. First, they have uncovered the regions of the human brain that are critical to working memory. Second, they have allowed us to compare the neuroanatomy of human working memory with working memory in other animals to reveal the importance of certain regions such as the prefrontal cortex, as reviewed by D'Esposito and Postle. However, these studies are compromised in at least two ways. First, naturally occurring lesions that produce working memory deficits are often large, making it difficult to localize precisely the damage that disrupts processing. Second, given the brain's capacity for plasticity and compensation in the face of damage, the study of patients with brain injury may not accurately reveal neural processes in normal individuals.

Functional Neuroimaging Studies of Working Memory

Neuroimaging techniques are an important source of information about the neuroanatomical basis of working memory and are free from the weaknesses of behavioral studies with patients. The use of PET and fMRI especially has provided important insights into circuitry and in so doing has tested some of the psychological claims about working memory.

It would be disappointing if the findings from neuroimaging studies of working memory were in conflict with those from the study of patients. Indeed, there is consistency. A prominent result that confirms this has to do with the circuitry that is activated by different types of materials.

For verbal material, activations in neuroimaging studies have been found predominantly in the inferior frontal gyrus, premotor cortex, supplementary motor cortex, superior parietal cortex, and inferior parietal cortex, most prominently in the left hemisphere. The sites in the inferior frontal gyrus and premotor cortex are similar to ones involved in the production of speech, and evidence suggests that these are involved in rehearsal of verbal material. The site in the inferior parietal cortex is consistent with studies of patients with deficits in verbal working memory who most often have damage there. The site in the superior parietal cortex is probably involved in controlling attention to different items of verbal material, and is consistent with the frequent identification of this site in studies of attentional allocation in other contexts. Some verbal working memory studies have also found activation in the dorsolateral prefrontal cortex, frequently in the right hemisphere, and this may be a result of the operation of executive processes on material that is stored when some manipulation of that material is required. For example, one test that often shows dorsolateral prefrontal activation is the 'two back' task. In this task, the participant sees a succession of letters presented one at a time, once every 3 s. The task is to decide whether each letter matches the one presented two letters back in the sequence. This clearly requires storage of verbal information but also requires continual reconfiguring of what is stored, so the information that is retained is not static. It may be this additional requirement that recruits dorsolateral structures.

Studies of spatial working memory have revealed a quite different neural architecture. Spatial tasks recruit structures in extrastriate occipital cortex, superior and inferior parietal cortex, premotor cortex, supplementary motor cortex, and sometimes inferior frontal gyrus, all largely in the right hemisphere. It has been suggested that the superior parietal site together with the superior frontal sites are involved in a rehearsal circuit for spatial material that is stored in regions of the inferior parietal and occipital cortex. While it is not clear what the homology is between humans and monkeys for different regions of the brain, the fact that there is activation of frontal and parietal sites in human studies is at least qualitatively consistent with studies of spatial working memory in monkeys. Some spatial tasks have also resulted in activation of the dorsolateral prefrontal cortex, as with verbal tasks, and this activation may once again be an indication of processes involved in the executive manipulation of spatial material.

One might think that the important distinction between verbal and spatial circuitry has to do with auditory versus visual material. This, however, does not appear to be so. First, the circuitry for verbal material appears to be the same whether that material is delivered by eye or by ear. Second, the circuitry for visual working memory when the stimuli are shapes is quite different from that for spatial material: it appears to recruit structures of temporal and frontal cortex, possibly largely in the left hemisphere. In this way, the spatial and shape working memory circuitries seem to honor the

distinction between a visual processing pathway specialized for spatial information (involving dorsal structures) and a pathway specialized for information about shape and form (involving ventral structures).

How do these findings about neural circuitry inform us about psychological theories? One issue to which they are certainly germane is whether there are different working memories for different types of material. The answer appears to be that there are, at least for spatial, verbal, and shape materials. Another issue has to do with whether working memory is the same as long-term memory, with the difference merely being levels of activation. In that working memory tasks seem to activate some associative cortex that may be the seat of long-term memory, there appears to be some currency to this idea. However, in that working memory tasks also recruit structures that are not routinely involved in long-term memory tasks (e.g. the superior parietal cortex), the evidence suggests that there may be processes specific to working memory *per se*.

Yet another issue has to do with executive processes. At present there is still too little information about these processes to be sure what brain structures they recruit; yet evidence emerging from studies of working memory is leading to the view that there are prefrontal and superior parietal structures involved in allocating attention, in inhibiting irrelevant material, in manipulating information stored in working memory, and in keeping track of multiple goals in working memory when the individual is engaged in multiple tasks.

The archive of data from neuroimaging studies of working memory is still small, but is already revealing a network of structures which mediate a complex function essential to complex cognitive life.

CONCLUSION

Much has been learned about working memory that goes beyond James's important introspections. We know about its capacity, duration, and function from behavioral experiments; we know what happens to it with damage to selected parts of the brain; and we know what regions of the brain are activated when humans and other animals are engaged in working memory tasks. These three sources of evidence, together with other techniques such as studies of receptor binding for neurotransmitters, promise to reveal a detailed picture of the architecture of working memory in the next epoch of research on the topic.

Action, Philosophical Issues about

Intermediate article

Alfred R Mele, Florida State University, Tallahassee, Florida, USA

CONTENTS

The philosophy of action concerns theories about what actions are, how they are to be explained, and the mental events and states associated with intentional action.

INTRODUCTION

In striving to analyze, understand, and explain actions, philosophers of action are concerned primarily with intentional actions. In discussions of freedom of action, intentional action also naturally occupies center stage. And although people are morally accountable for some unintentional actions, as in cases of negligence, moral assessment of actions is focused primarily on intentional actions. What is the nature of intentional action and how are intentional actions to be explained?

CENTRAL PHILOSOPHICAL ISSUES ABOUT ACTION

There are two main philosophical questions about actions: What is an action? How are actions to be explained? The first question directly raises two others: How are actions different from nonactions? (For example, how does an ordinary instance of running hard differ from an ordinary unintentional instance of breathing hard?) How do actions differ from one another? (For example, if I turn on my computer by pressing a button, are my turning it on and my pressing the button different actions or the same action?) If not all actions are intentional, the first question also raises another: What is it for an action to be intentional? The question about the explanation of actions is also a question for cognitive science. The challenge is to produce a theory of the springs of action in light of which we can, in principle, explain particular intentional actions – in light of which we can explain, for example, why you are reading this article, why I wrote it, and why the editor decided to publish it. If proper explanations of actions are causal explanations, part of what we would like to understand is how the events or states that explain actions help to produce actions.

PHILOSOPHICAL VIEWS AND THEORIES OF ACTION

According to a popular answer to the question how actions differ from nonactions (Brand, 1984; Davidson, 1980; Mele, 1992), actions are like sunburns in an important respect. The burn on Al's back is a sunburn partly in virtue of its having been caused by exposure to the sun's rays; a burn that looks and feels just the same is not a sunburn if it was caused by a heat lamp. Similarly, a certain event is Al's raising his left hand – an action – partly in virtue of its having been appropriately caused by mental items. An influential version of this view claims that reasons, understood as combinations of beliefs and desires, are causes of actions and that an event counts as an action partly in virtue of its having been suitably caused by a reason (Davidson, 1980). Alternative conceptions of action include an 'internalist' position according to which actions differ experientially from other events in a way that does not depend on how, or whether, they are caused; a conception of actions as composites of nonactional mental events or states (e.g. intentions) and pertinent nonactional effects (e.g. an arm's rising); and views identifying an action with the causing of a suitable nonactional product by an appropriate nonactional mental event or state – or, instead, by an agent (for discussion of these alternatives, see Davis, 1979; Ginet, 1990).

Promising theories about how actions differ from one another include a fine-grained theory (Goldman, 1970), a coarse-grained theory (Davidson,

1980), and componential theories (Ginet, 1990). According to a fine-grained theory of actions, *A* and *B* are different actions if, in performing them, the agent exemplifies different act-properties. For example, if Ann starts her car by turning a key, her starting the car and her turning the key are two different actions, since the act-properties at issue are distinct. A coarse-grained theory asserts that Ann's turning the key and her starting the car are the same action described in two different ways. A componential theory claims that Ann's starting her car is an action having various components, including her moving her arm, her turning the key, and the car's starting. Where the first two theories claim to find, alternatively, a collection of related actions, or a single action under different descriptions, component theories assert that there is a 'larger' action having 'smaller' actions among its parts.

Most philosophers agree that at least a sketch of an explanation of an intentional action can be provided by identifying the reasons for which the agent performed it. Whether reasons can have a place in *causal* explanations of actions is controversial. In 1963, Donald Davidson challenged anti-causalists about 'reasons-explanations' to provide an account of the reasons for which we act that does not treat (our having) those reasons as causes of relevant actions. Imagine that Ann has a pair of reasons for using her leaf blower this morning. First, she wants to blow the leaves off her lawn today and she regards this morning as a very convenient time. Second, she has a desire to repay her neighbor for awakening her yesterday with his leaf blower and she believes that blowing the leaves off her lawn this morning would do the trick. As it happens, Ann uses her leaf blower this morning only for one of these reasons. In virtue of what is it true that she uses it for this reason, and not for the other, if not that this reason (or her having it), and not the other, makes an appropriate causal contribution to her using it? Detailed attempts to meet this challenge have been revealingly problematic (for discussion, see Mele, 1992, chap. 13).

IMPACT OF COGNITIVE SCIENCE ON ISSUES ABOUT ACTION

Philosophers of action have explored the nature of psychological states and events thought to play important causal/explanatory roles in intentional action, including beliefs, desires, and intentions. Some philosophers appeal to intentions in an effort to avoid the problems 'deviant causal chains' pose for attempted analyses of intentional action featuring reasons as causes (Brand, 1984; Mele, 1992). The alleged problem is that whatever psychological causes are offered as necessary and sufficient for a resultant action's being intentional, scenarios can be constructed in which, owing to an atypical causal connection between the favored psychological antecedents and a pertinent resultant action, that action is not intentional. For example, Ann wants to awaken her husband and she believes that she may do so by making a loud noise. Motivated (causally) by this desire and belief, Ann may search in the dark for a suitable noise-maker. In her search, she may accidentally knock over a lamp, producing a loud crash. By so doing, she may awaken her husband, but her awakening him in this way is not an intentional action. The task for those who wish to analyze intentional action causally is to specify not only the psychological causes of actions associated with their being intentional but also the pertinent roles played by these causes. Some philosophers have sought help from cognitive science in undertaking this task (Brand, 1984; Mele, 1992).

Presumably, intentions play important roles in the production of intentional actions. Functions plausibly attributed to intention in the philosophical and psychological literature include initiating and motivationally sustaining intentional actions, guiding intentional behavior, helping to coordinate agents' behavior over time and their interaction with other agents, and prompting and appropriately terminating practical reasoning (see Brand, 1984; Bratman, 1987, 1999; Mele, 1992). The initiating, sustaining, and guiding roles are relevant to the problem of deviant causal chains.

Intentions, like many psychological states, have both a representational and an attitudinal dimension. The representational content of an intention may be understood as a *plan*. The intending *attitude* towards plans may be termed an *executive* attitude. Plans, on one conception, are purely representational and have no motivational power of their own (Brand, 1984; Mele, 1992). People may have any number of attitudes towards plans, in this sense. They may believe that a plan is elegant, admire it, hope that it is never executed, and so on.

To understand the executive dimension of intention, compare an intention to attend a concert with a *desire* to attend a concert. Both encompass motivation to attend a concert, and the content of each is or includes a representation of the prospective course of action. But although one can have a desire to attend a concert without being at all *settled* on doing so, intending to attend a concert is partially constituted by being settled on so doing. This is compatible with intentions' being

revocable and revisable. Though Al is now settled on meeting a friend for dinner, he would cancel the arrangement were a pressing problem to arise at home.

An important motivational difference between desires and intentions may lie in their *access* to the mechanisms of intentional action. This difference coheres with the claim that intending to *A* entails being settled on *A*-ing while desiring to *A* does not. Whereas our becoming settled on *A*-ing straightaway is normally sufficient to initiate an *A*-ing at once, this is not true of the acquisition of desires to *A* straightaway. To be sure, someone's being settled now on *A*-ing later normally will not initiate an *A*-ing now. But if the intention is still present at the later time and the agent recognizes that the designated time has arrived, an attempt at *A*-ing will normally be immediately forthcoming. This is not true of someone who still has a mere desire at the later time to *A*; such a person may simply choose not to *A* and behave accordingly.

If intentions initiate actions, it is *proximal* intentions that do so – roughly, intentions to do something straightaway. (More precisely, it is the *acquisition* of a proximal intention that plays this role.) But why do proximal intentions initiate and sustain the actions that they do? Why, for example, does an intention to drive home tend to initiate and sustain one's driving home rather than one's cycling home or one's driving to a friend's house? Return to the representational side of intentions. An intention to *A* incorporates a plan for *A*-ing, and *which* intentional action or actions an intention generates is a partial function of the intention-embedded plan. In the limiting case, the plan is a simple representation of one's *A*-ing. Often, intention-embedded plans are more complex. For example, Al's proximal intention to check the oil in his car incorporates a plan that includes his first unlatching the hood, then opening the hood, then unscrewing the oil cap, and so on. An agent who successfully executes an intention is *guided* by the intention-embedded plan.

An intention-embedded plan identifies a goal and (in non-limiting cases) provides action-directions, as it were. Exactly how deep the representational content of intentions runs is a partly empirical and partly conceptual question. Even when what is intended is routine and very simple behavior for the agent – a doctor's signing a prescription, for example – a great deal is going on representationally. Some psychologists take the representational content of motor schemata to run quite deep, suggesting, for example, that motor schemata involved in handwriting include representations of the neuromuscular activity required to achieve the movement represented by their higher-level components. Standard philosophical conceptions of intention seem not to countenance such representations as parts of the representational content of a normal agent's intention to write her name, probably because of the apparent inaccessibility of these representations to consciousness. On standard conceptions, however, intentions guide behavior in a way that depends on their representational content. If plans embedded in standard writing intentions do not incorporate representations of low-level neuromuscular activity, they can provide guidance at a higher level, with the assistance of motor schemata that are external to intentions. Perhaps a solution to some problems posed by deviant causal chains can be produced by careful attention to the guiding function of proximal intentions.

RELEVANCE OF ACTION THEORY TO COGNITIVE SCIENCE

The philosophy of action has produced theories about what actions are and about how actions are to be explained. In both connections, philosophers have speculated about how mental events and states figure in the production of intentional actions. Theories of the former kind are useful to cognitive scientists concerned to explain human actions, insofar as these theories provide conceptions of what is to be explained. Some philosophical theories of the explanation of action are fertile ground for cognitive science. These theories have elements that are testable, or suggestive of empirical hypotheses, and the theories reveal interesting patterns in our own common-sense explanations of why we do what we do.

Aesthetics

Intermediate article

Jerrold Levinson, University of Maryland, College Park, Maryland, USA

CONTENTS

Aesthetics is that branch of philosophy devoted to conceptual and theoretical inquiry into art and aesthetic experience.

THE DOMAIN OF AESTHETICS

We may usefully distinguish three conceptions of the domain of aesthetics, according to what is taken as the focus of attention:

- The practice of making and appreciating works of art.
- Aesthetic properties, features, or aspects of things.
- Aesthetic attitudes, perceptions, or experiences.

There are intimate relations among these three conceptions. Thus, art might be conceived as a practice in which people aim to make objects possessing valuable aesthetic properties, or that are apt to give subjects valuable aesthetic experiences; aesthetic properties might be conceived as those properties saliently possessed by works of art, or those on which aesthetic experience is centrally directed; and aesthetic perception might be conceived as the sort of perception that is central to the appreciation either of works of art, or of the aesthetic properties of things, whether natural or man-made. Finally, it can be argued that art, in its creative and receptive aspects, provides the richest and most varied arena for the exploration of aesthetic properties and the enjoyment of aesthetic experiences.

The aesthetics of nature may be included in the second or third of these conceptions, if it is understood as the study of certain distinctive properties of natural phenomena that can be classified as aesthetic (e.g. beauty, sublimity, grandeur), or of certain kinds of experience provoked by nature, or of certain kinds of attitudes to nature. The theory of criticism may be included in the first conception, if it is understood as the study of that part of the practice of art concerned with the reception of artworks, including their description, interpretation, and evaluation. Craft, too, can be understood as an art-related or quasi-artistic activity, and hence may be included in the first conception.

Art

One conception of art sees it as specially concerned with the exploration and contemplation of perceptible form for its own sake. This view has roots in the work of the eighteenth-century German philosopher Immanuel Kant, who thought that the beauty of objects and phenomena, whether natural or man-made, consisted in their ability to stimulate the free play of the cognitive faculties in virtue of their pure forms, both spatial and temporal, and without the mediation of concepts. In the early twentieth century, the English art theorist Clive Bell took a similar line, holding that spatial form was the only artistically relevant aspect of visual art, and that possessing 'significant form' was the necessary and sufficient condition of a work of art.

Another conception of art sees it as essentially a vehicle of expression or communication, especially of states of mind or nonpropositional contents. In the early twentieth century, the Italian philosopher Benedetto Croce claimed that the essence of art is in the expression of emotion. He emphasized the indissociability, even identity, of content and vehicle in art. The English philosopher R. G. Collingwood developed this line further, observing that making works of art was a way for the artist to articulate or make clear the nature of his or her emotional condition. The Russian novelist Leo Tolstoy identified art with emotional communication from one person to another by indirect means, namely, a structure of signs in an external medium.

A third conception of art sees it as concerned with the imitation or representation of the external world, perhaps in distinctive ways or by distinctive means. This conception can be found in the earliest works in the canon of aesthetics, the *Republic* of Plato and the *Poetics* of Aristotle. Modified so as to allow for representation of matters beyond the visible, it finds expression among later thinkers in the aesthetic theories of Lessing, Hegel, and

Schopenhauer. Some modern discussions of art as representation regard it broadly as semiotic or symbolic in nature.

Art has also been conceived as an activity aimed explicitly at the creation of beautiful objects, including representations of natural and human beauty; as an arena for the exhibition of skill, particularly in fashioning or manipulating objects capable of exciting admiration (Sparshott, 1982); as a development of play, stressing the structured and serious aspects of play (Gadamer, 1986); and as the sphere of experience per se, in which attention is drawn to the interplay of active (creative) and passive (receptive) phases in engagement with the external world (Dewey, 1934).

More recently, art has been conceived as the production of objects intended to afford aesthetic experience (Beardsley, 1981); as the investing of objects with 'aboutness' in the context of a specific cultural framework (Danto, 1981); as a particular social institution identified by its constituent rules and roles (Dickie, 1997; Davies, 1991); and as an activity identifiable only historically through a connection to earlier activities or objects whose art status is assumed (Wollheim, 1980; Levinson, 1990, 1996; Carroll, 2001).

Aesthetic Property

It is generally agreed that aesthetic properties are perceptual or observable, experienced in a fairly direct manner, and relevant to the aesthetic value of the objects that possess them. Various further characteristics of aesthetic properties have been proposed, including: having gestalt character; requiring a certain sensitivity for discernment; having an evaluative aspect; affording pleasure or displeasure in contemplation; not being governed by conditions, or applicable by rule; supervenience on lower-level perceptual properties; requiring imagination for attribution; requiring metaphorical thought for attribution; being notably revealed in aesthetic experience; and being notably present in works of art.

Although the relative status of the characteristics is debated, there is substantial intuitive agreement as to which perceivable properties of things are aesthetic. These include, for example: beauty, sublimity, grace, elegance, delicacy, harmony, balance, unity, power, anguish, sadness, tranquility, serenity, and melancholy. It is evident that expressive properties, which arguably belong only to works of art and not to natural objects, constitute a significant subset of aesthetic properties.

Aesthetic Experience

Among the characteristics that have been proposed as distinguishing aesthetic states of mind (whether attitudes, perceptions, emotions, or acts of attention) from others are: disinterestedness, or detachment from desires, needs and practical concerns; non-instrumentality, or being undertaken or sustained for their own sake; contemplation or absorbtion, with consequent effacement of the subject; focus on an object's form; focus on the relation between an object's form and its content or character; focus on the aesthetic features of an object; and centrality in the appreciation of works of art. It is still a matter of debate whether these criteria, either individually or in some combination, adequately define aesthetic experience.

PROBLEMS IN AESTHETICS

Evidently, among the problems aesthetics addresses are the interrelated characterizations of art, aesthetic properties, and aesthetic experience. These broad problems engender many more specific ones.

The issue of the definition of art leads naturally to many further issues: the ontology of art; the process of artistic creation; the demands of artistic appreciation; the concept of form in art; the role of media in art; the analysis of representation and expression in art; the nature of artistic style; the meaning of authenticity in art; and the principles of artistic interpretation and evaluation. The philosophy of art is, in fact, sometimes conceived of as metacriticism, or the theory of art criticism (Beardsley, 1981).

The ontology of art concerns the question of exactly what sort of object a work of art is, and how this might vary between different art forms. Philosophers have asked whether a work of art is physical or mental, abstract or concrete, singular or multiple, created or discovered, notationally definable or only culturally specifiable; and they have asked what authenticity of a work of art consists in.

Interest in the creative process in art concerns the question of whether the creative process can be characterized in any general way, and the relevance of knowledge of the creative process (and more generally of the historical context of creation) to appreciation of works of art.

Issues about artistic form include the status of formalism as a theory of art, the different kinds of form manifested in different art forms, and the relation of form to content and of form to medium.

Among the modes of meaning that inhere in works of art, perhaps the most important are representation and expression. Goodman (1976) argues that exemplification is an equally important mode.

Accounts of representation (usually with special reference to pictorial representation) have been proposed in terms of resemblance between object and representation; perceptual illusion (Gombrich, 1960); symbolic conventions (Goodman, 1976); 'seeing-in' (Wollheim, 1987); world-projection (Wolterstorff, 1980); make-believe (Walton, 1990); recognitional capacities (Schier, 1986); resemblance between experience of object and experience of representation (Budd, 1995; Hopkins, 1998); and information content (Lopes, 1996).

Accounts of artistic expression (usually with special reference to the expression of emotion) have been proposed in terms of personal expression by the artist; induced empathy with the artist; metaphorical exemplification; correspondence (Wollheim, 1987); evocation (Matravers, 1998); imaginative projection (Scruton, 1997); expressive appearance (Kivy, 1989; Davies, 1994); and imagined personal expression (Vermazen, 1986; Levinson, 1996).

Concerning artistic style, attention has focused on the distinction between individual and period style, on the psychological reality of style, on the interplay between style and representational objective, and on the role that cognizance of style plays in aesthetic appreciation.

Concerning the interpretation of art, attention has focused on the relevance of artists' intentions; on the diversity of interpretative aims; on the debate between critical monism and critical pluralism; on the similarities and differences between critical and performative interpretation; and on the relationship between interpretation and maximization of value.

Concerning the evaluation of art, attention has focused on the question of its objectivity or subjectivity; on the relation between artistic value and pleasurability; on the relation between the value of art as a whole and the value of individual works of art; on the existence of general criteria of value across art forms; and on the relevance of a work's historical influence, ethical import, emotional power, and cognitive reward to its evaluation as art.

Certain concepts are relevant to the understanding of many, if not all, works of art: for example, the concepts of intention, fiction, metaphor, genre, narrative, genius, forgery, performance, and tragedy.

There are other questions concerning the relationships between art and other domains or aspects of human life, such as emotion, knowledge, and morality. For example, there are the questions of how we can coherently have emotions for characters whom we know to be fictional; whether art can be a vehicle of knowledge; and whether art can contribute to moral education.

There are also questions relating to particular art forms: for example, whether photography is an inherently realistic medium; whether poetry can be usefully paraphrased; whether the basic form of music is local or global; and whether narration operates similarly in novels and films.

The question of the nature of aesthetic properties leads naturally to questions about realism in relation to such properties; the supervenience relation between aesthetic properties and the non-aesthetic properties on which they depend; the range of aesthetic properties to be found in the natural world; the special status of beauty among aesthetic properties; the difference between the beautiful and the sublime; the degree of objectivity of judgments of beauty; the relations between artistic, natural, and human beauty; and the relationship between the aesthetic properties of artworks and their artistic properties, such as originality or seminality (which, although appreciatively relevant, are not directly perceivable as are aesthetic properties).

Finally, discussions of aesthetic experience open into discussions of the nature of perception, reason, imagination, feeling, memory, and mood, in relation to art or nature.

UNDERSTANDING WORKS OF ART

Categorial Perception

Walton (1970) follows Beardsley and Sibley in taking aesthetic properties to be perceptual, gestalt-like, non-rule-governed, and dependent on an object's lower-level perceptual properties. But Walton insists that aesthetic properties are dependent as well on the artistic categories (for example, of style, genre or medium) into which works of art may be said to fall. The category of a work is partly a matter of art-historical context, including factors such as the artist's intention, the artist's previous work, the artistic traditions in which the artist worked, and the artistic problems to which the artist is responding. If, as Walton argues, a work's aesthetic properties do not reside in perceivable structure alone, it is even more evident that its artistic properties depend on non-perceivable factors.

Artistic Expression

For Goodman (1976), artistic expression is a matter of an artwork exemplifying or drawing attention to some property it metaphorically possesses, in virtue of its general symbolic functioning.

For Tormey (1971), artistic expression is a matter of an artwork's possessing expressive properties that are related to intentional states, and which are ambiguously constituted by the non-expressive structural features underlying them.

Wollheim (1987) suggests that expressiveness in painting is a matter of intuitive correspondence or fit between the appearances that works of art present and feeling states of the subject, which are then projected onto those works in complex ways.

Davies (1994) offers a theory of musical expressiveness in terms of resemblances between musical patterns and human emotional behavior, and explores the variety of responses that listeners have to perceived expressiveness.

Scruton (1997) locates the perception of musical expression in our ability to inhabit 'from the inside' the gestures that music appears to embody, and thus to adequately imagine the inner states correlative with such gestures.

Levinson (1996) accounts for musical expressiveness in terms of music's ready hearability as the personal expression of an indefinite agent or persona.

Pictorial Representation

There are various accounts of our capacity to see what pictures depict and then respond to those depictions in aesthetically relevant ways. Currently the two most influential theories are Wollheim's (1987) 'seeing-in' theory and Walton's (1990) 'make-believe' theory.

Wollheim's theory is a development of Wittgenstein's idea of aspect perception, or 'seeing-as', for example, seeing a gnarled tree as an old woman. 'Seeing-in' applies to the parts of a picture as well as to the picture as a whole; and it involves simultaneous ('twofold') awareness of the picture's surface and the depicted content.

For Wollheim, seeing-in is a primitive visual capacity, at first exercised on natural phenomena, like stained rock faces, and later deliberately harnessed for making images. A large part of the aesthetic interest in pictures is due to the twofoldness of seeing-in, whereby we appreciate what is depicted, in a virtual three-dimensional space, in relation to the real two-dimensional pattern of marks before us.

Walton understands pictures as props in visual games of guided imagining, or make-believe. The configuration of marks that constitutes a picture prompts us to imagine we are seeing an object, and we imagine that our seeing those marks is a seeing of the object. Pictures generate fictional worlds; and what it is correct to imagine seeing in a picture is determined by implicit rules and conventions. In addition, in interacting with a picture visually, the viewer generates transient fictional worlds specific to him or her.

It is not yet clear whether Wollheim's and Walton's proposals are reconcilable. For Walton, Wollheim's seeing-in is to be analyzed in terms of imagined seeing, whereas for Wollheim, seeing-in is an activity prior to and more fundamental than imagined seeing, however important such seeing is in later phases of pictorial appreciation.

AESTHETICS AND COGNITIVE SCIENCE

Underlying aesthetic experience are certain mental states and processes: those involved in creating, perceiving, understanding and appreciating works of art. Accordingly, much recent work in aesthetics has taken into account empirical research on the human mind.

Pictorial Perception

Schier (1986) appeals directly to facts about ordinary visual processing in support of a theory of pictures. He proposes that a representation is pictorial just insofar as it recruits the visual recognitional capacities subjects already possess for familiar objects, so that a picture represents an object *O* if it triggers in subjects who view it the same capacities for recognition that would be triggered by the sight of *O* in the world. Schier emphasizes that pictorial competence, unlike language learning, is characterized by 'natural generativity', whereby once a subject can decipher a few pictures of a given sort, he or she can generally decipher any number of such pictures, however novel.

Lopes (1996) maintains that the essence of pictorial representation is the furnishing of similar visual information by picture and object. He proposes an 'aspect-recognition' theory of depiction, according to which successful pictures embody nonconceptual aspectual information sufficient to trigger recognition of their objects in suitable perceivers. Developing a theme of Gombrich (1960), Lopes proposes that the essence of depiction as a mode of representation is its inevitable selectivity, so that

a picture of whatever style (unlike a description) is explicitly noncommittal about certain represented properties of its object, precisely in virtue of being explicitly committal about others.

Lopes (1997) argues for the possibility of purely tactile pictures (though he overlooks certain experiential asymmetries between tactile and visual pictures (Hopkins, 2000)). And Lopes (1999) draws on color perception theory to demonstrate how pictures depict the colors of the world without actually replicating them.

Musical Comprehension

Raffman (1993) investigates aspects of the apparent ineffability of music in terms of facts about the mental processing of music. She sketches a cognitivist account of music perception that draws on the work of Jackendoff and Lerdahl, whereby an experienced listener unconsciously assigns a structural description to heard music in accordance with internalized rules governing musical parameters. Though a subject may become aware in an inarticulate way of how he or she is parsing the music, the representations involved elude verbal grasp. Raffman calls this 'structural ineffability'.

'Feeling ineffability' is a result of the fact that knowledge of music is sensory-perceptual: to know a piece is to know how it sounds. Knowledge of music depends on knowing what, say, a minor third actually sounds like.

Raffman also sketches a psychology of musical nuances – those highly specific values of pitch, rhythm and timbre that characterize any musical event – and shows how this underpins what she calls 'nuance ineffability'. Nuance ineffability arises from the fact that in aural experience we are conscious of differences, say, in pitch more subtle than we can inwardly label or classify: we are unable to remember and judge of such nuances. The basic problem is one of memory: reporting a perception requires retention of information in a manner that allows for stable association with verbal labels, but our ability to register musical nuances exceeds the mental schemata we seem to have available for storing them. Nuance ineffability in the reception of musical events poses a problem for those accounts of consciousness that identify it with sentential episodes: if we consciously experience aural nuances but cannot represent them propositionally, then there must be more to consciousness than sentential-type representation can allow.

DeBellis (1995) discusses statements of the form '*S* hears *x* as *F*'. He takes the meaning of such ascriptions to be given by the content of the mental states that ground or justify them; and he takes these mental states to be ones in which passages of music are represented, correctly or incorrectly, as having certain properties.

DeBellis argues that the music-hearing of an ordinary (experienced but untrained) listener is both weakly and strongly nonconceptual. Weak nonconceptuality is the claim that the ordinary listener's hearing of music does not involve those concepts in terms of which an analyst might describe that hearing. Strong nonconceptuality is the claim that the ordinary listener's hearing of music does not involve concepts of any sort, even narrowly perceptual ones. A consequence of both theses is that ordinary musical perception is not a process of acquiring beliefs, since beliefs presuppose concepts. Rather, the comprehending ordinary listener represents the music being heard as having some qualities or features, without thereby believing that it has those qualities or features.

DeBellis's argument for strong nonconceptuality is as follows. Current psychological theory suggests that ordinary listeners represent all heard sound events of a given kind *K* in the same way. Yet they generally prove unable to discriminate between *K* and non-*K* events, and generally fail to judge two *K* events to be similar. This suggests that such listeners lack even a perceptual concept of *K*, and that the conversion of ordinary listeners into expert listeners is in large part the acquisition of perceptual concepts for musical features which ordinary and expert listeners register alike.

Robinson (1994) explores the relevance of recent research on emotions to theories of musical expression.

Jackendoff (1991) proposes an explanation of musical affect in terms of discrepancies between conscious knowledge of musical progression and unconscious states of a postulated musical parser.

Levinson (1998a) questions the extent to which basic musical understanding requires a grasp of large-scale form.

Fictional Appreciation

Feagin (1996) uses simulation theory to help understand what responding appropriately to a work of literary fiction might involve. She proposes that appreciation of a literary text typically involves mental shifts in response to the flow of the text. Such mental shifting is a prerequisite to empathizing with fictional characters. Empathizing involves simulating another's mentality, in effect conforming

one's own mind to that of one's target, by putting one's mind 'offline' and then 'inputting' what one takes to be the experiences of one's target, thus generating an affective 'output' in oneself. This account might explain how, in responding empathically to a work of fiction, one may thereby be acquiring real knowledge – knowledge of 'what it is like' to be a certain person in a certain situation – which is often said to be one of the rewards of reading imaginative literature.

Currie (1995a) criticizes meta-representational theories of pretence, according to which pretending involves decoupling inner symbols from their normal semantic implications or flagging such symbols with special 'pretence' markers. He suggests that such views confuse mental contents and psychological attitudes towards them, and make it hard to explain the specific character of individual pretendings.

Currie questions whether, as has been claimed, empirical studies of autism and related cognitive disorders support meta-representational theories of pretense. He argues instead that such studies support the identification of imaginative pretense with simulation. He suggests that imagination is an 'internal simulator', a part of our mental equipment that evolved for the purpose of strategy-testing. This hypothesis can explain some aspects of appreciation of literary fiction, in particular our capacity to be affected by the plights of fictional characters: empathizing with characters involves the same process as empathizing with real people, taking on their beliefs and desires in imagination. The only additional requirement is that we first imagine them to exist.

Currie (1995b) considers a number of central issues in film theory from a cognitivist perspective, such as how films represent, what cinematic content consists in, and how we interpret cinematic narratives. He argues that the essence of cinematic experience is not seeming to see, or even imagining seeing, the objects and events represented in a film, but rather 'impersonally visually imagining' those objects and events. Since imagining is construed as a form of simulation – whether of others' states or of one's own states on other occasions – the essence of cinematic experience is thus simulated perceptual belief.

Currie accounts for the special 'realism' of film in terms not of its capacity to induce perceptual illusion, but of its mode of representation, whereby temporal properties are represented by temporal ones and spatial properties by spatial ones, which makes cinematic experience of objects similar to experience of those objects in the world.

Anomalous Monism

Intermediate article

Louise M Antony, Ohio State University, Columbus, Ohio, USA

CONTENTS

According to the theory of anomalous monism, every individual mental event is identical with some physical event, but there are no strict laws relating physical kinds to mental kinds.

INTRODUCTION

Anomalous monism (AM) is a theory of the mind–body relationship developed by Donald Davidson (1970, 1974, 1980). The theory states that while every individual mental event is identical with some physical event, there are no strict laws relating physical kinds to mental kinds.

HISTORY

AM grew out of Davidson's attempt to defend a causal theory of intentional action. In Davidson (1963) he considered the question of how appeal to an agent's reasons could serve as an explanation of the agent's actions. Earlier accounts of these 'rational explanations' (or, as Davidson referred to them, 'rationalizations') had it that the explanatory power of such appeals lay entirely in their revealing the action performed to be one that was reasonable for the agent. Advocates of such accounts argued that rational explanations could not be causal in character, for two reasons: (1) the normative element in rational explanation is not present in nonteleological causal explanation; and (2) rationalizations involve mere redescriptions of the action explained, instead of citing prior events contingently connected to the action explained.

Davidson's main objection to such views was that they could not adequately account for the force of the 'because' in rational explanation. A belief and desire of mine may make it reasonable for me to perform a certain action, but something more is needed for it to be true that it is because of the belief and desire that I do it. This 'something more', Davidson argued, could only be a causal connection.

It remained for Davidson to answer objections to the suggestion that reasons were causes. In addition to the objections noted above, there was the following: causation involves laws, and there are no laws relating beliefs and desires to the behavior they rationalize. Davidson's response contained the germs of the theory of anomalous monism: for a law to back a singular causal claim, it is not necessary that the law describe the subsumed events in the same vocabulary as is used in the causal claim. This set the stage for anomalous monism: Davidson would accept his opponents' contention that there was an irreducibly normative element in rational explanations, but would argue that this counted only against there being psychological laws, not against psychological explanation's being causal.

AM is one version of what is now known as 'nonreductive materialism', a view of mind that emerged in the early 1970s, partially in reaction to the 'strong' or 'type–type' reductionism of such philosophers as U. T. Place (1956) and J. J. C. Smart (1962), who argued that mental state types could be identified with, and hence reduced to, neurophysiological state types. Davidson is widely credited with one set of arguments (to be discussed below) against the possibility of such strong reductions for at least one important class of mental states, namely propositional attitude states. A different kind of argument against strong reductionism for mental states came from Hilary Putnam (1967), who argued that, because mental states were functional states, they could be 'multiply realized', that is, realized in a variety of physically different systems: pain might be a matter of c-fibres firing in humans, but of something altogether different in a Martian. (See also Fodor, 1974.) Putnam's arguments were designed to show that there could be no physical necessary conditions for the instantiation of a mental state type; Davidson's were meant to show that there could be no

physical sufficient conditions. Both views are properly classed as 'token-reductionist' materialist theories, for according to both, it makes sense to identify individual mental events with physical events.

ARGUMENTS FOR ANOMALOUS MONISM

Davidson's (1970) argument for AM was that the theory provided an attractive solution to an important puzzle, namely, how the following three principles could all be true together:

> Principle of causal interaction (PCI): At least some mental events interact causally with other events.
> Principle of the nomological character of causality (NCC): Events related as cause and effect fall under strict deterministic laws.
> Principle of the anomalism of the mental (AOM): There are no strict deterministic laws on the basis of which mental events can be predicted and explained.

According to anomalous monism, every mental event is identical to some physical event. In fact, all it is for an event to be a 'mental event' is for there to be a true description of the event in mentalistic terms: the same event could be just as accurately described using purely physicalistic terminology. Thus, every interaction between a mental event and a physical event is equally an interaction between two physical events. This secures PCI. To reconcile PCI with NCC and AOM, Davidson argues that there is a crucial difference between causation and subsumption under laws. The former is an extensional relation, holding of events however described, whereas the latter is an intensional relation, sensitive to the way in which events are picked out. AOM can then be understood as saying that there are no strict deterministic laws covering events described mentalistically, or that there are no such laws utilizing mentalistic predicates. Interpreted in this way, AOM can be seen to be consistent with NCC, which simply states that any pair of causally related events is subsumed under some law or other. If we assume, as Davidson seems to, that all physical predicates are apt for use in the statement of strict, deterministic laws, then the token-identity of every mental event with some physical event suffices to ensure that whenever a mental event interacts causally with a physical event, there is a way of describing the events so that they are covered by an appropriate law.

Perhaps the most controversial of the three principles is AOM (although NCC is also open to challenge – see below). Davidson offers brief and somewhat enigmatic remarks in its defence. Broadly, there are two arguments. The first is that psychological ascriptions answer to different kinds of evidence, and are constrained by different kinds of norms, from nonpsychological claims. As a result, Davidson (1970) says, 'mental and physical predicates are not made for each other'. Since laws can only 'bring together' predicates that are made for each other, there can be no psychophysical laws. The second argument is based on the 'holistic character of the cognitive field' (Davidson, 1974). According to Davidson, the content of a belief or desire depends on its role in the overall pattern of the agent's psychology and behavior. This makes it impossible for there to be local sufficient conditions for the correct ascription of a propositional attitude.

Possibly Davidson has something like the following arguments in mind. The norms that govern mental predicates are the norms of cogency and rationality: we are constrained to attribute beliefs and desires to agents in such a way as to make agents' behavior appear (as much as possible) rational, or else we will fail in ascribing psychological states at all – we will be 'changing the subject' (Davidson, 1970). Since physical predicates are not subject to this normative constraint, the possibility of laws connecting the mental to the physical entails the possibility of competition between the evidence relevant to the physical attributions and the considerations of 'overall cogency' appropriate to the psychological realm. If we could know, for example, that all x-neuron firings were, as a matter of law, beliefs that it is raining, then the physical evidence that someone's x-neurons were firing might warrant the attribution of this belief even if that attribution was not supported by the kinds of behavioral evidence we otherwise rely on, and even if the belief did not cohere properly with others of the agent's mental states. Moreover, if such a law were available, then we would have a localistic basis for the attribution of a belief with the content 'it is raining', in violation of the supposition that what constitutes a mental state's having a particular content is its playing a certain role in the agent's overall patterns of thought and action. Such a situation, Davidson thinks, would amount to the abandonment of our conception of ourselves as rational agents: 'we must conclude that nomological slack between the mental and the physical is essential as long as we conceive of man as a rational animal' (Davidson, 1970).

CRITICISMS OF ANOMALOUS MONISM

There are three major objections to Davidson's theory. The first concerns the conception of causation on which Davidson's original puzzle depends. NCC expresses a commitment to a regularity theory of causation. But there are competing accounts, according to which singular causal claims need not be 'backed' by general laws. If one adopts one of these alternative accounts of causation, then the original problem that was supposed to motivate anomalous monism is dissolved.

The second objection is that the theory does not, in fact, solve the problem of accounting for the explanatory force of rational explanations, because it leaves the rationalizing part of the explanations detached from the causal part. That is, because, according to AM, there is no possibility of relating, in a systematic way, the physical properties of a mental event with its mental properties, and because it is only the physical properties of the mental event that figure in causal laws, the mental properties appear to be causally inert, or 'epiphenomenal'. Davidson's response to these objections can be found in Davidson (1993). (That essay and many others on the issue of the causal relevance of mental properties can be found in Heil and Mele, 1993.) The issues raised in this connection led to a general debate as to whether the mental properties of mental events are causally relevant to the production of action.

The third objection challenges the adequacy of the arguments for AOM. Critics contend that if agents are in fact rational – and the degree to which they are is, arguably, an empirical matter – then the constraints of 'overall cogency' do in fact come into play in determining the adequacy of a proposed physical account of propositional attitude states. For suppose that we have some candidate reductive account of beliefs and desires. If we have independent justification for thinking that agents' behavior is usually reasonable given their beliefs and desires, then there will be a constraint on the adequacy of our candidate reduction theory that it have the consequence that the beliefs and desires we attribute on the basis of purely physical evidence coincide with the ones that we would attribute on the basis of considerations of overall cogency. There is thus no need to fear a competition between norms and evidence pertinent to the respective domains. (See Antony, 1989 and Van Gulick, 1980.)

A number of essays containing critical discussion of AM and the arguments for it can be found in McLaughlin and LePore (1985).

ANOMALOUS MONISM AND COGNITIVE SCIENCE

An important philosophical question in cognitive science is whether the concepts and generalizations of our ordinary mentalistic talk – 'folk psychology' – can be preserved and explained within a scientific psychological theory. If Davidson's theory is correct, then the prospects for such a scientific vindication of our pretheoretic notions seem poor.

Consider, for example, the computational model of mind. According to this view, psychological states are functional states of the brain involving physically realized mental representations. Cognitive processes like rational deliberation are computations defined over these representations. In this way, the causal transactions within the agent's brain can be shown to mirror rational relations among the agent's mental states. If this computational model is accurate, then there would be lawful connections between physical state-types of the brain and mental state-types, of the sort that would support inferences, at least in principle, from local physical evidence to conclusions about an agent's beliefs and desires. And this, it appears, would be incompatible with AOM.

If one rejects the computational model of the mind in favor of, say, a connectionist architecture, then the relevance of AM will depend on whether one thinks that the alternative architecture permits a type reconstruction of propositional attitude states.

However, Davidson is not altogether clear about whether AOM is supposed to rule out any kind of nomic connection involving mental types, or only strict (i.e., exceptionless) nomic connections. The former claim seems to be what the arguments in (Davidson, 1970) mean to establish; if the claim is weakened in the latter way, then the thesis seems considerably less interesting, and AM itself would appear to amount to little more than the claim that psychology is not a basic science. See Davidson (1993) for further discussion.

Artificial Intelligence, Gödelian Arguments against

Intermediate article

Peter Slezak, University of New South Wales, Sydney, Australia

CONTENTS

Gödel's incompleteness theorem says that there are arithmetical truths expressible in certain formal systems which cannot be proven within those systems. This result reveals certain inherent limitations on what is computable, which, according to some theorists, show that minds are not machines because they are not subject to the same limitations.

WHAT ARE GÖDELIAN ARGUMENTS?

Gödelian arguments attempt to exploit the famous incompleteness theorem of Kurt Gödel (1931) to show that the mind cannot be a machine. In slightly different forms, such arguments have been advanced by J. R. Lucas (1961) and R. Penrose (1989, 1995). Gödel himself expressed sympathy for such views, but there are significant differences among these accounts regarding the relevance of the mathematics to the nature of the mind.

In general terms, Gödelian arguments conclude that minds cannot be machines because there is something that minds can do but no machine can do. A similar kind of argument was made by René Descartes (1637), who claimed that no purely mechanical contrivance could show the infinite, creative novelty revealed in human language or action guided by knowledge. Descartes' argument concerned machines as understood at that time – namely, clockwork devices with a finite repertoire of behaviors. It was only with the work of Alan Turing (1936) that we arrived at a fundamentally different conception of machines that are not subject to the limitations recognized by Descartes.

Gödel's incompleteness result holds for formal, axiomatic systems such as that described in the *Principia Mathematica* of Russell and Whitehead (1910–1913), but it may be stated as a limitation on any computing machine that realizes a formal system. Gödel's theorem shows that there are true arithmetical propositions that are neither provable nor disprovable; that is, they are undecidable within their own system. Gödel's proof specifies such an arithmetical statement, but the claim that it is undecidable is not itself an arithmetical proposition, but a metamathematical one, since it is concerned with the notion of provability. That is, Gödel's theorem concerns statements about mathematical systems rather than statements of, or within, such systems. The undecidability of propositions within arithmetic is a syntactical claim of such metamathematical proof theory. However, since the undecidable proposition is, in fact, true, the formal axiomatic system is said to be 'incomplete', meaning that there are truths expressible in the system that are unprovable in it.

Gödel himself favored an anti-mechanist position. However, Hao Wang (1987, p. 146) says that Gödel recognized that 'his theorem does not settle the question of mind surpassing matter' and 'unlike certain ignorant philosophers, G[ödel] realizes that his incompleteness theorem does not by itself imply that the human mind surpasses all machines' (1987, p. 197). Wang cites the additional premises that Gödel required, including (1) that the mind is separate from matter, and (2) that the mind is not static, but constantly developing and therefore there is reason to believe the mind's states might converge to infinity (see Wang, 1974, p. 325).

Regarding the first of the above premises Gödel believes that materialism is a 'prejudice of our time' which will be disproved with the progress of science. His skepticism about the thesis of mechanism depends essentially on a belief in dualism, indeed a vitalism (Wang, 1974, p. 326; 1996, p. 193) and not directly on the implications of his incompleteness theorem.

The second of the above premises is the more significant. It is further explained by Wang (1974, p. 325; 1996, p. 194), who cites Gödel's conviction that 'Turing's argument for the adequacy of his definition [of computation] includes an erroneous proof of the stronger conclusion that minds and

machines are equivalent'. Gödel takes the argument of Turing's (1936) landmark paper as supporting the mechanist thesis, but Gödel suggests that the case is inconclusive because it depends on the assumption that a finite mind is capable of only a finite number of distinguishable states. Nevertheless, Gödel recognizes that 'the incompleteness results do not rule out the possibility that there is a theorem-proving computer which is in fact equivalent to mathematical intuition' (Wang, 1996, p. 186). In Wang's opinion, 'clearly he himself realized that such a refutation of mental computabilism is not convincing, as we can infer from his continued efforts to find other ways to achieve the desired refutation' (1996, p. 185). While inclining towards the anti-mechanist position, Gödel says that his incompleteness results imply only that if we are machines then 'either we do not know the exact specification of the computer or we do not know that it works correctly' (Wang, 1996, p. 186). Related conclusions about the limitations of self-knowledge have been drawn from Gödelian arguments by Whiteley (1962), Benacerraf (1967) and Slezak (1982, 1984).

J. R. Lucas (1961) articulated the Gödelian argument against mechanism in a detailed form which has given rise to a considerable critical literature. Lucas states the fundamental difference between minds and machines by saying that it follows from Gödel's theorem 'that given any machine which is consistent and capable of doing arithmetic, there is a formula which it is incapable of producing as being true – i.e., the formula is unprovable-in-the-system – but which we can see to be true' (1968, p. 44). From this alleged difference between the abilities of minds and machines, Lucas concludes 'that no machine can be a complete or adequate model of the mind, that minds are essentially different from machines' (1968, p. 44).

Against critics, Lucas (1999) has continued to insist that his argument must be understood as having a special, essentially 'dialectical' form in which he does not claim the superiority of minds in all respects over all machines, but only that a mind can surpass any particular machine that might be proposed as a model in each case. Lucas claims that he can refute each particular instance of a machine offered by the 'mechanist' as a model of Lucas's mind. However complicated a machine we construct, it will always be vulnerable to the Gödel procedure for finding a formula unprovable-in-the-system that corresponds to the machine. 'This formula the machine will be unable to produce as being true, although a mind can see that it is true.' Lucas concludes that, since this procedure may be repeated endlessly with any machine proposed by the mechanist, 'the mind always has the last word' (1961, p. 48).

RESPONSES TO GÖDELIAN ARGUMENTS

Alan Turing (1950) considers the 'mathematical objection' to intelligent machines specifically arising from Gödel's theorem. In his brief treatment, Turing acknowledges that Gödel's theorem shows that there are certain questions which any machine must fail to answer correctly. However, Turing asks whether this 'proves a disability of machines to which the human intellect is not subject … it has only been stated, without any sort of proof, that no such limitations apply to the human intellect' (1950, p. 16). Nevertheless, Turing concedes that 'a certain feeling of superiority' over machines is 'no doubt quite genuine' and seems to acknowledge the force of the anti-mechanist argument, while discounting its importance.

Lucas (1961, p. 49) notes the irrelevance of such an argument to the central question at issue, which is not whether minds are superior to machines, but whether they are the same. Conceding that machines may be superior to minds in many, perhaps even most, respects, Lucas notes that it is enough to show that they are unable to do one thing, however trivial, that a mind is able to do, to establish that minds and machines are essentially different.

Putnam (1960) has argued that Lucas's argument rests on a misapplication of Gödel's theorem, which in fact asserts the conditional 'if T is consistent, then G is true', where T is the formal system and G is the undecidable sentence. Putnam's point is that Lucas cannot assert the truth of the Gödel sentence G alone, but only the entire conditional of which it is the consequence. Lucas (1968, p. 158) has conceded that the question of consistency is a matter of 'faith' and not susceptible to formal proof. However, Lucas points to the normative character of consistency in regulating our deliberately asserted statements. In any case, Putnam's objection is not decisive, because he says that the consistency of T is only 'unlikely if T is very complicated'.

Pertinently, Benacerraf (1967, p. 19) asks what exactly it is that Gödel's theorem precludes the machine from doing. The impossibility is clearly to prove G from the machine's own axioms according to the machine's own rules. Benacerraf asks: 'but can Lucas do that?' Evidently not. Chihara (1972), too, has noted a certain unclarity in Lucas's claimed ability to 'produce as true' the

Gödel sentence. Lucas uses the expression 'produce as true' to capture both what a machine is precluded from doing and also what a mind can do. Slezak (1982) suggests that Lucas's phrase appears to conflate the notions of proof and truth, which Gödel showed must be distinguished. What minds can do in following Gödel's theorem is to establish the truth of *G* at the level of a metamathematical argument, whereas what the machine cannot do is to generate the sentence *G* from the system's axioms. Thus, the notion of 'produce as true' is being used in two different senses, to describe both what minds can do and what machines cannot do. In spite of the crucial difference between truth and provability, Lucas incorporates them both in his notion of 'produce as true', and relies on the resulting equivocation to establish his desired conclusion. Whatever may be the admitted difficulty in understanding how minds can determine the truth of sentences such as *G* (Lucas, 1968, p. 148), Gödel's theorem has no bearing on this, nor does Gödel's theorem suggest any reason why machines might be incapable of doing it too.

Lucas insists that his argument depends on the mechanist proferring a specific machine which purports to model Lucas's mind before he can refute it by 'producing as true' its Gödel sentence. Lucas (1968, p. 146) says: 'If the mechanist maintains any specific thesis, I show that a contradiction ensues. But only *if*. It depends on the mechanist making the first move and putting forward his claim for inspection.' However, the relevant facts for assessing the mechanist thesis are objective ones concerning the relative abilities of minds and machines. These could not be inherently dependent on whether the mechanist chooses to make the first move by proposing a specific model. Lucas's dialectical strategy relies on the fact that he is able to determine the truth of a machine's unprovable sentence only by virtue of being outside the system; that is, by operating in the metalanguage. However, this amounts to merely restating Gödel's result, and not to demonstrating any essential difference between minds and machines. As J. Webb (1980, p. 230) has pointed out, 'the real source of Lucas's feeling of superiority here is just the *effectiveness* with which he can find the Achilles' heel of any machine'. Gödel's diagonal argument is itself a formal procedure which can be carried out by a machine.

Benacerraf's (1967) reconstruction of Lucas's argument leads him to conclude that, if we are Turing machines, then it seems we may be precluded from obeying the injunction 'know thyself'. Benacerraf construes this as a limitation on empirical psychology. However, Slezak (1982, 1984) has suggested that, if the indexical, self-referential features of the relevant statements are properly taken into account, Benacerraf's own account suggests a limitation for self-knowledge only in the sense of first-person, introspective knowledge. As we saw earlier, this was precisely the alternative to an anti-mechanist conclusion that Gödel himself suggested. The appropriate question for Lucas is not what he can know about the machine, but rather what he can know about himself. Slezak (1982) suggests that the close affinities of Gödel's result with familiar paradoxes of self-knowledge (Popper, 1950; Gunderson 1970) are highly suggestive, so that, far from refuting mechanism, Gödel's theorem may even provide persuasive support for it. As Webb (1980, p. vii) suggests in his detailed study, quite the reverse of Lucas's claims, 'Gödel's work was perhaps the best thing that ever happened to both mechanism and formalism'.

A foundational tenet of cognitive science is the computational character of the mind. The 'functionalist' view of so-called 'strong AI' (Searle, 1980) asserts that minds may be not only simulated on machines, but embodied or realized in them. Accordingly, as Penrose (1995) asserts, if Gödelian arguments are sound, then the ambitions of cognitive science and artificial intelligence are unattainable in principle. In a slight variant of Lucas's argument, Penrose (1995, p.75) takes the computational insolubility of the 'halting problem' to imply that mathematical intuition cannot be formalized in any algorithm. In particular, Penrose sees Gödelian arguments as showing that certain features of minds, such as consciousness, free will, creativity, and insight, are beyond the realm of ordinary rule-governed – and therefore psychological or even physical – explanation. However, Dennett (1989) suggests that such arguments constitute a *reductio ad absurdum* which counts against the Gödelian arguments themselves. Moreover, Dennett points out that it is a non sequitur to conclude that no algorithm can characterize a human ability such as playing chess, or understanding mathematics, just because there is no rule for checkmate, or mathematical insight. These tasks may be performed at any level, including our own, by heuristic problem-solving methods, which are algorithms in the sense of being rule-governed computer programs, but are not recipes that guarantee success.

Artificial Intelligence, Philosophy of

Introductory article

Eric Dietrich, Binghamton University, Binghamton, New York, USA

CONTENTS

The philosophy of artificial intelligence examines the foundational assumptions, methodologies, and consequences of the field of artificial intelligence.

WHAT IS THE PHILOSOPHY OF ARTIFICIAL INTELLIGENCE?

The philosophy of artificial intelligence is a collection of issues primarily concerned with whether or not artificial intelligence (AI) is possible; that is, with whether it is possible to build an intelligent thinking machine. Of ancillary concern is the issue of whether humans and other animals are best thought of as machines themselves.

The most important of the 'whether-possible' problems lie at the intersection of theories of the semantic contents of thought and the nature of computation. One view of human thinking is that it is the manipulation of contentful thoughts. When we engage in such cognitive processes as making inferences, recognizing patterns, planning and executing activities, etc., the thoughts we have and manipulate pick out or refer to various things in our world. This view seems so plausible that it is difficult to imagine how it could be false; but when it is translated to computers, its truth is much easier to doubt, for it entails that machine cognition would be just algorithmic manipulation (computing) of certain kinds of contentful data structures. Here is where the philosophical problem enters: while thoughts obviously have content, it is far from clear that the computations and data structures do. When a computer adds 1 to 1, do its internal states actually denote, or refer to, the number 1? If a computer derives 'Fido will chase cats' from 'Dogs chase cats' and 'Fido is a dog,' do any of its internal states actually pick out Fido, dogs, cats, and the act of chasing? If computations are radically different from thoughts in that they cannot have semantic content, then it is unlikely that computers can think.

Such problems are usually referred to in AI and cognitive science as 'the problem of mental content' or 'the problem of representational content.' In philosophy, the problem of mental content is sometimes called 'the problem of intentionality.' Often this latter term is used when problems of content are combined with the problems of epistemology and consciousness. The Chinese Room problem fits in here (see later).

A second set of 'whether-possible' problems surrounds the nature of rationality. Humans constantly evaluate ways of achieving goals and rank them according to various measures such as the probability of success, efficiency, and consequences. Humans also evaluate the goals themselves, as well as the means needed to achieve the goals. In so doing, humans constantly gauge the relevance of one piece of information to another, the relevance of one goal to another, and the relevance of evidence to achieving a goal or holding a belief. Humans do this evaluation with varying degrees of success, but often are quite successful at it. However, some philosophers believe that computers cannot do such evaluation at all; or that if they can, their methods of evaluation are too brittle to capture anything as robust as human rationality. But if human-level rationality is not obtainable, then the project of building an intelligent machine will fail.

A third set of problems revolves around the seemingly transcendent reasoning powers of the human mind. All these problems begin with Kurt Gödel's famous 'incompleteness theorem'. This theorem states that logic together with number theory (and consistent extensions) contains true statements that are unprovable. Gödel's theorem basically states that any suitably robust, formal

system is incomplete; but all computer systems precisely instantiate formal systems, hence all computer systems are incomplete. Moreover, from within the given formal system, the incompleteness cannot be proved; to do that, one has to step outside the formal system and prove a metamathematical result (this is exactly what Gödel did). Computer systems, being instantiated formal systems, cannot step outside of themselves. Hence humans can do something computers cannot, so humans aren't computers. And since humans' ability to step outside formal systems is a crucial part of their intelligence, it seems to follow that computers cannot be intelligent, at least not in the same way as humans.

A final collection of 'whether-possible' problems concerns the architecture of an intelligent machine. Currently there are four main positions in this debate, each claiming that its approach to building intelligent machines is the best (or the only) way to achieve success. Accordingly, the philosophical issues here are methodological: What are the real differences between the four main approaches? Is it likely that one could succeed where the others could fail? And if so, why?

There are many other important philosophical questions apart from the whether-possible type. Can a computer be conscious? Can a computer have a moral sense? Is it moral for humans to attempt to build an intelligent machine? If we did build such a machine, would turning it off be the equivalent of murder? If we had a race of such machines, would it be immoral to force them to work for us as slaves?

EARLY WORK ON AI

AI research is dedicated to the proposition that it is possible to build a machine, a computer, that is as intelligent as, if not more intelligent than, a human. Why would anyone believe that such an endeavor is possible? Computers are not even alive. A brief examination of the historical beginnings of AI will help to put into context the doubts about AI that philosophers raise.

The roots of AI are often said to lie in the work of Alan Turing and Alonzo Church whose development of the mathematical theory of computation was one of the most important developments in the entire history of mathematics. However, the relevance to AI of the theory of computation was established after AI had already emerged. The primary influence on the early AI researchers was the work of cyberneticists and neurophysiologists.

The first idea was that the computer was not just capable of numerical calculations; it was a general symbol manipulator capable of performing virtually any task having to do with information. The symbols manipulated could represent anything: words, propositions, concepts, dogs, cats, rocks, etc. The idea that computers could be more than 'number crunchers' was revolutionary. ENIAC, one of the first computers, was intended solely for numerical calculations. And Howard Aiken, who built the first electromechanical computer in the United States, once said: 'If it should ever turn out that the basic logics of a machine designed for the numerical calculation of differential equations coincide with the logics of a machine intended to make bills for a department store, I would regard this as the most amazing coincidence that I have ever encountered.' Aiken, of course, was amazed.

From the work of the neurophysiologists, around the middle of the twentieth century, came the idea that at least some neural activity was information processing, and hence that some kinds of thinking could be explained in terms of processing information.

Then, late in 1955, Alan Newell and Herbert Simon (and others) brought these two ideas together. Computers manipulate information; thinking is manipulating information; therefore, thinking might be computing. This insight resulted in a profound hypothesis that is the heart of AI. Newell and Simon also provided researchers with the fundamental ingredient of information manipulation, namely, the *symbol*. A symbol, or what is now called a *representation*, is considered to be a fundamental constituent of both thinking and computing.

THE PROBLEM OF REPRESENTATIONAL CONTENT

Philosophers have been intensely interested in symbols (words, primarily) and their meanings since before Socrates. Essentially, the puzzle is: how can we think about things in the world? It is clear that our thoughts about the things around us (such as a pet dog) are really quite different from the things themselves, if for no other reason than thoughts abstract and leave out information relative to what is being thought about (dog thoughts are not dogs). How then do these thoughts manage to represent what they do if they leave out information? How can one's thought, or mental representation, of one's pet dog be about *this* dog rather than some other dog if the representation leaves out information? Moreover, we can think about things that are not immediately present (the dark side of the moon), things that do not exist

(unicorns), and things that cannot exist (round squares). How is this possible?

However it is that human thoughts have content, many doubt that the computations going on inside a computer are about anything at all. When a computer adds 1 and 1 to get 2, its data structures do not seem to refer to numbers and adding. It is noted sometimes that computers do not seem to *know* anything about the numbers 1 and 2 and the function 'plus'. When a computer adds, a cascade of causal processes occurs which implements an algorithm which in turn, if followed exactly, guarantees that two numbers will be added. Consider an analogy: When a mousetrap catches a mouse, the mousetrap does not represent the mouse; it merely catches it (the mousetrap clearly does not know anything about mice or even the mouse it is catching). Why is the situation any different for computers and their processes? If there is no difference, perhaps computations are contentless. But thoughts are not. Hence thinking cannot be computing. Hence a computer cannot think: it can merely compute. Yet we saw above that there are good reasons for hypothesizing that thinking is computing, and that a computer can think.

One way out of this dilemma is to attempt to develop a philosophical theory of mental content that clearly explains how thoughts get the content that they do. Then we could just check to see whether computations could get content in the same way. If they can, then AI is on firm ground; if they cannot, then AI is without hope.

Much work is going into this project. For many years, there were two general strands, depending on how one views the nature of semantics. One strand investigated world–mind relations. It saw semantics as essentially associated with truth, causation, and getting along in the world. The second strand investigated mind–mind relations. It saw semantics as essentially associated with being able to draw certain inferences, construct plans, and in general determine how one thought or representation relates to another. Philosophers are now tying these two strands together in an effort to develop a complete theory of representational content. Various camps emphasize the different strands, but most agree that both strands are needed.

Neither strand seems beyond the reach of computers. Computers can be causally connected to their environments – such machines are called *robots* or *agents*, depending on whether the relevant environments are virtual or not. And computers can easily implement vast networks of representations and determine how the representations relate to one another. This strand, in particular, receives much attention in AI. So, to many AI scientists and AI-friendly philosophers, the future looks bright: on the best proto-theories of semantics they have, nothing about content seems beyond the capacities of computers.

THE FRAME PROBLEM AND HUMAN RATIONALITY

The human mind does more than merely think about things. When it thinks, the mind is governed, at least in part, by the rules of logic and inductive reasoning, and by analyses of the strength of evidence for and against certain beliefs, desires, and actions. In short, the mind is rational, at least from time to time. It is plausible that computers would be quite good at calculating evidential strength, using various logics. So, on the face of it, computers could be rational, maybe even more rational than humans. But again, closer analysis reveals serious difficulties.

Suppose a human is given a new piece of information: it is snowing outside. Such new knowledge occasions some new inferences and updating of older information, such as: 'If I go outside, I'll need my coat,' 'I will have to shovel the sidewalk in a few hours,' 'The roads will be slick when I drive, so I should drive slowly and hence leave earlier for my meeting,' etc. However, given the information that it is snowing outside, it would not occur to a human to check to make sure her phone number is still the same, or to check whether her bank account is still active. Snowing is not the sort of thing of that affects phone numbers or bank accounts. This is so obvious that it seems silly even to wonder about it. But when it comes to programming an intelligent machine, this problem is not silly; indeed it is quite serious.

When a computer is given a new piece of information – it is snowing outside – it *does* have to check everything else in its store of knowledge to see what has to be updated and what does not. In order to know that a phone number does not have to be updated given that it is snowing outside, the computer has to check the phone number in order to determine that it is not the sort of thing that has to be updated because of the snow. But what is true for snow is true in general. Hence, any time a new piece of information is input, an intelligent computer has to check everything it knows in order to find out what has to be updated. Such checking takes a lot of time because, typically, the computer's knowledge base is large. So an intelligent

computer will spend most of its time checking its knowledge base finding out that most things do not need updating.

This problem is known as the *frame problem*. It was first formulated by John McCarthy and Pat Hayes in 1969. The alleged implications of the frame problem for machine rationality were first discussed by Jerry Fodor in 1983; he revisited the issue in 2000. Since then, narrow aspects of the problem have been solved using nonmonotonic logics, but the general philosophical problem remains. We know why humans are not subject to the frame problem. Humans use the following rational heuristic to update their knowledge: given a piece of new information, update the knowledge that is *obviously relevant* to the new knowledge and leave everything else alone. This is only a heuristic because it does not guarantee that *all and only* the relevant knowledge will be updated, but as a heuristic it works quite well. The problem is that AI researchers do not have, but philosophers insist on, a universal, precise definition of 'obviously relevant.' The answer to the philosopher, however, is that AI does not need a universal, precise definition of 'obviously relevant.'

What gives the 'obviously relevant' heuristic its power in humans is that humans can alter what they consider relevant information; their definition of 'obviously relevant' can change. For example, we can learn that smoking is relevant to lung cancer, that driving is relevant to global weather changes, that computers are relevant to understanding the human mind, etc. We can see analogies such as the one between the structure of the solar system and the structure of the atom, which may suggest that the structure of the solar system is relevant to the structure of the atom. We can construct new categories 'on the fly', relevant to new situations: given that the house is on fire, we can construct the new category 'things to save from a burning house' immediately. Understanding how humans do these things requires understanding how humans do their science, how analogical thinking works, and how humans form new categories and concepts. All of these are difficult questions, but they do appear tractable. Computers, too, successfully use the 'update the information that is obviously relevant' heuristic. It is relatively easy to program simple versions of this heuristic; and, using machine learning techniques, what counts as 'obviously relevant' can change over time. AI researchers have not yet implemented a machine that is as flexible as a human in defining what counts as 'obviously relevant', but there are reasons to believe that they might.

Many philosophers want to know what 'obviously relevant' means across all cases and uses of the heuristic. They want, for example, *one metric* that tells them, for any question and any domain, which information in that domain is relevant to that question. Other philosophers insist that such a thing cannot be obtained. They point out that in-principle solutions are rare in science, and are almost completely unknown outside of basic theoretical physics. Many AI researchers now believe that 'obviously relevant' is going to have only local, pragmatic definitions that change constantly. The AI research task now is to implement the capability to pragmatically use and alter such definitions.

GÖDEL AND METAMATHEMATICS

The logical problems surrounding self-reference and the incompleteness of certain logical systems seem to some to present insurmountable problems to building an intelligent machine. In 1931, Kurt Gödel proved that every consistent, formal, logical system which includes some number theory contains true but undecidable propositions; that is, propositions that cannot be proved true nor proved false *within the given formal system*. Gödel constructed a proposition in logic, which rendered in English is: 'The proposition with the Gödel number G cannot be proven.' (This proposition, often referred to as a *Gödel sentence* for the given formal system, was actually written in first-order logic with identity, the natural numbers, and the arithmetic operations added in.) In Gödel's construction, the sentence with Gödel number G is the proposition 'The proposition with the Gödel number G cannot be proven.' When coupled with the assumption that the formal system, logic with number theory, is consistent, Gödel's theorem establishes that the formal system is necessarily incomplete: there are true propositions that cannot be proven, namely G itself.

This stunning result in logic is thought by some to present problems for AI and intelligent machines because it is assumed that computers are formal systems, no stronger than logic with number theory and hence susceptible to Gödel's results. Hence, it seems, humans know something the machine cannot know, namely that G is unprovable. Hence, humans can do something which computers cannot. To the extent that this kind of insight is crucial to intelligence, it seems that computers cannot be intelligent.

The most common reply to this argument is that it misses the role of the assumption of consistency. What we humans actually know, and what Gödel

proved, is that *if* a suitably powerful formal system is consistent, *then* it contains an undecidable proposition like G, above. And for complex, robust formal systems like logic with number theory, we cannot know if they are consistent (and their consistency cannot be proved within the system, either), so we merely assume consistency. Gödel's famous theorem is not that formal systems are incomplete; it is that if the given system is consistent, then it is incomplete. An intelligent computer can prove Gödel's theorem, it seems. All that is required is the concept of consistency (given the rest of the formal apparatus). Let T be a computer and *G* its Gödel sentence (i.e., *G* is the Gödel sentence of the formal system describing T). It is not the case that we humans know that *G* is true, but T cannot know *G* is true. We know that if the system describing T is consistent, *G* is true. But T can know this, too, provided that it has the concept of consistency. And, it seems, there is nothing inherently noncomputational about this concept.

In spite of this reply, the Gödelian whether-possible argument continues to strike many as a serious problem for AI.

COGNITIVE ARCHITECTURE AND AI METHODOLOGY

A fourth major problem for philosophers is what is the best architecture for an intelligent machine. Deciding on an architecture goes hand in hand with which methodology to use to build an intelligent machine. Currently, there are four major architectures that AI researchers and cognitive scientists are using:

1. Symbolic architectures based on high-level computational representations and algorithms. High-level representations are those that are relatively easy to translate into sentences in a natural language, such as English.
2. Connectionist architectures (sometimes called artificial neural networks) based on some level of neural organization within the brain.
3. Dynamic system architectures based not on the 'hardware' of the brain, but on the dynamical properties of neurons.These architectures are based on the theory of nonlinear dynamics.
4. Embodied robotic architectures based on layering on more and more abstract kinds of robotic control until abstract thought is achieved.

The issues surrounding these four approaches to building an intelligent machine are fascinating. Briefly they are:

- To what extent can intelligence emerge out of non-intelligent processing?
- What is the relationship between perception and cognition?
- What is the role of high-level representations in intelligent thought?
- What is the role of representations, at any level, in intelligent thought?

We can sum up the fourth philosophical problem as follows. The last three architectural approaches discussed above are closely tied to what is known about human cognitive architecture. The idea is that since humans are intelligent, perhaps AI ought to model them. But the first architectural approach is committed to the view that the details of human cognitive architecture (e.g. that we have brains) is merely an implementational detail and not relevant (at least not in theory, though it may be practically). Is this view plausible?

THE CHINESE ROOM ARGUMENT

Probably the most famous 'whether-possible' argument is the anti-AI position called the 'Chinese Room argument'. This does not fall neatly into any of the four categories discussed so far. Instead, it is an amalgam of philosophical issues concerning representational content, a system (machine or human) knowing and understanding its environment, and consciousness.

Imagine someone locked in a room. Chinese texts written on sheets of paper are slipped through a slot in the door. The person's task is to take the sheets, write further Chinese characters in response to them, and pass the responses back out through the slot. Imagine also that the person knows no Chinese at all, either written or spoken. Fortunately, the room includes a large book written in English (or the language in which the person is fluent) which stipulates what to write in response to certain Chinese characters in certain sequences. The person goes about laboriously reading and following the rules in the book, completely ignorant of what the characters mean. Unbeknownst to the person in the room, outside are several Chinese scholars discussing, say, Chinese history. Because of the apparent insightfulness of the comments coming out through the slot, they believe that the person in the room is an expert on China's history.

It has been argued that the person in the room is precisely analogous to a computer, engaging in computations by following the rules. Since there is no difference in this respect between the person in the room and a computer, and since the person knows nothing about Chinese history, it must be the case that no computer can know anything about Chinese history, either. Since there is nothing

special about Chinese history in this situation, it must be the case that computers in general can know nothing.

The replies to this argument would fill a library. One of the most interesting concedes that the person in the room knows no Chinese history, but claims that the *virtual machine* consisting of the person together with the book of rules (and perhaps the interlocutors outside the room) constitutes a genuine understander or knower. Other replies introduce robotic connections to the external environment, or try to pick apart knowing (or understanding), representational semantics, and consciousness. The current consensus is that the Chinese room argument is flawed, but beyond that there is little agreement as to why.

CONSCIOUSNESS AND MORAL ISSUES IN AI

Beyond the whether-possible problems, there are moral issues surrounding the project to build an intelligent machine. Is this something we should be doing at all? For example, computers are not alive, so currently there is nothing morally wrong with tossing one out of an airplane. But would this still be true of an intelligent computer? To answer this, we would have to know whether an intelligent computer would have emotions, dreams, hopes, and plans. Consciousness is crucial to any notion of morality. Would an intelligent computer be conscious? How could we tell? Would an intelligent computer know and care what happened to it? An embodied robotic architecture might well know and care, in a very real way. So would it not be immoral to push such a robot off a cliff on a whim?

Behaviorism, Philosophical

Intermediate article

Max Hocutt, University of Alabama, Tuscaloosa, Alabama, USA

CONTENTS

Philosophical behaviorism, the belief that states and traits of mind are behavioral dispositions, was the dominant philosophy of mind for much of the twentieth century.

INTRODUCTION

Reduced to a slogan, behaviorism is the belief that states and traits of mind are behavioral dispositions. Behaviorism in psychology began with the recommendation that introspective analysis of consciousness be replaced by systematic observation of behavior. Behaviorism in philosophy was the attempt to formulate a theory of mind and personality that would justify this new methodology. According to philosophical behaviorism, thoughts and feelings are not private states of invisible but introspectible minds; they are observable dispositions of visible animals. Thus, fear is a disposition to flee; anger a disposition to destroy; desire a disposition to prefer; belief a disposition to assent; and so on.

HISTORY

Although it had roots in the seventeenth-century empiricism of Thomas Hobbes and the nineteenth-century pragmatism of Charles Peirce, behaviorism as an explicit doctrine began in the first quarter of the twentieth century at the University of Chicago with J. B. Watson, whose colleagues James Angell and John Dewey advocated a kindred idea which they called functionalism. Watson criticized the dependence of psychologists on introspection because its claims could not be independently confirmed (Carnap, 1931; Watson, 1913). As the philosopher of science Arthur Pap would later explain:

> Scientific propositions must be intersubjectively verifiable; the verdicts of introspection, however, are not intersubjectively testable; therefore a science based on introspection is not really a science. (Pap, 1962)

Watson concluded that psychology should cease being a first-person study of private consciousness and become a third-person study of public behavior.

An early formulation of behaviorist philosophy was by the logical positivist Rudolph Carnap, who argued that, if consciousness cannot be studied scientifically, the reason must be that minds and their contents are unreal: the reality is bodies and their behavior. Carnap concluded, to quote Pap again, that 'there is but behavior, dispositions to respond in specific ways to specific stimuli, and neurophysiological processes within the human and animal body'. 'Behaviorism' was the name of the first half of this conjunction; Carnap named the second half 'physicalism'.

To Carnap, physicalism meant the belief that everything is describable in the language of physics. An advocate of the unity of science, Carnap thought that psychology could be reduced to physics, in two stages. First, statements about the mind would be translated into statements about behavior; then these would be translated in their turn into statements about the motions of bodies in space. Thus, mentalistic statements such as 'Sam feels hungry' would give way to behaviorist remarks such as 'Sam is disposed to eat'; then these remarks would themselves be reformulated using the more austere terminology of the physicist.

This programme of analysis – which has been called logical, or analytic, behaviorism – encountered difficulties at the very first step. A glance at our behaviorist analysis of hunger will show why. 'Mary feels hungry' is clearly not synonymous with 'Mary is disposed to eat'. The two statements do not even have the same truth conditions. Mary might feel hungry without being disposed to eat, perhaps because she is fasting; or be disposed to eat without feeling hungry, perhaps because she wants to gain weight.

The usual behaviorist reply to this problem was that it demonstrates not the inadequacy of

behavioral analysis as such but only the inadequacy of a particular analysis: in this case, the analysis of hunger, which could be improved by defining hunger as a disposition to eat that usually results from deprivation of food and will usually manifest itself in eating unless there is some stronger disposition to the contrary. In short, a hungry person is one who has not eaten recently and is, as a result, disposed to eat, other things being equal. Since *ceteris paribus* clauses such as this are common in the physical sciences, behaviorists saw no reason why they should not exist in psychology too; but critics protested that the resulting analyses were illegitimately ad hoc. Worse, they sounded tautological, like saying that people who are disposed to eat are disposed to eat unless they are not. Because the logical behaviorists were seeking analyses that are true by definition, they were not greatly perturbed by this complaint, but it seemed to their critics to be damning.

Perhaps seeking to deflect this criticism, Ludwig Wittgenstein formulated behaviorism more cautiously, by claiming that inner states require outward criteria (Wittgenstein, 1953). What Wittgenstein meant by this was that differences in states of mind must manifest themselves in some way, if not always in a particular way; the mind cannot be a fifth wheel, which spins idly, making no difference to the progress of the vehicle. To see how this Wittgensteinian observation applies to a particular case, consider pain, which a logical behaviorist might define as a disposition to moan and groan. Hilary Putnam's observation that there might be Spartans who grit their teeth and grimace but do not moan may refute Carnap's logical behaviorism, but it does not refute Wittgenstein's criterial behaviorism. To refute criterial behaviorism, one would have to show that there can be a state of mind that manifests itself in no observable response, overt or covert; and it is not obvious how this could be so.

After Wittgenstein had made this point in Cambridge, another blow for behaviorism was struck in Oxford by Gilbert Ryle. Influenced by Wittgenstein, Ryle mounted an assault on behaviorism's *bête noire*: Cartesian dualism, the belief that a human being is a mind, which thinks, within a body, which takes up room. Ryle (1949) argued that this Cartesian belief is the result of a 'category mistake'. What Ryle had in mind can be brought out by using an analogy. Suppose that Jones is a fast runner. Then she may be said to 'have speed'. It would, however, be an error to ask: 'Where does Jones keep her speed?' This would mistake an attribute for a thing; a predicate adjective for a noun. A runner's speed is not one of her possessions; it is one of her characteristics. It is not a thing that she owns; it is a way that she is – namely, able to run fast.

Ryle had the same view of statements about the mind. To say that visible people have minds does not mean that they possess invisible and intangible things that do their thinking and feeling for them. It means that they have visible capacities for visible feeling and thought. Thus, saying that Smith has great intelligence means not that Smith possesses a large quantity of some mysterious stuff, but that Smith can usually be observed to behave in ways that are well adapted to his ends. As Watson's colleague Dewey had put the point: mind is not substantival; it is adjectival. In other words, it is not our minds that do our thinking. It is not even we who do our thinking with our minds. Rather, it is simply we – i.e., we bodily beings – who do our thinking.

Most behaviorists agreed; but there was a problem. Could not someone think silently, without anybody else being able to discover the fact just by watching her? Indeed, would it not make sense to suppose that intelligence never manifested itself in visible behavior? Faced with these questions, behaviorists divided into two groups. Some, reverting to Carnap's physicalism, took the position that mental abilities are rooted not in an invisible mind but in visible brains, glands and muscles. Thus, Ullin Place and Jack Smart held that sensations are events in the brain (Place, 1956; Smart, 1959). As such, they are observable in principle, if not always in practice (because they take place under the skin, which is opaque).

Ryle avoided this conciliatory line because it seemed to him to entail too mechanistic a view of human beings. An Aristotelian, Ryle did not share the physicalist hope of reducing psychology, which concerns purposive action, to physics, which recognizes only mechanical motion. Unaware that B. F. Skinner had undertaken to explain purposive behavior mechanistically by invoking Thorndike's 'law of effect' – which says that the likelihood of future behavior is modified by the effects of past behavior of the same sort – Ryle protested that human beings are animals, not machines. Noting that the physiologist may have an explanation for the patellar tendon reflex, Ryle doubted that he could explain the act of kicking a football. Here Ryle disagreed with Carnap.

In defence of his scepticism, Ryle argued that statements about psychological states and traits are 'mongrel categoricals': conditional statements in categorical disguise. To see what he meant, consider again the statement 'Mary is hungry'. This

resembles 'Mary is short', but if Ryle was right, the similarity of grammar is misleading. In Ryle's view, there is nothing 'iffy' about the statement that Mary is short; but, analysed behaviorally, the statement that she is hungry means that she will eat if food is available. Believing that conditional statements could not be reduced to categorical statements, Ryle did not believe that psychology could be reduced to physiology.

Few philosophers have been convinced by this argument. To see why not, consider the statement: 'The bar is magnetic.' It implies that the bar will attract iron filings if any are present, which is a conditional remark. But this is true only because the constituent molecules of magnets are arranged in dipole, a fact that is in no way 'iffy'. In this case, the conditional fact presupposes the categorical fact; it does not rule it out. Similarly, although '*x* is hungry' implies the conditional statement '*x* is likely to eat if offered food', it also implies the categorical statement '*x*'s blood sugar level is low'. In opposing the conditional to the categorical, Ryle had posed a false dichotomy.

Later, Daniel Dennett, a disciple of Ryle, proposed a variant on behaviorism that would correct Ryle's error. Dennett argued that states of mind are best regarded as states of the body having certain typical causes and effects (Dennett, 1978). Thus, hunger is that state of the body that usually results from food deprivation and usually gives rise to eating; pain is that state of the body that is usually caused by tissue damage and usually elicits moaning; and so on. This showed how categorical facts about the body might be not only connected with but even equivalent to conditional facts about behavior.

Hilary Putnam proposed a somewhat different view that he called functionalism. According to this view, functionally equivalent states of mind might have both different physical embodiments and different behavioral manifestations (Putnam, 1978). Thus, suppose that a Martian and I both feel pain. Because the Martian will have a different nervous system, his pain will take a different form in his brain; and because he is brave while I am a coward, he will suffer in silence while I moan and groan. This possibility – the multiple realizability of mental states – had apparently been suggested to Putnam by the fact that two computers might be constructed with different chips, use different operating systems, and display their result in different ways, yet be performing the very same operation – say, adding two and two.

By taking this line, Putnam changed behaviorism, which had grown out of one kind of functionalism, into a different kind of functionalism, thereby allowing cognitive science – the study of the mental workings of the physical brain – to mature.

ARGUMENTS FOR PHILOSOPHICAL BEHAVIORISM

As noted above, the distinctive feature of behaviorism was its resolve to make psychology scientific by confining it to observable responses and their observable causes. This resolve, which required the psychologist to abstain from discussing what could not be observed, worked well for several decades, turning the analysis of behavior into a flourishing science with useful applications in psychotherapy, advertising, education, and industry. The variety and utility of this technology is evidence of the great value of behavioral psychology and the legitimacy of the philosophy behind it.

Nevertheless, many people believe that behaviorism has been decisively refuted by, among others, the linguist Noam Chomsky in his review (1959) of B. F. Skinner's *Verbal Behavior*. Challenging Skinner's account of speech as reinforced operant, Chomsky argued that the rules of grammar, which are innate, give us the capacity to formulate an unlimited number and variety of sentences. Chomsky's criticism is valid if the rules of grammar are innately known and if Skinner's theory implies that our verbal facility consists of a limited and predetermined repertoire; but the first of these claims has not been proved and the second is not obviously true. Besides, even if Chomsky is right, it is one thing to refute Skinner, another to refute behaviorism, which is not committed to Skinner's analysis of language.

A second criticism of behaviorism, one emphasized most recently by John Searle but stated earlier by Roderick Chisholm, is that it gives no satisfactory account of the mind's intentionality: the directedness of desires towards ends and thoughts towards objects. This criticism is accurate, but in fact intentionality is an unsolved puzzle for every philosophy, behaviorist and nonbehaviorist alike. Thus, Searle declares it a biological given. The case may be comparable to that which once existed in biology. Intentionality is closely related to purpose. Until Darwin showed how natural selection could mimic deliberate design, there was no explanation of the teleology, or purposiveness, that seems to be present in nature.

Recently, behaviorism has been the object of two further charges. Psychologists have charged that it discourages the scientific study of the brain; and

philosophers have charged that it discourages the introspective study of consciousness.

To begin with the first charge: emphasis on studying overt behavior has indeed distracted behaviorists' attention from the brain, the workings of which are observable in principle but not, until recently, easily observed in practice. Thus, the psychologist B. F. Skinner actively discouraged speculation about the brain. However, not even Skinner doubted that understanding behavior would eventually require understanding its biological, including its neurophysiological, underpinnings. Watson emphasized biology from the beginning, and, as noted earlier in this article, Carnap endorsed Watson's approach. Among important behaviorist philosophers, only Ryle can be accused of believing that biology is irrelevant, and his error was soon corrected by Dennett. In short, the first charge is aimed at a straw man.

In fact, so is the second: the charge that, by disallowing introspection, behaviorism entails neglect of consciousness. The problem with this claim is that talk of introspection is ambiguous. No behaviorist has ever denied the uses of introspection if by this is meant the familiar practice of discerning one's feelings, sizing up one's motives, giving voice to one's opinions, noticing what one perceives, or observing one's conduct and appraising one's character. What behaviorists have emphatically denied is that introspection yields knowledge that is either privileged or infallible. The behaviorist acknowledges that you can know whether you are angry, but he insists that other people can know it too – by observing what you say and do. Furthermore, against the Cartesian he adds that you can also fail to know that you are angry – for example, by being so angry that you do not pause to recognize the fact.

Now consider consciousness. Again there is ambiguity. No behaviorist has ever denied that there is a difference between someone who is awake and someone who is asleep, or between someone who is alert and someone who is drugged. Nor, to come back to introspection again, has any behaviorist denied the reality of self-consciousness, if that means being aware of one's own mental condition. What behaviorists have denied are the claims made for consciousness by followers of Descartes, who held that consciousness has features that can be known only by means of introspection and cannot fail to be known by it.

Followers of Descartes are legion. The commonplace view that nobody can know what another person feels is supported both by Thomas Nagel (1974), who argues that no one can know 'what it is like to be a bat', and by Frank Jackson, who argues that there is something which a color-blind physicist could not know – namely, what colors look like.

Behaviorists believe that these Cartesians have been victimized by an ambiguity in the concept of knowledge. Grant that I cannot have, or share, your (or a bat's) feelings. It does not follow that I cannot recognize or identify them. On the contrary, if the behaviorist is right, your feelings (or the bat's) can be known in two ways: by studying your (or its) behavior and by examining your (or its) nervous system, glands, and musculature. As to the color-blind physicist Mary, it is true that she lacks knowledge that other people have, but if the functionalist David Lewis (1980) is right, her problem is not that she is ignorant of some facts; it is that she cannot make certain discriminations, which is a behavioral disability.

Cartesians often buttress their position by arguing that, since only I can know my thoughts and feelings from the inside, only I can know their phenomenal properties. To see what this metaphor and this piece of philosophical jargon mean, suppose that Smith and Jones both look at a red fire engine. David Chalmers and Galen Strawson maintain that each of them will know what sensations he is having but that neither can know what the other's sensations are like, because although every person can look into his or her own mind, no person can look into the mind of another. Therefore, even if Smith and Jones agree that they are both looking at a red fire engine, they may not be having the same sensation. Let us call this the argument from introspection.

U. T. Place said that this argument is based on the phenomenological fallacy: treating the appearances of things as if they were themselves things that appear, only to a limited audience of one person. The idea seems to be that each of us has a personal moving picture screen, which nobody else can view. Objects in the world project pictures onto that screen for the viewer's private edification. Each viewer knows what his or her own pictures look like, but can have no idea whether the pictures on other screens resemble them.

The fallacy lies in the belief that people see not things but their appearances. What we call the thing's appearance is not the thing we see; it is how we see it. To quote Wittgenstein, it is 'what we see the thing as'. Thus, Smith and Jones see a red fire engine; they do not see its appearances. Seeing something requires you to have your eyeballs aimed at it, and by hypothesis, Smith and Jones are aiming their eyeballs at the red fire engine, which is in front of their eyes, not at their

sensations, which, being events in their brains, are behind their eyes.

What about the redness of the sensation of red and the painfulness of the sensation of pain? There are no such things. It is the fire engine, not the sensation of red, that is red; it is the hot poker, not the sensation of pain, that is painful.

To say so is not to deny that the fire engine might present different appearances to different people. For example, it might look blurry to Smith, who has astigmatism, and small to Jones, who is far away. To explain this, however, we do not need to suppose that Smith and Jones are seeing their private sensations rather than public objects. On the contrary, if sensations are events in their brains, their intrinsic nature and character will be better known to the neurophysiologist than to Smith and Jones. It is only if sensations are events occurring in invisible and intangible minds that they become inscrutable, and in that case we have good reason to regard them as unreal. What is real can be detected by more than one person, in more than one way.

PHILOSOPHICAL BEHAVIORISM AND COGNITIVE SCIENCE

Confusion about this may have been augmented in recent years by an idea that has become the basis of much cognitive science: the comparison of the human mind to an electronic computer. According to the usual accounts, coded information is input by peripherals such as a keyboard through a cable to the central processing unit (CPU). This message, a representation of something in the external world, exists in the CPU as a pattern of electrical impulses and, after interpretation by the computer's program, is converted into appropriate outputs to peripherals such as a printer, or a robot welding a plate to an automobile.

As Jerry Fodor has noted, this way of describing the workings of a computer closely resembles the Cartesian account of the mind. According to this account, our sense organs send physically coded messages to the brain, where our mind reads and interprets them as appearances of things external. Having done this, the mind then orders the brain to activate the appropriate muscles or glands in order to produce suitable behavior. The mind is thus a calculating machine.

The behaviorist objection to this account is not that it seeks to understand the brain by comparing it to a computer, but that it seeks to understand the computer by comparing it to a mind. We do this when, speaking metaphorically about neurophysiological processes that are still largely unknown to us, we describe the brain as an 'interpreter' of 'information'. Having set out to mechanize man, we end up anthropomorphizing the machine, thus coming full circle back to Cartesianism, the very outcome Skinner warned against. Dennett aptly calls this Cartesian materialism.

What is needed, if Dennett is right, is not to reject the computational theory of the mind but to purify it of Place's internal cinema screen. As Place himself liked to point out, this can be done by regarding the brain as a connectionist machine, or parallel distributed processor, of the sort described by Rummelhart and McClellan. Instead of having what might be thought of as internal representations, these machines convert inputs (stimuli) to outputs (responses) in accordance with connection weights that are gradually altered using an algorithm designed to respond to feedback by eliminating unsuccessful responses in favor of successful ones – providing a working model of the workings of the behavioral law of effect.

The behaviorist likes this approach, for three main reasons. First, it has been purified of those anthropomorphic notions that the behaviorist finds objectionable in taking literally the idea of the computer as a mind engaged in processing information. Second, it is in better accord with our present knowledge of the brain, which is almost certainly a parallel processor. Third, and most importantly, the connectionist understanding of cognition as adaptation to external stimuli retains the externalist emphasis that is missing from Cartesianism, which is essentially solipsistic. Let us close by saying something about this third point.

Behaviorism came into being shortly after the publication of Darwin's theory of biological evolution, and was inspired by it. According to this theory, nature weeds out organisms that are ill-adapted to cope with their environments. This implies that cognition is best regarded not just as something going on in our heads but also as something that enables us to cope with our surroundings. So what matters in cognition is that internal processing manifests itself in behavior that is appropriate to the external world. What Wallace Matson calls an 'outside-in' philosophy sits better with this than the 'inside-out' philosophy of Cartesianism, and behaviorism is the pre-eminent outside-in philosophy.

Blindsight

Introductory article

Robert W Kentridge, University of Durham, Tyneside, UK

CONTENTS

Patients with damage to primary visual cortex or its afferents report that they are blind in the area of the visual field corresponding to this damage. Blindsight refers to the ability demonstrated by some of these patients to perform a variety of visual tasks despite denying awareness of the stimuli to which they are responding – a dissociation between performance and consciousness.

WHAT IS BLINDSIGHT?

Blindsight is the term given to the remarkable abilities found in a small number of neurological patients who have damage affecting striate cortex, the first cortical area of the brain which normally processes visual information. Despite its rarity, the condition has profound implications for our understanding of consciousness. As a consequence of its rarity and the importance of its implications it is a condition surrounded by controversy. (*See* **Blindsight, Neural Basis of**)

As a result of their brain damage patients with blindsight deny being aware of visual stimuli in the area corresponding to their damage. For example, a patient with damage to the left side of striate cortex reports that he cannot see stimuli presented to the right of his direction of gaze. When tested using standard procedures these patients are classified as clinically blind in the area corresponding to their damage (that is, they have a scotoma). However, if the patients are tested in a way which forces them to make decisions about stimuli presented in their scotoma then, even though the patients deny seeing anything and maintain that their decisions are simply guesses, they usually make the correct response to the unseen stimuli on a variety of visual tasks.

Blindsight, then, is the dissociation between awareness of visual stimuli and the ability to respond appropriately to them found in patients with damage to striate cortex or the neural connections leading directly to it. It is clear that blindsight subjects can detect whether a spot of light within their scotoma accompanies an auditory signal, whereabouts it is, and, if it is moving, in which direction and how fast it is going. The evidence for more complex residual abilities is less strong.

HISTORY

Striate cortex gets its name from a fine white line identifiable near its surface in slices of the brain. This 'stripe of Gennari', discovered in 1782, was the first evidence that the anatomy of the cortex was not uniform and hence that different areas of cortex may be specialized to serve particular functions. Striate cortex lies at the occipital pole of the brain; in humans much of it is hidden on the adjoining lateral surfaces of the cerebral hemispheres (Figure 1).

In addition to being the first identified anatomically specialized cortical area, it was also the focus of the earliest work on functional specialization. Observations of stroke patients dating back to the 1850s suggested that damage to the brain's occipital pole had specific effects on vision. Towards the end of the nineteenth century, experiments on monkeys showed that lesions of occipital pole large enough to include all of striate cortex rendered animals blind, and it was generally agreed that the occipital lobes were indispensable for vision. From the mid-1930s, however, it became apparent that animals with lesions restricted to striate cortex and not impinging upon other parts of the occipital lobes retained some visual abilities – they could be conditioned to respond to flashes of light and could follow moving spots of light with their eyes.

Starting in the mid-1960s, Nicholas Humphrey studied a single monkey, named Helen, who had bilateral striate cortex lesions. On the basis of many years of observation, Humphrey concluded that Helen retained many (but not all) visual abilities, despite her lesion. For example, she would

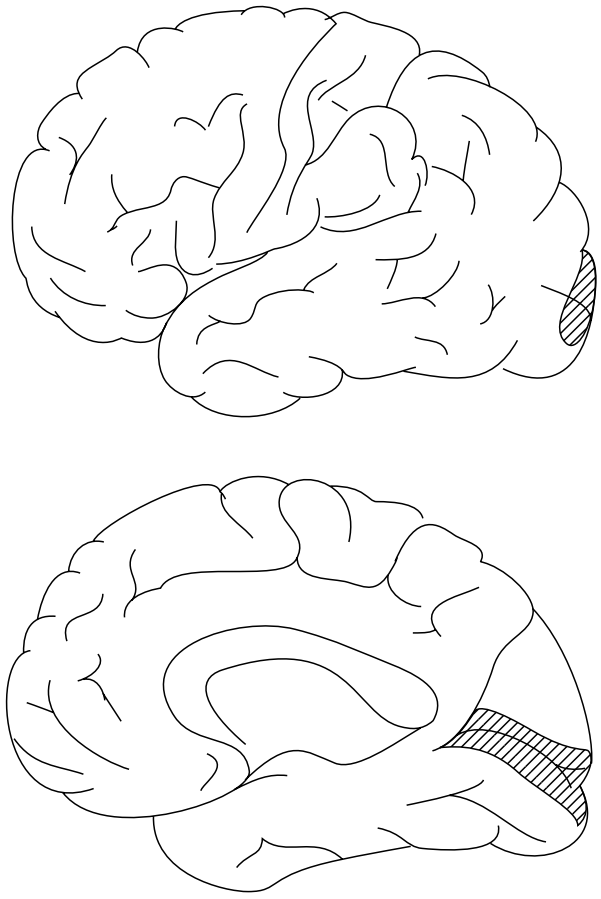

Figure 1. Lateral (upper panel) and medial (lower panel) views of the human cerebral cortex showing primary visual cortex (hatched). Note how little of primary visual cortex is exposed on the surface of the brain. Most of primary visual cortex lies on the medial surface of the brain and is therefore hidden between the two cerebral hemispheres.

routinely pick up very small objects with great precision; however, it was clear that she could not identify what these objects were until she explored them with her mouth. Helen apparently retained the ability to detect and locate visual stimuli despite her lesion, but she could no longer identify them.

Although the animal studies of Humphrey allowed the visual abilities remaining after striate cortex lesions to be identified, they could not provide any insight into the subjective nature of visual experience without striate cortex. To do so one must be able to ask a human patient lacking striate cortex to describe what they see. Such patients had been studied for many years and reported that they saw nothing in the region corresponding to their brain damage. One exception, to which we will return later, was the perception of movement. During the First World War, George Riddoch found that soldiers with injuries to the occipital cortex, although blind to stationary stimuli, reported that vigorously moving stimuli did elicit visual experience. Studies of wounded soldiers feature prominently in the history of visual neuropsychology. Careful collation of the locations of gunshot wounds and areas of lost vision in soldiers from both World Wars provided the evidence for maps of the representation of the visual field in striate cortex.

In 1973 the team of Ernst Pöppel, Richard Held, and Douglas Frost, working at Massachusetts Institute of Technology, decided to test whether soldiers (and one stroke patient) with visual scotomata as a result of damage to the visual cortex could, nevertheless, move their eyes so as to direct their gaze at spots of light presented in their regions of blindness. Pöppel, Held, and Frost were prompted to attempt this experiment by earlier work which, amongst other things, had shown intact responses of the pupil and intact optokinetic nystagmus (a slow drift of eye-gaze in one direction, interrupted by occasional flicks back in the opposite direction, induced by presentation of a continually moving pattern) in patients with occipital lesions. Since both of these responses are mediated by midbrain structures, it might be the case that neural pathways transmitting information directly from the retina to the midbrain without passing through striate cortex could support a range of simple visual abilities in these patients. As at least one circuit used in the control of eye movements is entirely subcortical, eye-movement control was a clear candidate for such a potentially spared function. Although the patients found the task puzzling, one remarking 'how can I look at something I haven't seen', there was a consistent relationship between the location of visual targets and the eye movements the patients produced when asked to look at the locations where they 'guessed' these targets had been presented. The appropriate behavioral response of patients to visual targets shown in this task, coupled with their complete denial of awareness of those targets, is acknowledged as the first systematic experimental demonstration of blindsight.

The term was not, however, coined until a year later when Lawrence Weiskrantz described similar work he had carried out on a patient who, as a result of surgery to alleviate pain caused by abnormalities in the blood supply to the occipital pole of the brain, had lost most of the striate cortex on one side of his brain. Weiskrantz found that not only

did this patient (known as DB) move his eyes appropriately towards unseen targets, but he could also point towards target locations accurately with his finger, detect the presence of a luminance grating (a smoothly varying pattern of light and dark stripes), discriminate the orientation of lines and discriminate between the shapes 'X' and 'O' in his blind field, all while denying any visual experience. Blindsight was clearly a complex phenomenon requiring considerable work, both to evaluate the range of visual functions spared after damage to striate cortex, to determine the extent of the dissociation between behavior and visual consciousness, and to test models of the anatomical basis of residual function.

EXPERIMENTAL WORK ON BLINDSIGHT

Four questions need to be addressed in the experimental study of blindsight. Apart from evaluating the anatomical basis of blindsight, the range of spared functions, and the dissociation between behavior and awareness, it is crucial to demonstrate that blindsight is a real phenomenon and that the results obtained cannot be explained by experimental artefacts which allow subjects to perform tasks using the intact portion of their visual field or in some other unintended manner.

Artefacts

Blindsight patients are quite rare. Moreover, in virtually all reported cases, visual field loss is not total. These patients therefore retain normal conscious vision in part of their visual field. The residual visual abilities of interest in blindsight are those used in response to stimuli presented in the blind portion of the visual field. If, however, visual targets presented to a patient's scotoma also illuminate their intact visual field, then any response they make is not truly indicative of blindsight. Light from a target presented within the scotoma may reach intact areas of the visual field as it is scattered from objects in the room where testing is being conducted or as it is scattered by the internal structures of the eye.

The first of these potential artefacts is relatively easy to detect and control, the second much harder. One approach that has been taken is to use the area of visual field within the scotoma corresponding to the blind-spot in a control condition. The blind-spot is the small area of retina where photoreceptors are absent as nerve fibers from receptors throughout the rest of the eye converge to leave the eye as the optic nerve. A target presented exactly within the blind-spot could not therefore directly activate any pathway, cortical or subcortical. One would therefore expect that the subject's ability to respond appropriately to a target will be eliminated if the target is presented in the blind-spot, whether the subject has blindsight or has an undamaged cortex. If, however, the subject's response to a target depends upon light scattered to remote (and intact) portions of the visual field, it should not matter whether the target is presented over the blind-spot or an adjoining area of retina – the presence of receptors at the target location is neither here nor there. The performance of blindsight subjects does indeed fall to chance when targets are presented to the blind-spot, suggesting that residual performance in blindsight does not depend upon a scattered light artefact. This does not, however, mean that scattered light can be ignored. It may still provide cues to a subject unless steps are taken to control it. The most common of these is to use dark targets against a bright background wherever possible, and to flood the subject's intact visual field with bright light.

Light-scatter is not the only means by which information from stimuli intended to reach the scotoma alone can travel to intact regions of the visual field. The most common method of presenting stimuli to patients is with a computer display screen. Stimuli presented in one part of a computer display can produce unintended but visible effects in other parts of the display. Presentation of a bright spot, for example, can cause a small brightening in a narrow horizontal band at the same height as the spot across the entire width of the screen. Care must, therefore, be taken to mask portions of the screen visible outside a patient's scotoma when using such stimuli.

Anatomical Bases of Blindsight

The processing of visual stimuli starts in the array of interconnected photoreceptors of the retina at the back of the eye (Figure 2). The most prominent output from the retina projects to a midbrain structure called the lateral geniculate nucleus (LGN) and from there to striate cortex. This is not, however, the only output from the retina which projects to many other structures. Initially it was supposed that blindsight was mediated by such structures which controlled basic responses to light without any cortical involvement. For example, the superior colliculus can control reflexive eye movements which direct gaze towards a visual target without involving cortex. Although subcortical circuits

mediate very specialized responses, blindsight patients might learn to monitor these specialized responses in the course of performing more general tasks. It might, for example, be possible to monitor the location towards which one is about to move one's eyes and use this information to choose whether or not to press a button even if the eye movement itself is suppressed. According to this scenario, blindsight may be mediated by subcortical visual pathways.

Although the bulk of visual input to the cortex passes through the striate cortex, there are ways in which visual information can reach the cortex while bypassing the geniculo-striate route. The superior colliculus sends projections, via the pulvinar, to a number of cortical areas involved in vision (V2, V3, V4, and MT). These are parts of cortex involved in visual processing which normally receive their major input via the striate cortex. Since these areas can receive visual input in the absence of the geniculo-striate projection, it is possible that blindsight may be mediated by visual pathways outside the striate cortex.

In addition to mediation by subcortical or extrastriate cortical routes, there remains the possibility that damage to striate cortex in blindsight patients is not, in fact, complete. Rather than demonstrating that circuits other than the major geniculo-striate route support visual function but do not give rise to visual awareness, residual visual function in blindsight would then essentially be a demonstration that the magnitude of stimulation required to evoke awareness from the geniculo-striate system is greater than that required to support simple behavioral responses. Blindsight would not, under these circumstances, be a particularly special phenomenon since it would differ little from the abilities of normal subjects when presented with stimuli near the limits of their visual abilities (e.g., very faint or very short duration stimuli).

A number of studies have been made of patients who have had small spared regions of striate cortex surrounded by damage. These patients did not experience stimuli falling in these spared regions, yet, as in blindsight, they could perform simple visual discriminations in these regions. Can such spared cortex explain the apparently extensive region of

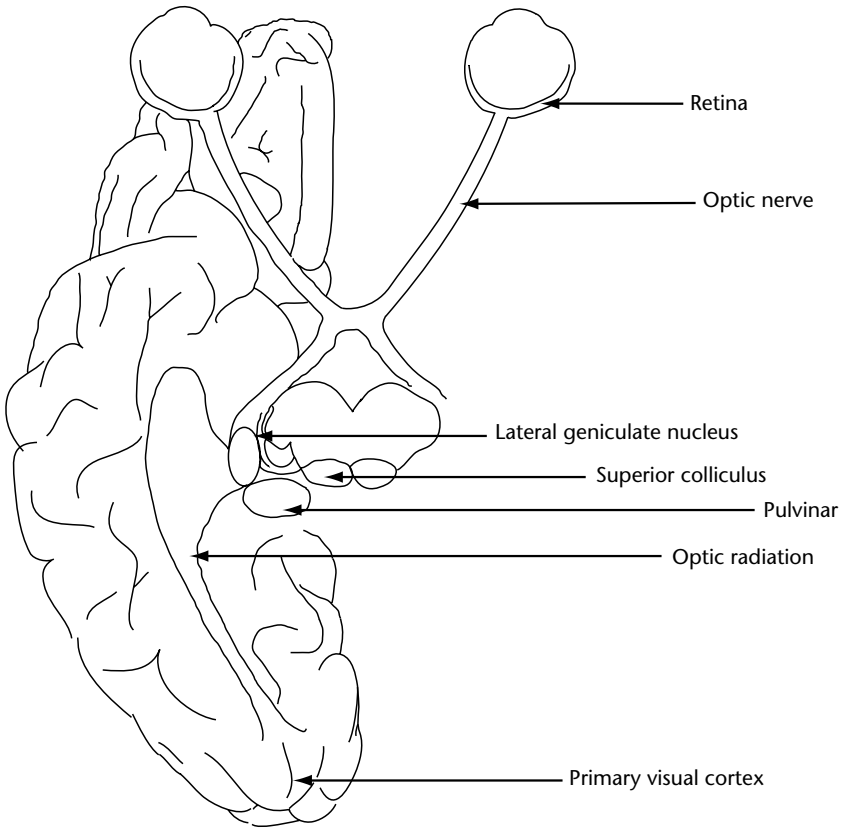

Figure 2. A basal view of the human brain showing major components of the visual system which may be involved in the mediation of blindsight.

blindsight found in other blindsight subjects? Patches of residual vision surrounded by areas of complete blindness might not be revealed in most studies if random eye movements fortuitously brought stimuli into a region of the retina which activated a patch of spared cortex. If, however, one ensures that eye movements cannot affect the location in the cortex which a visual stimulus potentially activates, then any patchiness should become apparent. It is possible to do this by using eye-movement measurements to yoke stimulus position to the direction of gaze. A study using this technique in a patient with blindsight covering a large proportion of one visual field did not reveal patches of residual vision surrounded by blindness, suggesting that an explanation of all blindsight in terms of islands of spared cortex is untenable.

Diffuse, as opposed to patchy, subtotal damage is harder to detect behaviorally. The undamaged neurons in a diffusely damaged region of cortex should, however, still be metabolically active. Functional neuroimaging, which detects changes in blood flow or blood oxygen levels indicative of metabolic activity, has not revealed activity in the striate cortex of blindsight patients when a visual stimulus was presented, although changes did occur in extrastriate cortex.

If blindsight relies on a visual pathway used in normal vision, albeit seriously damaged, the implication is that blindsight should be like very poor normal vision. The apparent dissociation between the abilities of blindsight patients and their reports of awareness may be explained in terms of a change in their willingness to report that they have seen a stimulus – not a surprising change given their knowledge that they have a serious visual impairment. It is, however, possible to disentangle the effects of such biases from the underlying visual sensitivity. The results of such experiments indicate that, for normal subjects presented with stimuli near the limits of visual ability, there is no difference between mechanisms which serve conscious report and those which serve the 'forced-choice' discrimination tasks typically used in assessing blindsight. A similar comparison in a blindsight patient showed quite different properties for conscious report and forced-choice discrimination, indicating behaviorally that blindsight is not simply near-threshold normal vision.

Ingenious experiments have been devised which show that monkeys with unilateral visual cortex lesions treat stimuli in their 'blind' and normal visual fields quite differently, even though they are quite capable of making behavioral responses to those blind-field stimuli. The monkeys were first trained to point at visual targets presented in either their blind or normal hemifields and the minimum brightness contrast required was measured for each hemifield. The target contrasts were then adjusted so that they easily exceeded these thresholds for the rest of the experiment. The monkeys now learned a new task in which they had to make different responses depending on whether one or two stimuli were presented. They performed accurately when both stimuli were presented in the intact hemifield. However, when two targets were presented but one of them fell in the lesioned hemifield, the animals made the 'one target' response. They behaved as if they had seen only one target even though the target they ignored was easily bright enough for them to point at accurately.

There is no question that these monkeys had no spared cortex – striate cortex was surgically removed and the completeness of the damage verified at the end of the experiment. Unless one accepts that there are fundamental differences in the anatomy of vision and awareness between monkeys and man, these results suggest that blindsight cannot rely on spared striate cortex.

Blindsight and Awareness

Although blindsight is the dissociation between awareness of visual stimuli and the ability to respond appropriately to them, it is not the case that blindsight subjects are unaware of all visual stimuli presented in their scotoma. We have already seen that injuries to the occipital cortex leave patients able to report conscious experience of vigorously moving stimuli, as Riddoch discovered at the end of the First World War. Blindsight subjects also report some experience of rapidly moving stimuli or stimuli with sudden onsets or offsets. It is not clear whether these experiences are anything like *visual* sensations. Blindsight subjects differ in the descriptions they give of these experiences, ranging from a feeling that the response they are making is not quite a guess, to descriptions of movement being like a black hand moving across a black background.

Some authors have argued that the fact that blindsight subjects sometimes have an experience induced by visual stimuli, even if it is quite dissimilar to a normal visual experience, invalidates the contention that visual processing and visual consciousness are dissociated in blindsight. Weiskrantz has suggested that blindsight be divided into two subtypes:

- Type 1 blindsight conforms to the 'classical' definition and is residual visual function in the absence of any acknowledged awareness.
- Type 2 blindsight is defined as residual vision accompanied by an acknowledged experience of events in the blind field but in the absence of acknowledged 'seeing'.

It can be hard to draw broad conclusions about the nature of awareness from type 2 blindsight, as distinguishing between visual and nonvisual experience involves a difficult subjective decision about the nature of experience. Interesting results have, however, been obtained by comparing brain activation in blindsights patient when they do and do not report this type 2 nonvisual experience. These results suggest that frontal areas of the brain are activated during the experience of knowing but not seeing, whereas subcortical structures are primarily active during trials in which there is no report of experience whatsoever.

It is important to point out that the distinction between type 1 and type 2 blindsight is not based on performance. It is possible to show that the ability to perform a task and awareness of the stimuli involved are quite dissociated in type 1 blindsight. For example, as task difficulty is varied the performance of blindsight subjects can increase from chance to being near 100 percent correct without any change in their reported absence of awareness. With appropriate stimuli the dissociation in blindsight between awareness and performance remains unequivocal.

Residual Abilities in Blindsight

The early work of Weiskrantz with patient DB showed that a range of visual functions were spared in blindsight. Since then some controversial new claims have been made about the abilities of blindsight patients. First we shall look at some uncontroversial findings.

There is little doubt that blindsight patients can localize single bright or dark visual targets in their blind fields. Similarly, they can discriminate when such targets appear in a task where the subject is required to indicate in which of two time intervals a target is presented (a temporal two-alternate forced choice task). There is evidence from a number of sources that blindsight patients retain some ability to discriminate the color of stimuli presented in their blind fields, although they are impaired in comparison with normal subjects. Blindsight patients can also detect the presence of a pattern of alternating bright and dark stripes even if the average brightness of the pattern does not differ from the background. Their ability to detect these patterns is much poorer than normal in their blind field – they are unable to detect very fine or faint patterns of stripes. The ability to discriminate between stimuli composed of lines with different orientations is also preserved, albeit in a severely impaired guise and with some variations between patients. GY, for example, can discriminate the orientation of single lines but not patches of stripes. His performance becomes poorer than normal as the lines get shorter than 10 degrees of visual angle.

The ability to discriminate the orientation of lines is one of the basic building blocks of form perception. The extent to which blindsight patients can discriminate between complex forms is, however, a vexed question. Weiskrantz found that his patient DB could discriminate reliably between circles and crosses. As he showed, however, this discrimination may be based on discrimination of differences in the components of these shapes, such as the orientation of the line segments that make them up, rather than discrimination of the shapes *per se*. This is borne out by findings that blindsight subjects fail to discriminate between different shapes constructed from the same line segments, for example equilateral triangles with the point either at the top or at the bottom (Δ versus ∇) and are poor at discriminating between rectangles differing in the ratio of side lengths but not orientation.

Early results indicated that form discrimination is absent or severely impaired in blindsight. More recent studies which have tested form-processing abilities indirectly appear to tell a different story. Studies of the manual responses of blindsight subjects to objects placed wholly or partially in their blind fields indicate that shape, orientation, or size properties which could not elicit appropriate verbal or forced choice discriminations nevertheless influenced hand movement and grasp. Other studies have sought to identify whether shapes presented in the blind field influence subsequent responses to stimuli presented to the conscious good field. Although a number of groups have apparently failed to find any such effects, there have been at least two reports of positive results. In one case words presented to the blind field were reported to influence the interpretation of ambiguous words in the good field. For example, if the word 'money' was presented to the blind field then the subject was more likely to describe the word 'bank' in the good field as a financial institution than as the edge of a river. Unfortunately, relatively few short ambiguous words could be used in this study and so the result, which is of great interest given the weakness of simple form processing in blindsight, is based

on relatively few observations. Further evidence derives from a study in which the similarity between the shape of stimuli (in this case single letters) presented in the blind and good fields influenced reaction time to the good field stimulus in a letter discrimination task. The most dramatic evidence supporting the existence of complex shape discrimination without awareness comes from a study on the perception of emotion in blindsight. The blindsight patient GY correctly attributed one of four emotions (happiness, sadness, fear, or anger) to video clips presented to his blind field of an actress expressing one of these emotions.

What are we to make of the apparent contradiction between the limited shape-processing abilities indicated by studies of simple geometric shapes and the abilities necessary to make the complex discriminations required in order to be influenced by letters, words, and facial emotions presented in the blind field? One possibility is that most of the latter tasks did not involve the subject in responding directly to the stimulus in the blind field. By assessing blind-field shape-processing through its effects on seen targets, subjects are relieved of the problem of making decisions about stimuli they do not believe they can see. Perhaps removing the conflict for the subjects between their conscious blindness and the demands of a task in which they must respond to stimuli they cannot see uncovers abilities hidden in direct tasks. It may also be the case that certain properties of stimuli and methods of response are mediated by specialized neural circuits. Perhaps the processing of emotion is of such basic evolutionary importance that facial cues to emotion are processed by systems independent of the brain's general shape identification system. These are open questions; at present there is insufficient evidence to come to a firm conclusion about why and whether blindsight subjects can discriminate complex shapes without awareness.

The basis of another residual ability in blindsight is also controversial. The ability to detect the direction or speed of moving stimuli has been studied in blindsight for many years, and there is good evidence that such discriminations can be made both with and without an accompanying experience (rapidly moving high-contrast stimuli are particularly likely to elicit reports of awareness). There are, however, two ways in which motion can be inferred from the stimuli typically used in these experiments. One of these is not strictly a matter of motion perception. One can infer the direction and speed of a moving dot or line by noting its position at one instant and comparing this with its position some time later. Unfortunately there are stimuli with which such a positional comparison method will not work. For example, one can construct a stimulus comprising many dots, in which each dot is displayed for only a short time before it disappears and another dot appears at a different place. If each of these dots moves in a different direction, but on average the dots move more in one direction than any other, then a normal observer will easily be able to report the average direction and speed of the pattern (this is an example of a random dot kinematogram). In some experiments (but not all) the blindsight subject GY failed to discriminate the direction of motion when stimuli which precluded the use of position comparison were used. He could, however, still distinguish moving from stationary stimuli. It is therefore not safe to assume that motion processing is fully preserved in blindsight, even though some forms of motion can be discriminated by blindsight patients.

Some recent studies indicate that residual abilities in the blind field can be modulated by processes of alerting and spatially selective attention. GY's ability to perform a spatial localization task is enhanced if the visual stimuli are immediately preceded by an auditory warning. He is also faster at responding to a visual target if it appears in the location indicated by a preceding cue. This effect can be found even when the cue itself is also presented in the blind field. Such results may have profound implications for our understanding of the relationship between consciousness and attention.

RELEVANCE OF BLINDSIGHT FOR CONSCIOUSNESS AND COGNITIVE SCIENCE

For years consciousness was a taboo word in psychology. If blindsight has done one thing for psychology and cognitive science it is to make the scientific study of consciousness respectable once again. As well as providing insights about the relationship between processing visual stimuli and visual awareness, blindsight offers some insight into the modularity of psychological processes and the extent to which apparently complex processes can, in fact, occur essentially automatically, without awareness.

Blindsight is often used in philosophical arguments about the nature of consciousness. In particular, the apparent dissociation between access to visual information and visual experience in blindsight has been used to explore the role, and even

existence, of experiences as something distinct from the properties of stimuli in the outside world, our knowledge of them, and our responses to them. One of the attractions of blindsight to philosophers is that it appears to offer a real, albeit partial, example of a favorite of the philosophical thought experiment – the zombie.

The philosophical zombie is a being whose behavior is indistinguishable from that of real people, but who is supposed to have no inner experience at all of the world in which it is behaving. These inner experiences are often referred to as 'qualia'. Thought experiments about zombies sometimes hinge on a *reductio ad absurdum*, purporting to show that presupposing the existence of zombies leads to some paradoxical difference between our observation of the world of real people and that of zombies. It is argued that if zombies and beings with inner experience differ behaviorally, zombies who lack inner experience and yet are indistinguishable from us behaviorally must be an impossibility. Since the only difference between ourselves and zombies is the presence or absence of qualia and zombies cannot exist, then qualia have no explanatory power and hence no existence outside an individual's mind. On the other hand, one might argue that inner experiences are real (it makes sense to discuss them, as I am doing here, for example); perhaps they just do not have causal consequences for the physical world. (*See* **Zombies**)

Blindsight appears to make zombiehood concrete. Blindsight has been used to argue that inner mental states are real and correspond to physical, that is neural, states. In fact blindsight adds an extra twist to zombiehood – well-tested blindsight subjects come to know consciously that they respond appropriately to visual stimuli even though they do not know what they see and have no inner experience of seeing. Of course, it might be the case that blindsight people do have inner experiences, it is just that they do not know they have them. Unfortunately, many of these arguments are weakened when they either ignore some abilities of real blindsight people or use thought experiments which go far beyond the actual abilities of blindsight subjects. Philosophical consideration of the real properties of blindsight (as opposed to those of nonexistent super-blindsighters) does suggest that inner experiences are real, can be investigated scientifically, and make a difference in the real world, even if they do not solve the problem of telling us what such inner experiences are and why they feel the way they do.

Change Blindness

Intermediate article

J Kevin O'Regan, Centre National de Recherche Scientifique, Université Paris 5, France

CONTENTS

Change blindness is a phenomenon in visual perception in which very large changes occurring in full view in a visual scene are not noticed.

WHAT IS CHANGE BLINDNESS?

A number of studies have shown that under certain circumstances, very large changes can be made in a picture without observers noticing them. What characterizes the experiments showing such 'change blindness' in visual scenes is the fact that the changes are arranged to occur simultaneously with some kind of extraneous, brief disruption in visual continuity, such as the large retinal disturbance produced by an eye movement, a shift of the picture, a brief flicker, five or six small, localized disturbances flashed briefly on the picture, an eye blink, or a film cut in a motion picture sequence. These phenomena are attracting an increasing amount of attention from experimental psychologists and from philosophers, because they suggest that humans' internal representation of the visual world is much sparser than usually thought.

EXPERIMENTAL WORK ON CHANGE BLINDNESS

In the first experiments that triggered interest in change blindness (McConkie and Currie, 1996), observers viewed high-resolution, full-color everyday visual scenes presented on a computer monitor, while their eye movements were being measured. The computer could make changes in the scene as a function of where the observer looked. For example, when the observer looked from the door of a house to the window, the window (or some other element of the scene such as the sky, or the car parked in front of the house) changed in some way: it could disappear, be replaced by a different element, change color, change position, etc. It was found that when the change occurred *during* an eye movement, surprisingly large changes could be made without observers noticing them. Elements of the picture that occupied as much as a fifth of the picture area would not be seen. At first, the explanation of the phenomenon was assumed to have something to do with the mechanisms the brain uses to combine information from successive eye fixations to form a unified view of the visual world. In particular, every time the eye moves, the retinal image shifts. Some mechanism in the brain may correct for such shifts in order to create a stable view of the world. However, the mechanism could be imperfect and not take into account certain differences in the visual content across the shift, thereby explaining why changes made during saccades might sometimes go unnoticed.

But a subsequent set of experiments showed that, in fact, the change blindness phenomenon was not specifically related to eye movements. Rensink *et al*. (1997) used what they called the 'flicker' technique, in which, instead of an eye movement, a brief flicker was introduced between successive images. A first picture (picture A) would be shown for, say, 250 ms, followed by a modified picture (picture B). In between A and B, a brief blank screen (bl) would be shown. This would cause a flicker, lasting about 80 ms, that is, a duration similar to that of an eye movement. The cycle A-bl-B-bl-… was then repeated. Observers were told that something was changing in the picture every time the flicker occurred, and they were asked to search for it.

Under conditions where no flicker was inserted in between the pictures (A-B-A-B-…) the change was immediately visible and totally obvious (animated gif (158 kb): http://nivea.psycho.univ-paris5.fr/ECS/bagchangeNoflick.gif). However, with the flicker, it was often extremely difficult to locate the change. This was particularly true for changes which concerned aspects of the scene which were not of 'central interest'. For example, the reflection

of houses in a lake scene, though occupying a very large part of the picture, would not be considered to be what the picture was about. Observers sometimes were unable to see such changes at all, even after searching actively for as long as one minute. On the other hand, the changes were perfectly visible once they were pointed out to observers (animated gif (158 kb): http://nivea.psycho.univ-paris5.fr/ECS/kayakflick.gif).

The flicker technique is very easy to implement using widely available computer software (for example, software to make video presentations), and so lends itself to easy experimentation. Pictures as well as symbolic or text material can be used. The timing of the flicker between original and modified images is not critical. What is important about the flicker technique is that it shows that change blindness can be obtained without the change being synchronized with eye movements. This shows that in the earlier experiments where changes *were* synchronized with eye movements, the inability to detect the change was probably not specifically related to the eye movement and to the mechanisms that the brain uses to combine images of the world during eye explorations.

Following the discovery that change blindness was not specifically related to eye movements, but to the brief disruption that is inserted between the two versions of the picture, considerable interest in the phenomenon developed, and a large number of further experiments have been performed. These can be classified according to the nature of the disruption that is used between successive images: global disruptions, local disruptions, and progressive changes. (A review of different change blindness experiments can be found in Simons and Levin (1997).)

Global disruptions are ones in which the picture change is accompanied by a disruption which covers the whole area of the picture. The experiments where the changes occurred during eye movements were global disruption experiments, since the whole retinal image is completely smeared during the time of approximately 20 to 80 ms that it takes for the eye to move from one fixation point to the next. The flicker experiments are also global disruption experiments, since the blank displayed briefly between the original and modified images covers the whole picture. Other examples of experiments with global disruptions are experiments involving eye blinks, picture shifts, and film cuts. In the blink experiments, observers' eye blinks, registered by online computer monitoring, are used to trigger the picture change. The blink produces a global disruption similar, though somewhat longer in duration, to the disruption caused by an eye movement. In the picture shift experiments, a picture is suddenly shifted in position, and a change made at the same time. Here a global disruption is caused by the retinal smearing that accompanies the eye movement that observers make to refixate the shifted picture. In film cut experiments, observers view motion picture extracts, and at the moment when the camera 'cuts' from one view to another, a large change is made – for example, an actor is replaced by a different actor. The camera cut produces a global disruption similar to the blank in the flicker experiments.

An additional, amusing, variant of the experiments with global disruptions are experiments in which the change occurs in real life. In a typical scenario described by Simons and Levin (1998), the experimenter stops a person in the street and asks for directions. While the person is speaking to the experimenter, workers carrying a door pass between the experimenter and the person, and an accomplice takes the place of the experimenter. The person usually goes on giving directions after the interruption, and very often does not notice that the experimenter has been replaced by the accomplice.

Change blindness experiments with *local disruptions* are experiments in which, at the moment of the change, five or six small, localized disturbances are superimposed on the picture, like mudsplashes on a car windscreen (O'Regan *et al*., 1999). The disturbances can be small in comparison to the size of the change and they need not coincide with the location of the change: the change takes place in full view. As for change blindness with global interruptions, changes are very often not noticed (animated gif (378 kb): http://nivea.psycho.univ-paris5.fr/ECS/dottedline.gif).

Experiments with *slow changes* are experiments in which there is no local or global disruption at all. Instead, the change is made so slowly that the attention-grabbing processes that would normally cause attention to be attracted to the change location can no longer operate. Again, it is found that in many cases, changes are hard to detect (Quicktime video (1.4 Mb): http://nivea.psycho.univ-paris5.fr/ECS/sol_Mil_cinepack.avi).

RELATED PARADIGMS

The change blindness phenomenon is strongly related to a well-established line of research in experimental psychology that started in the 1970s and concerns visual short-term memory (for a review, see Haber, 1983).

In this literature, experiments analogous to the change blindness experiments had been performed using briefly displayed arrays of simple elements such as letters. These experiments showed that although observers have the impression of seeing all the letters in, say, a 12-element array, in fact they notice changes to or report the identity of only about four or five letters. It appears that there is a kind of attentional 'bottleneck' which limits information transfer into memory: only a fraction of the information available in a scene is transferred into visual storage for later report or comparison. Further work additionally showed that the code in which the information is stored in visual short-term memory is not a visual code, but a code in which only the category or identity of the elements is available. This work was also coherent with another line of research showing that information from successive eye fixations is combined only in categorical form, and not as a picture-like composite image (for a review, see Irwin and Andrews, 1996).

We shall see in the next section that the conclusion from these experiments, showing that visual storage is sparse and categorical, is also applicable to the change blindness results. Because in the case of change blindness, natural, highly detailed visual scenes are used as stimuli, the conclusion is more striking than it was in the older literature using simple stimuli.

Change blindness, in addition to links with research on visual short-term memory, also has relations with several more recent lines of research showing that attentional capacity in short-term visual processing is severely limited, both in spatial extent, and in the way it extends over time. Thus in 'inattentional blindness' (Mack and Rock, 1998), observers do an attention-demanding visual task. At a given moment, a large, unexpected visual event takes place. Even though such an event would be totally obvious under normal circumstances, and even though the event takes place in full view, it is often not noticed. For example, Simons and Chabris (1999) used a task in which observers look at a film of two groups of players, a black-clad and a white-clad group, each playing with their own ball in the same small room. The observer's task is to try to track the number of times one group exchanges the ball. While the observer is doing this task a woman with an umbrella walks through the room, in full view. Observers often fail to notice this totally obvious event.

An example of a temporal restriction on the deployment of attention is the 'attentional blink' (for a review, see Shapiro and Terry, 1998): in this, an observer is required to identify a target letter in a stream of rapidly presented letters. It is found that the observer often fails to report the occurrence of a second target letter if the second target follows the first by less than about 450 ms: it is as though attention had to recover for a brief period after having been solicited. In 'repetition blindness' (Kanwisher, 1987), a visual stimulus such as a letter, symbol, picture, or word tends not to be noticed if it is the second of two identical occurrences of the item in a rapidly presented series.

Another field of research that has connections to change blindness is the extensive literature on memory and cognitive descriptions (for a review, see Pani, 2000). Part of the explanation for change blindness may reside in memory limitations rather than in perceptual limitations. If this is so, then we expect that change blindness will be affected by factors similar to those that affect memory. This is compatible with the finding that changes made to elements in a scene which are of 'central interest' will in general be easier to detect than 'marginal interest' changes. Other work has shown that variables such as semantic coherence, observer familiarity, and task to be achieved, affect change blindness in a way similar to how they affect normal memory.

THEORIES OF CHANGE BLINDNESS

The currently accepted explanation of change blindness owes much to the work done in the 1960s and 1970s showing how visual information is transferred via an attentional 'bottleneck' to a very low capacity short-term visual storage (e.g. Gegenfurtner and Sperling, 1993). Within this context, the explanation of change blindness involves two components: a component related to what is called 'visual transients', and a component related to the way a scene is encoded in memory.

Visual transients are fast changes in luminance or color in the retinal image, such as would be produced by a sudden appearance or disappearance, or through motion of an element of the scene. It is known that such transients are detected in the first levels of the visual system, and that attention is automatically attracted to the location where they occur. Under normal viewing conditions, therefore, when a change occurs, it produces a visual transient which attracts attention to the change location. The transient thus provides information *that* a change has occurred, and it says *where* it occurred, but it does not provide information about *what* the change was.

In order for an observer to be able to determine *what* the change was, he or she will have had to have encoded into visual memory what was at the change location before the change occurred, and compare it to what is there after the change. There are thus two things that can go wrong in change detection: either the transient that attracts attention to the change location may be interfered with (thereby causing a deficit in detection *that* or *where* the change has occurred), or the encoding and comparison process may be interfered with (causing a deficit in determining *what* the change was).

Both these mechanisms may be at work in the change blindness experiments. In the paradigms using global disruptions, such as the flicker, blink, and film cut experiments, the global disruption presumably creates a large number of transients all over the picture, which mask or compete with the local transient corresponding to the sought-for change, and which prevent attention being automatically drawn to it. The change will be immediately noticed only if an observer happens to have been attending to the changing element at the moment it changes. Failing this, in order to find a change, the observer must search through the scene looking for an element which is different from what was previously encoded about the scene. However, because of the limitations in short-term visual memory, very little of the scene is likely to have been previously encoded, and the chances of success are very limited.

In change blindness paradigms using local disruptions like 'mudsplashes', the situation is very similar, with the difference that the local transient corresponding to the change location is missed by observers, not because it is swamped by a global transient, but because the mudsplashes act as 'decoys', attracting attention to locations other than the true change location.

In change blindness paradigms with slow changes, the change occurs so slowly that no local transient is generated. Attention is thus not attracted to the change location, and again, the observer must rely on the very sparse information that he or she has encoded about the scene in order to locate the change.

Whereas researchers working in change blindness will broadly agree on the explanation just outlined of the phenomenon, further work is necessary to ascertain the relative roles of the different component mechanisms involved. To what extent does the flicker in the flicker paradigm act to mask or 'wipe out' the internal representation? Or does it act essentially like the mudsplashes in the mudsplash paradigm to create local transients that act as decoys? Exactly how much information is encoded concerning the initial and final views of the scene? Is the overall 'gist' of a scene coded in some way? Does what is encoded depend on the observer's attentional state, on the task, on viewing strategies, on the semantic relation between the gist of the scene and the element that is changing? Are certain aspects of elements (their layout? their color?) automatically encoded and easier to detect when they change? Even if little information is available to make conscious judgments about display changes, could it be that some information is retained unconsciously? A number of recent lines of research are investigating these issues.

RELEVANCE OF CHANGE BLINDNESS FOR CONSCIOUSNESS AND COGNITIVE SCIENCE

Change blindness raises an important question: if the information that is encoded about a visual scene is so sparse, how is it that we have the subjective impression of visual richness, that is, of seeing everything there is to see in our field of view, so to speak in 'glorious technicolor and cinemascope'?

Perhaps the most natural view to take is to suppose that what we have the subjective impression of seeing is not the very sparse, more semantically coded, content of visual memory, but the content of a shorter-lived but higher quality, image-like replica or 'icon' of the visual scene. The impression of richness that we have from the world would derive from this high-quality icon. On the other hand, only a small portion of the icon's contents, namely the parts that have been attended to, would at any moment be transferred into memory and be available for doing such tasks as change detection – the rest would be forgotten. This view of visual processing has been called 'inattentional amnesia' (Wolfe, 1999): the idea is that we see everything, but forget most of it immediately.

The notion that what underlies the richness of vision is a high-quality internal replica of the outside world is the basis of some of the current work in neurophysiology and neuroanatomy, where cortical sites are being sought which provide the 'neural correlate of consciousness'. Indeed, area V1 of the visual cortex contains a distorted map of the visual field which might be a plausible locus for visual consciousness, possibly in relation to other brain structures.

A more radical answer to the question of why we have the impression of continuously seeing everything in our visual field has also been suggested

(O'Regan and Noë, 2001). The idea is that in fact the experience of seeing does not derive from the activation, inside the brain, of an 'icon' of the outside world. Rather, the experience of seeing is somewhat like the temporally extended, multifaceted experience of driving a car, involving a kind of 'give and take' between the observer and the environment, a kind of attunement to the laws that link the observer's actions to the changes in sensory input.

Under this view, the outside world serves as a form of 'external memory'. Only those aspects of the environment that are currently being 'visually manipulated' are actually available for conscious processing at a given moment. We have the impression of seeing everything because we know we have access to everything, even though without actually accessing something, no detailed information is available about it. This explains the apparent paradox between the feeling of richness we have of our visual environments, and our striking inability, in change blindness experiments, of knowing what has changed.

Chinese Room Argument, The

Intermediate article

John Searle, University of California, Berkeley, California, USA

CONTENTS

The Chinese room argument is a refutation of 'strong artificial intelligence' (strong AI), the view that an appropriately programmed digital computer capable of passing the Turing test would thereby have mental states and a mind in the same sense in which human beings have mental states and a mind. Strong AI is distinguished from weak AI, which is the view that the computer is a useful tool in studying the mind, just as it is a useful tool in other disciplines ranging from molecular biology to weather prediction.

SUMMARY OF THE ARGUMENT

Strong AI is often expressed in the formula: 'Mind is to brain as program is to hardware.' On this view, the human mind is a program running in the hardware, or 'wetware', of the brain. The Chinese room argument against strong AI proceeds by a thought experiment. If strong AI were true, then one could acquire any cognitive capacity that one does not have by simply implementing the program for that cognitive capacity in a way that would enable one to pass the Turing test.

Imagine that I, who am a native English speaker, unable to speak any Chinese at all, am locked in a room containing several boxes of Chinese symbols (the database). Imagine that I have in the room a set of instructions for manipulating Chinese symbols (the program). I receive, through a window in the room, Chinese symbols which, unknown to me, are in the form of questions. I follow the instructions in the program, and give back through the window Chinese symbols which, unknown to me, are answers to the questions. For the purposes of the thought experiment we may suppose that the programmers get so good at writing the programs, and I get so good at shuffling the symbols, that after a time my answers are indistinguishable from those of the native Chinese speaker. I pass the Turing test for understanding Chinese, and I do so by implementing the program. But I do not understand a word of Chinese. This is the point of the thought experiment: if I do not understand Chinese by virtue of implementing the Chinese-understanding program, then neither does any other digital computer by virtue of doing so.

Why is it that I do not understand Chinese? The answer seems obvious. Though I manipulate the symbols, I have no knowledge of what any of the symbols mean. One can see this by contrasting my manipulation of Chinese symbols with my answering questions in English. Suppose that the people on the outside of the room also submit written questions in English and I submit written answers to the questions. My answers to the questions in Chinese are as good as those of a native Chinese speaker because I have been appropriately programmed. My answers to the questions in English are as good as a native English speaker because I am a native English speaker. From the outside, from the third-person behavioral point of view, my behavior is equally good in Chinese and in English. From the inside it is obviously quite different: in English I understand perfectly both the questions and my answers; while in Chinese I understand nothing – I am just a digital computer.

Construed as a deductive argument, the Chinese room argument has three steps and a conclusion. We may formulate these as follows.

> Computer programs are defined entirely in terms of symbolic or syntactic operations. (1)

The implemented program consists entirely of symbol manipulations. To put this somewhat more precisely: the notion 'same implemented program' defines an equivalence class that is specified entirely in symbolic or syntactic terms, and independently of the physics of the underlying medium. There is nothing more to the implemented program, qua implemented program, than symbol manipulations.

> Minds – actual human minds such as yours and mine – have mental contents or semantics. (2)

For example, when I understand a sentence in English I have more than just symbols going through my head: I know what the symbols mean.

> By themselves, the implemented syntactic steps of the program are neither constitutive of mental content nor sufficient to guarantee the presence of mental content. (3)

This is what was shown by the Chinese room thought experiment. I went through the appropriate syntactic steps, but I had no Chinese thought content, no Chinese semantics, associated with them.

> Conclusion: the implemented computer program is insufficient by itself to constitute or to guarantee the presence of the appropriate mental states. (4)

I went through the right steps of the program, I had the right behavior, but I did not have the appropriate mental states. Therefore, strong AI is false.

The argument rests on two fundamental logical principles: firstly, syntax is not semantics, and secondly, simulation is not duplication. Any problem-solving process that can be described as an effective procedure, that is, a procedure going through a finite number of exactly specifiable discrete steps, can be programmed on a computer. That is why the computer is so powerful: we can represent any domain that we can describe precisely. Thus we can represent the stages of the weather, the flow of money in the economy, or the understanding of Chinese sentences. The syntax of the program states can be used to represent anything. They can be used to represent weather changes, economic developments, and even semantics. But the simulation of the process, whether it be atmospheric, economic, or semantic, is not a duplication of the process. You do not produce a rainstorm by doing a computer simulation of a rainstorm. You do not produce wealth by doing a computer simulation of the production of wealth. And you do not produce understanding and thought processes by doing a computer simulation of understanding and thought processes.

RESPONSES TO THE ARGUMENT

A number of responses have been presented against the Chinese room argument. We will consider four of these.

The Systems Reply

Perhaps the most commonly presented answer is this: the person in the room does not understand, but the person is only an element in a larger system. The system consists of the room, the program, the database, etc. So the understanding should be found in the entire system, not in the person, because the person is only the central processing unit.

Just as we would not say of a single neuron in the brain that it understood English, so we should not say of a single element, the person, in the whole system that that person understands Chinese.

Answer to the systems reply

The answer to this reply is that the reason the person does not understand is that he has no way to attach any meaning to the symbols. But if he has no way to attach meaning to the symbols, neither does the whole room. The whole room has no way to get from the syntax to the semantics any more than the person does. To see this, simply imagine that the person internalizes the entire system. Imagine that the person memorizes the database, memorizes the program, does all of the calculations in his head, and works outdoors in the middle of an open field. In this variation there is nothing in the room that is not in the person, and still there is no understanding in the person.

The Robot Reply

The robot reply is based on a variation of strong AI whereby the unit of understanding is not the computer, but the computer within a motorized system that will be able to process sensory inputs and produce motor outputs computationally. The robot would move about, with video cameras attached to its head; it would take in information from the video cameras, and adjust its movements accordingly.

According to the robot reply, the computer by itself does not have semantic content, but the causal relations between a robot and the external world would be sufficient to give semantic content to the symbols processed by the robot.

Answer to the robot reply

The robot reply tacitly abandons the thesis of strong AI, which is that the implemented computer program by itself is sufficient to guarantee or constitute understanding. The idea behind the robot reply is that the addition of causal relations between the system and the external world would

be sufficient to produce semantic content or understanding.

The answer to the robot reply is that even this amendment to the strong AI thesis will not be sufficient to produce understanding. Imagine that the robot has a very large cranium, and inside the cranium is a room, and I am inside the room. I receive inputs in the form of Chinese symbols. I process them according to the program, and I produce outputs in the form of Chinese symbols. Unknown to me, the input symbols are the product of video cameras and other sensors attached to the outside of the robot. The input stimuli are converted by transduction into Chinese symbols, and the output that I provide is converted into motor output of the entire robot system. But I have no way of understanding what is going on because I have no way of attaching any meaning to any of the symbols, or to anything else that is going on in the robot's brain. I am the robot's homunculus, but unlike the usual homunculi of philosophical literature, I understand nothing, because I have no way of attaching any meaning to any of the symbols that I process.

The robot reply tries to defeat the Chinese room argument by adding causal relations. But the causal relations will produce semantic content only if there is some conscious agent who can become aware of the causal relations. I, as a human being, can become aware of the causal relations between the Chinese symbol for chicken chow mein and the actual food type of chicken chow mein if I can *see* chicken chow mein associated with this symbol. But in the robot, I am just a computer and, like any other computer, I function by processing meaningless symbols. The symbols in the computer brain are meaningless in a way that is quite different from the symbols passing through my mind when I think in English. When I think in English, symbols do indeed go through my mind, but I know what they mean.

The Brain Simulator Reply

Suppose we simulated the actual operations of a Chinese person's brain when that person understands sentences in Chinese. Suppose we produced a perfect computer simulation of all of the synaptic transmissions in the Chinese brain. Then we would have to say that the system understood, otherwise we would have to deny that the Chinese person understood. Since the brain operates, like a computer, with a series of state transitions, there is no reason why we could not produce a perfect replica of these state transitions on a digital computer.

Answer to the brain simulator reply

The computer simulation of the brain is not duplicating the relevant features of the brain. It is merely duplicating the formal pattern. The actual human brain, like any other organ, is a causal mechanism, and it causes consciousness and intentionality by quite specific neurobiological processes. The computer merely produces a model or representation of these processes, but the model or representation lacks the causal features of the original.

To see this, compare the brain to any other organ. We can do a perfect simulation of the digestive processes in the stomach on a digital computer. But even if we have a perfect simulation on the computer, to any degree of accuracy, we do not produce actual digestion. When we run the digestion program, we cannot put a pizza into the computer and expect the computer to digest it. The computational simulation is merely a matter of zeros and ones, not a matter of the enzymes and other chemicals that actually carry out digestion. The situation in the brain is similar. Specific biochemical processes cause consciousness and intentionality. We cannot reproduce those by doing a simulation with zeros and ones, any more than we can reproduce digestion with zeros and ones.

The Parallel Distributed Processing Reply

The Chinese room argument works against the von Neumann symbolic digital computer, but recent developments in computer technology have created new types of computational systems which are immune to the Chinese room argument. These new types of systems are known variously as 'parallel distributed processing' (PDP), 'neural net modeling, 'connectionism' or 'new connectionism'.

PDP systems function in a way that is quite different from the traditional von Neumann system. They have a series of computational processes going on in parallel, distributed over a network. Whereas the traditional von Neumann machine works in a series of discrete steps, PDP systems do massively parallel distributed processing.

Answer to the parallel distributed processing reply

There is an ambiguity in the PDP reply. It is not clear which of the differences between the connectionist machine and the von Neumann machine are being appealed to in order to claim that the connectionist machine is not subject to the Chinese room argument. Either what is claimed is that there is some computational power of the connectionist

machine lacking in the von Neumann machine, or it is claimed that there is some hardware feature of the connectionist architecture which is superior to the von Neumann architecture. But neither of these approaches is successful in answering the Chinese room argument.

According to Church's thesis, there is no computation that can be performed on a connectionist machine that cannot be performed on a von Neumann machine. According to this thesis, any computable function whatever, any problem that can be solved algorithmically, can be computed on a Turing machine. All effective computability is Turing computability. Church's thesis is one of the foundational principles of the modern theory of computation and is universally accepted by the parties to this dispute. It has the consequence that there cannot be any computational power possessed by a PDP system that is not possessed by a von Neumann machine.

The other possibility is that something is being claimed for the connectionist architecture: for the actual structure of the wiring and the hardware. But if this is so, it is no longer strong AI. Strong AI is a thesis about the powers of computation. If it is claimed that the particular hardware of the connectionist machines can duplicate the powers of the brain to cause mental content, then the thesis is no longer strong AI, but is rather a form of speculative neurobiology. The Chinese room argument is not intended to answer any claims in speculative neurobiology, but is intended as a logical thesis about the distinction between the syntax of the implemented program and the semantics of actual human minds.

Either we are to think of the essential feature of the system as being its computational power, or we are to think of it as some causal property of the specific hardware in which the computation is implemented. If it is a matter of computational power, no new power is added by the connectionist architecture. If we are to think of it as an architectural feature, then it is no longer the thesis of strong AI. Actual human brains cause consciousness and other mental phenomena by way of specific neurobiological processes operating in a 'bottom-up' fashion. That is, processes at the level of neurons and synapses cause consciousness and other mental phenomena that are features of much larger elements of the brain system.

The thesis of the PDP reply, if followed to its logical conclusion, would have to be that the connectionist architecture is capable of duplicating and not merely simulating the causal powers of the brain to cause higher-level consciousness, etc., by way of bottom-up causation. Nothing in the neurobiological literature would tend to support this thesis. In any case, it is not strong AI, and in consequence, is irrelevant to answering the Chinese room argument.

COMMON MISUNDERSTANDINGS OF THE CHINESE ROOM ARGUMENT

The Chinese room argument is sometimes misinterpreted, and several of these misinterpretations are common in the literature. Firstly, it is sometimes supposed that the argument is intended to show that 'machines cannot think'. But that is not the point of the argument. The argument assumes that the brain is a machine. The problem with computation is that in the relevant sense it does not name a machine process. It names an abstract mathematical process that we can implement on machines, but computation is not defined in terms of machine processes such as energy transfer. Thus, on the view implicit in the Chinese room argument, the brain is a machine, and brain processes are machine processes. 'Computers' of the ordinary kind are indeed machines, but computation is not essentially a machine process.

Another misinterpretation of the Chinese room argument is that it is attempting to show that only human brains have the power of thinking. But that is not the point of the argument. Whether or not we can build an artifact out of some other type of material capable of producing consciousness is an empirical scientific question. In principle there is no more serious logical obstacle to building an artificial brain than there is to building an artificial heart. The point of the argument is that we do not produce the same causal powers by simply duplicating the formal pattern. The computer gives us a picture, or a model, of thought processes, but it does not actually produce thought processes.

CONCLUSION

In the early days of cognitive science, the computationalist model of cognition was the dominant paradigm. At present there is a gradual paradigm shift away from computational cognitive science towards cognitive neuroscience. As we learn more about the brain we see that cognition is essentially a matter of a certain sort of brain processing. We may be able to simulate this on a digital computer, and we may eventually be able to duplicate it in some other medium. But the Chinese room argument shows that simulation by itself does not guarantee duplication. To guarantee duplication, the artificial

creation of a real mind, we would have to duplicate, and not merely simulate, the powers that actual brains have to cause consciousness and cognition.

Cognitive Science: Philosophical Issues

Introductory article

Barbara Von Eckardt, University of Nebraska-Lincoln, Lincoln, Nebraska, USA

CONTENTS

Numerous philosophical questions can be raised about cognitive science, including what cognitive science is, what counts as representation, computation, and explanation in cognitive science, and what the limits of cognitive science are.

INTRODUCTION

Cognitive science is a multidisciplinary approach to the study of cognition and intelligence. It emerged in the late 1950s and early 1960s when researchers in psychology, linguistics and computer science worked together to develop an alternative to behaviorist approaches to mind and language. At its core, it holds that the human mind is a kind of computer which processes information in the form of mental representations (in this article, references to 'mind' are in the sense of a functional description of the brain). The major disciplinary participants in the cognitive science enterprise are psychology, linguistics, neuroscience, computer science, and philosophy. Other fields that are sometimes included are anthropology, education, mathematics, biology, and sociology.

Broadly speaking, there are two kinds of philosophical issue associated with cognitive science: theoretical and conceptual issues raised within or about cognitive science to which philosophers have made a contribution; and traditional philosophical issues to which cognitive science research is relevant. Examples of the first would be: By virtue of what do mental representations have semantic properties? Are 'symbolic' or connectionist models more likely to account for our cognitive capacities? Examples of the second would be: Are there innate ideas? Is color an objective or a subjective property?

This distinction is somewhat blurred because theoretical and conceptual issues in cognitive psychology are sometimes very similar to those that have historically been discussed by philosophers. This article deals only with issues of the first type.

WHAT IS COGNITIVE SCIENCE?

The Core Research Framework of Cognitive Science

Because cognitive science is immature, complex, and continually changing, the question 'What is cognitive science?' is not easy to answer. One way to start is to identify a relatively stable 'core' and then describe various ways in which some cognitive science research deviates from that core.

The aim of core cognitive science is to explain the human cognitive capacities. These include our capacity to use language (perceive it, comprehend it, produce it, translate it, communicate with it, and so on), to perceive visually, to apprehend music, to learn, to solve problems (reason, draw inferences), to plan actions, to act intentionally, to remember, and to imagine. Each of these capacities can be explored in several ways. Consider, for example, the capacity for language. Cognitive scientists study language in normal adults; language development; language variation between cultures, groups (e.g. men and women, first and second language learners), and individuals; pathologies of language (speech disorders, aphasia); and how language is realized in the brain.

In studying the cognitive capacities, cognitive scientists make three basic assumptions: that the human mind is a kind of computer, that it has mental representations, and that it exhibits both conscious and unconscious processing. A popular way of describing cognitive science research is in terms of the three levels proposed by the vision scientist David Marr: a computational level, an algorithmic level, and an implementation level. At the

computational level, we ask what precisely any given capacity is as a (mathematical) function from inputs to outputs; at the algorithmic level, we attempt to explain how a person executes the capacity characterized at the computational level; and at the implementation level, we ask how the capacity is implemented in the human brain.

Core cognitive science is also characterized by methodological assumptions. The most important are: that the research methods of cognitive science are scientific; that a complete theory of human cognition will not be possible without a substantial contribution from each of the contributing disciplines of cognitive science; that human cognition can be successfully studied by focusing on the individual cognizer and his or her place in the natural environment; and that answers to the basic questions of cognitive science in terms of information processing are constrained by the findings of human neuroscience.

The research framework of core cognitive science is, in principle, a framework to which each of the contributing disciplines of cognitive science conforms. However, each of these disciplines contributes to the research program built on this framework in its own distinctive way (see list below). (Note that not all subdisciplines of the contributing disciplines are part of cognitive science. For example, philosophy encompasses ethics and political philosophy, which are not considered part of cognitive science.)

Psychology

Enhances our understanding of the nature and limits of our cognitive capacities.
Proposes hypotheses concerning normal adult cognition, including hypotheses about the mental representations and computational processes involved in any given cognitive capacity, and devises experiments for testing these hypotheses.
Studies the acquisition of cognition in children and the development of cognition throughout our lifetime.
Studies individual and group differences in cognition.
Studies the psychopathology of cognition.

Computer science

Proposes computationally detailed models of cognition and tests these models against the data provided by psychology and neuroscience.
Develops hypotheses regarding the computational nature of the representation-bearers for the human system of mental representation.

Neuroscience

Studies the realization of our capacities in the brain.
Studies what happens when our cognitive capacities are exercised abnormally due to some neural abnormality or lesion.
Develops computational and representational hypotheses concerning cognition in normal adults, children, and abnormal individuals on the basis of low-level information about the brain.

Linguistics

Provides a theory of ideal capacity (a competence model) for language comprehension, production, and acquisition.
Proposes hypotheses regarding the representations involved in language comprehension and production.

Anthropology

Studies cognition across cultures.

Philosophy

Articulates the foundations of the field.
Explores the viability of the cognitive science research program.
Contributes to the development of a theory of content determination for the system of representation posited by cognitive science theories.
Contributes to the discussion of controversial theoretical and empirical issues in cognitive science, often involving adjudication between competing claims.
Helps to develop theories of ideal capacity (competence models) for reasoning and language use.

Areas of Disagreement and Evolution Within Cognitive Science

Within core cognitive science, the primary area of disagreement and change has been the conception of a computer. Initially, computers were thought to be 'physical symbol systems', a view proposed by Allen Newell and Herbert Simon in 1976. Research based on this assumption has been given various labels: 'classical', 'conventional', 'symbolic', and 'rules- and representation-based'. In the mid-1980s a new class of 'connectionist' or 'parallel distributed processing' computers began to attract the attention of cognitive scientists, resulting in heated disagreements about whether symbolic or connectionist computers were the best model of the human mind. Recently, two further views have emerged. The 'dynamic' approach models cognition in terms of a set of quantitative variables that change over time in accordance with dynamical mathematical laws (generally expressed by differential or difference equations). And many neuroscientists hold that the brain is not a physical

symbol system nor a connectionist device nor a dynamic system; rather, it is a fourth, specifically biological kind of computational device, still poorly understood.

Deviations from core cognitive science can be found with respect to its domain, its approach, and the role it assigns to neuroscience. Since the late 1970s and early 1980s, when cognitive scientists started making statements about what cognitive science is, there has been a split (largely along disciplinary lines) over whether the domain of cognitive science is human cognition, or intelligence in general, including human, machine, and possibly animal intelligence. A further area of disagreement concerns whether cognitive science is concerned only with cognition or whether it includes all aspects of the mind, including touch, taste and smell, emotion, mood, motivation, and personality.

Although there is fairly widespread agreement that the core working assumption of the cognitive science 'approach' is that the mind is both a computational and a representational device, there are researchers, who consider themselves to be under the cognitive science umbrella, who have rejected either one of these assumptions: There are those who hold that the mind performs computations without representations; and there are also those who posit representations without computations.

A final area of disagreement concerns the role of neuroscience. Because cognitive science originally emerged from cognitive psychology, artificial intelligence research, and generative linguistics, in the early years neuroscience was often relegated to a secondary role. Citing the fact that descriptions of a system in purely functional terms can always be 'multiply realized', some cognitive scientists even declared that neuroscience, as the science of the physical realization of the functional mind, was irrelevant to cognitive science. Most researchers adopted a more moderate position: that the particular neural realization of the human mind imposes important constraints on what functions the mind can compute. But even such moderates sometimes held that research on the mind could (and should) proceed in a 'top-down' fashion. Most cognitive scientists, however, now believe that research on the mind should proceed in an interactive way: simultaneously top-down and bottom-up. The prevailing view in the field of cognitive neuroscience seems to be that neuroscience will be at the centre of efforts to develop a computational or information-processing theory of the mind driven primarily by bottom-up considerations.

Cognitive Science and Folk Psychology

The relationship between the conceptual frameworks of cognitive science and folk psychology is complex. As one might expect of an immature science, cognitive science has strong roots in common sense, but is also striving to develop its own empirically-based theoretical categories. Thus, cognitive science has clearly taken on board the ordinary notion of a cognitive capacity and the ordinary taxonomy of the specific cognitive capacities we take ourselves to have, including many of their associated states (such as states of perceiving, understanding and intending). However, since folk psychology has little to say about the unconscious processing that goes on when we exercise those capacities, it has been necessary for cognitive science to introduce a variety of subpersonal unconscious information-processing states to describe that processing. Furthermore, to complete the description at the subpersonal level, subpersonal information-processing states are also posited as 'underlying' the conscious states described in folk psychology. Thus, for example, recognizing that a given string of letters is a word of English becomes, in the theoretical language of cognitive science, successfully accessing the appropriate entry in the mental lexicon on the basis of a graphemic representation of the word.

REPRESENTATION IN COGNITIVE SCIENCE

Mental Representations

A mental representation is a structure or state in the mind that has semantic properties, such as referring to phenomena in the world, expressing a proposition, or predicating some property of something. In addition to having semantic properties (content), cognitive scientists generally assume that mental representations are carried by some representation bearer, that their content is 'grounded' in naturalistic properties and relations, and that they have significance for the individual that has them.

Given the assumption that the mind is a kind of computer, the bearers of mental representations are hypothesized to be computational structures or states. The specific nature of these structures or states depends on the kind of computer one takes the mind to be. The representation bearers of classical ('symbolic') computers are typically data structures; in contrast, the representation bearers of connectionist computers are activation

states of nodes or sets of nodes (corresponding to occurrent mental states), or states consisting of links having certain weights (corresponding to dispositional mental states).

In attempting to explain cognition and intelligence, cognitive scientists have posited many kinds of mental representation. There is no neat taxonomy of these kinds. Sometimes representations are grouped together based on what they represent (phonological, lexical, syntactic and semantic representations in psycholinguistics), sometimes on their computational characteristics (local and distributed representations in connectionist systems), and sometimes on both (sentences, frames, schemas and scripts).

Theories of Content Determination

Philosophers interested in mental representation have focused primarily on the problem of what determines the semantic content of mental representations. Such theories are sometimes misleadingly referred to as theories of 'semantics' (e.g. 'informational semantics', 'functional role semantics'). It is more accurate to call them theories of 'content determination'. It is generally assumed that mental content is not a basic fact about the world, hence, that it comes about because the bearers of our mental representations have other naturalistic (non-intentional, non-semantic) properties. These content-determining properties can be considered the 'ground' of representational content.

There are currently a variety of proposals about this ground. They appeal either exclusively or in some combination to: the structure of the representation bearer (Palmer); actual historical or counterfactual causal relations between the representation bearer and phenomena in the world (Fodor, Devitt, Dretske); actual and counterfactual (causal, computational, inferential) relations between the state of the representation bearer and other states in the mind (Block, Cummins); the information-carrying or other functions of the state of the representation bearer and associated components (based on the qualities for which they were selected in evolution or learning) (Millikan); and the phenomenal properties of the representation. All current theories of content determination have problems. A major problem is how to account for the fact that we can falsely represent. For example, we can have a perceptual experience of a state of affairs that does not actually exist, or entertain a thought that is false.

COMPUTATION IN COGNITIVE SCIENCE

Philosophers have discussed two issues concerning the computational assumption of cognitive science. Cognitive science assumes that the mind is a computer. But what exactly is a computer? This question becomes particularly important given that alternative 'machine' models have been proposed (e.g. physical symbol system, connectionist device). Are these all different kinds of computer, as suggested above, or did cognitive science move away from the computational assumption when it became interested in connectionism? To answer these questions we need to know what a computer is.

The second issue concerns the dispute between the 'symbolic' and connectionist approaches. Which is the most promising approach? And can we decide this question on the basis of currently available evidence about cognition?

Computation and Computers

The term 'computer' is used in many different ways. Arguably, the ideal conception of a computer for cognitive science would be one that: (1) builds on the mathematical theory of computation; (2) encompasses classical 'symbolic' models, connectionist devices, and talk of a 'computational' brain; (3) isn't vacuous, and (4) is sufficiently informative to provide some guidance for construction of a theory. Point (3) is important: both Putnam and Searle have argued that the current conception of a computer is so vague as to be vacuous, in the sense that we can interpret any physical system as instantiating any computational characterization.

The theory of computation in mathematics defines a variety of different kinds of abstract machines capable of 'computing' functions in the mathematical sense. Although, in principle, functions can be defined over any domain (e.g. 'father of' maps people to people), mathematicians generally study functions defined over the natural numbers; theorems concerning such functions can then be generalized to functions over other domains. An important discovery has been that different kinds of automata (abstract machines) are associated with different sets of functions distinguished by various interesting mathematical properties.

The kind of machine of greatest interest to cognitive science is the Turing machine, named after the British mathematician Alan Turing. Such machines are important because it is believed that any

function that can be computed by an *effective* method, that is, a method specified by a finite number of exact instructions, in a finite number of steps, to be carried out by a human unaided by any machinery except paper and pencil, and demanding no insight or ingenuity, can be computed by a Turing machine. (This claim is called the 'Church–Turing thesis'.) The so-called 'universal Turing machine' can compute all such Turing-computable functions.

Many cognitive scientists think that the notion of a computer relevant to cognitive science can simply be borrowed from the mathematical theory of computation. Unfortunately, the matter is not so straightforward. To see why, we must first distinguish between a physical system P being *equivalent* to an abstract automaton A and its being an *implementation* of A. Assuming we have some way of systematically mapping the inputs and outputs of A onto the inputs and outputs of P, we take P to be equivalent to A if and only if it can compute the same functions as A. To determine what counts as a legitimate implementation is much more difficult. Basically, the idea is that P counts as an implementation of A if and only if P is equivalent to A and there is a mapping from the formal states of A onto the physical states of P such that the formal state transitions of A are mirrored, both actually and counterfactually, by causal sequences in P.

There are many problems with defining a computer in terms of equivalence to some kind of abstract automaton: principally that such a definition fails to satisfy criterion (4) above, since it tells us nothing about the internal structure of the system. In contrast, while a definition in terms of implementation can be theoretically informative, saying that the mind is an implementation of a Turing machine seems false: at least, on any 'natural' way of doing the mapping. A Turing machine, even a universal Turing Machine, is in only one state at a time and uses a very small number of basic operations. In contrast, the causal structure of the brain relevant to cognition is extremely complex, and brains can change their structure in response to the information being processed. Some researchers, such as Copeland, have even suggested that the brain may have primitive operations that can compute functions that are not Turing-machine computable.

An alternative to defining a computer in terms of one or another class of abstract automaton is to provide a characterization that generalizes over different architectures but also, possibly, excludes some. One such characterization (due to Von Eckardt) is that a computer is a device capable of automatically receiving, storing, manipulating, and outputting information, by virtue of receiving, storing, manipulating and outputting representations of that information in accordance with a finite, effective set of rules that are, in some sense, in the machine itself. Another characterization (due to Copeland), specifically designed to encompass non-classical computation, is that a computer is a device, capable of solving a class of problems, that can represent both the problems and their solutions, contains some primitive operations (which may include operations that are not Turing-computable), can sequence these operations in some predetermined way, and has provision for feedback.

Computational Models and Human Cognition

A major dispute within cognitive science, to which philosophers have contributed in important ways, has been whether the mind is a classical or 'symbolic' computer ('classicism') or a connectionist computer ('connectionism'). Much of the discussion has centered around a challenge to connectionism put forward in 1988 by two proponents of classicism, Jerry Fodor and Zenon Pylyshyn. Fodor and Pylyshyn argued as follows:

1. An adequate theory of cognition must explain the fact that our cognitive capacities exhibit systematicity, that is, roughly, that some capacities are intrinsically connected to others. (If a native speaker of English knows how to say 'John loves the girl' she will know how to say 'The girl loves John'.)
2. Classical models can explain this property of cognition.
3. But it is not clear that connectionist models can, unless they are implementations of a classical model – in which case connectionism wouldn't constitute an alternative to classicism.
4. Therefore, classicism is to be preferred to connectionism.

Their reason for advocating premises 2 and 3 is that it is 'characteristic' of classical systems but not of connectionist systems to be 'symbol processers', that is, systems that posit mental representations with constituent structure (parts ordered in a certain way) and process these representations in a way that is sensitive to that structure.

Since 1988 there has been a flood of responses to this argument; in addition, the argument itself has evolved in two significant ways. First, it has been emphasized that to be a counterexample to premise 2, a connectionist model must not only exhibit systematicity; it must also explain it. Second, it has

been claimed that what needs explaining is not just that human cognitive capacities are systematic; it is that they are *necessarily* (on the basis of scientific law) systematic.

Every aspect of the Fodor–Pylyshyn argument has been subjected to scrutiny. Numerous authors have noted the need for, and proposed, a more precise conception of systematicity. There has also been discussion of what it means to model cognition at the cognitive level, under what conditions one model counts as an implementation of another, and what is required for a model to explain (rather than merely model) either the fact or the necessity of systematicity.

In addition, each of the premises has been questioned. Several computer scientists and philosophers have sought to demonstrate that connectionist systems can model systematicity without being classical implementations, thus refuting premise 3. Some have accepted the Fodor–Pylyshyn conceptualization of the challenge whereby any connectionist model that processes symbols is, *ipso facto*, a classical implementation, and have sought to demonstrate that systematicity can be modelled by a system that is not a symbol processor. Others have resisted the Fodor–Pylyshyn dichotomy, arguing that a system can be connectionist, and have structured representations and structure-sensitive processes, without also being classical. Although proponents of classicism have not explicitly conceded defeat on this point, recent defences of the Fodor–Pylyshyn argument have concentrated on the claim that connectionists will never have the resources to explain either the fact or the necessity of systematicity, rather than that they will not be able to simply model systematicity.

Premise 1 has been questioned by researchers who have variously argued: that our cognitive capacities aren't, in fact, systematic; that that systematicity is a matter of conceptual necessity and, hence, not something that an empirical theory needs to explain; or that the explanation of their systematicity need not come from a theory of cognition. Another point is that the empirical facts about systematicity may be more complicated than Fodor and Pylyshyn assume.

The questions regarding premise 2 are especially important. The Fodor–Pylyshyn argument rests on classical systems being able to do something that connectionist systems (at a cognitive, non-implementational level) cannot. However, it has been pointed out that the fact that a system is a symbol processer (and, hence, classical) does not by itself explain systematicity, much less the lawfulness of systematicity: additional assumptions must be made about the system's computational resources. Thus, if it is true that certain kinds of connectionist system can also explain systematicity, then the explanatory asymmetry between classicism and connectionism will no longer hold (that is, both classical and connectionist systems may or may not explain systematicity when appropriately supplemented) and the Fodor–Pylyshyn argument will be unsound.

EXPLANATION IN COGNITIVE SCIENCE

From the late 1960s onwards, several philosophers have noted that explanation in cognitive science has certain distinctive features. Scientific explanation had commonly been taken to be an answer to a 'why' question ('Why did this event occur?' 'Why do these regularities hold?'), and to involve subsumption of the phenomenon to be explained under laws. In contrast, it was noted, cognitive scientists seek to explain capacities, rather than events or regularities – either by virtue of what we have them (Haugeland's 'systematic explanation') or how we exercise them (Cummins's 'functional analysis') – by appeal to the organized interaction of subcapacities.

While these early discussions succeeded in drawing philosophical attention to some important distinctive features of explanation in cognitive science, the full story turns out to be more complicated. If one adopts the view that explanations are answers to certain kinds of questions and that kinds of explanation are distinguished ('individuated') both by what is being explained and by the kind of explaining being done, then, as Barbara von Eckardt has emphasized, there are many different kinds of explanation to be found in cognitive science. Each of the various questions associated with each type of cognitive capacity has its own kind of explanation. For any given capacity *C* (say, the capacity to perceive visually), cognitive scientists attempt to explain how a normal adult generally exercises *C*, how a child generally acquires *C*, in what ways *C* breaks down under various conditions of psychopathy, what kinds of cultural variation there are in the exercise of *C*, and so on. Further, insofar as cognitive science entertains alternative ways of answering questions – for example, by means of a classical AI program, connectionist model, or dynamical system – even more forms of explanation can be distinguished. Classically explaining how a child acquires the capacity to speak a natural language involves a different kind of explanation than explaining the same phenomenon in a connectionist way.

Do the accounts offered by cognitive science succeed in being explanatory? Do they at least provide possible explanations for what they are intended to explain? Philosophers have raised two sorts of concern. First, the human cognitive capacities that cognitive science seeks to explain are ultimately rooted in our commonsense conception of ourselves. Thus, among the properties of these capacities that require an explanation is their intentionality, that is, the fact that they have content (we perceive or understand that something is the case). The explanatory strategy adopted by cognitive science is to explain the intentionality of mental states, as ordinarily construed, by appealing to the existence of mental representations with content at the subpersonal level. The concern is that this strategy will not work because none of the possible ways of construing subpersonal representational content gives this content the required explanatory role.

A second concern arises from the fact that although most forms of explanation in cognitive science involve 'how' or 'what' questions, cognitive scientists do sometimes seek to explain why people behave in certain ways. (The ability to explain a subject's behavior under experimental conditions constitutes the evidence for proposed answers to the 'how' and 'what' questions.) Typically, of course, these explanations purport both to be causal and to appeal to individual mental representations. But, it has been argued, there are reasons for thinking that it is not a representational state's having a certain content that is doing the causal work; rather, it is the computational or neural structure which 'has' that content (just as what causes me to perceive a word on the printed page is not the word's meaning but its physical embodiment in ink). So there really isn't any genuinely mental causal explanation.

There is one final worry. Granted that explanations that appeal to mental representations could provide possible explanations, are such explanations really needed? For example, couldn't cognitive science simply posit processing that is purely formal, or purely low-level computational (number crunching), or purely neurophysiological?

LIMITS OF COGNITIVE SCIENCE

For more than twenty years, critics of cognitive science, such as John Haugeland, have put together lists of mental phenomena that, they claim, cognitive science will never be able to explain. These include: that people 'make sense' in their actions and speech; that they have sensations, emotions, and moods; that they have a self and a sense of self; that they have consciousness; that they are capable of insight and creativity; that they can possess highly developed intellectual and artistic skills; and that they interact closely and directly with the world in which they live. When cognitive science consisted simply of a top-down, classical ('symbolic') approach, it was quite plausible to view some (or even all) of these phenomena as representing limits of the field. However, given the increasing integration of the non-neural cognitive sciences with neuroscience and the apparent flexibility of the notions of representation and computation, it is now far less clear whether these phenomena are really 'limiting'. Perhaps the most difficult aspect of mentality for cognitive science to explain is what philosophers have called 'phenomenal consciousness', that is, the 'feeling' or experience we have in connection with various kinds of mental state. In particular, as Joseph Levine has emphasized, there seems to be an 'explanatory gap' here: even if we can determine what the neural basis of a certain kind of experience is, cognitive science doesn't seem able to explain why that neural state gives rise to this kind of experience. However, even if this problem of phenomenal consciousness does represent an absolute limit to what cognitive science can explain, it is not obviously a limit to the *scientific* research program of cognitive science, that is, to the programme of developing a scientific theory of the mind.

CONTENTS

The main philosophical issues about color concern whether objects have colors, and what sorts of properties colors are. Some philosophers hold that nothing is colored, others that colors are powers to affect perceivers, and others that colors are physical properties.

INTRODUCTION

According to our everyday experience, many things are colored. Roses are red and violets are blue. On the other hand, according to physical science, roses and violets are composed of colorless particles (or if not particles, something equally colorless). These two pictures of the world are not obviously compatible, and some thinkers have considered them to be plainly incompatible. Galileo, for example, thought that physical science had shown that objects are not really colored, and that colors are 'in the mind'. Philosophical theories of color in modern times have attempted either to reconcile the two pictures, or else to explain why one of them should be rejected.

Until recently, philosophers drew most of their data about color and color perception from their own experience of color. Although personal experience is a valuable source, a good deal of information relevant to abstract philosophical questions about color and the world as revealed by science is to be found in the work of color scientists. Many contemporary philosophers take the view that the physical, biological, and behavioral sciences place significant constraints on philosophical theories of color.

CENTRAL PHILOSOPHICAL ISSUES ABOUT COLOR

The Problem of Color Realism

If someone with normal color vision looks at a lemon in good light, the lemon will appear to have a distinctive property – a property that bananas and grapefruit also appear to have, and which we call 'yellow' in English. However, it does not follow from the fact that an object visually appears to have a certain property that the object has that property. To use an example known to the ancient Greeks, a straight oar half-immersed in water appears bent, but of course it does not have the property of being bent. Ordinarily we take for granted that lemons and other objects are as they appear, but in a philosophical mood we naturally wonder whether we are right to do so.

Such reflections give rise to the central philosophical problem concerning color, the problem of color realism. It is posed by the following two related questions. First, do objects like lemons, bananas and grapefruit really have the distinctive property that they appear to have? That is, are any objects yellow? Second, what is this property? Is it a physical property of some sort (for example, a certain way of reflecting light)? Or is it some kind of property that is specified partly psychologically (for example, a power to produce certain sorts of sensations)? One can ask similar questions for other color properties that objects appear to have.

These questions seem especially important when we consider the physically diverse nature of objects that look colored, and the way the visual system processes color information. As noted above, color is not a property attributed to objects in fundamental physics. In addition, the perception of color is a complex process and the relation between the physical properties of an object and the color it appears to have is far from straightforward. For example, it is not true that yellow-looking objects are those that reflect 'yellow light': there is no simple relationship between the light reaching the eye from an object and the color that object is perceived to have.

The problem of color realism is fundamentally a problem about perception – vision, in particular. The questions concern the nature of certain properties that objects visually appear to have, and whether reality is in these respects as it appears to be. The problem is not primarily about how we talk and think, although of course facts about color language and color concepts may be relevant. It is plausible to assume that the way we use color language is closely connected to the character of human color vision, but the problem of color realism itself concerns perception and not language. These points have to be stressed because it is always tempting to think that philosophical questions are basically questions about how words should be defined, and so are of little relevance to science. The problem of color realism is no more about the definitions of words than is the problem of why the dinosaurs disappeared.

The Representational Content of Visual Experience

It is helpful to put the problem of color realism in terms of what visual experience represents, its representational content. When someone has a visual experience, the scene before his or her eyes visually appears a certain way: for example, it might visually appear to someone that there is a yellow ovoid object in the bowl, or that two lines are the same length. In other words, the experience represents that there is a yellow ovoid object in the bowl, or that two lines are the same length. The experience represents the world correctly if there is a yellow ovoid object in the bowl, or if the two lines are the same length; otherwise, the experience represents the world incorrectly. In the former case the subject's experience will be veridical, and in the latter case illusory. For example, if the subject is looking at lines of the same length with appropriately oriented arrowheads on the ends (the Müller–Lyer illusion), the subject's experience will represent the lines to be of different lengths (even if the subject believes that they are of the same length). The experience represents the world incorrectly and is therefore an illusion.

In this terminology, the problem of color realism concerns certain properties (the colors) represented by visual experience, and whether such experiences represent the world correctly. There is a large philosophical (and, of course, psychological) literature on mental representation, and some philosophical discussions of color draw heavily on it (e.g. Boghossian and Velleman, 1991).

Why Color Matters to Philosophy

Although color is of interest in its own right, in philosophy it mainly serves as a tractable example that can be used to investigate problems of more general scope. One reason why color is particularly suitable for these purposes is that a great deal is known about the relevant physical properties of objects, and the way in which color information is extracted and processed.

One of these more general problems concerns the relation between appearance and reality – whether, or to what extent, the world is as it appears. This problem may be investigated in a reasonably manageable way by restricting attention to a specific instance of it, namely the problem of color realism.

There are a number of other philosophical problems that can be usefully addressed by focusing (not necessarily exclusively) on color. Examples include many central issues in the philosophy of perception: how to distinguish the various sensory modalities; the relationship between perception, thought, and action; and whether we see objects like lemons 'directly', or via our awareness of mental intermediaries. And the famous 'inverted spectrum' thought experiment, which (with some qualifications) supposes that objects that look green to me look red to you, and vice versa, has been used to illuminate a variety of philosophical topics, from the nature of consciousness (Block, 1990) to our knowledge of others' minds (Palmer, 1999).

PHILOSOPHICAL VIEWS AND THEORIES OF COLOR

Eliminativism

Eliminativism is the view that nothing is colored – at least, not ordinary physical objects like lemons. The eliminativist therefore regards much ordinary experience as erroneous. Historically, eliminativism has been the dominant philosophical view; it has its roots in the ancient Greek atomists.

Some eliminativists are 'projectivists': they hold that we 'project' colors that are 'in us' onto objects in our environment. According to the projectivist, some things are colored (for example, neural events, or mental entities like sensations or visual experiences), which we then mistakenly take for properties of objects like lemons. Projectivism is often found in psychology textbooks: Stephen Palmer (1999, p. 95), for instance, writes that 'color is a *psychological* property of our visual experiences when we look at objects and lights, not a *physical* property of those objects and lights'.

An obvious problem with projectivism is that the 'inner' things the projectivist says are colored do not have the right colors, if indeed they have any color at all. Nothing inside the brain becomes yellow when one is looking at a lemon, and it is hard to imagine how a visual experience could be colored.

But an eliminativist need not be a projectivist. One may simply take the view that nothing is colored, not even sensations or visual experiences.

The main line of argument for eliminativism proceeds by claiming that science has shown that objects like lemons do not in fact have colors. The surface of a lemon has a reflectance, various microphysical properties, and is disposed to affect perceivers in certain ways. No other properties are required to explain causally our perceptions of color. But the color properties, whatever they are, do causally explain our perceptions of color. So there is no reason to suppose that the lemon is yellow.

This argument represents a challenge to those who think that lemons are yellow but that this property is not to be identified with a reflectance (the percentage of light reflected by a surface), a microphysical property, or a disposition to affect perceivers (see the discussion of primitivism below). But it begs the question if one simply identifies the property yellow with (say) a reflectance.

The case for eliminativism therefore depends on showing that colors cannot be identified with properties that do causally explain our perceptions of color.

Dispositionalism

Dispositionalism is the view that colors are dispositions (powers, tendencies) to cause certain visual experiences in certain perceivers in certain conditions; that is, colors are psychological dispositions. (Strictly speaking we should add that, according to dispositionalism, at least sometimes our perceptions of color are veridical. This qualification should also be added to the three other views discussed below.) A simple version of dispositionalism is this: the property yellow is just the disposition to look yellow to typical human beings in daylight (for other versions, see Byrne and Hilbert, 1997).

Dispositionalism is often associated with the seventeenth-century English philosopher John Locke who, incidentally, also invented the 'inverted spectrum' thought experiment mentioned above. Locke, like other seventeenth-century philosophers, drew a distinction between 'primary' and 'secondary' qualities. Primary qualities have been characterized in a number of different (and often incompatible) ways, but the essential idea is that they comprise a set of fundamental properties in terms of which all material phenomena can be explained. For Locke, the primary qualities included shape, size, motion, and solidity. Because objects have certain primary qualities, they will be disposed to affect perceivers in certain ways: these dispositional properties are the secondary qualities. In this terminology, dispositionalism is the view that colors are secondary qualities. It is not clear whether Locke was himself a dispositionalist: his view sometimes interpreted as projectivism.

Poisonousness is a straightforward example of a dispositional property. To be poisonous is to be disposed to cause bodily harm if ingested or otherwise taken into the body. According to dispositionalism, yellowness is like poisonousness: to be yellow is to be disposed to cause certain visual experiences if placed in certain viewing conditions. The comparison with poisonousness reveals the relational nature of dispositionalism. Just as a substance may be poisonous for certain organisms and harmless to others, many dispositionalists hold that lemons are only yellow 'for us', and might even be blue relative to some other class of perceivers.

One objection to dispositionalism is that 'certain perceivers' and 'certain conditions' cannot be specified in a principled way. Perhaps a more fundamental problem is that it is not obviously well motivated. It is certainly plausible that yellow objects are disposed to look yellow (at least, once various qualifications are made). However, it is equally plausible that square objects are disposed to look square. It is not very tempting to conclude from this that squareness is a disposition to look square – as noted above, shape properties were supposed by Locke to be paradigmatic examples of properties that are not secondary qualities. It is not clear why color should be treated differently. The dispositionalist needs to explain why perceivers should be mentioned in the account of color, but not in the account of shape. Here the arguments are varied and complex. Dispositionalists often draw their arguments from Locke's own discussion of primary and secondary qualities.

The Ecological View

Thompson *et al*. (1992) have recently developed an 'ecological' view of color, inspired by J. J. Gibson. The ecological view rejects the orthodox account of

vision as 'inverse optics' – the process of extracting information about the scene before the eyes from retinal stimulation together with built-in assumptions about the environment. On the other hand, the ecological view stresses the connection between perception and action, and insists that the animal and environment should not be treated as 'fundamentally separate systems'; environmental properties are supposed to be partly 'constituted' by visual perception. Colors, in particular, 'are not already labelled properties in the world which the perceiving animal must simply recover. … Rather, colours are properties of the world that result from animal–environment codetermination' (Thompson *et al.*, 1992, p. 21).

The ecological view is perhaps best seen as a version of dispositionalism, identifying the colors with 'ecological-level dispositions' to affect perceivers (Thompson, 1995, p. 751). However, it must be emphasized that the ecological view's proponents see the comparison to traditional dispositionalism as somewhat superficial.

One obvious criticism of the ecological view is that it relies on controversial claims about perception. But there is a more basic difficulty, namely that crucial components of the theory are hard to understand. In particular, the meaning of the claim that colors are 'codetermined' by the perceiver and its environment is unclear.

Physicalism

Physicalism is the view that colors are physical properties of some kind, for example, microphysical properties, or reflectances.

Physicalism has been disputed on a number of grounds. First, it is argued that physicalism cannot account for the apparent similarities and differences between colors. In other words, the physicalist cannot explain the structure of phenomenal color space (Boghossian and Velleman, 1991).

Second, and relatedly, it is argued that physicalism cannot account for important observations about the way colors appear to us. For example, it is argued that physicalism cannot explain why orange is a 'binary' hue (every shade of orange is seen as reddish and yellowish), while yellow is a 'unique' hue (there is a shade of yellow that is neither reddish nor greenish) (Hardin, 1993).

Thirdly, it is argued that studies of color vision in animals show that there is no single kind of physical property (e.g. a reflectance) detected by color vision. So, since colors are whatever is detected by color vision, it is concluded that colors are not physical properties (Thompson, 1995).

Primitivism

According to primitivism, objects are colored, but the colors are neither dispositions to affect perceivers, nor physical properties (Yablo, 1995). In fact, the primitivist claims that there is no specially informative account of the nature of the colors. If primitivism is correct, the colors are analogous to fundamental physical properties, like the property of being electrically charged. Given the reductive cast of mind in cognitive science, it is not surprising that few cognitive scientists subscribe to primitivism.

Like eliminativism, primitivism is unmotivated if there are already good candidates to be the colors, for instance, physical properties of some sort, or psychological dispositions. The basic argument for primitivism, then, is similar to the argument for eliminativism: alternative explanations must first be eliminated.

There is little consensus on the best approach to the problem of color realism. The arguments for and against particular theories are rarely conclusive. But it would be wrong to think that no progress has been made. Philosophy is often advanced by showing that apparently unrelated theses are after all closely related, thereby forcing a proponent of, say, dispositionalism to take on a particular burden of commitments. Much recent work in the philosophy of color is of this kind.

INFLUENCE OF COGNITIVE SCIENCE ON ISSUES ABOUT COLOR

One notable feature of recent philosophical work on color is the attempt to integrate philosophical concerns with what is known empirically about color and color vision. Below we discuss a few areas in which this interaction either has been or has the potential to be especially significant.

Color Spaces and Opponent Processes

The colors stand in a complex web of similarity relations to each other. For instance, purple is more similar to blue than to green; and shades of red can be more or less similar to each other. Relations of color similarity also have an opponent structure. Red is opposed to green in the sense that no reddish shade is greenish, and vice versa; similarly for yellow and blue. Further, there is a shade of red ('unique red') that is neither yellowish nor bluish, and similarly for the three other 'unique' hues yellow, green and blue. Thus, in experiments summarized by Hurvich (1981), a

normal observer looking at a stimulus produced by two monochromators (light sources that emit in a narrow band of wavelengths) is able to adjust one of them until he reports seeing a yellow stimulus that is not at all reddish or greenish. In contrast, every shade of purple is both reddish and bluish, and similarly for the other three 'binary' hues orange, olive and turquoise. The binary hues are sometimes said to be 'perceptual mixtures' of the unique hues. These sorts of observations, supplemented with physiological data, form the basis of the opponent process theory of color vision. The main idea of this theory is that color perceptions are the result of two opponent processes (red–green and yellow–blue) and one non-opponent process (light–dark).

As mentioned above, two objections to physicalism start from these facts. We can now elaborate somewhat on the second of these. If physicalism is true, the objection runs, then the difference between the unique and binary hues must be explained in terms of 'unique' and 'binary' physical properties of objects like lemons and oranges. However, the correct explanation is in terms of neural opponent processes, and does not involve the physical properties of objects at all. This objection is controversial, but at least the opponent process theory has led philosophers to a renewed interest in understanding relations of similarity and difference among the colors.

Animal Color Vision

One active area of empirical research is comparative color vision: the study of color vision in non-human animals. Color vision is very widely distributed among animals: some degree of it appears to exist in all the major groups of vertebrates, and it is also common among invertebrates. But there is great variation in the precise type of color vision and the purposes for which it is used. Traditionally, philosophers have restricted their attention to human color vision, although this seems now to be changing. As mentioned above, the kinds of variation in color vision found in animals have been used to argue against physicalism, and also to support the ecological view.

Variation in Perceived Color

The perceived color of an object depends in complicated ways on both the illumination and the other objects in the scene before the eyes. As many people have discovered, even lightness relationships can be reversed by sodium lighting of the sort often found in parking lots. And interior decorators know that the perceived color of an object can depend on the color of its surroundings.

The perceived color also depends on the perceiver: color vision in human beings is surprisingly variable for a basic perceptual ability. Approximately 10 percent of men suffer from a substantial deficit of red–green color vision, and complete red–green color blindness is not rare. There is also substantial variation, among people classified as having 'normal' color vision, in, for example, the spectral location of unique green – ranging over 30 nanometers, nearly 10 percent of the visible spectrum. In addition to variation between subjects, there is variation within subjects. For example, the optical media of the eye, in particular the macula and lens, tend to yellow with age, producing shifts in perceived hues.

These facts have implications for philosophical theories of color. For example, dispositionalism appeals to a notion of 'certain perceivers'. Given the degree of normal variation, slightly different specifications of the privileged class of perceivers will lead to big differences in the resulting dispositionalist theories. The dispositionalist needs to give a principled reason for selecting one group rather than another to be the 'certain perceivers'. Similar remarks apply to the dispositionalist's 'certain viewing conditions'.

Color Constancy

As mentioned above, perceived color depends on the illumination. It is less well known that in many circumstances perceived color is relatively insensitive to changes in illumination. This feature of human (and animal) color vision is known as approximate color constancy. It implies that in many circumstances the perceived color of an object is more closely dependent on its (illumination-independent) surface properties than on the spectral character of the light reaching the eye. Some cognitive scientists have attempted to explain color constancy by treating color vision as a system that extracts information about the surface properties of objects, in particular their reflectances, from the light reaching the eye. This provides one of the inspirations for physicalist theories of color (Hilbert, 1987).

The Inverted Spectrum

It is often supposed that there is no reason to believe that people are 'spectrally inverted' with respect to each other. Indeed, under the influence of

the logical positivists of the early twentieth century, it used to be a common philosophical opinion that spectrum inversion makes no sense at all, because it is not 'verifiable'. However, with improved understanding of the genetic and physiological basis of color blindness, since the 1970s some color scientists have speculated that there might be actual cases of spectrum inversion in the human population. Red–green color blindness is caused by genetic defects that result in two of the three types of cones containing pigments that are very similar in their spectral sensitivity (their readiness to absorb light of different wavelengths). There are two types of red–green color blindness, depending on whether the spectral sensitivities of the two relevant cone types match that of the normal middle-wavelength-sensitive pigment or that of the long-wavelength-sensitive pigment. A person who has inherited the genes for both forms of red–green color blindness would have the two pigments switched from the normal condition. If the development of the neural circuitry for color vision depends only on the cell type and not on the pigment it contains, then this scenario should result in spectrum inversion. In fact, though, there does not seem to be the required independence between circuitry and pigment. Still, the fact that spectrum inversion is treated as a testable empirical hypothesis shows that it cannot be dismissed as a philosopher's fiction.

Metamers

Lights with quite different spectra, and surfaces with quite different reflecting characteristics, can appear to be identical in color. This phenomenon, known as metamerism, is a consequence of the fact that all the information available for perception of color derives from just three cone types with broad spectral sensitivity. If the light reaching the eye from two objects produces the same response in each of these three cone types then they will appear to have exactly the same color, no matter how their spectra or reflectances differ. This fact about (human) color vision has been significant in philosophical discussions of color since the 1970s. The central question is whether metamerism is incompatible with taking colors to be physical properties, because the phenomenon seems to show that there is no single spectrum (or reflectance) that all objects with a particular color share. For a variant of this argument see (Hardin, 1993, pp. 63–64); for a response see (Jackson, 1996).

Computation, Philosophical Issues about

Intermediate article

Matthias Scheutz, University of Notre Dame, Notre Dame, Indiana, USA

CONTENTS

'Computation' is a cluster concept and has been characterized in many different ways (e.g. 'the execution of algorithms'). It underwrites philosophical analyses of what can be done in principle by a mechanism, and is intrinsically connected to the idea of manipulating symbols or representations by formal rules.

INTRODUCTION

The notion of computation is undoubtedly one of the very central, increasingly influential notions of our time. It has captured the attention of researchers from many disciplines for different reasons. In cognitive science it was the capacity of computers to process information that inspired cognitive psychologists to think of cognitive functions in terms of programs and of the brain as a computer running these programs. To be able to appreciate this view of cognition and the central role of computation within it, one needs a clear understanding of what 'computation' means and what computations are.

WHAT IS COMPUTATION?

An Intuitive Perspective

Like many widely used notions 'computation' does not have a single, clear-cut meaning, but rather, *qua* cluster concept, takes on different meanings depending on the context in which it is used. A glance in Webster's dictionary reveals the ordinary language conception of 'to compute': derived from the Latin 'com + putare' – to consider, it means something like 'to determine or to calculate especially by mathematical means'. However, this definition is rather vague and furthermore too restrictive to do justice to the variety of uses to which the notion of computation is put in computer science alone.

More to the point is defining computation as 'the execution of algorithms', which, in turn, puts the burden on the notion of *algorithm* and what 'executing an algorithm' means. Roughly speaking, an algorithm consists of a finite set of instructions, which operate on certain entities (symbols, representations of numbers, etc.) and can be *implemented* in some mechanism. To execute an algorithm then intuitively means to have the mechanism carry out the instructions for any given input in a deterministic, discrete, stepwise fashion (without resorting to random or analog methods and devices). The mechanism goes through a sequence of atomic steps in such a way that (one or more of) these steps correspond to some instruction, for all the instructions specified by the algorithm. Note that nothing is said about the nature of the mechanism yet: it could be concrete or abstract, natural or artificial. Depending on the kind of mechanism, the algorithmic specification will take different forms: in the case of computers, it is expressed in a *programming language*; in the case of humans, instructions may be given in ordinary language (as long as the individual steps are clearly distinguishable and described at a sufficient level of precision) – just think of cooking recipes or the instructions on public phones for making phone calls.

Computation defined as the execution of algorithms does not commit one as to what the computation is about or what it is supposed to achieve. Rather, it ties algorithmic descriptions to *mechanically realizable processes*. This leaves two issues to be addressed: first, it needs to be made clear what a mechanism is, and second, a precise specification of the notion of algorithm is required. The following brief historical overview reveals the origin of the idea of mechanism as well as that of using representations for calculations.

A Historical Perspective

The history of computation traces back to Leibniz and before, when daring philosophers pondered mechanical systems that could aid humans in performing calculations, and possibly even calculate by themselves without any assistance. The first functioning mechanical calculators were built in the seventeenth century and were composed of various mechanical parts (such as gears, cogs, etc.). Leibniz, having constructed calculators himself, was one of the first to envision an application quite different from their typical commercial and military use, that of 'mechanical reasoners'. His view that calculations, in particular, and logical reasoning (i.e. thinking), in general, could be *mechanized* lies at the heart of the notion of computation as used in cognitive science today.

Another crucial contribution to the modern notion of computation is also a product of that time (due to Descartes, Hobbes, Locke, and others), namely the idea that reasoning or, more generally, thinking involves *representations*. The mathematical practice of using marks and signs as representations in calculations became a paradigm for thought itself, as expressed by Hobbes' famous dictum that everything done by our mind is a computation (Pratt, 1987).

Computation was, therefore, already very much tied to the idea of mechanically manipulating representations, and prototypical manipulators were found in the mechanical calculators of those days. While many attempts were made at building mechanical calculators up to the end of the nineteenth century (with varying success: e.g. see Williams, 1997), the computing capabilities of these machines remained very modest. It was only the twentieth century that witnessed major progress in the construction of computers and the conception of computing. This was largely due to two quite independent developments: (1) the thorough logical analysis of the notions 'formal system' and 'formal proof' (leading to further studies of notions such as 'effectively computable function' and 'algorithm'), and (2) the rapid progression in the engineering of electronic components (from vacuum tubes, to transistors, to integrated circuits, and beyond).

A Logico-philosophical Perspective

In the 1930s, logicians laid the main philosophical groundwork for a well-defined formal notion of computation in their attempt to make the intuitive notion of computation, then called 'effective calculability', formally precise. Being logicians, they were solely concerned with the class of functions (over the positive integers) that can be effectively calculated *in principle* – besides, digital computers did not exist yet. Church (1936) was the first to give this class of effective calculable functions a formal characterization through a definition postulate, which later came to be known as 'Church's Thesis' (CT): 'We now define the notion … of an effectively calculable function of positive integers by identifying it with the notion of a recursive function on positive integers (or of a λ-definable function of positive integers)' (Church, 1936, p. 356). Note that by virtue of relating an intuitive notion and a formal notion, CT cannot be proved in principle, as mentioned by Church himself: 'This definition is thought to be justified by the considerations which follow, so far as positive justification can ever be obtained for the selection of a formal definition to correspond to an intuitive notion' (Church, 1936, p. 356).

While this was a first step to capture the meaning of 'computable', it was not quite satisfactory, as CT is silent about what 'effectiveness' of a calculation means. As it stands, the notion of 'effectively calculable function' implies that two ingredients are needed to understand computation: a notion of 'effective procedure or algorithm' and a notion of 'function computed by an algorithm'. The latter can be straightforwardly explicated: it is the mapping obtained by pairing all possible inputs with the corresponding outputs resulting from applying the algorithm to them. The former, however, received a satisfactory account only after Turing (1936) had introduced his machine model of a 'computer', which resulted from his analysis of the possible processes a human – what he then called 'the computer' – can go through while performing a calculation using paper and pencil applying rules from a given finite set. It was crucial to Turing's conception of computation that the human computer follow the rules 'blindly', that is, without using insight or ingenuity. In his analysis of the limitations of the human sensory and mental apparatus five major constraints for doing 'automatic computations' crystallize: (1) only a finite number of symbols can be written down and used in any computation; (2) there is a fixed bound on the amount of scratch paper (and the symbols on it) that a human can 'take in' at a time in order to decide what to do next; (3) at any time a symbol can be written down or erased (in a certain area on the scratch paper called 'cell'); (4) there is an upper limit to the distance between cells that can be considered in two consecutive computational steps;

(5) there is an upper bound to the number of 'states of mind' a human can be in, and the current state of mind together with the last symbol written or erased determine what to do next.

Turing then defined a mathematical model of an 'imagined mechanical device' that satisfies all of the above, later referred to as a 'Turing machine' (TM) by Church. A TM consists of an unbounded tape divided into squares, each of which can hold exactly one symbol, a tape head for reading and writing symbols from a given alphabet on the squares, and a controller, which is in exactly one of finitely many states at any given time. Each computational step of the machine first involves reading the symbol under the tape head and then, depending on the current state of the controller, writing a new symbol on the square, possibly switching to another state and possibly moving the tape head one square to the left or to the right. 'The computation proceeds by discrete steps and produces a record consisting of a finite (but unbounded) number of cells, each of which is blank or contains a symbol from a finite alphabet. At each step the action is local and is locally determined, according to a finite table of instructions' (Gandy, 1988, p. 81). This way the TM became a model of human computing, an *idealized* model to be precise, since it could process and store *arbitrarily long, finite sequences of symbols*. The TM model is also a very abstract model, for it only captures high-level processes that take place in humans when they compute (as opposed to low-level neuronal processes, for example).

Turing intended his analysis to show that *any function computable by a human being following fixed rules can be computed by a TM*. And, furthermore, he also believed the converse, that every function computed by a Turing machine could (in principle) be computed by a human computer. Note that this equivalence *per se* does not preclude humans from being able to find answers to problems (expressed in terms of functions) which no TM can compute (e.g. using intuition).

PHILOSOPHICAL VIEWS OF COMPUTATION

Turing Computability and Beyond

The logico-philosophical analyses of the intuitive notion of computation led to the crucial insight that different attempts to characterize it can all be proven extensionally equivalent: recursive functions, λ-definable functions, and TM-computable functions all define the same class of functions. These equivalence results are possible, because what 'computing' means with respect to any of the suggested formalisms is expressed in terms of functions from inputs to outputs, which are used as mediators in the comparison of the various classes of functions defined by the different formalisms. Later, other formalisms such as Markov algorithms, Post systems, universal grammars, PASCAL programs, as well as various kinds of automata, were also shown to give rise to the same class of functions. Hence, by CT, any of the above mentioned formalisms captures our intuitive notion of computation, that is, *what it means to compute*. (Some disagree with this conclusion, arguing that the equivalence results capture only a restricted notion of computation as shared by certain philosophers of mathematics and logicians, e.g. Sloman (1996).)

Common to all the above computational formalisms (besides their attempts to specify formally the intuitive notion of 'computation') is their property of being independent from the physical: computations in any of these formalisms are defined *without* recourse to the nature of physical systems that (potentially) realize them. Even the TM model, which is often considered the prototype of a 'mechanical device', does not incorporate physical descriptions of its inner workings, but abstracts from the mechanical details of a *physical realization*. The first to incorporate physically motivated mathematical constraints into a formal model of computation was Gandy (1980) in his attempt to define a notion of computation for any discrete, deterministic, physical machine. He formulated five conditions to determine whether any system qualifies as a 'mechanical machine' and proved that any function computable by a discrete deterministic device (in his sense) is effectively computable and vice versa. Hence, TM-computability (i.e. effective computability) and computability by mechanical devices are equivalent notions. Some even extend the claim by suggesting that the behavior of any finitely realizable physical system can be 'computed' (in the sense of 'perfectly simulated') by a TM (e.g. see Deutsch, 1985).

It is not clear, however, whether computation should be equated with 'effective computability', since there are, at least in principle, imaginable computing devices that give rise to 'Super Turing computability' (i.e. compute functions that no TM can compute). An example of such a device is Turing's 'oracle machine' (O-TM), which is a TM with additional atomic operations to query an 'oracle'. The oracle itself is a device that somehow produces values of a particular (possibly TM-uncomputable)

function – how the results are obtained is left unspecified. It is easy to see that any O-TM with an oracle for any uncomputable function can compute more functions than any TM. Whether such a machine could be physically realized is an open question (maybe there are physical quantities that happen to encode some TM-uncomputable function). The interesting point is simply that an O-TM would be perfectly mechanistic in the classical sense without being effective as it uses some noneffective device, namely the oracle. O-TMs, hence, drive a wedge between the notions of 'effectiveness' and 'mechanism' (e.g. see Copeland, 2000). A similar point can be made with respect to the notions of 'effectiveness' and 'algorithm'.

There are other suggestions along the same lines coming from neural network research: it can be shown, for example, that certain neural networks (consisting of about 1000 neurones) with rational-valued connection weights between neurones can compute any TM-computable function (Siegelmann and Sontag, 1995). And if real-valued weights are allowed, they can compute any function whatsoever.

Other Construals of Computation

Although TMs have become the canonical models of computation and permeate various academic disciplines in that role, there are other construals targeted more towards possible philosophical merits and potential practical applications of computation. Following Smith (forthcoming), for example, the following views should all be distinguished as they emphasize and capture different aspects of computation:

1. *formal symbol manipulation*: the manipulation of symbols by virtue of their formal properties (without regard to possible interpretations or semantic content);
2. *effective computability*: what can be done effectively by a mechanism;
3. *rule-following* or *execution of an algorithm*: what is involved in following rules or instructions;
4. *finite (digital) state machines*: automata with a finite set of internal states;
5. *information processing*: what is involved in storing, manipulating, and displaying information;
6. *interactive systems*: computation as interaction and communication embedded in an environment;
7. *dynamical systems*: computation expressed in the language of dynamic systems (using concepts like state space, trajectory, attractors, etc.).

To some extent all of the above notions play a role in various disciplines (especially in computer science), but some of them are more dominant in specific intellectual areas: (1) figures mainly in philosophical debates and meta-mathematics, where (2) and (3) are tied to logical investigations; (4) is largely an engineering concept, while (5)–(7) have become increasingly important in cognitive science, the theory of complex systems, and, of course, computer science.

While the above list is far from exhaustive, it is intended to give a flavor of the wealth of different aspects the notion of computation has acquired, especially in the course of the last century. For that very reason, it is argued, we are still lacking the 'grand unified theory' (similar to physics) that can accommodate all these multiple facets, if such a theory is possible in the first place.

Real-life Computation

Despite the theoretical success of TM-computability, computer science *qua* practice is concerned not so much with the limits of what can be computed in theory, but rather with the more modest, mundane question of what can be computed within reasonable limits (using given resources). A whole new discipline within computer science called 'complexity theory' – an offspring of the classical investigations of effective computability – is dedicated to the study of what is computationally feasible. Still other issues arise from computational practice with which the TM model, for example, can hardly cope, in particular, the need for computational systems (embedded in various kinds of devices) to continually interact with their environments: what function does an operating system compute (or the world wide web, for that matter)? According to the classical view, such questions cannot be answered easily as the underlying functions are simply not defined for inputs on which computational processes run forever. (A simple example of a program that loops forever on all of its inputs is the following control code of a 'router' for the internet, which simply copies messages from its input to its output port.) Yet, there is a strong intuition that computational processes as they occur in operating systems or web browsers do have a purpose, can accomplish certain tasks or fail at achieving them. As a consequence the notion of 'computation of a function', and with it the classical notion of algorithm, had to make room for the notion of interaction:

> Interaction is shown to be more powerful than rule-based algorithms for computer problem-solving, overturning the prevalent view that all computing is expressible as algorithms. The radical notion that

> interactive systems are more powerful problem-solving engines than algorithms is the basis for a new paradigm for computing technology built around the unifying concept of interaction. (Wegner, 1997)

This paradigm shift from programs to processes renders many of the old reservations to the notion of computation obsolete, which were a consequence of taking computation to be defined solely in abstract syntactic terms thereby abstracting over physical realization, real-world interaction, and semantics. The new approach reveals computation, contrary to standard orthodoxy, as interactive and embodied, hence very much concerned with the constraints imposed on computational processes by the real world.

ROLE OF COMPUTATION IN COGNITIVE SCIENCE

The Midwife: Computation and the Birth of Cognitive Science

The independence of computations (in the sense of TM-computations) from their physical realizers was one major source of attraction for cognitive psychologists in the late 1950s. The information-processing capabilities of computers, an ability thought to underlie human cognition, and the potential of computer programs to specify exactly *how* information is processed was another. Together they led to the thought that cognition, viewed as 'the processing of information', could be completely understood and explained in terms of computations: if cognitive functions *are* computations, then explanations of mental processes in terms of programs are scientifically justifiable without having to take the 'implementing' neurological mechanisms into account, similar to computers, where it is the programs implemented on the computer hardware, not the hardware itself, that explain (if not entirely, then at least for the most part) what the computer does. The *computer metaphor* implicit in this view has been summarized as the claim that 'the mind is to the brain as the program is to the hardware' (Johnson-Laird, 1988) (note that this should really read 'the mind is to the brain as *computational processes* are to the hardware' to avoid conflating the program–process distinction). Its guiding ideas eventually became so prominent (originally in psychology, later in artificial intelligence) as to assist in the birth of cognitive science and establish *the computational claim about mind*, also called *computationalism*, as a genuine research paradigm.

The Paradigm: Computation and the Computational Claim about Mind

As with the notion of computation, computationalism is not a unified view, but construed differently by philosophers, psychologists, or neuroscientists. Various condensed slogan-like phrases such as 'the brain is a computer', 'the mind is the program of the brain', or 'cognition is computation' can be found in the literature, to name just a few. Yet, they cannot be taken at face value, for if they were read together, they would equivocate essentially distinct notions (such as program and process, mind and cognition, etc.). Furthermore, depending on their subdiscipline within cognitive science, researchers stress different aspects of computations: their information-processing capabilities, their formal nature, their control functions, their potential to have semantics, and so on.

Common to different views of computationalism are the assumptions that (1) mental processes are computational processes and (2) the same kind of relation that obtains between programs and computer hardware (i.e. the *implementation* relation) obtains between mental descriptions and brains too. It follows that cognitive functions can be described by and explained in terms of programs, and that the right level of abstraction at which to understand cognition is the computational level and not the level of the implementing mechanism (i.e. the brain), even though it might be helpful to know the functional organization and role of certain brain areas in determining what they implement.

Computationalism has many appealing facets, especially when it comes to high-level cognition: many features related to logic and language (such as systematicity, productivity, compositionality, and interpretability of syntax or the compositionality of meaning, e.g. see Fodor and Pylyshyn, 1988) are supported by computations 'almost for free', and many mental operations on various kinds of representations such as rotating three-dimensional images, searching for a good move in a chess game, reasoning about other people's behavior, planning a route through a city avoiding construction sites, etc. can be described computationally and implemented on computers. After all, this is what computers do: they manipulate symbol tokens (e.g. strings of bits), some of which are representations of the subject matter the computation is about. These representations, in turn, have both formal and semantic properties, of which the former are causally efficacious. Computational processes then manipulate symbols by virtue of their formal and not their semantic properties (e.g. Fodor, 1981).

While computationalists take this to be a virtue of their approach, it is a major shortcoming for others and various arguments have been advanced to establish that formal symbol manipulation is not sufficient for human intentionality and semantics (e.g. Searle's Chinese Room, 1980) or that minds are not TM-computable (e.g. Lucas's Gödelian argument, 1961). More recently, connectionists and dynamicists have tried to replace the notion of computation with alternatives, arguing that the representational level of description of a cognitive system so crucial to computationalism cannot be taken for granted. In fact, most dynamicists find the symbolic/representational level of description superfluous altogether and argue instead for an explanation of cognition in terms of *dynamic systems* (e.g. Port and van Gelder, 1995).

The Method: Computation and the Simulation of Cognition

While there are undoubtedly tendencies in cognitive science to replace the classical notions of computation, either by dynamic systems or by more adequate notions of computation (e.g. notions based on interaction, real-time constraints, etc.), even those opposed to computationalism agree at least that computation is still a valuable tool in the study of cognition (regardless of its explanatory success). In particular, computer simulations and computational models (of aspects) of cognition have become increasingly important in cognitive science. While computational models, at least to some extent, presuppose that whatever is modeled is computational, simulation models do not have to make such an assumption. Rather, they implement a computational approximation of the mathematical description of the phenomenon under scrutiny, and as long as any resultant error is within predetermined bounds the simulations are considered 'models'. In particular, they might elucidate complex dynamical relations between various parts of the simulated model, which are difficult to see (and often not 'visible' at all) from the formal, mathematical description. From trajectories through complex state spaces of dynamic systems to evolutionary processes in artificial environments, computer simulations provide a testbed for cognitive scientists to evaluate their hypotheses without always having to study them in 'real systems'. Furthermore, simulations can focus on different aspects of cognitive systems at different levels of description, they can be reproduced, slowed down, sped up, and modified in various other ways (e.g. simulating damage, disease, and various other disorders), in which no real cognitive system could be manipulated while preserving its normal functionality (obviously, ethical considerations would enter the picture here as well).

A crucial difference between simulation and computational models is, however, that the former usually does not share all the relevant causal properties with the modeled system, whereas the latter, being a computational model of computational processes, can in principle have the right causal structure (depending on various constraints on inputs, outputs, real-time, etc.).

SUMMARY

'Computation' is a multifarious notion, which defies a single, simple characterization. Yet, it is often explicated as 'executing an algorithm', presupposing some sort of mechanism able to 'execute' instructions as specified by the algorithm. For many logicians and philosophers it was the notion of Turing machine computability that for the first time gave precise meaning to the intuitive notion of computation understood as 'blindly following rules or instructions', thereby answering the question of what 'effective calculability' is supposed to mean. The connection of 'effectiveness' and computation goes back at least to the seventeenth century, when 'calculation' was very much tied to mechanical devices. Only in the twentieth century did effectiveness, mechanism, and computation become separated, when alternative models of computations such as interactive systems were considered. Various construals of the notion of computation (such as 'formal symbol manipulation' or 'information processing') emphasize different aspects of computation, although none of them seems to capture what computation may signify in its entirety. In cognitive science, computation played a crucial role right from the start. It figured prominently in the emergence of the discipline and became the basis of computationalism, the paradigmatic view that mental processes are computational, leading to the development of computational models of cognitive functions. Even for researchers objecting to computationalism, computations can be of great utility when used to simulate cognitive processes.

Concepts, Philosophical Issues about

Intermediate article

Jesse Prinz, Washington University, St Louis, Missouri, USA

CONTENTS

Concepts are generally defined as representations that allow us to think about properties or categories. Philosophers have debated the nature of these representations and the cognitive functions that they serve.

INTRODUCTION

Concepts (sometimes called 'ideas') are the tools by which we think about the world. They have been an object of philosophical scrutiny since Plato's time. New theories of concepts have been developed in recent decades, arising from interactions between philosophers and researchers in other disciplines. There is no consensus about which theory of concepts is correct, but there is wide agreement on the challenges that an adequate theory of concepts must meet.

FUNCTIONS OF CONCEPTS

Concepts are theoretical posits, introduced to play a variety of explanatory roles. This article will present the functions that concepts are most often alleged to serve. Some theorists doubt whether a single kind of entity can serve all of these functions (Rey, 1983), but others are more optimistic (Prinz, 2002). If all these different functions are served by different kinds of entities, there may be no non-arbitrary way to determine which of those entities deserve to be called concepts and the utility of the construct may be called into question.

One function that is often emphasized in philosophy involves reference: concepts are said to represent categories or properties. A category is a class of things consisting of zero or more members (e.g. the class of all actual and possible elephants); and a property can be characterized as that by virtue of which things form a cohesive class (e.g. elephanthood). Some philosophers think that concepts must represent properties rather than categories, because we can have distinct concepts corresponding to distinct properties of the same class (e.g. the class of triangles is the same as the class of trilaterals, but we can distinguish between these conceptually).

Concepts are also widely (though not universally) alleged to serve an epistemic function: they embody the information by which we understand categories. That information is often believed to take the form of 'features'. Features are usually construed as concepts themselves, designating properties possessed by category members. For example, an *elephant* concept may encompass the features *has a trunk* and *is an animal*. If concepts are associated with features, they can serve a categorization function. I determine that Jumbo is an elephant because he is an animal, has a trunk, and so on. Psychologists emphasize the categorization function above all others.

There are two main views about how concepts embody knowledge or information. According to 'decomposition' views, concepts are literally parts of other concepts (e.g. Smith, 1989). For example, an *elephant* concept might be construed as a data structure containing *trunk*. According to 'conceptual role' views, concepts are related to each other by inputs and outputs (e.g. Block, 1986). For example, an *elephant* concept might be construed as a mental predicate ('*X* is an elephant') that licenses certain inferences ('*X* has a trunk').

Decomposition and conceptual role views may be behaviorally indistinguishable. Defenders of decomposition views generally assume that constituent features can be used to draw inferences. If my *elephant* concept contains the feature *trunk*, and I believe that Jumbo is an elephant, I may infer that Jumbo has a trunk. On either approach, then, concepts can be said to serve an inference function.

Concepts also have a combination function: they combine to form compound concepts and thoughts. We often form thoughts that have never been entertained before, even when we have not acquired any new concepts. This suggests that concept combination is a compositional process. Concepts are said to combine compositionally when the content of a compound concept is a function of the concepts that comprise it together with the rules of combination. For example, one can form a concept of a clumsy elephant if one has an *elephant* concept and a concept of clumsiness, even if one has never considered or encountered clumsy elephants before. A compositional system can generate boundless novel compounds from a finite set of more basic concepts.

Concepts are also said to serve functions related to language. Firstly, they contribute to communication. Two people successfully communicate when they associate the same (or similar) concepts with their words. The communication function is related to a meaning function. The simplest version of this thesis says that concepts constitute the meanings of words. Philosophers have developed different theories of meaning, which lead to different interpretations of this hypothesis. 'Meaning-as-use' theories, for example, associate meanings with abilities. According to one version, the meaning of a word is determined by how that word is used in various conversational contexts (Wittgenstein, 1953). If concepts are meanings, it would follow that concepts are verbal abilities; and if concepts are verbal abilities, then one cannot possess a concept without language. On this view, creatures lacking language lack concepts.

Many philosophers reject that conclusion. It makes it more difficult to talk about apparent cognitive similarities between humans and non-human animals. It also makes it difficult to explain how language is acquired in the first place. How can one learn what our first words mean if understanding a meaning requires mastery of verbal abilities (Fodor, 1975)? Not all meaning-as-use theories face these difficulties. According to another meaning-as-use theory, the meaning of a word is determined by how a concept underlying that word is used in thought. This preserves the idea that knowing meanings involves mastering abilities, while denying that those abilities are necessarily verbal.

Proponents of a different class of theories equate the meaning of a term with a 'mode of presentation' (Frege, 1893). A mode of presentation can be a representation of features possessed by whatever the term represents. For example, the meaning of the word 'zebra' might be comprised of a representation of striped, horse-like animals roaming the African savannah. If concepts decompose into features, they are ideally suited to serve as modes of presentation and, thus, meanings. Even conceptual roles can be regarded as modes of presentation if the latter term is very broadly construed.

According to another theory, the meaning of a word is exhausted by its referent. The word 'zebra' simply means the class of all actual and possible zebras or the property of being a zebra. If this theory is correct, it makes little sense to identify concepts with meanings. It would be better to say that concepts are the bearers of meanings. More specifically, one might say that the meaning of a word is exhausted by the referent of the concept with which it associated. If meanings are exhausted by referents, then the features associated with a given concept are not part of linguistic meaning, as mode of presentation theories and meaning-as-use theories imply.

THEORIES OF CONCEPTS

Philosophers and psychologists have proposed a number of theories of concepts. One point of disagreement concerns the question of which concepts are 'primitive' (Fodor, 1981). As noted above, some theorists assume that many concepts are comprised of other concepts. On pain of regress, decomposition must end somewhere. A primitive concept is one whose identity conditions do not depend on any other concept. The British empiricists claimed that primitive concepts are sensory. This view has fallen out of favor, because it is very difficult to analyze abstract concepts into sensory features (but see Prinz, 2002). The issue of primitive concepts has received relatively little attention in recent times.

Another point of disagreement concerns the ontological status of concepts (Peacocke, 1992). According to some philosophers, concepts are abstract entities; while according to others they are mental tokens that reside inside our heads. There may be room for reconciliation here, however. If concepts are mental tokens, and if concept sharing is possible, it must still be possible to talk about them belonging to common types: two tokens of an *elephant* concept must be capable of belonging to a common type. Conversely, those who favor the view that concepts are abstract entities must admit that individuals grasp concepts, and, to the extent that grasping is a psychological process, token mental states must be involved.

A more divisive issue concerns the kind of information that concepts embody. One terminological

caveat must be made before we survey these disputes: the word 'concepts' is sometimes used as shorthand for 'the majority of lexical concepts'. A lexical concept is a concept expressed by a single word in a natural language, such as English. A theory of concepts would thus be better described as a theory of the kind of information embodied in most of our lexical concepts.

The Definition Theory

Overview

The dominant theory in the history of philosophy claims that most lexical concepts are definitions (e.g. Katz and Fodor, 1963). A definition is a collection of features that are jointly sufficient and individually necessary for membership in a category. The concept *bachelor*, for example, is said to entail or decompose into the features *unmarried* and *male*.

Adherents of the definition theory (also called the 'classical' theory) draw a sharp distinction between those features that define a concept and those that are merely known to apply to the category designated by the concept. This generates two kinds of true sentences, those that are true by definition (e.g. 'bachelors are unmarried') and those that are true by virtue of how the world is (e.g. 'bachelors tend to like martinis'). The former are called 'analytic' and the latter 'synthetic'.

There are several different versions of the definition theory. According to the tradition deriving from Plato, each of us implicitly knows how to define the concepts we possess, but that information is not easily accessed. One must engage in arduous philosophical reflection (facilitated by dialogue) to reveal definitions. This process of discovering definitions is said to be *a priori*, because it relies on conceptual intuition rather than observation of experience. *A priori* conceptual analysis is one of the predominant methods used in philosophy.

According to a second version, definitions are discovered *a posteriori*, not by intuition and reflection (Rey, 1983). This account is thought to be most applicable to concepts that designate natural kinds (such as concepts of animals or substances found in nature). The definition of the concept *gnu* might be a description of the gnu genome, or some other scientifically determined conditions that are necessary and sufficient for being a gnu. One might hold a mixed view, according to which some definitions are discovered *a posteriori* and others are discovered *a priori*.

A third version of the definition theory has it that definitions are not discovered at all, but rather invented (Carnap, 1934). Defenders of this version recognize that many of our concepts are unclear, or variable between individuals. Communication is greatly facilitated, they argue, by stipulating definitions. These may roughly coincide with prior intuitions, but they are more precise. The primary motivation for this program of 'precisification' is to facilitate science. If different scientists agree on how their terms are defined, any remaining debates between them must be substantive (e.g., pertaining to data) rather than verbal.

Assessment

Despite its long philosophical pedigree, faith in definitions began to wane in the middle part of the twentieth century. One attack derives from Quine's (1951) famous critique of the distinction between the analytic and the synthetic. Believers in that distinction traditionally hold that analytic truths are known *a priori* and are invulnerable to empirical refutation.

Quine presents an alternative account of how sentences are confirmed, which contradicts this assumption. According to Quine, no sentence is empirically verified in isolation. When we encounter evidence that conflicts with a sentence held to be true, we have the option of either revising that sentence or revising various background assumptions, including those that may appear independent of experience. What we revise will depend on what we observe, what we take to be true, and a variety of pragmatic principles by which we strive to minimize disruption as we revise our theories. Because sentences face the 'tribunal of experience' collectively, any sentence is vulnerable to empirical refutation.

If Quine's 'confirmation holism' is correct, the traditional notion of analyticity is undermined. This has implications for the definition theory of concepts. Proponents of that theory say that some of the features associated with a concept define it and some do not. But which are the definitional features? They cannot be the features that are analytically related to the concept, because that notion lacks foundation. Without a principled way to distinguish defining features from collateral information, the definition theory is in jeopardy of being usurped by 'concept holism' (see below). This is damaging to Carnap's 'precisification' view. Science can stipulate definitions, but these will remain sensitive to the pressures of observation and discovery. No claim is purely verbal.

Another challenge to the definition theory was articulated by Wittgenstein (1953). Wittgenstein notices that certain terms cannot be captured by a

single set of necessary and sufficient conditions. His famous example was the word 'game'. Every plausible defining condition on games has obvious counterexamples. For instance, games do not always have winners (consider catch), and they do not always have two or more sides (consider solitaire). This point may generalize. Every time one philosopher publishes an analysis of a concept, another publishes a convincing example of a case that the analysis fails to subsume. Even concepts that seem to have incontrovertible definitions are vulnerable. A *bachelor* is widely defined as an unmarried male, but there is a strong intuition that Catholic priests are not bachelors even though they satisfy the definition. Conditions thought to be defining often capture a salient range of cases, but they rarely capture all cases.

Psychologists have also criticised the definition theory (see Hampton, 1993, for a review). Experimental evidence has overwhelmingly shown that definitions do not figure prominently in conceptual tasks. People categorize on the basis of family resemblance, associate non-defining features with concepts, have difficulty learning definitions, and fail to rely on definitions once they have been learned. If concepts are mental representations, then it seems unlikely that concepts are definitions.

Defenders of the *a posteriori* version of the definition theory have a response to such arguments. On their view, definitions are scientifically discoverable facts unknown to most concept users. The fact that people have difficulty formulating adequate definitions only shows that most of us do not understand completed science. This might rescue the view that concepts are definitions, but it would not satisfy many cognitive scientists. If definitions are largely unknown, they will play little role in behavior. Even if concept users believe that definitions will someday be discovered, that article of faith cannot distinguish my *elephant* concept from my *walrus* concept. If a theory of concepts is to explain how different concepts affect behavior, then we would be better off identifying concepts with the actual knowledge that ordinary people use to categorize elephants and walruses.

Clusters, Stereotypes, and Prototypes

Overview

The arguments against the definition theory have spawned several alternative theories. Wittgenstein came to see many concepts as revolving around large clusters of features. Rather than having a universal essence, concepts like *game* are applied by determining whether something has a preponderance of the features in a cluster. All games exhibit a subset of features from the same cluster, but few if any cluster features are exhibited by all games. Wittgenstein calls *game* a 'family resemblance' concept, because each of its instances shares features with each other, but no features are universally shared.

Putnam (1975) explores a related idea. He argues that people think about categories by means of stereotypes. A stereotype is a collection of features that are thought to be highly characteristic of category instances. Such features are typically widespread, salient, and diagnostic. For example a *dog* stereotype might include such features as *barks*, *has a tail*, and *is a pet*. Stereotype features are also presumed to be contingent. There are wild dogs that lack tails and never utter a sound. Stereotypes can even contain features that are erroneously associated with categories (e.g., gorillas are stereotyped as ferocious). Putnam observes that when people explain the meaning of a word, they often list stereotypical features, rather than provide a definition. Putnam thinks that stereotypes are generally concise, in contrast to Wittgenstein's clusters. As with clusters, however, members of a category are often presumed to exhibit some sufficient proportion of the stereotype rather than the whole of it.

Stereotypes can be compared to what psychologists call prototypes. According to prototype theory, most lexical concepts are identified with representations of prototypical category instances (Hampton, 1993). Sometimes, a prototype is thought to be a representation of the actual instance that best captures the category's central tendency. More commonly, prototypes are regarded as weighted lists of features corresponding to the properties most frequently recognized in category instances. Features that are more frequently recognized or more diagnostic may be given higher weights. Categorization depends on passing a critical threshold of similarity, computed by comparing a target instance to the features contained in the weighted list. Prototype theorists emphasize the graded nature of category judgments. People regard certain category instances as more typical than others. These are said to reflect increased similarity to the prototype.

Assessment

There is ample evidence that people often categorize on the basis of judged similarity to collections of non-defining features. The psychological reality of

something like clusters, stereotypes, or prototypes is rarely challenged. However, some researchers are reluctant to identify such cognitive structures with concepts. To see why, consider some of the objections to stereotypes (all of which apply to prototypes as well).

Putnam points out that stereotypes are insufficient to determine reference. To demonstrate, he has us imagine two very similar individuals living on different planets. One lives on Earth, where the thirst-quenching, clear liquid in rivers and streams is H_2O. His doppelgänger lives on Twin Earth, where the liquid that has those properties is a different chemical compound, XYZ. These individuals (who are ignorant of chemistry) have the same stereotypes associated with the word 'water', but apparently their concepts refer to different substances. Some researchers believe that concepts with different referents cannot be identical. One is a *water* concept, and the other is a *twin water* concept. If this is the case, then stereotypes can, at best, be one component of our concepts. In addition, we must individuate concepts by their referents. (Putnam draws this conclusion about meanings rather than concepts.)

The insufficiency of stereotypes can also be demonstrated by considering categorization judgments. While we often categorize on the basis of superficial similarity, we recognize that appearances can deceive. A wolf in sheep's clothing is still a wolf even if its disguise is good enough to resemble a stereotypical sheep. This is a psychological analogue of Putnam's observation; concept users know that similarity to their stereotypes is insufficient for reference. Stereotypes are good for rough and ready categorization, but we must be capable of transcending them.

This last observation is connected with a general concern. Stereotypes comprise only a small portion of the knowledge we have about categories. They generally capture superficial appearances. We also know a great deal about features hidden from view, the relations between superficial features, how category instances function, how they relate to instances of other categories, and so on. All of this information can potentially influence our judgments concerning categories. There may be no reason to privilege superficial features from this rich reservoir of information.

One of the most serious concerns about stereotypes is that they do not combine compositionally. For example, the stereotype for *pet bird* includes the feature *being caged*, which is not included in the stereotype for *pet* or the stereotype for *bird* (see Fodor, 1998, for a review). If concepts combine compositionally (as argued above), they cannot be identified with stereotypes.

The Theory Theory and Concept Holism

Overview

Psychologists have developed an alternative to the prototype theory, called the theory theory. Theory theorists maintain that most lexical concepts are similar to scientific theories in a number of ways.

Firstly, theory theorists say that concepts encode knowledge about causal and explanatory principles just as scientific theories encode knowledge about laws and mechanisms (Murphy and Medin, 1985). In addition to knowing that birds fly and that birds have wings (two stereotypical features), people know that wings enable flight. Features that enter into such explanatory relations are more likely to be included in concepts and highly weighted.

Secondly, theory theorists claim that concepts encode the knowledge that the features essential to category membership may be unobservable, like the postulates of many scientific theories. Something is identified as being a horse by virtue of its appearance, but it really counts as being a horse only by virtue of having a particular microstructure. Echoing the *a posteriori* definition theory view, theory theorists recognize that concept users have faith in such essences without knowing what they are in detail. Keil (1989) demonstrates this experimentally. He asked subjects to consider an animal that began looking like a horse but was painted to look just like a zebra, and acted like one. Young children are deceived by the transformation, but the rest of us recognize that such a creature would still count as a horse.

Keil's experiments also illustrate a third claim of theory theorists. In contrast to the horse case, mature concept users believe that artefacts can change their identity when they are superficially transformed. When a coffee pot is modified to look and function like a bird feeder, subjects say it has become a bird feeder. This suggests that we treat different kinds of concepts differently. Theory theorists speculate that concepts are parceled into distinct cognitive domains, each dedicated to knowledge about a distinct class of entities and driven by distinct principles. For example, we may have naive theories of artefacts, biological kinds, intentional agency, and physical mechanics.

The fourth claim of the theory theory involves conceptual change. Children often use words in very different ways from adults. For example, a

young child might extend the word 'alive' to include cars and other inanimate objects (Carey, 1985). Such observations lead Carey to conclude that children's concepts may differ significantly from adults'. She argues that these differences lead to a certain degree of incommensurability, an idea she borrows from Kuhn's (1962) philosophy of science. Sometimes, a child's terms can be translated into our own without loss of meaning. This echoes the conclusion that Kuhn draws about terms used within different scientific theories.

The theory theory has been most explicitly defended by psychologists, but it is related to a class of theories that some philosophers defend. Quine emphasizes the continuity between theoretical knowledge and the totality of ordinary beliefs about a category. There is no obvious boundary between the knowledge that comprises our informal theory of a category and all other information associated with that category (recall Quine's confirmation holism). If concepts are identified via intuitive theories, then any given concept will be identified by a vast collection of beliefs comprised of other concepts, which will be identified by vast belief sets of their own. Following this logic, the identity conditions of any particular concept may depend on just about every other concept known to its possessor. This may be called 'concept holism'.

Without a clear boundary between theoretical knowledge and collateral information, theory theorists may be forced to embrace concept holism. Concept holism is often associated with meaning holism. If concepts are meanings, and concepts are identified by their place in a vast network of beliefs, then it is natural to conclude that the meaning of a term depends on a vast network of beliefs as well. As we saw earlier, concept holism is an unwelcome idea for defenders of the definition theory, who would wish to restrict concepts to discrete sets of necessary features. But it enjoys considerable support in its own right. Concept holists do not always emphasize the theoretical nature of concepts, and theory theorists do not always emphasize concept holism, but these two approaches may have a tendency to coincide.

Assessment

The theory theory and concept holism are open to objections. Like the stereotype theory, they face difficulties with concept combination: how do vast bodies of information combine compositionally? But there is a more pressing problem. If concepts are comprised of everything we know about a category, then no two people would share concepts, because different people's knowledge varies to some degree (Fodor and LePore, 1992). One might try to avoid this problem by saying that people have similar concepts rather than identical concepts. But Fodor and LePore reply that holism offers no way of quantifying similarity between people's concepts. We cannot say that concepts are similar by virtue of having some of the same constituent features, because each feature is itself a concept that, for the theory theorist, must be identified with an entire body of knowledge. If concepts cannot be shared, it is difficult to explain how communication ever occurs. To avoid such difficulties, theory theorists can try to distance themselves from concept holism by identifying a boundary between theoretical knowledge and collateral information.

Informational Atomism

Overview

All of the accounts considered thus far assume that most lexical concepts embody knowledge of the categories they represent. Fodor (1998) argues that any proposal of this kind is doomed to failure. Concepts cannot be definitions, because definitions are too scarce; they cannot be stereotypes, because stereotypes are not compositional; and they cannot be theories, because theories are not shared. The only way to avoid all of these problems is to deny that concepts embody knowledge.

Fodor calls his theory 'informational atomism'. It is called atomism, because it asserts that most of our lexical concepts are primitive. They neither entail nor decompose into any features. Instead, concepts are individuated by the properties to which they refer. They come to refer by means of 'informational semantics'. Informational semantics says that a concept refers to a property by virtue of being lawfully caused by that property. A *dog* concept refers to doghood because it becomes active when one encounters dogs. Fodor does not deny that we associate a considerable amount of knowledge with our *dog* concepts (including dog prototypes and dog theories), but he denies that this knowledge is conceptually constitutive. The *dog* concept can be regarded as an inner label in a language of thought. In principle, one could have the very same label even if one's dog prototypes and theories changed or disappeared entirely.

Inner labels can be compositionally combined, because their content is exhausted by their referents. There is no problem of compounds having features not found in their components. Inner labels can also be readily shared. Two people have the same concept by virtue of having labels

that are lawfully caused by the same objects, even if their beliefs about those objects differ radically.

Assessment

Fodor's concepts are well suited to serve reference, combination, and communication functions, but these benefits come at a price. If concepts do not decompose into features, they cannot satisfy the knowledge, inference, or categorization functions: the very functions that motivate most psychological work on concepts. Fodor also faces the challenge of explaining concept acquisition. Traditionally, primitive concepts are presumed to be innate. If most lexical concepts are primitive, then most lexical concepts are innate (Fodor, 1975; but cf. Fodor, 1998). Many find this consequence unsettling.

CONCLUSION

Concepts are postulated to serve a variety of functions. These include roles in reference, knowledge, inference, categorization, combination, communication, and meaning. A number of theories have been proposed, but each seems to have serious limitations. Some researchers argue that we must reduce the list of functions that concepts ought to serve, while others hope for a more encompassing theory.

Connectionism and Systematicity

Intermediate article

Robert J Matthews, Rutgers University, New Brunswick, New Jersey, USA

CONTENTS

Connectionists claim that human cognitive computational architecture is connectionist. Proponents of classical computational architectures have challenged this claim, arguing that a pervasive feature of human cognition, its 'systematicity', cannot be explained in connectionist terms.

INTRODUCTION

Connectionists claim that human cognitive computational architecture is connectionist, specifically that connectionist computational architectures provide an empirically more plausible foundation for computational theories of cognition than do more familiar classical computational architectures. Classicists, who conceive of cognition as implemented by a classical computational architecture, specifically as the structure-sensitive processing of syntactically structured mental representations, argue that the prospects for a connectionist theory of cognition are remote. Connectionist models, they contend, cannot explain, or at least have not shown that they can explain, any of the fundamental aspects of human cognition, most notably its seemingly pervasive 'systematicity', namely: the fact that many cognitive capacities are systematically related, so that as a matter of psychological law one possesses one capacity if and only if one possesses the other.

THE FODOR–PYLYSHYN CHALLENGE TO CONNECTIONISM

As first issued by Fodor and Pylyshyn (1988), the challenge to explain systematicity was one that connectionists purportedly could not meet because connectionist architectures lacked an essential feature found only in classical computational architectures, namely, representational states with a compositional constituent structure. Classical architectures, Fodor and Pylyshyn argued, postulate certain syntactically structured mental representations that, like the sentences of a natural language, exhibit a compositional syntax and semantics, such that the semantic content of a complex representation is a function of the semantic content of its constituents and of its syntax structure. (The sentence-like character of the postulated representations explains why classicists sometimes call these 'language of thought' architectures.) The computational processes that operate over these compositionally structured representations apply by virtue of their syntactic properties. Connectionist representations, by contrast, lack such compositional constituent structure; hence, the computational processes postulated in connectionist architectures cannot, Fodor and Pylyshyn argued, be causally sensitive to constituent structure. But such sensitivity, they claimed, is essential to explaining systematicity. Fodor and Pylyshyn concluded not only that connectionist architectures could not explain systematicity, but that they were unable even to exhibit systematicity: 'the architecture of the mind is not a connectionist network'.

Fodor and McLaughlin (1990) put the challenge to connectionists this way: how can you 'explain the existence of systematic relations among cognitive capacities without assuming that cognitive processes are causally sensitive to the constituent structure of mental representations'? Fodor and McLaughlin argue that connectionists are faced with a dilemma: 'if connectionism can't account for systematicity, it thereby fails to provide an adequate basis for a theory of cognition; but if its account of systematicity requires mental processes that are sensitive to the constituent structure of mental representations, then the theory of cognition that it offers will be, at best, an implementation architecture for a "classical" (language of thought) model.' Given that a classical architecture could be

implemented on a connectionist architecture (just as connectionist architectures can be, and often are, implemented on a classical architecture), the challenge to connectionists, Fodor and McLaughlin argue, is to demonstrate that connectionism can explain systematicity without implementing a classical architecture.

Fodor and Pylyshyn (1988) offer little by way of a characterization of the property – systematicity – that connectionists are challenged to explain. Instead they offer numerous examples of systematically related cognitive capacities. Many of their examples are drawn from language. They note, for example, that you do not find subjects who know how to say in English that John loves the girl, but who do not know how to say in English that the girl loves John; or who can understand the English sentence 'the monkey bit the lab technician', but who cannot understand the systematically related English sentence 'the lab technician bit the monkey'. In Fodor and McLaughlin (1990), and especially in McLaughlin (1993), systematicity is described more broadly, as a capacity for *intentional*, more specifically 'propositional attitude', states whose contents are systematically related, such that one has the capacity for one such intentional state (e.g. believing that the circle is above the square) just in case one has the capacity for systematically related states (e.g. believing that the square is above the circle).

PHILOSOPHICAL RESPONSES TO THE CHALLENGE

Some connectionists have been willing to accept the classicists' challenge, undertaking to demonstrate that their networks can, at least in principle, explain systematicity (and furthermore do so without implementing a classical architecture). Others have rejected the challenge, arguing that as posed the challenge is impossible to meet. They argue that the classicists' notion of what it would be to explain systematicity, indeed their notion of systematicity itself, at least as regards thought, is such as to insure that there can be no non-classical explanation of systematicity. Some also question the classicists claim to have an explanation themselves, thus challenging the presumption that connectionists are worse off in this respect than classicists.

The classicists' notion of systematicity in language processing capacity is relatively uncontentious: a language processor can be said to exhibit systematicity if when it can process a sentence s it can also process systematic variants of s, where systematic variation is understood in terms of permuting syntactic constituents or substituting constituents of the same syntactic category. Their notion of systematicity of thought is considerably more contentious. Fodor defines it in terms of being able to think thoughts of one form (e.g. *aRb*) just in case one can think other thoughts whose forms are systematically related to the first (e.g. *bRa*). But this characterization, as Cummins (1996) points out, begs the question, since it assumes that thoughts have the form of their classical linguistic representations. This objection can be avoided by reformulating the systematicity claim as follows:

> Anyone who can think a thought with the content c can think a thought with the content c^*, where c^* is a systematic variant of c. (1)

But this reformulation, Cummins notes, relativizes the systematicity of thought to the choice of some representational scheme for thought contents. Yet surely the systematicity of thought, which connectionists are challenged to explain, should not depend on the representational scheme that we, as theorists, choose to employ. For without some way of picking out systematically related thought contents (and hence systematically related thoughts), a way that is neutral regarding the representation scheme, it is not clear that any real property of thought has been identified for connectionists to explain. Nor is there any non-question-begging way of arguing from the systematicity of thought to the conclusion that human cognitive architecture is exclusively classical.

The challenge to connectionists is to *explain* systematicity, not simply to construct a connectionist network that exhibits it. Classicists have a narrow notion of what would count as an explanation of systematicity, one that connectionists might have difficulty satisfying even if they were successful in constructing a network that exhibited systematicity. McLaughlin (1993), for example, requires that explanations of cognitive capacities, including systematically related cognitive capacities, explain what the capacity 'consists in'. More precisely, he requires that the explanation take the form of a 'functional analysis'; i.e. an explanation of a complex cognitive capacity such as the capacity for systematic thought in terms of the cooperative interaction of certain more primitive cognitive capacities that are constitutive of the complex capacity. Systematically related cognitive capacities, McLaughlin assumes, are so related by virtue of certain shared constitutive capacities, so that to explain the former is to specify and describe these shared constitutive capacities and their interaction.

Functional analysis offers a plausible form of explanation if classicists are right in their assumptions about the nature of systematically related cognitive capacities. But these are not assumptions that connectionists accept; moreover, it is not clear, as Matthews (1997) argues, that any cognitive explanations that connectionists might provide could take this form. Connectionist networks do not have constitutive capacities of the sort that functional analysis envisions. Of course, the individual units that compose connectionist networks are constituents of those networks, but arguably they are not cognitive constituents of the networks in the classicists' sense of that term; i.e., they are not amenable to cognitive or intentional interpretation. And even if they were constituents in the requisite sense, there would still be a problem of explanatory 'grain': it would in most cases be very difficult, if not impossible, to grasp how the molar capacity of the network comprises ('consists in') the capacities of the individual units that constitute it. The specific contributions of individual units would typically be so diffuse as to preclude any claims about which units are responsible for which aspects of the networks' molar capacity; moreover, the number of units would typically be so large, and their interaction so complex, that it would be beyond our cognitive capacity to grasp how the molar capacity of the network could 'consist in' the capacities of the individual constitutive units.

To concede that connectionist explanations of cognitive capacities are unlikely to take the form of a functional analysis is not to concede that connectionists are unable to meet the classicists' challenge to explain systematicity (assuming that we can define in a non-question-begging way just what it is for thought to be systematic). Rather, it is to point out that *a priori* assumptions about the appropriate form of cognitive explanation are vulnerable to empirical discoveries about the nature of human cognitive architecture. Empirical discoveries about the bases of cognition may entail corresponding changes in what we take to be the appropriate form that explanations of cognition should take.

EMPIRICAL RESPONSES TO THE CHALLENGE

The empirical response to the classicist challenge has thus far been directed primarily towards demonstrating that connectionist networks can, in principle at least, *exhibit* systematicity in domains such as language processing. Thus, for example, Chalmers (1990) describes a connectionist network that is, he says, a 'direct counterexample' to the argument of Fodor and McLaughlin (1990) that to support structure-sensitive processing, representations of constituent structure must contain explicit tokens of the constituents. In part, this response has been prompted by suggestions to the effect that connectionist architectures are unable to explain systematicity because they cannot perform certain computational tasks that classical architectures can. No one challenges the well-known formal proof that connectionist architectures can compute (or at least approximate to any arbitrary degree) any computable function (Hornik *et al*., 1989), but some have suggested that connectionist architectures may be limited computationally in ways that classical architectures are not. McLaughlin (1993), for example, speaks of connectionist architectures being able only to 'respect' certain syntactic operations that classical architectures can actually execute. Connectionists would naturally wish to dispel any suggestion that connectionist architectures are computationally limited in ways that would prevent them from exhibiting, and hence from explaining, systematicity.

Smolensky has argued that connectionists can explain systematicity, and furthermore can do so without implementing a classical architecture (Smolensky, 1991, 1995; Smolensky *et al*., 1992). He argues that: (1) connectionist networks are naturally viewed as computing functions defined over vector product representations (i.e. over representations of a vector algebraic form); (2) such representations are adequate to express all constituency relations expressible by means of classical representations; (3) all computational operations definable over classical representations can be effected by connectionist operations defined over vector product representations; and hence (4) connectionists can explain systematicity in terms of such representations. Smolensky presents what he calls an 'integrated connectionist/symbolic architecture' that provides an algorithmic encoding scheme for moving between these two forms of representation. Fodor and McLaughlin (1990) criticize Smolensky's explanatory claims, largely on the grounds that vector product representations only encode but do not actually possess the constituent structure that a classicist explanation of systematicity presumes.

Whatever the merits of these criticisms, Smolensky's argument is clearly a non sequitur. It takes non-epistemological premises regarding the computational capacity of connectionist devices and the availability of a vector product representation of their operations, and reaches an epistemological conclusion regarding the availability of an

explanation of the systematicity that connectionist networks so described can exhibit. But the argument nonetheless draws attention to both the known capacity of connectionist networks to compute arbitrary computable functions and the availability of a principled non-classical, specifically vector product, description of the computations of such networks.

CONCLUSION

Much of the empirical response of connectionists to the classicists' challenge has focused on establishing that connectionist networks can do the sorts of things that classicists have claimed that they cannot do. Connectionists have made a good case for the claim that connectionist networks can in principle exhibit systematicity, at least in domains such as language processing where it is tolerably clear what systematicity amounts to. But arguably connectionists have yet to demonstrate that what is in principle possible can in fact be accomplished. It also remains to be seen whether connectionists can actually explain systematicity, especially the systematicity of thought, assuming that classicists and connectionists can agree on what is to be explained and what is to count as an explanation. Ultimately, these are matters for empirical investigation, and cannot be decided *a priori*.

Consciousness and Attention

Gregory J DiGirolamo, University of Cambridge, Cambridge, UK
Harry J Griffin, University of Cambridge, Cambridge, UK

CONTENTS

The concepts of consciousness and attention have been used in many ways and the processes that constitute them are not well agreed upon. Attention may be considered as an agency for bringing a stimulus into conscious awareness.

INTRODUCTION

It is hard to define consciousness or attention because these concepts have been used in many ways and the processes that fall under these umbrella terms are not well agreed upon. It is even more difficult to specify the functions and mechanisms of consciousness that lead to coherent behavior. Our strongest indication of consciousness remains the subjective experience. Nevertheless, advances in the scientific study of consciousness such as neuroimaging studies of perceptual awareness have given an anatomical and functional reality to both attention and consciousness in the human brain. This article looks at models of attention in order to explore the cognitive processes and neural substrates that may be shared between attention and consciousness. Evidence from cognitive neuroscience (the study of how the human brain carries out psychological processes) is applied to elucidate the complex relationship between consciousness and attention, and to enhance our understanding of both concepts.

THE RELATIONSHIP BETWEEN CONSCIOUSNESS AND ATTENTION

As early as the nineteenth century, psychologists and philosophers were suggesting a close relationship between attention and consciousness. William James (1890) succinctly captured this intuitive connection: 'Everyone knows what attention is … Focalization, concentration of consciousness are of its essence … My experience is what I agree to attend to.'

Attention and consciousness share many features, perhaps the most striking commonality being that at any given moment, one object or thought seems to predominate in the focus of attention and hence in our conscious awareness. In most situations in everyday life we are constantly bombarded by a variety of external stimuli from all sensory modalities (e.g. tactile, visual, and auditory) as well as by our own internal thoughts and memories. It would be difficult for an organism to achieve coherent, goal-directed behavior if all stimuli in the environment were processed and responded to in turn without prioritization. One can bring attention to bear on any of these objects (such as the background noises while you are reading this page), and suddenly this stimulus becomes the primary sensation or attribute in conscious awareness. It is, of course, possible to switch quickly between disparate thoughts or different objects in the environment; yet, the subjective experience is that only a single object is in attention or consciousness. Note that the perception of other objects in the environment remains, but when not the focus of your concentration the unattended objects have a vague, indistinct quality. (*See* **Consciousness, Unity of**)

With advances in neuroimaging it is now possible to investigate noninvasively the workings of the human brain as the subject attends to and becomes consciously aware of a stimulus. In addition, disorders of conscious awareness and attention following injury or psychosis have furthered our understanding of how these processes are carried out by the human brain as well as the relationship between attention and consciousness. (*See* **Consciousness, Disorders of**)

EXPERIMENTAL WORK ON ATTENTION AND CONSCIOUS AWARENESS

An important issue in the field of attention is how attention influences stimulus processing. Does attention manifest itself as alterations in the beta parameter (response biases), of a signal detection analysis or as changes in the d′ parameter (perceptual sensitivity)? In a typical experiment, participants were asked to keep their gaze fixed at a central point of a screen with four peripheral locations marked by small boxes. One location was cued (either by a brightening of that location's box, or by an arrow pointing to that location) so that participants could move their attention (but not their eyes!) to that location ahead of the actual target. A near-threshold target then appeared either at the cued location (valid) on 75% of trials, or at one of the uncued locations (invalid) on 25% of the trials. Reaction times to targets at the attended location were significantly faster and more accurate than targets at the uncued location. In addition, perceptual sensitivity changed at the location that was validly cued. Such studies demonstrate that attention to a location changes the sensitivity to incoming stimuli and makes these stimuli more perceivable. Targets at uncued locations were sometimes completely missed; that is, near-threshold targets at unattended locations did not receive sufficient attentional processing to enter conscious awareness. This simple behavioral paradigm suggests that items that are attended are processed more efficiently and enter consciousness; without attention, the individuals may not be aware of the item at all. (*See* **Attention, Neural Basis of**)

CONSCIOUSNESS AND ATTENTION IN NEUROPSYCHOLOGY

Neuropsychological evidence also elucidates the relationship between attention and awareness. One of the most striking findings is that lesions of the parietal lobe (particularly the right parietal lobe) produce specific deficits in attention. In the immediate aftermath of damage to the right parietal lobe, these patients will 'neglect' (not attend to or be aware of) information coming from the contralesional side of space (the side opposite to the hemisphere with damage). The side of space is important, as information from the left side of space is processed first by the right hemisphere, and vice versa; in addition, each hemisphere controls the opposite side of the body. In its severest form, patients with neglect fail to comb one side of their hair (the contralesional side) and eat off only one side of their plate (the ipsilesional side). If approached by a person on each side, these patients will look at the person on their ipsilesional side, even if the person on the contralesional side is the one who is speaking. They seem to fail to be consciously aware of information coming from the side of space processed by the damaged hemisphere. In fact, this deficit is so severe that, following a stroke producing neglect in the German painter Anton Räderscheidt, a self-portrait shows that, in the painting, he fails to represent the information from the contralateral side of space, including one side of his face. Fortunately, this deficit often resolves over time. (*See* **Attention, Neural Basis of**; **Attention**)

This deficit is not perceptual but rather attentional. For example, if patients with neglect are asked to create a visual mental image (e.g., the central square of their home town), they fail to report items on the left side of their mental image. However, if they are then asked to imagine walking to the opposite end of the square and turning around (so that the left and right sides are reversed), and to report what they see in their image, they will then report all of the items they failed to report from the previous view, and fail to report all the items they have just described. In this case, the patients are neglecting not incoming sensory information, but the represented visual image. Since the information is clearly present (as they report the entire representation between the two perspective shifts), these results suggest that the impairment is nonsensory in nature.

This deficit is not a general impairment, but specific to aspects of spatial attention. In people with neglect, their ability to shift attention to the contralesional side is severely impaired. Stimuli from the contralesional side appeared to have greater difficulty in summoning attention under conditions when the person is already processing something on the ipsilesional side. Thus, while normal people showed only a small deficit in reaction time when the target appeared in the opposite visual field from an attentional cue (invalid trials), people with neglect were often simply unaware of targets presented in the neglected field. Since these people were unable to report the mere presence of a target if their attention had been previously summoned to the good visual field, this finding suggests that attention is necessary for objects to come into conscious awareness. (*See* **Attention**)

Additional studies indicate that stimuli are processed in the neglected visual field even if unconsciously, and awareness is still possible under the

appropriate conditions. For example, while experimental subjects might miss a contralesional target (a circle) in isolation, they might report the stimulus if it integrated with material on the ipsilesional side to make a single form, such as a dumbbell. Moreover, information in the neglected field can sometimes affect processing of items in both fields. Some patients will fail to be aware of an item in the neglected visual field if the item is also present in the good visual field (extinction). This deficit is ameliorated if the two items are different objects (e.g. a spoon and fork) rather than identical. Interestingly, these patients can tell if two objects (one in each visual field) are different, without being able to identify the object in the neglected field; this suggests that patients can process some information without attention, to the extent of telling differences between objects, while identity remains unavailable to conscious report. In addition, semantic information in the neglected visual field will affect processing in the good visual field – that is, the patient will respond faster to the word 'cat' in the good visual field if it has been preceded by the word 'dog' in the neglected visual field, than if it had been preceded by a neutral word in the neglected field. Hence, the word in the neglected visual field is processed to the level of meaning in the absence of attention and without conscious awareness.

These neuropsychological studies have outlined the depth of processing applied to an attended stimulus and implicated a strong relationship between spatial attention to and awareness of a stimulus. While most of these studies have dealt with deficits in spatial attention particular to disengaging and shifting attention in external space, we turn to one final syndrome following brain damage that suggests that attention also works on the object level to help bring stimuli into conscious awareness.

Damage to both parietal lobes (and the occipital lobes) can produce a condition known as Balint's syndrome in which patients can perceive only one object at a time. The visual system of these patients can 'see' the objects; however, attention can only be directed to one object at a time. Hence, these patients are only consciously aware of a single object. If presented with a comb, pen and fork, they will see only the comb, and then only the pen or only the fork. These results suggest that competition for conscious recognition is resolved through attentional processes, and without these processes objects cannot come into consciousness. Balint's syndrome demonstrates that objects excluded from awareness in favor of others need not lie within a specific region of external space. Rather, the simultanagnosia (inability to perceive two objects at the same time) indicates that a lack of awareness can be object-based. A single object may remain outside awareness despite being moved into a previously attended region of space. The return of this object to awareness may occur spontaneously; that is, the patient goes from seeing the fork to the pen. However, if the experimenter moves the object that is not currently in consciousness (the fork), the change in the attentional salience causes the patient to become aware of the moving object. This external change in the stimulus causes a shift in attentional bias from one internal representation (the pen) to the other (the fork). Likewise, a spontaneous shift in the object perceived is likely to be caused by a similar change in attentional bias between representations, but now in the absence of an external cue. (*See* **Attention**; **Attention, Neural Basis of**)

The lack of awareness in both neglect and simultanagnosia illustrates how the human brain chooses, from the representations offered to it, which objects enter into conscious awareness. When the neural areas underlying attention are damaged the number and breadth of these conscious interpretations becomes limited; these patients do not have even a vague, indistinct awareness of other objects in the environment (as normal people do even for objects outside their attentional focus). We now turn to studies in normal individuals that help to clarify the relationship between multiple representations, neural mechanisms of attention, and the entrance into conscious awareness.

DIFFERENT THEORIES OF CONSCIOUSNESS AND ATTENTION

Studies following brain damage have certain disadvantages as the lesions have ill-defined boundaries and may spread over areas that perform different functions. In addition, one must always be aware of the possibility of plasticity of function and the importance of patient strategies. However, a phenomenon exists that allows the study in normal people of the neural mechanisms of attention and its link to visual awareness: binocular rivalry.

Binocular rivalry occurs when dissimilar images (e.g. a face and a house) are presented to each eye. Instead of seeing a permanent mixture of the two monocular images, a multi-stable percept occurs in which the percept switches rapidly and involuntarily between the objects presented to each eye. Short periods of transition may also occur during

which the percept is a fusion of the two images. The more different the two stimuli are in orientation, color, contrast or movement, the less prevalent are periods of piecemeal perception. Also, increasing the contrast of one of the stimuli increases its superiority, leading to it being perceived for longer periods. Despite being out of conscious awareness when suppressed, the subordinate stimulus can still influence cognitive processing (e.g. adaptation or priming).

Usually, functional magnetic resonance imaging (fMRI) studies compare brain response under equivalent rivalry and nonrivalry conditions. The rivalry condition is achieved by presentation of two images (one to each eye). The nonrivalry condition consists either of alternating binocular presentations of each of the two stimuli, or of alternating dichoptic presentation of an image to the relevant eye and a uniform gray field to the other. The rate of alternations is matched to the participant's pattern of awareness in the rivalry condition. In the nonrivalry condition, changes in awareness are caused by an alteration in the visual stimulation, whereas in the rivalry condition, changes in awareness are caused by involuntary shifts from the internal representation of one stimulus (the house) to the representation of the other (the face) in the absence of an external cue. By comparing these two conditions, we are able to study the neural mechanisms of shifts of visual awareness.

Binocular rivalry provides an opportunity to study shifts in conscious perception in the absence of any changes to the external stimuli. Using functional imaging with binocular rivalry, we can measure neural activity in visual awareness associated with both stable perception and perceptual transitions. It is also possible to distinguish neural areas of the visual system in which activation corresponds to the changing percept from areas in which activation corresponds to the fixed retinal stimulation. If the activation of a neural area corresponds to the reported percept, it suggests that the visual scene has been resolved at that stage of processing in the visual system (or, that feedback from attention is modulating the neuronal response in order to coherently resolve and stabilize the visual percept). (*See* **Attention, Neural Basis of**)

Activation of the right frontal and parietal cortices has been noted in perceptual transitions during the rivalry condition. The association of right frontal and parietal areas with tasks requiring shifts of spatial attention (both voluntary and involuntary) is well established. As we have discussed above, damage to the parietal cortex leads to disorders of visual awareness, and indeed, the similarity between binocular rivalry and extinction is worth noting. In both cases, two objects are presented in the environment and impinge upon the retina, but one of the objects is suppressed from visual awareness. Although a perceptual shift in binocular rivalry does not involve a shift in external space, it does involve a shift in object-based attention. The reason for perceptual shifts may be differential activity in the neurons representing each object caused by selective habituation to the perceived stimulus. When sufficient habituation has occurred, attention may shift to the object that now has greater neuronal activity. Once this shift has taken place and attention is now directed to the other object's representation, attention acts to stabilize the percept by increasing the neuronal activity associated with the previously suppressed object in lower visual levels and to push the visual system into a different but equally stable perceptual state. The threshold for the attentional shift is likely to be smaller than the threshold for a change in awareness; hence, the activation of neural areas involved in attention (e.g. the parietal cortex) amplifies the representation prior to conscious awareness. As suggested in the section on extinction, one gateway into conscious awareness is the relative amplification of the representation of an object through attention.

This cyclic habituation and attention capture could produce a multi-stable state, which would be beneficial as it allows accurate perception of at least one part of the visual scene rather than a confused interpretation of the entirety of the visual input. The constant shifts may be indicative of the tendency of the visual system to shift attention automatically towards a salient or novel stimulus in order to orient towards possibly important events (either external objects or internal representations). For example, movement of an object in the environment is salient and produces a capture of attention. As discussed above, patients with Balint's syndrome will become aware of an object currently out of awareness if it is moved about (as attention is drawn to the movement, and then the object enters consciousness). In binocular rivalry, the salience of a stimulus is not associated with changes in the external stimulus, but with its neural representation reaching a threshold level of activation that is sufficiently greater than the representation of the other monocular input. The function of parietal structures could be to disengage attention from the previously perceived object representation and shift it to the now more active representation.

Traditionally it was thought that the resolution of the ambiguous visual scene in binocular rivalry was carried out at a relatively late stage in the visual stream after the processing of each monocular image. Indeed single-cell studies have demonstrated that the activity of the majority of neurons in the striate cortex is unaffected across perceptual changes during rivalry; that is, activity in primary visual cortex correlates with the retinal stimulation whereas activity in later visual areas corresponds significantly to the changing percept. In the inferotemporal cortex, the activity of the majority of neurons follows the percept rather than the retinal stimulation. Functional MRI studies have shown that areas linked to perception of specific object categories increase their activity when an exemplar is perceived. For example, activation in part of the fusiform gyrus correlates with the presentation of a face and is relatively specific for faces or face-like stimuli. During a binocular rivalry condition in which a face and a house are presented to each eye, activation in this fusiform face area is seen only when the percept is that of a face. The changes in activity of these later visual areas, in contrast to that of V1, are as large in the rivalry condition as they are in the nonrivalry condition where the stimulus is presented binocularly (e.g. a face is presented to each eye). These results suggest that the awareness is resolved in a somewhat gradual fashion throughout the visual system. However, at least in later visual areas, neural activity correlates with conscious awareness, not the retinal stimulation. (*See* **Attention, Neural Basis of**)

CAN THERE BE ATTENTION WITHOUT CONSCIOUS AWARENESS?

Finally, we turn to one other neuropsychological disorder to help constrain the relationship between attention and consciousness. As previously explained, people who have sustained brain damage often acquire disorders of thought, perception, or even consciousness. People with damage to the primary visual cortex may deny any conscious sensation of visual stimulation presented in their blind visual field; yet, their 'guesses' of whether an object is in this part of the visual field yield accuracy rates that are often over 90%. This astonishing effect, 'blindsight', has been observed in both monkeys and humans with either unilateral or bilateral damage to the primary visual cortex. (*See* **Blindsight**)

The phenomenon of blindsight suggests that the disruption of primary visual cortex results in a disturbance of visual consciousness; hence, intact primary visual cortex seems necessary for visual consciousness. Although lacking conscious representations of visual stimuli, blindsight patients seem to be 'aware without being aware', which bears upon how attention and consciousness are related. For detailed information into the experiments on patients with blindsight, we refer the reader to the excellent summary by Weiskrantz (1997). (*See* **Consciousness, Function of**)

Although the incidence of damage confined to primary visual cortex is rare, the research that has been performed on blindsight patients is consistent with experimental work on nonhuman primates. Two types of tasks have been used with human blindsight patients. One relies on the patient's conscious report. In this method, one of two possible stimuli is presented on each trial: on half the trials the stimuli are presented to the blind visual field, and the person is instructed to decide which of the two stimuli were presented. The blindsight participants always report seeing nothing in the blind visual field; however, they are able to report some information about or respond to the stimulus in the blind visual field (although they report that there is nothing there, they will eventually guess). These patients can orient their eyes or hands to the approximate position of a stimulus; they can also discriminate stimulus orientation or stationary versus moving objects, as well as the direction of a moving stimulus.

The other method of testing blindsight patients involves measuring whether information presented to the patient's blind visual field influences (i.e. primes) the subsequent material presented to their intact hemifield. Results suggest that blindsight patients often experience implicit processing of stimuli presented in their blind hemifield. For example, information presented to a participant's blind field (e.g. the word 'river') significantly changes the way processing occurs for stimuli presented in the intact hemifield (e.g. the word 'bank'). In this case, when an ambiguous word ('bank') was presented in the good visual field, its conscious meaning was significantly prejudiced by a previous presentation of a semantic relative in the bad visual field. This finding suggests that the primary visual cortex may be unnecessary for some types of unconscious processing (such as priming) that influences our conscious experience.

These results suggest that much of the information that is sensed in the world can be processed without conscious awareness. Does the processing of this information rely on attentional processes even without conscious awareness? Alternatively,

can attention work in the absence of conscious awareness? One telling experiment on a blindsight patient addressed this very issue (Kentridge *et al*., 1999). The researchers asked whether orienting of attention would occur in the blind visual field. Using cuing experiments, blindsight patients were given an arrow cue that either correctly or incorrectly predicted the location of a subsequent target. The cue and the target could occur in either the good or blind visual field. As with normal participants, there was a benefit in performance for targets that occurred in the validly cued location, even when the target occurred in the blind visual field and the patient reported no target but 'guessed' that a target was present. Even more revealing, there was a benefit for the validly cued target location even when the cue itself occurred in the blind visual field and was not 'seen'. These results suggest that attention and consciousness are not absolutely linked. Even in the presence of attentional benefits (speeded and more accurate response to a validly cued target), conscious awareness of the stimulus is not guaranteed. Nor is conscious awareness of the cue necessary for attentional benefits. Hence, attention is not a sufficient conduit to ensure conscious awareness, and awareness is clearly not necessary for attentional processing. (*See* **Attention, Neural Basis of**)

In our view, attention is one agency for conscious awareness of each stimulus. Attention works to increase the neural response of salient, task-relevant stimuli. A shift of attention (and the increased neural activity) brings a stimulus into conscious awareness; however, attention can act on a stimulus without bringing that stimulus into consciousness. As suggested in the section on binocular rivalry, the level of neural activity to attract attention is likely to be below that necessary for conscious awareness. While it is clear that attention can be sufficient to bring a stimulus into consciousness, further research is required to determine what the necessary conditions are for conscious awareness of a stimulus.

Consciousness and Higher-order Thought

Intermediate article

David M Rosenthal, City University of New York Graduate School, New York, New York, USA

CONTENTS

The higher-order-thought hypothesis is a proposed explanation of what it is for a mental state to be a conscious state and hence of how conscious mental states differ from mental states that are not conscious.

INTRODUCTORY

Any satisfactory theoretical treatment of consciousness must begin by distinguishing several phenomena to which the term 'consciousness' applies. We describe people and other animals as being conscious when they are awake and responsive to sensory stimulation. What it is for a creature to be conscious in this sense is primarily a biological matter and peripheral to cognitive science and related theory.

We also describe creatures as being *conscious of* various things, for example, when they sense those things or think about them as being present. Sensing and thinking are central to cognitive functioning, but their nature is not what theorists typically have in mind in discussing consciousness. Rather, theorists have in mind primarily a third application of the term 'consciousness', by which we describe thinking and sensing itself as being conscious or not. It is this third use which dominates theoretical discussion about consciousness. The central issue is what it is for a mental state, such as thinking, sensing, and feeling, to be conscious, and more specifically what distinguishes the conscious cases from those which are not.

THEORIES OF CONSCIOUSNESS

It is fundamental to a mental state's being conscious that the individual in the state is aware of being in it. This is clear from consideration of mental states an individual is unaware of. If somebody is altogether unaware of thinking, feeling, or sensing something, that thinking, feeling or sensing does not count as conscious. Part of what it is for a state to be conscious is that one is conscious of being in that state.

Some theorists deny this, arguing that we are never conscious of our conscious states (Searle, 1992), or at least that conscious states occur without one's being conscious of them (Dretske, 1995). Thus Dretske, for example, urges that a state's being conscious consists not in one's being conscious of it, but in one's being conscious of something by virtue of being in that state.

This view has a disadvantage. Since sensing and thinking about things typically make one conscious of them, such states could not, on this view, occur without being conscious. Such theorists accordingly argue that the usual examples given of mental states that are not conscious are unconvincing. One especially common type of example does seem vulnerable to this charge. Armstrong (1978/1980) and others have appealed to the case of the long-distance driver who seems for a time not to notice the road consciously. But it may be that the driver notices the road consciously but simply does not at all remember doing so.

There are, however, other examples of mental states that more indisputably occur without being conscious. People often act in ways that betray some feeling, or belief, or desire of which they are wholly unaware until it is pointed out to them; this even happens with pains that are revealed by gestures or bodily movements. And people sometimes respond in a very fine-grained way to things that

occur so far in the periphery of their visual field that they have no conscious perception of them.

Many experimental results confirm these commonsense observations (Merikle *et al*., 2001). In masked-priming experiments, subjects presented very briefly with two successive stimuli report not being aware of the first at all, even though that stimulus has a demonstrable effect on mental processing (e.g. Marcel, 1983a, 1983b). And blindsight subjects, in whom part of the primary visual cortex has been destroyed, deny seeing visual stimuli in the relevant area of the visual field, though they can be prompted to guess the visible characteristics of such stimuli with startlingly high accuracy (Weiskrantz, 1997). Though conscious sensing is absent in these cases, subjects' behavior indicate the occurrence of sensing that is not conscious.

Some theorists have argued that it is circular to explain a mental state's being conscious in terms of an individual's being conscious of that state, since that would be to explain consciousness by appeal to consciousness (e.g. Goldman, 1993). But that explanation is not circular. Being conscious of something is sensing it or thinking about it as present. And, since we understand what it is to sense something or think about it even when that sensing or thinking is not conscious, we understand what it is to be conscious *of* something independently of knowing what it is for mental states to be conscious.

Even if a state's being conscious consists in one's being conscious of that state, theories divide about just how one is conscious of one's conscious states. The traditional and most widespread view is that one senses or perceives one's conscious states. But thinking about something can also make one conscious of that thing, and an alternative theory has been developed on which we do not sense our conscious states, but instead are conscious of them by having thoughts about them. It is useful to refer to the thoughts or sensations in virtue of which one is conscious of one's mental states as 'higher-order thoughts' or 'higher-order sensations'.

THE INNER-SENSE MODEL

The idea that we sense our conscious states has a long history. Locke (1700/1975) speaks of an 'internal sense' by which we are conscious of our mental states, and Kant (1787/1998) speaks of 'inner sense.' More recently, the idea has been defended by Armstrong (1978/1980) and by Lycan (1996).

Several factors suggest an account in terms of such higher-order sensing. For one thing, nothing seems to mediate between the the things we sense and our sensing them. And this intuitively unmediated character of sensing might explain why the way we are aware of our conscious states seems to be direct and immediate.

Another factor has to do with the qualitative character of conscious sensory experience. That qualitative character enters our mental lives through sensing; thinking has no qualitative character. So it may seem that the only way we could be conscious of this qualitative aspect of experience is by sensing it. A third source of the idea that we sense our conscious states is the sense we have that we are regularly and reliably conscious of many of our own mental states. And the best explanation for this may be that we monitor our mental states in the way that our exteroceptive senses monitor the environment (Armstrong, 1978/1980; Lycan, 1996).

But these considerations are far from decisive. Although nothing seems to mediate between our mental states and our consciousness of them, we need not appeal to higher-order sensing to explain that appearance of immediacy. Having thoughts about our mental states would also make us conscious of those states, and if we aware of nothing mediating between those thoughts and the states they are about, our consciousness of those states would also seem to be unmediated.

Perhaps some monitoring mechanism in the brain does subserve our being conscious of many of our mental states, but monitoring need not be sensory. The brain monitors many bodily functions in ways that do not at all resemble sensing. What differentiates sensing from other processes are the distinctive qualitative properties that occur when we sense. When sensing is conscious, we are conscious of these distinguishing qualities, qualities that vary with what is sensed, though these qualities also occur without our being at all aware of them.

The third consideration that seemed to support the inner-sense model, namely, the qualitative character of sensing, actually provides a compelling reason to reject the model (Rosenthal, 1997). Although sensations and perceptual states exhibit distinguishing qualitative properties, the way we are conscious of our own mental states does not. This is evident when the states we are conscious of are thoughts, beliefs, desires, and other so-called intentional states; these states have no qualitative properties, and there is no qualitative character to the way we are conscious of them. But even when the states we are conscious of are qualitative, as with our sensations and emotions, the qualities

belong to the states we are conscious *of*, not to the way we are conscious of them.

Some theorists describe the inner-sense model in terms of higher-order perceiving of mental states (Güzeldere, 1995). Since perceiving, like sensing, has qualitative character, a higher-order perception view faces the difficulty that no higher-order qualities occur. But perceiving not only has qualitative character, but also resembles thinking in having conceptual content. So, if we had higher-order perceptions of our mental states, we would still need to determine whether the qualities or conceptual content of the perceptions were responsible for our being conscious of our mental states. Compare Güzeldere (1995), who argues that the higher-order-perception model collapses into a model that invokes higher-order thoughts.

THE HIGHER-ORDER-THOUGHT MODEL

The two ways of being conscious of things are sensing them and having thoughts about them as being present. Since we are not conscious of our mental states by sensing them, the best explanation of how we are conscious of some of our mental states is that we have higher-order thoughts (HOTs) about them (Rosenthal, 1986, 1993; in press a, b). It would be explanatorily empty to insist that we are conscious of them in some third way unless we have an independent grasp of what that third way consists in.

Difficulties with the inner-sense view actually suggest the HOT model. The higher-order states in virtue of which we are conscious of our mental states lack qualitative properties, and a thought that something is present makes one conscious of that thing in a way that involves no higher-order qualities. If there is a brain mechanism that monitors mental states, it might well make one conscious of those states by producing HOTs about them. And, if those HOTs seemed to arise independently of any inference, it would seem subjectively as though one is conscious of one's mental states in a way that is direct and unmediated.

It is important to distinguish between the ordinary way in which mental states are conscious and the focused, reflective way in which states can become conscious when we introspect them. The HOT model affords a natural explanation of this difference. The HOTs in virtue of which we are conscious of our mental states in ordinary, nonintrospective cases are not, themselves, conscious thoughts; HOTs make one aware of various mental states, but without one's being conscious also of the HOTs themselves. When one introspects a state, one deliberately focuses attention on it. One thereby becomes aware not only of the introspected state, but also of one's being conscious of it. So in these cases the relevant HOTs are themselves conscious thoughts (Rosenthal, 2000a).

Because HOTs need not be conscious, and indeed usually are not, people will normally be unaware of their presence. The occurrence of HOTs is not established by our being aware of them, since we are conscious of them only in the special case of introspection. HOTs are theoretical posits whose occurrence is established by theoretical considerations of the sort sketched above.

These considerations help dispel a certain misunderstanding. It is sometimes held (e.g. Block, 1995a; Chalmers, 1996) that the HOT model explains only introspective consciousness. That would be so if the model appealed only to conscious HOTs, establishing their occurrence by way of subjects' reports. But the HOTs the model invokes typically are not conscious, and they are intended to explain ordinary, nonintrospective consciousness.

A HOT is a thought to the effect that one is in a particular state, and so makes reference to oneself. Such reference to the self does not require any sophisticated concept of the self, but only a concept strong enough to distinguish oneself from everything else and to form thoughts about the self thus distinguished (Rosenthal, in press c). Nor do HOTs need to describe their target states in terms of some concept of the mind; they can describe those states simply in terms of their role in perceiving, or thinking or in information-processing terms.

VARIANT HIGHER-ORDER-THOUGHT THEORIES

A number of variants HOT theories have been put forth. Some differ in only minimal ways from the hypothesis just described. For example, Mellor (1977–78) appeals to second-order beliefs to explain only what it is for beliefs to be conscious, and denies that such an explanation works for any other types of mental state. But the foregoing arguments apply equally to all types of mental state. And Rolls (1998) has argued for a model on which the HOTs must be linguistic in character. Since Rolls construes being linguistic to cover any syntactically composite mode of representation, this again is at most a slight modification of the model.

Brentano (1874/1973) argued that the higher-order state in virtue of which one is conscious of a

mental state is internal to the target state in question. Brentano's examples are largely perceptual, which leads Brentano to see the higher-order state as being perceptual as well; so his view may be best construed as a variant of the higher-order sensing model. Others have advanced views, however, that posit HOTs that are internal to their targets (Kobes, 1996; Gennaro, 1996).

But no view on which HOTs are internal to their targets is likely to succeed. Intentional states are individuated not only by their content but also by mental attitudes, such as mental affirmation, doubt, wonder, hope, and the like. Just as no single state can have two distinct contents, so no single state can exhibit two distinct mental attitudes. The mental attitude of HOTs is always assertoric; HOTs affirm that one is in a particular state. But, if HOTs were internal to their targets, then a conscious case of wondering something would exhibit the mental attitudes both of wondering and of affirming. So HOTs cannot in general be part of their targets. Similar considerations apply to Brentano's perceptual variant, since every perceptual state belongs to some sensory modality, and none of those standard modalities is suitable for making one conscious of one's mental states.

On another variant of the model developed by Carruthers (1996, 2000), a state need not be the object of an actual HOT to be conscious; it is enough that the state simply be *disposed* to cause a HOT about it. One main motive for this variant is that it avoids the high cost, both in computational capacity and cognitive space, of having actual HOTs for each of one's conscious states.

But that consideration is not all that compelling. HOTs very likely take less to implement cortically than their targets, since a HOT simply represents one as being in a particular state; so their causal connections will likely be far less complex than those of the perceptual and cognitive states the HOTs are about. And, since cortical capacity is known to be far from fully utilized, the cost of implementing actual HOTs is unlikely to be significant. Introspection makes this objection seem more pressing than it is. Because we are never conscious of many thoughts at once, it seems that we could not have many HOTs. But HOTs are seldom conscious, and we could have many at once that are not conscious. And introspection cannot be a reliable guide to the mind's nonconscious operations.

The principal reason for a higher-order account is to explain how we are conscious of all our conscious states. But being disposed to have a thought about something does not make one conscious of that thing. So the question arises about how a state's being disposed to cause a HOT could result in one's being conscious of that state.

Carruthers's answer appeals to a particular theory of mental content. On that theory, the content a state has is a matter of what it is disposed to cause. So Carruthers argues that a state's simply being disposed to cause a HOT can confer suitable higher-order content on the state itself. Both teleological (e.g. Millikan, 1984) and inferential-role (e.g. Block, 1986; Peacocke, 1992) theories of content might allow for this result. A state's having such higher-order content directed upon itself would then explain why one is conscious of being in that state.

This reply faces several difficulties. For one thing, these theories of content are far from uncontroversial, and it is preferable to have one's theory of consciousness committed to as little as possible that is not widely accepted. Moreover, since the higher-order content in virtue of which one is conscious of the state is internal to the state itself, the dispositional theory would face the difficulty about mental attitudes that faces any model on which the higher-order state is internal to its target.

Most important, any state with suitable first-order content would, on this model, have dispositional properties that result in its having higher-order content. So one would be conscious of any state that had that first-order content. Since a state's being conscious or not would depend on its first-order content, the model seems unable to explain how states of a given type can sometimes be conscious and sometimes not.

HIGHER-ORDER THOUGHTS AND SPEECH

It is widely accepted that, given a creature with suitable linguistic capacities, a mental state's being conscious coincides with that creature's ability to report noninferentially that it is in that state. Indeed, it is likely that this ability to report mental states noninferentially is what underlies the traditional intuition that we have special access to our mental states (Sellars, 1963).

This fits well with the HOT hypothesis. A noninferential report that one is in some mental state expresses one's thought that one is in that state, a thought that seems subjectively to rely on no inference. And it is arguable that the best explanation of this ability to report one's mental states noninferentially is that one actually has the HOTs that those reports would express (Rosenthal, 1993).

Some theorists hold that we cannot introspectively seem to be in a state that we are not in (e.g.

Nelkin, 1996). Moreover, the seemingly noninferential character of our HOTs may suggest that they reflect some special access we have to our mental states. But thoughts need not be accurate, and thoughts about one's own mental states are no exception. Our consciousness even of what states we are in can be erroneous.

This is evident from compelling experimental findings in which subjects report thoughts and desires that they do not actually have. As with reports of thoughts and desires that do occur, these confabulations tend to make *ex post facto* sense of subjects' behavior, by rationalizing that behavior or by conforming to expectations or preconceived ideas. But in these cases evidence exists that subjects do not actually have the thoughts and desires they report (Nisbett and Wilson, 1977). Such confabulation appears to happen even with qualitative states, such as bodily or perceptual sensations (Staats *et al*., 1998; Holmes and Frost, 1976).

These findings again fit well with the HOT model. When one confabulates being in some mental state, one is conscious *of oneself as being in that state*. And consciousness is a matter of how one appears to oneself. So, if one has a HOT that represents one as being in some state, there is nothing subjectively, from the point of view of consciousness, that could enable one to tell whether any such state actually occurs.

When one thinks that something has a certain property, one in effect interprets that thing as having the property. So having a noninferential HOT that one is in some mental state amounts to spontaneously interpreting oneself as being in that state. This echoes Dennett's (1991) interpretivist account of consciousness. But Dennett (1987, 1991) holds that one's being in a mental state at all, independent of whether that state is conscious, is a matter of one's being subject to some appropriate interpretation. The HOT model does not endorse that more general view.

Because conscious states are sometimes confabulated, the states one is conscious of oneself as being in do not always exist. So we cannot describe a conscious state as a state that bears some actual relation to a HOT. Rather, a state's being conscious must consist in its being the *intentional object* of a HOT, the object that the thought seems to be about. And, because the state may not actually occur, we also cannot require that it cause the HOT.

OBJECTIONS

The HOT hypothesis is sometimes seen as a claim about the *concept* of a mental state's being conscious (Goldman, 2000). Construed as a hypothesis about conceptual analysis the hypothesis is implausible, since it seems *conceivable* that a state accompanied by a HOT could fail to be conscious (Balog, 2000; Rey, 2000). But the HOT model is best taken not as a conceptual claim, but as an empirical hypothesis about the nature of consciousness. On that construal, though we can conceive of a state's being accompanied by a HOT without being conscious, it turns out empirically that this never happens. One might also object that any specification of the nature of consciousness purports to state a metaphysical necessity, and the HOT hypothesis is not metaphysically necessary. But, even apart from the difficulty of determining what is metaphysically necessary in a way that is not question begging, it is arguable that the HOT hypothesis is necessary if at all only in the way in which truths of natural science are.

It is sometimes argued that the stipulation that HOTs be noninferential is arbitrary, since it should not matter to a state's being conscious whether the accompanying HOT is caused by an inference (Byrne, 1997; Seager, 1999). But the aetiology of the HOT does not matter, only the appearance of aetiology. A state is conscious only if we are conscious of it in a way that *seems* spontaneous and noninferential. As long as it seems that way, it does not matter how it is caused. Nor is there any problem about establishing a causal or other connection between HOTs and their targets, as Natsoulas (1993) argues, since the targets are simply whatever states the HOTs are about.

Having a thought about something normally has no effect on it, and in particular does not make that thing conscious. So it may be objected that having a thought about a mental state could not result in that state's changing from not being conscious to being conscious (Block, 1995b; Byrne, 1997; Rey, 2000). But when a state becomes conscious that is not a change in the state itself, but only in whether one is noninferentially conscious of it; being conscious is not an intrinsic property of mental states.

Still, an objector might persist, since having a noninferential thought about a physical object does not result in that object or state's being conscious, why should having a HOT about a mental state result in that state's being conscious? But the only way objects might be conscious is the way a creature can be, by being awake and responsive to sensory input; objects cannot be conscious in the way mental states are. Still, having noninferential thoughts about states of one's liver presumably would not make those states conscious (Block, 1995b). But not every state can count as conscious.

A state can be conscious only if being in it, even when the state is not conscious, results in one's being conscious *of* something, and states of the liver do not qualify (Rosenthal, 2000b).

Dretske has argued that a mental state's being conscious cannot consist in one's having a HOT about it, since there are cases in which a state is conscious without one's being conscious of it. Dretske offers the example of consciously seeing two scenes that differ in some single way without one's consciously noticing that they differ at all. Since one does not notice that the scenes differ, one also does not notice the difference between one's conscious visual experiences of the scenes. But every part of the two experiences is presumably conscious. So, if one is not conscious of that part of the experiences in respect of which they differ, that part is a conscious experience of which one is not conscious (Dretske, 1995). But all that Dretske's case shows is that one need not be conscious of that part *as* the part that makes a difference between the two experiences, not that one is not conscious of that part in some other way (Seager, 1999; Byrne, 1997; Rosenthal, 1999). It may well be that we are conscious of all our conscious experiences.

Conscious states presumably occur not just in humans, but in other animals as well. So perhaps conscious states occur even in animals whose mental functioning is too primitive to accommodate HOTs (Block, 1995a; Dretske, 1995; Byrne, 1997). Indeed, Carruthers (2000) actually argues that few if any nonhuman animals have HOTs. And he concludes that they lack conscious states, though many will resist that conclusion.

In any case, the reasons for thinking that few nonhuman animals have HOTs are not fully convincing. Carruthers (2000) argues that animals with HOTs would also have thoughts about the mental states of others. And he holds that having thoughts about the mental states of others would express itself in deceptive behavior, which he urges nonhuman animals do not engage in (cf. Povinelli, 1996). But it is arguable that many nonhuman animals do engage in deceptive behavior (Whiten, 1996; Whiten and Byrne, 1997). Nor, in any case, is it obvious that creatures would not have HOTs unless they had thoughts about the mental states of others (Ridge, 2001).

It might seem that nonhuman animals lack the conceptual resources needed to have HOTs. But HOTs do not require the elaborate conceptual apparatus characteristic of humans; they are simply thoughts that one is in states of particular types, states which we humans classify as mental.

At the same time, it is not obvious which nonhuman species do have mental states that are conscious. Though many such species plainly do sense and think, that does not show that their thinking and sensing are conscious; states can exhibit the characteristic causal roles of mental states without a creature's being conscious of being in those states. Some way independent of human subjective impressions is needed to establish which species do have mental states that are conscious.

As noted above, it is one thing for a creature to be conscious and another for its mental states to be conscious. Still, it might seem that a creature cannot be conscious unless at least some of its mental states are conscious; whenever humans are awake, after all, they are in some conscious states. But this may not hold generally. For a creature to be conscious it must function in characteristic mental ways, but it can do that without its mental states being conscious.

It is natural to think that a mental state's being conscious serves some useful function, such as enhancing the rationality of thinking and planning (Nelkin, 1996). But the function a mental state serves is a matter of its causal role, and the causal role a state has may well be largely unaffected by being accompanied by a HOT (Dretske, 1995).

Accompanying HOTs might, however, actually alter a state's causal role, and a state together with a HOT will in any case have a different combined role from the state without any HOT. Indeed, it has been argued that HOTs enable the correction of plans that result from first-order processing (Rolls, 1998).

There are also experimental findings that subjects sometimes perform tasks better when stimuli are consciously perceived than when perceived nonconsciously (Merikle and Daneman, 1998). Since the relevant tasks require conscious thought, the difference may be due to operation of HOTs in the conscious cases.

There is a compelling intuition that our conscious states constitute some kind of unity, and one might object that a theory on which mental states are conscious in virtue of many distinct HOTs cannot do justice to that intuition (Shoemaker, in press). But since the content of each HOT is that one is, oneself, in some state, such reference to oneself will give rise to a conscious sense of unity (Rosenthal, in press c).

QUALITATIVE CONSCIOUSNESS

Perhaps the most important objection has to do with qualitative consciousness. It has been argued

that HOTs cannot capture the enormous detail characteristic of conscious qualitative states (Byrne, 1997). And some have argued also that HOTs, which are nonqualitative, could not result in there being something it's like for one to be in various qualitative states (Byrne, 1997; Siewert, 1998; Balog, 2000).

It is easy to exaggerate the qualitative detail we are conscious of at any moment. It is well known that Parafoveal vision yields scant detail. More dramatically, recent work on change blindness shows that we often fail consciously to notice significant changes in a scene we are attentively looking at (Grimes, 1996; Rensink, 2000; Simons, 2000), which suggests that our impression of great conscious qualitative detail is erroneous (Dennett, 1991). And HOTs could presumably capture the detail present in any relatively small area of a sensory field on which one consciously focused.

We do not have concepts for all the individual qualities we are conscious of, but we have concepts for the ways those qualities vary. So HOTs can represent individual qualities comparatively. This may explain why we can judge whether qualities are the same far better when they are all present than when we must rely on memory (Raffman 1995). And, though concepts may be ill suited to capture the way qualitative states represent things, we are typically conscious of the relevant qualities in a way that lends itself to conceptualized description.

It is important not to place excessive demands on an explanation of qualitative consciousness. Very likely no explanation will reveal a conceptual or rational connection between nonconscious resources and conscious qualities (Levine, 2001), but scientific explanation seldom does that. Nor should we expect to discover an introspectible connection between conscious qualities and nonconscious resources, since nothing that is not conscious is available to introspection.

In any event, there is reason to think that HOTs do figure in there being something it's like to be in conscious qualitative states. We often come to be conscious of qualitative differences only when we come to have concepts fine-grained enough to draw those qualitative distinctions: for example as between similar musical instruments or tastes of wine. Such concepts would matter to how those experiences are conscious only if our thoughts about the experiences made a difference to how we are conscious of them (Rosenthal, in press a).

THE SCIENCE OF CONSCIOUSNESS

Although the foregoing arguments in support of the HOT hypothesis do not rely on empirical investigation, the hypothesis meshes fruitfully with scientific findings. Two examples already noted are change blindness and confabulated mental states. But there are others as well. As Weiskrantz (1997) has urged, a HOT model helps explain the phenomena of blindsight. Rolls (1998) argues for his linguistic version of the HOT hypothesis by appeal to different neural pathways that seem to subserve conscious and nonconscious stimulation. Dienes and Perner (2001) have appealed to the HOT model in distinguishing implicit from explicit knowledge and representation, and Dienes (in press) has applied the model in connection with implicit learning and subliminal perception.

The HOT model is particularly useful in explaining the finding by Libet (Libet, 1985) that the neural readiness potentials identified with subjects' decisions occur measurably in advance of subjects' awareness of these decisions, findings recently replicated and extended (Haggard and Eimer, 1999). It is natural to explain this result by supposing that the HOTs in virtue of which subjects become aware of their decisions occur measurably later than those decisions (Gomes, 1999; Rosenthal, in press d).

Frith and Frith (1999) report a number of studies in which functional brain imaging reveals neural activation in subjects who were asked to report their mental states. Strikingly, conscious monitoring of states results in activation of a single brain area, medial frontal cortex, even when the states monitored are as disparate as pain, tickles, emotions aroused by pictures, and spontaneous thoughts. This activation does not occur cortically where the monitored states occur; so a single, independent brain mechanism seems to subserve the monitoring that makes possible the reporting of mental states. Since reports of one's mental states express one's thoughts about those states, it is inviting to construe that activation as indicating the occurrence of HOTs.

Consciousness and Representationalism

Intermediate article

Benj Hellie, Sage School of Philosophy, Cornell University, Ithaca, New York, USA

CONTENTS

The representationalist theory of consciousness is the view that consciousness reduces to mental representation. This view comes in several variants which must explain introspective awareness of conscious mental states.

INTRODUCTION

Some mental states and processes are like something to their subjects; others are not. For instance, the states of seeing a stop sign, of hearing a screech, and of smelling gasoline are like something; as are the states of feeling fear, elation, or pain; as is the process of talking oneself through a problem. In contrast, states and processes that are not like anything to their subjects are accepted by both scientific and common sense psychology. Chomskian linguistic theories and Marrian theories of vision posit complex subpersonal operations, which make a difference to what one's mind is like to one only by their effects; common sense recognizes states of believing and intending that persist through dreamless sleep. States and processes that are like something to their subjects are conscious; otherwise not.

Among conscious states, what they are like to their subjects can differ: what seeing a red thing is like is standardly different from what seeing a green thing is like; what both are like differs from what smelling gasoline is like. A state has a 'phenomenal character' just in case it is conscious, or like something to its subject; two states have the same phenomenal character just in case what one is like to its subject is the same as what the other is like to *its* subject.

Phenomenal characters pose special problems for a fully naturalistic theory of the mind, for it may seem baffling how these properties can arise ultimately from interactions of particles and fields, or from processes in the brain. Wittgenstein famously wondered how *this* – his then current headache – could be a brain state; such bafflement is a proper reaction to the great difference in the ways in which phenomenal characters present themselves when thought of as phenomenal characters from the ways in which brain properties present themselves when though of as brain properties.

Representationalism is a view that attempts to naturalize phenomenal character without generating such bafflement by adopting a two-stage naturalistic reduction. The representationalist hopes that an intermediate reduction to certain representational properties will not generate bafflement; and that these representational properties may be reduced in turn, through one of the many ambitious projects for naturalizing mental representation.

WHAT IS REPRESENTATIONALISM?

Representationalism is the view that phenomenal characters somehow reduce to representational properties. The notion of a representational property deserves some expansion.

A state has a representational property when, to put it intuitively, it has a meaning or somehow stands in in some process for something else, such as an object, or a 'proposition' – a putative fact. Paradigmatic mental representational states are beliefs: one who believes that snow is green is in a state which means that snow is green, and which stands in for the putative fact that snow is green in a subject's reasoning. Another example is the state of thinking of Vienna: such a state means, or is about, Vienna; and stands in for Vienna itself in the subject's reasoning. Belief and thought-about are known to common sense psychology; scientific psychology also posits representational states: in some linguistic theories, for instance, in a many stage process of linguistic comprehension, a

language-processing module goes into states which represent phonological, syntactic, and semantic properties of heard sentences.

Hoping that snow is green differs from believing that snow is green, although both are representational states and concern the proposition that snow is green. Standard philosophical theories consequently take representational states to involve a relation between a subject and a 'content' – what is meant – via an attitude or the relation borne to that meaning. When one believes that snow is green, the attitude is belief; when one hopes that snow is green, the attitude is hope. A representational property of a representational state may thus be characterized as a pair composed of an attitude and a content.

Representational states have correctness, or satisfaction, conditions partly determined by the correctness conditions for their contents. A proposition is correct just in case it is true; correctness conditions for other sorts of contents, such as Vienna, are less well understood by philosophy. So, for instance, a belief is correct just in case its content is; a desire or hope is satisfied just in case its content is correct.

VARIETIES OF REPRESENTATIONALISM

This crude formulation allows for a good deal of variation, along at least three dimensions.

What Sort of Reduction?

Any attempt at reduction may be more or less ambitious. This ambition influences the relation taken to hold between the reduced entity and the reducing entity.

The weakest interesting relation for reductive purposes is 'supervenience': the reduced entity cannot vary without variation in the reducing entity. Supervenience seems to be a necessary condition for reduction of any sort; whether it is sufficient is hotly debated.

A stronger thesis brings about an ontological reduction by identifying particular phenomenal characters with particular representational properties: for each phenomenal character ϕ there is a representational property ρ such that for a state to be ϕ is for it to be ρ; moreover, the property's status as representational is somehow fundamental, whereas its status as phenomenal is somehow more superficial.

A still stronger thesis brings about an epistemological or explanatory reduction by claiming the relevant identities to be *a priori* (under canonical ways of conceptualizing the properties in question).

Which Phenomenal Characters are Reduced?

The many different sorts of conscious states canvassed in the introduction have a wide variety of phenomenal characters: perceiving is unlike imagining; feeling sad is unlike feeling a physical pain. A representationalist may attempt to reduce all phenomenal characters, or only some privileged set of them, such as experiences of visually perceiving color.

There may be some purposes for which a limited theory would be interesting, such as that of avoiding a perceptual epistemology of sense-data (Russell, 1912; Harman, 1990). However, if the main purpose of representationalism is bringing consciousness under a unified naturalistic umbrella, less ambitious theories with narrower scope are less interesting; moreover, less ambitious theorists are forced to explain what it is about those special phenomenal characters which makes them susceptible to representationalist treatment when others are not.

First-Order and Higher-Order Representationalism

Not all representational states give rise to consciousness: e.g. sound sleepers continue to store memories. Which do?

Some mental states represent other mental states: I can think about my thinking about Vienna. Here the thought about Vienna is 'first order'; the thought about the thought is 'higher order'.

According to first-order representationalism (Harman, 1990; Tye, 1995) (sometimes called 'intentionalism'), some representational states that do not concern other mental states, such as seeing a green tree, are by their nature sufficient to give rise to phenomenal character. First-order representationalists identify phenomenal characters with a pair of a content and an attitude. First-order representation historically developed with the partial intent of avoiding a sense-datum epistemology (Harman, 1990), so that advocates of the view are often concerned to show that any conscious content must concern nonmental reality; but there is no obvious reason why a naturalist must hold this nonmentalist position: represented mental states might be themselves natural, and themselves represented as instancing natural properties.

By contrast, according to higher-order representationalism self-representation is necessary for consciousness, so that first-order states cannot by themselves give rise to consciousness (unless the first-order state is essentially such as to be self-representing; more below). There are several dimensions of variation in higher-order theory.

Perhaps the higher-order attitude is belief (Rosenthal, 1997); perhaps it is perception (Lycan, 1997; Lormand, 1994); perhaps it is a form of Russellian 'acquaintance' (Russell, 1912), which could be thought of as a relation which grounds the meanings of demonstrative concepts such as 'this' and 'thus'; further options are certainly available.

Moreover, there is room for variation in the causal relation the representing state bears to the represented state: perhaps no constraint is required, or perhaps a tight constraint, along the lines of that necessary for veridical perceiving is required. Or, alternatively, perhaps the representing and the represented states are in a tighter metaphysical relation of partial constitution.

Finally, though it would seem natural for the higher-order representationalist to take the phenomenal character of a state to be determined by how it is represented by the higher-order state, the fact that some conscious states are themselves representational gives rise to a choice here. What if the content of the lower-order state is misrepresented by the higher-order state – so that, for instance, an experience of seeing a red thing is misrepresented as an experience of seeing a green thing? Neither option is happy: if the higher-order content determines phenomenal character, although the subject would say 'that's red', he would seem irrational to himself in doing so; if the lower-order content determines phenomenal character, the higher-order content seems otiose. This dilemma can be dissolved if either the higher-order attitude is infallible, or if only noncontent properties of the lower-order state are represented.

A Mixed View

Finally, first- and higher-order views can be combined, if the 'special' first-order attitude is one which essentially involves self-representation: one bears this special attitude A to a content c only if one bears some further attitude A' to one's bearing A to c. If $A = A'$, an infinite hierarchy of bearings of A result (more on this point follows in the subsection: 'A Russellian view').

ARGUMENTS FOR REPRESENTATIONALISM

Higher-Order Representationalism

Higher-order representationalism can seem truistic. Intuitively, the phenomenal character of a mental state makes some impact on the subject's awareness: the idea of a state which has phenomenal character, but of which the subject is not in any way aware, is bizarre in the extreme. The impact need not consist in the presence of an occurrent opinion about which phenomenal character one is currently enjoying: a daydreamer might fail to notice subtle shifts in visual experience resulting from the gradual descent of the sun. However, in subjects with the conceptual capacity for such thoughts, the ground of such thoughts must be present (more on subjects without such capacity follows in the subsection: 'A Russellian view').

More must be done, of course, to specify what such grounding amounts to, and what it is to have an opinion about which phenomenal character one is currently enjoying. However, an analogy to perception may prove a fruitful source of investigation: just as perception provides the ground for occurrent thoughts about which colors and shapes are before one by serving as a stock of representations distinct from occurrent thought, so may awareness of phenomenal character do so by serving as a stock of representations distinct from occurrent thought.

Higher-order representationalism seems to be a commitment of the common idioms of consciousness. We say that a conscious state is 'like something to its subject'; under analysis, this predicate is revealed to apply to a state just in case the subject represents the subject is acquainted with certain features of the state. On a slightly less common, but still natural, way of speaking of phenomenal character, we say that a state 'feels a certain way to its subject': here analysis is not needed to reveal that language draws an analogy between consciousness and perceptual representation. With a suitable theory of the link between truth-conditions and metaphysics, these observations could be extended to a proper argument for higher-order representationalism.

Phenomenology and First-Order Representationalism

The first source of support for first-order representationalism is an effect observed in

phenomenological investigation, commonly known as 'transparency' (Harman, 1990; Tye, 1995): allegedly, when one sees a blue bead, one cannot detect any 'intrinsic' or nonrepresentational property (aside from the bead's apparent property of blueness) making a difference to the phenomenal character of this experience of seeing. If phenomenal characters are as they seem, no nonrepresentational property does make a difference; and what applies for this experience is held to apply for all experiences.

This argument does not show anything deep about consciousness, however. Even if transparency holds for states of seeing, the phenomenal character of one's total experience is complex, and there are contributions made by further mental states one is in: transparency may fail for these. There is nothing incoherent about the idea of a nonrepresentational property of a mental state or process: a mental process might procede at a certain rate, or be subject to voluntary control with a certain number of degrees of freedom. Nor is there anything incoherent about the idea of such a property being introspectively detectable, and thereby influencing phenomenal character. Consequently, if transparency holds, it does so at best contingently. Moreover, it does not even seem to hold generally for actual human phenomenal character (see subsection: 'Straightforward counterexamples to the first-order view').

Epistemology and First-Order Representationalism

The second source of support for the first-order view appeals to a 'recycling' theory of concepts of phenomenal character. Allegedly, when one forms an introspective judgment about which phenomenal character one is enjoying, one singles out that phenomenal character only by reusing discriminative capacities already conferred by undergoing an experience with a certain first-order content, together perhaps with a highly general concept of mental states of a certain sort (Evans, 1982). So for instance, when one sees a blue bead, one singles out the phenomenal character of the experience of seeing the blue bead roughly by taking it to be that phenomenal character had by experiences which represent things as thus, where one's grasp of 'thus' is grounded in the experience itself: here, the material before the 'thus' is responsible for the concept's application to one among the phenomenal characters; 'thus' is responsible for distinguishing the phenomenal character from all others. The end result is to distinguish phenomenal characters in general as representational properties. Hence, if our introspective concepts of phenomenal characters are true to and exhaustive of the natures of phenomenal characters, phenomenal characters just are properties involving representing nonmental reality as a certain way. Some terminology: the perceptual state responsible for grasp of the concept 'thus' contributes 'novel' content; whichever state is reponsible for the concept of phenomenal character contributes 'recycled' content.

The recycling argument has the same flaw as the transparency argument. Even if some discriminations of phenomenal characters recycle novel content concerning nonmental reality, this is compatible with there being introspective concepts with novel content concerning mental states and processes.

Mentalism and Nonmentalism

These objections only concern nonmentalist formulations of first-order representationalism. The recycling and transparency arguments do seem to go through once they have been weakened to allow for the sorts of phenomena to be discussed in the next section.

ARGUMENTS AGAINST REPRESENTATIONALISM

Spectral Inversion and the First-Order View

The first-order view must explain the data that suport the higher-order view: perhaps this can be done by adopting the mixed view described earlier. Once this challenge has been met, two other objections arise.

Consider first a sample inversion argument (Block, 1990). Perhaps there are three possible subjects s_1, s_2, and s_3, such that s_1 and s_2 are alike phenomenally and differ from s_3, and s_2 and s_3 are alike representationally and differ from s_1. For the first condition, suppose that s_1 and s_2 are alike intrinsically in those respects which matter for phenomenal character, while s_3 differs intrinsically enough to make phenomenal character differ.

In support of the possibility of such a trio, many have felt a powerful intuition that phenomenal character supervenes on a subject's intrinsic nature. For the second condition, suppose that internal constitution does not much matter for

representational properties (the sign is arbitrary), so that the difference between s_2 and s_3 does not prevent them from being the same representationally – perhaps as a result of compensating divergences in their environments. A number of ways of establishing that there could be such compensating divergences in the presence of intrinsic likeness have been described in the literature; a typical attempt appeals to s_2 and s_3 being spectrally inverted with respect to one another but nonetheless deferring to the same experts in forming opinions about the colors of things. If thought content is deferential, and people standardly believe things are as they perceptually represent them to be, then s_2 and s_3 standardly perceptually represent things to be of the same color, violating supervenience.

The difficulty with this argument is that the premises both that thought content is deferential and that people standardly believe things are the way they perceptually represent them to be yield together the odd conclusion that perceptual representation is deferential: if perceptual content is nonconceptual, as many take it to be, it is unclear how deference could influence it. Moreover, however plausible deference may be for the concept 'red', it is less so for indexical predicate concepts such as 'thus'. Conversely, while 'thus' seems essentially tied to perceptual content, 'red', if subject to deference, is potentially less so.

The difficulties with this particular argument hold more generally: opinions about the narrowness of phenomenal character and the breadth of content may individually seem initially plausible, but the methodology for establishing such results has come under heavy attack in recent years. Moreover, even if color content is universally wide, the first-order representationalist may still retreat to the view that the phenomenal character-fixing first-order contents concern mental qualities, such as the degree to which certain retinal circuits are stimulated.

Straightforward Counterexamples to the First-Order View

Consider then a putative counterexample (for others see Peacocke, 1983): perhaps the most striking is double vision of the sort that results when one pokes one's eye with a finger. If one were to attempt to describe this experience, the most natural description would apply nonrepresentational predicates to one's own mental processes: one would say that one's visual field fragmented into two portions, which came to transparently overlay one another and move with respect to one another. If this description is correct, we seem to be introspectively aware of nonrepresentational properties of experience.

Mentalist first-order theorists may happily accept such examples. Anti-mentalist first-order theorists standardly reply to such counterexamples by redescribing the experience as one involving only ascription of properties to nonmental entities (Tye, 1995). For example: everything before me was suddenly replaced by a pair of transparent ghostly replicas of the scene before my eyes which then proceeded to move with respect to one another. Unfortunately, this description is implausible. The first-order representationalist should be concerned about this, for the transparency and recycling arguments both rely on a fairly high degree of privileged access to the nature of conscious mental states. Moreover, it is unclear what constrains such a strategy of redescription. Once initial plausibility has been set aside as a constraint, the position quickly threatens to become vacuous.

The Higher-Order View

Now consider the higher-order view. First, note that inversion-style objections can be readily modified to attack higher-order theory with more or less success.

Objections in the literature peculiar to the higher-order view have tended to focus less on the general higher-order approach than on particular hypotheses concerning the higher-order attitude. Of these, those receiving the most attention have been that the attitude is thought (the 'higher-order thought' view) and that it is perception (the 'inner-sense' view). A gamut of objections have been raised against each, too many to cover in detail. I will focus on the predictions these positions make concerning the nature of introspective knowledge of phenomenal character.

Epistemology and Higher-Order Thoughts

According to the higher-order thought view, a state is conscious just in case one has a belief about it; presumably the content of the belief concerns which phenomenal character the state has. Since one can open one's eyes without being flooded with an infinite hierarchy of conscious thoughts about one's perceptual states, the view must thus permit the higher-order beliefs to be themselves not conscious. The motivating idea behind higher-order representationalism was that a state has

phenomenal character only if its subject is in some sense aware of it, in a way that grounds conscious introspective thought about which phenomenal character it has. The higher-order thought theorist should thus regard the possession of the nonconscious higher-order thought as the sort of awareness which provides such a ground. Forming such a conscious thought should then be a matter of bringing the unconscious thought to consciousness.

Compare standard cases in which one brings a nonconscious thought to consciousness: one example is simply bringing a belief to consciousness; another is straining to recall someone's name. Both processes seem distinct from the processes by which one forms conscious thoughts about the phenomenal characters of one's conscious states. As discussed above, one can do so either by recycling content, or by a perceptionlike process. Either case is, intuitively, a matter of making a discovery – perhaps a relatively banal discovery but a discovery still – whereas according to higher-order thought theory, it is a matter of mere rethinking something one already knew.

Recycling and Inner Sense

According to the inner sense view, conscious states are themselves perceived. As noted above, the attractiveness of the idea that conscious states are perceived is encoded in idioms for discussing consciousness ('states that feel a certain way'). Since the concept of perception is not wholly clear, however, nor is the adequacy of the view. Suffice it to say that while the idea that we perceive double vision and other distortions has some plausibility, the analogy becomes rather strained when applied to experiences whose phenomenal characters are known by recycling.

A Russellian View

Thought and perception do not exhaust the space of possible attitudes one might bear to one's conscious states. A view according to which distortions are perceived, and perceptual states are known by recycling, would evade the concerns raised against higher-order thought and inner-sense views. Such a view could avoid being *ad hoc*, if perceiving, and that grasp of concepts of phenomenal character which underlies the capacity for recycling perceptual contents, can both be plausibly taken as determinates of a more inclusive notion of Russellian 'knowledge by acquaintance' (Russell, 1912). There are in fact substantial cognitive similarities between perceptual knowledge and knowledge by recycling that justify so treating them: both are sorted by content and modality, both seem to ground demonstrative and recognitional indexical concepts, and so forth. Then Russell's observation that when one stands in a relation of acquaintance one is in addition acquainted with this relation generates an infinite hierarchy of relations of acquaintance.

The existence of such a hierarchy is plausible: we can introspect, and introspect our introspection, and introspect our introspection of our introspection, and so forth. Nor does this proposal face the concern that scotched the higher-order conscious thought proposal; relations of acquaintance serve as grounds of potential conscious thought, and need not give rise to actual or occurrent conscious thought.

An objection to this approach is that if concepts of phenomenal character are required to get consciousness off the ground, the experiences of dogs and children are not conscious. The correct reply is to bite the bullet: after all, do we have any way of knowing that they are?

Zombies and Nonreductive Representationalism

A final objection to representationalism appeals to zombies: one could perhaps conceive of creatures functionally like us but which lack phenomenal characters; together with suitable principles passing from conceivability to possibility, supervenience would fail. Whatever one might think of conceivability–possibility principles, it is important to note that this argument at best threatens reductive versions of representationalism: if one regards it as inconceivable that there could be consciousness without awareness of phenomenal character, one might do better to accept a nonnaturalistic conception of representation than to give up the consciousness–representation link.

REPRESENTATION IN THE COGNITIVE SCIENCES

It would not be far-fetched to say that the cognitive sciences are only the study of computational operations on mental representation. The Chomskian revolution in linguistics began with the recognition that the (or at least a central) goal of linguistics is the study of the means by which the mind determines the semantic, syntactic, and phonological properties of sentences by running computational operations on mental representations of the

properties of those sentences. Marr's influential work on vision regards as the goal of the study of vision determining which operations must be performed on representations stemming ultimately from retinal stimulation, in order to generate representations of the properties of seen objects which have enough features to enable vision to do what it seems to do.

CONTENTS

Observable similarities between humans and other animals with respect to behavior and neurology, as well as considerations related to evolutionary continuity between species, underlie most opinions that animals have conscious experiences. The attempt to understand other forms of consciousness – other species of mind – may help us to understand the evolutionary roots of our own.

INTRODUCTION

In the last 30 years many innovative experiments by comparative psychologists and ethologists, both in the laboratory and in the field, have improved our understanding of the cognitive capacities of animals (see the edited collection by Bekoff *et al*., 2002, for contributions by more than 50 leading researchers). As a result of this work we have acquired much knowledge about memory, learning, spatial navigation, social communication, and other cognitive capacities in a wide variety of species. Much of the work has concentrated on primates, and particularly on the great apes, reflecting a certain anthropocentric bias. But there has also been notable progress in understanding the cognitive capacities of other mammals, some birds, and even a few invertebrate species. Nonetheless there are large gaps in our understanding of the distribution of cognitive capacities across all taxonomic groups which limits our ability to understand the evolution of cognitive and mental abilities.

Opinions vary on the relevance of the work in cognition for the topic of consciousness *per se*. Some researchers regard consciousness as in internal, subjective state that is entirely beyond the range of scientific methodology. Others believe that existing scientific investigations shed light on conscious reasoning, self-awareness, and qualitative experience. By raising the issue of animal consciousness in a series of books, Donald Griffin (1976, 1984, 1992) deserves credit for having inspired the field that he named 'cognitive ethology'. Griffin promoted the idea, also to be found in Charles Darwin's work (1881; see Crist, 2002), that careful naturalistic observation and experiments under natural conditions can reveal the operation of mental processes in nonhuman animals, including invertebrates. Griffin's agenda has been strongly criticized, and his methodological suggestions often dismissed as anthropomorphic (see Bekoff and Allen, 1997, for a survey). But such criticisms may have overestimated the dangers of anthropomorphism (Fisher, 1990), and Griffin's suggestions have certainly acted as a catalyst for sophisticated work in cognitive ethology (Cheney and Seyfarth, 1990; Allen and Bekoff, 1997; Bekoff *et al*., 2002). Although many scientists remain skeptical of Griffin's approach, and the question of whether other animals are conscious remains controversial among them, there are indications that the topic is no longer entirely taboo (see the edited collection by Bekoff, 2000).

There are two senses of consciousness that cause particular controversy when applied to animals: phenomenal consciousness and self-consciousness. Phenomenal consciousness refers to the qualitative, subjective, experiential, or phenomenological aspects of conscious experience, sometimes identified with qualia. To contemplate animal consciousness in this sense is to consider the possibility that, in Nagel's (1974) phrase, there might be 'something it is like' to be a member of another species. Self-consciousness refers to an organism's capacity to represent its own mental states, and is often related to the question of whether the organism possesses a theory of mind, can reason about its situation, and plan accordingly.

PHENOMENAL CONSCIOUSNESS

Observable similarities between humans and other animals with respect to behavior and neurology, as well as considerations related to evolutionary continuity between species, underlie most opinions that animals have conscious experiences. For

instance, the behavior, neurology, and evolution of responses to noxious stimuli all appear to point to similar experiences of pain in humans and other animals. Noxious stimuli that humans would report as painful produce responses in animals that are easily mapped onto those of humans in similar circumstances. High-pitched vocalizations, fear responses, nursing of injuries, and learned avoidance are among the responses to noxious stimuli that are all part of the common mammalian heritage. The neural systems underlying these responses are virtually identical to those in humans, and animals respond to the same pain-relieving drugs, such as opiates. These responses are visible to some degree or other in organisms from several taxonomic groups.

Also in the realm of behavioral evidence, but less accessible to casual observation, are scientific demonstrations that members of other species, even of other phyla, are susceptible to the same visual illusions as we are (e.g. Fujita *et al*., 1991) suggesting that their visual experiences are similar. Correspondingly, much of the basic research that is of direct relevance to understanding human visual consciousness has been conducted on the very similar visual systems of monkeys. Monkeys whose primary visual cortex is damaged even show impairments analogous to those of human blindsight patients (Stoerig and Cowey, 1997) suggesting that the visual consciousness of intact monkeys is similar to that of intact humans (see Carruthers, 2000 for dissent).

Such similarity arguments are somewhat weak for it is always open to critics to exploit disanalogies between animals and humans to argue that the similarities do not entail the conclusion that both are conscious (Allen, 1998). Even when bolstered by evolutionary considerations of continuity between the species, the arguments are vulnerable, for the mere fact that humans have a trait does not entail that our closest relatives must have that trait too. Thus, for instance, Povinelli and Giambrone (2000) argue that even quite similar behaviors in humans and chimpanzees are due to different underlying mechanisms, a point that Povinelli believes is demonstrated by his research into how chimpanzees use cues to track visual attention (Povinelli, 1996; but see Hare *et al*., 2000, 2001 for a different view).

Despite the relevance of empirical research to similarity arguments, direct research into the phenomenological aspects of animal consciousness is hampered by at least two factors. One is the general problem that we lack a good theory of phenomenal consciousness, even in the human case. There is great uncertainty about the ontological status of phenomenal consciousness, whether in humans or in other animals. Accounts of consciousness in terms of basic neurophysiological properties, the quantum-mechanical properties of neurons, or *sui generis* properties of the universe are incomplete and controversial. More 'functionalist' accounts which attempt to explain the nature of experience in terms of the complex interactions between various cognitive subsystems fare no better. Consequently, no current theory of consciousness is secure enough to hang a decisive endorsement or denial of animal consciousness upon it.

A second factor hampering progress is that we lack a substantial account of what biological functions might be served by phenomenal consciousness. This point can be put another way: given any putative function of conscious experience, it seems we can imagine the same function being carried out without being accompanied by conscious experience. Thus, for example, while it is commonly asserted that the function of conscious pain is to 'tell' the organism when damage is occurring and thus promote behaviors which protect against further injury, it is also known that spinal reflexes alone, which are presumably quite unconscious, are sufficient to promote quite sophisticated kinds of withdrawal behavior and even associative learning (Grau, 2002). This raises the specter that phenomenal consciousness is epiphenomenal – completely devoid of physical effects – as some philosophers have asserted. If this were correct, then a search for the functions of consciousness would be doomed to futility. In fact, if consciousness is completely epiphenomenal then it cannot have evolved by natural selection, for selection can only operate on the effects of a trait on organismic fitness. On the assumption that phenomenal consciousness is an evolved characteristic of human minds, and therefore that epiphenomenalism is false, an attempt to understand the biological functions of consciousness would be useful for identifying its occurrence in different species by allowing us to search for organisms with the relevant functional capacities.

Many scientists remain convinced that no amount of empirical research can provide access to the subjective states of nonhuman animals. This remains true even among many scientists who are willing to invoke cognitive explanations of animal behavior that advert to internal representations. Opposition to dealing with consciousness can be understood as a legacy of behavioristic psychology: first, because of the behaviorists' rejection of terms for unobservables unless they could be formally

defined; and second, because of the strong association in many behaviorists' minds between the use of mentalistic terms and the twin bugaboos of Cartesian dualism and introspectionist psychology (Bekoff and Allen, 1997). In some cases these scientists are even dualists themselves, but they are strongly committed to denying the possibility of scientifically investigating consciousness, and remain skeptical of all attempts to bring it into the scientific mainstream.

Because consciousness is assumed to be private or subjective, it is often taken to be beyond the reach of objective scientific methods (see Nagel, 1974). This claim might be taken in either of two ways. It might be taken to bear on the possibility of answering the question of whether members of another taxonomic group (e.g. bats) have conscious states. Or it might be taken to bear on the possibility of answering the question of what it's like to be a member of another species. The difference between believing with justification that a bat is conscious and knowing what it is like to be a bat is important because, at best, the privacy of conscious experience supports a negative conclusion only about the latter (Bekoff and Allen, 1997). To support a negative conclusion about the former one must also assume that consciousness has absolutely no measurable effects on behavior, i.e. one must accept epiphenomenalism. But such an assumption leads to the implausible conclusion that phenomenal consciousness did not evolve by natural selection.

REASONING AND SELF-CONSCIOUSNESS

René Descartes argued against animal minds on the grounds that animals do not use language conversationally or reason generally. While he was aware of the capacity of parrots to pronounce human words, he dismissed this as unintelligent, meaningless repetition. This judgment may have been appropriate for the few parrots he encountered, but it was not based on a systematic, scientific investigation of the capacities of parrots. Some would argue that Irene Pepperberg's multiple studies of the African Grey parrot 'Alex' (Pepperberg, 1999) should lay the Cartesian viewpoint to rest. This work, along with research into the acquisition of linguistic competence by chimpanzees (e.g. Gardner *et al*., 1989; Savage-Rumbaugh, 1996; Fouts *et al*., 2002), might be interpreted as undermining Descartes' assertions about lack of intelligent language use and general reasoning abilities in animals. There are now some serious questions about the interpretation of this work, however. Cartesians have pointed out the limitations shown by animals in such studies, and they are often joined by linguists who protest that the subjects of animal-language studies have not fully mastered the recursive syntax of natural human languages (e.g. Pinker, 1994).

Teaching human languages to animals tests their capacities on a task that is well outside the natural repertoire for the species. The same is true of testing animals on the capacity for mirror self-recognition (Gallup, 1970; Gallup *et al*., 2002). It was long known that chimpanzees would use mirrors to inspect their images, but Gallup developed a protocol that appears to allow a scientific determination of whether it is merely the mirror image *per se* that is the object of interest to the animal inspecting it, or whether it is the image qua proxy for the animal itself that is the object of interest. Using chimpanzees with extensive prior familiarity with mirrors, Gallup anesthetized his subjects and marked their foreheads with a distinctive dye. Upon waking, marked animals who were allowed to see themselves in a mirror touched their own foreheads in the region of the mark significantly more frequently than controls who were either unmarked or not allowed to look into a mirror. Gallup's protocol has been repeated with other great apes and some monkey species, but besides chimpanzees only orangutans consistently 'pass' the test. (Shumaker and Swartz, 2002, cite preliminary evidence that the failure of gorillas may be one of motivation rather than basic intellectual capacity.) Gallup interprets this procedure as showing whether animals are self-aware and can infer the states of mind of another individual. (See Heyes, 1998, for a different opinion.)

The capacity to attribute mental states to others is often described as possession of a theory of mind. (But not always – see simulation theory.) The theory of mind debate has origins in the hypothesis that primate intelligence in general, and human intelligence in particular, is specially adapted for social cognition (see Jolly, 1966; Humphrey, 1976; Byrne and Whiten, 1988). Evidence for the theory of mind in great apes beside humans is mixed. Povinelli (1996) argues that in interactions with human food providers, chimpanzees apparently fail to understand the role of eyes in providing visual information to the humans, despite their outwardly similar behavior to humans in attending to cues such as facial orientation. The interpretation of Povinelli's work remains controversial. Hare *et al*. (2000) conducted experiments in which dominant and subordinate animals competed with each other for food, and concluded that 'at least in some

situations chimpanzees know what conspecifics do and do not see and, furthermore, that they use this knowledge to formulate their behavioral strategies in food competition situations.' They suggest that Povinelli may have obtained negative results because his experiments involved cooperative chimp–human interactions. Hare and Wrangham (2002) argue that situations where chimpanzees are competing with each other for resources may be more ecologically relevant than cooperative tasks.

It is also likely that the mirror test is not an appropriate test for theory of mind in most species because of its specific dependence on the ability to match motor to visual information, a skill for which there may have been little selectional pressure. Consequently, it has been argued that evidence for the ability to attribute mental states in a wide range of species might be better sought in natural activities such as social play, rather than in laboratory-designed experiments which place the animals in artificial situations (Allen and Bekoff, 1997; see especially chapter 6; see also Hare *et al*., 2000, 2001; Hare and Wrangham, 2001). Early attempts to find strong evidence of theory of mind in nonhuman animals under natural conditions generally failed to produce such evidence (see, e. g. Cheney and Seyfarth 1990). But anecdotal evidence (Byrne and Whiten 1988) and the more recent experimental results mentioned here tantalizingly suggest that researchers still have not managed to devise the right experiments.

CONCLUSION

Where does this leave questions about animal consciousness? While it may seem natural to think that we must know more about human consciousness before we try to determine whether other animals have it, such an approach may not be the most effective. The attempt to understand other forms of consciousness – other species of mind – may help us to understand the evolutionary roots of our own. Although research on primates is attractive because of their close evolutionary relationship to humans, much more needs to be learned about the cognitive abilities and forms of consciousness in less closely related species. It is important not to stifle research on consciousness because of worries about how to define the relevant notions. In the early stages of the scientific investigation of any phenomenon, putative samples are identified by rough rules of thumb (or working definitions) rather than complete theories. Early scientists identified gold by contingent characteristics rather than its atomic essence, knowledge of which had to await thorough investigation of many putative examples – some of which turned out to be gold and some not. Likewise, at this stage of the game, the study of animal consciousness may boldly investigate interesting cognitive capacities with no firm commitment to the idea that all these examples will involve conscious experience but absent of prejudice that none of them will.

Consciousness, Cognitive Theories of

Intermediate article

Bernard J Baars, Neurosciences Institute, San Diego, California, USA

CONTENTS

'Consciousness' operationally consists of all the things human beings report experiencing, from perception to mental images, inner speech, recalled memories, semantics, dreams, hallucinations, emotional feelings, and aspects of cognitive and motor control. In cognitive theory, consciousness appears to be a global access function, presenting an endless variety of focal contents to executive control and decision-making.

THE SCIENTIFIC REDISCOVERY OF CONSCIOUSNESS

Until recently consciousness was considered a scientifically intractable problem. That deep skepticism has faded with remarkable speed since the 1990s due to a flow of findings about the brain basis of conscious experience in perception, imagery, alertness, selective attention, working memory, episodic memory, and executive control (see Baars *et al*., in press, for 70 scientific articles on the topic). Today a scientific race to consciousness is well under way. While the traditional philosophical paradoxes of mind and body are not resolved, many scientists now believe that significant progress can be made in the empirical study of conscious experience.

EVIDENCE TO BE EXPLAINED

To study anything in science we need to treat it as a variable. The concept of gravitational force would have been useless had Newton been unable to imagine zero gravity. Likewise, to understand consciousness we need to compare at least its presence to its absence; consciousness without unconsciousness is meaningless. In cases such as brain damage we can observe several degrees of consciousness, from full alertness to massive coma. But we need to compare at least two levels of consciousness to be able to ask the question 'what is the difference between them?' Only then can we deal with the issue of consciousness *as such*.

G. A. Mandler (1984) has made the penetrating observation that science is obliged to treat consciousness not as an observable datum but as an inferred concept based on public evidence. In science we can observe only the public *reports* people make about their conscious experience. Often we can make very reliable inferences about human conscious experience based on such reports. Almost 200 years of perceptual studies show that such reports correspond with exquisite sensitivity to the sensory stimulus array. Entire domains of research depend upon this well-established methodology.

Unconscious representations can also be inferred from public observations, though people cannot report them accurately. The simplest example is the vast multitude of memories that are currently unconscious. You may recall this morning's breakfast – but what happened to that memory before it was brought to mind? Apparently it was still somehow represented in the brain, though not consciously. Yet it has been known since Ebbinghaus that unconscious memories can shape mental processes without ever coming to mind; for example, it is easier to memorize material that was previously learned, even if you do not explicitly remember having learned it before. A case can be made for unconscious knowledge of many things: habituated stimuli, memories before and after recall, automatic skills, implicit learning and memory, the rules of syntax and semantics, unattended stimulation, presupposed knowledge, pre-conscious input processing, visual recognition of facial affect, and more.

To study consciousness as a variable, we can for example compare the reader's currently conscious contents, such as *these printed words*, to previous

words in this sentence which are no longer conscious at the moment you are reading this. Notice that those previously conscious words must still be actively represented in memory to allow currently conscious words to be interpreted correctly. Thus the study of immediate memory presents many opportunities for treating consciousness as a variable. As in the case of Newtonian gravity, we can compare an event with its absence by keeping everything constant while varying the dimension of interest. This kind of contrastive study has now become routine, having been applied to waking consciousness (contrasted with sleep, coma, and general anesthesia), visual consciousness (compared to cortical blindness), consciousness of attended input (compared to unattended input), and much else (Baars *et al.*, in press). Taken together this sizable body of evidence serves to constrain theory in a very exacting way.

Even a simple set of contrasts brings out some important facts. The most prominent of these involve the remarkable limitations of conscious contents at any given moment, compared to the vastness and complexity of unconscious processes taking place at the same time. Consciousness is associated with limited capacity, seriality, and integration of multiple sources of information, while comparable unconscious processes involve much greater capacity, parallelism, and distributed autonomy. While conscious contents are limited at any given moment, they appear to facilitate access to multiple unconscious knowledge sources in the brain. Several current theories propose that a conscious event is made widely available to multiple brain mechanisms of memory, skill control, decision-making, semantics, anomaly detection, and the like. Thus consciousness may have a broad, architectural role as a gateway to multiple knowledge sources in the brain (e.g. Crick, 1984; Baars, 1988, 1997, 1998; Schacter, 1990; Chalmers, 1996; Damasio, 1989; John *et al.*, 1997; Edelman, 1989; Tononi and Edelman, 1999).

Fringe Conscious Events

William James (1890/1983) thought that vague or 'fringe conscious' events were at least as important as focally conscious ones. Fringe conscious phenomena include feelings of rightness, familiarity, beauty, coherence, anomaly, tip-of-the-tongue, attraction, repulsion, and the like. These phenomena can be operationally defined by a combination of high subjective certainty and high accuracy, but low experienced detail. Mangan (1993) has developed James's ideas about the fringe in modern terms, suggesting that fringe contents may not be subject to the classical capacity limitations of conscious experiences. Since focal conscious capacity is limited to one internally consistent experience at a time, Mangan sees fringe experiences as a very useful way of circumventing that limitation when needed.

COGNITIVE ARCHITECTURE THEORIES

A small cluster of theories has emerged to account for some of these aspects of conscious experience. Early theories were primarily cognitive, but quite sophisticated brain-based 'neuronal resonance' theories are now available (see below). Not surprisingly, the cognitive theories generally do a better job with psychological evidence, while neuronal resonance theories are better with the rapidly emerging evidence on the brain basis of conscious processes. A major theoretical aim for the future is to combine these approaches in a single, unified framework.

Cognitive theories can be divided into those that try to account for the evidence for consciousness as described above, and those that focus mainly on the various roles of consciousness in memory or executive functions. Baars' Global Workspace theory is the best-known example of the first class, while Schacter (1990) has developed a closely compatible approach to memory systems; Hilgard (1977), Johnson-Laird (1988), and Shallice (1988) focus on the role of consciousness in executive control.

Baars' Global Workspace (GW) theory extends the concepts of cognitive architectures to the problem of consciousness, in the tradition of A. Newell, H. A. Simon, and J. R. Anderson (see Baars, 1988, 1997, 1998). Specific mechanisms are proposed to deal with a sizeable array of psychological processes, from perception to imagery, spontaneous problem-solving, memory retrieval, goals and action control, and self. GW theory appears to be the most thoroughly worked out cognitive theory of conscious processes today, at a high level of description. Consciousness is associated with a global 'broadcasting system' that disseminates information widely throughout the brain. If this is true, then conscious capacity limits may be the biological price to be paid for the ability to make single momentary messages available to the entire system for purposes of coordination and control. Since at any moment there is only one 'whole system', a global dissemination facility must be limited to one momentary content.

GW theory relies on three theoretical constructs: unconscious specialized processors, a global workspace, and contexts. The first construct, the specialized unconscious processor, is an 'expert network' of which there are assumed to be many, working in parallel. There is direct evidence for many types of specialized systems in the brain. There are single cells, such as cortical feature neurons for color, line orientation, or faces, but also entire networks and arrays of neurons, such as cortical columns, cortical areas like Broca's or Wernicke's, large nuclei such as the thalamic relay nuclei, and so on. Like human experts, unconscious specialized processors may be quite limited in scope. They are extremely efficient in specific task domains, able to act autonomously or in coalitions with each other. They can receive global messages, and by mobilizing other experts by way of the global workspace they may be able to control mental or muscular activities. In routine tasks they may work autonomously, without conscious involvement, or they may display their output in the conscious global workspace. Answering a question such as 'What is your mother's maiden name?' requires a mission-specific coalition of unconscious experts, which return their answer to consciousness.

The second construct is the global workspace (GW) itself. A GW is an architectural capability for system-wide integration and dissemination of information. A global workspace is much like the bright spot of light on a theatre stage, cast by a spotlight in a darkened auditorium. Specialized unconscious processors are comparable to members of the audience sitting in the darkened theater. Groups of experts may interact locally, but in order to effect system-wide change they must compete for access to the bright spot on the theatre stage, perhaps supported by a coalition of other audience members. Once an expert reaches the bright spot on stage, it can broadcast a global message to the system as a whole. New links between unconscious experts are made possible by global interaction via the bright spot, and can then spin off to become new autonomous processors. The stage allows novel expert coalitions to form, to work on new or difficult problems which cannot be solved by existing experts and coalitions. Tentative solutions to new problems can then be globally disseminated, scrutinized, and modified. Since conscious experience seems to have a great perceptual bias, it is convenient to imagine that perceptual regions of cortex – visual, auditory, or multimodal – can compete for access to a brain version of a GW.

Theater models of consciousness have been criticized by Daniel Dennett and Marcel Kinsbourne on the ground that they are 'Cartesian' and conceptually flawed (Dennett and Kinsbourne, 1992). However, global workspace architectures have been implemented in artificial intelligence simulations for decades, and are not vulnerable to the Dennett–Kinsbourne critique. They do not assume a Cartesian point centre, for example, and both Dennett and Kinsbourne have refrained from applying their critique to global workspace theory.

'Context', the third construct in GW theory, refers to the powers behind the scenes of the theater of mind. Contexts are coalitions of expert processors that may function like a theatrical director, playwright, or stagehand who can influence the actors that appear in the spotlight. They can be defined empirically as *unconscious factors that shape conscious contents,* just as a director behind the scenes can influence the words and actions of actors on stage without being visible from the audience. Conceptually, contexts are defined as pre-established expert coalitions that can evoke, shape, and guide global messages without themselves entering the global workspace. Indeed, Dennett himself has recently endorsed a 'neuronal global workspace' approach to consciousnes (Dennett, 2001).

Contexts may be momentary or long-lasting. Momentary contexts may shape the reader's conscious interpretation of a word such as 'set', which has many different meanings. The word 'tennis' before 'set' shapes the interpretation of 'set', even when 'tennis' has already slipped from consciousness. But the word 'tennis' needed to be conscious initially to create the unconscious context that interprets 'set'. Contexts can also be long-lasting. The reader's ideas about consciousness from years ago may influence his or her current experience of this paragraph, even if those memories do not become conscious again. In general, major life experiences appear to set lifelong attitudes or character traits. Such major events typically influence current conscious experiences unconsciously, rather than being brought to mind. It is believed that a shocking or traumatic experience can also set up largely unconscious expectations that can shape subsequent conscious experiences.

Several proposals aim to cast the global workspace framework in a more neurally realistic form, giving special regard to thalamocortical mechanisms. Newman and Baars (1993) and Newman *et al*. (1997) described ways to integrate global workspace theory with the neuronal resonance theories discussed below. Newman *et al*. (1997, p. 1195) propose that 'One would expect the neural mechanism for global attention to be complex, and

widely distributed. … But the basic circuitry can be described, to a first approximation, in terms of repeating, parallel loops of thalamo-cortico-thalamic axons, passing through a thin sheet of neurons known as the nucleus reticularis thalami.' The overall framework suggests a neurocognitive model in which consciousness is viewed as a global integration and dissemination system operating in a large-scale, distributed array of specialized bio-processors, which controls the allocation of processing resources in the central nervous system.

Almost all current theories agree that consciousness involves system-wide functions, rather than local ones that are mostly unconscious, and that specialized 'expert' systems tend to be unconscious and relatively isolated. Some detailed implications have been worked out by way of computer simulations (Franklin and Graesser, in press).

Consciousness, Memory, and Self Functions

Other cognitive theories focus on functions that are associated with consciousness, such as working memory, episodic memory, and executive or 'self' functions. Hilgard's framework (e.g. 1977) is based on several decades of research on hypnotic dissociation, in which people under conditions of suggestion appear to lack conscious access to such things as sensory input, memories, normal voluntary control, or aspects of their own identity. Under experimental conditions it is often possible to show that these responses are not merely faked or simulated. Suggestible states are not merely oddities: a fifth of the normal population is highly suggestible, and all humans are suggestible under some circumstances. Hilgard points out a number of implications for normal executive control and access to self.

Johnson-Laird's (1988) operating system model of consciousness emphasized control functions such as directing attention, planning and triggering action and thought, and purposeful self-reflection. Johnson-Laird's cognitive architecture consists of a parallel processing system dominated by a control hierarchy. The system is a collection of largely independent processors (finite state automata), which cannot modify each other but which can receive messages from each other; each starts to compute when it receives appropriate input from any source. Each passes messages up through a hierarchy to the operating system, which sets goals for the subsystems. The operating system does not have access to the detailed operations of the subsystems – it receives only their output. Likewise, the operating system does not need to specify the details of the goals it transmits to the processors – these take the goal, abstractly specified, and elaborate it in terms of their own capabilities.

In this model conscious contents reside in the operating system or its working memory. Johnson-Laird believes his model can account for aspects of self-reflection, intentional decision-making, and action control.

Daniel Schacter has also proposed a compatible approach, to integrate evidence on neuropsychological disconnections from consciousness, particularly implicit memory and anosognosia, called the Dissociable Interactions and Conscious Experience (DICE) model. 'The basic idea motivating the DICE model … is that the processes that mediate conscious identification and recognition – that is, phenomenal awareness in different domains – should be sharply distinguished from modular systems that operate on linguistic, perceptual, and other kinds of information' (1990, pp. 160–1).

Like Johnson-Laird, Schacter's DICE model assumes independent memory modules and a lack of conscious access to details of skilled, procedural knowledge. It is primarily designed to account for memory dissociations in normal and damaged brains. Schacter makes two main observations. First, with the exception of coma and stupor, failures of awareness in brain damage are usually restricted to the domain of the impairment; patients do not have difficulty generally in gaining conscious access to other knowledge. For example, amnesic patients do not necessarily have trouble reading words, while alexic individuals do not necessarily have memory problems.

However, implicit (unconscious) memory for lost conscious functions has been demonstrated in many conditions. For example, name recognition is facilitated in prosopagnosia (face-blind) patients when the name is accompanied by a matching face – even though the patient does not consciously recognize the face. Numerous examples are known of implicit knowledge in patients who do not have deliberate, conscious access to the information. These findings suggest an architecture in which various sources of knowledge function somewhat separately, since they can be selectively lost. These separable knowledge sources are not accessible to consciousness, even though they continue to shape voluntary action.

In DICE Schacter gives additional support to the idea of a system of separable knowledge sources, specifically to explain spared explicit knowledge in patients with brain damage. DICE does not try to explain the limited capacity of consciousness or the problem of selecting among potential inputs. In

agreement with Shallice (below) the DICE model suggests that the primary role of consciousness is to mediate voluntary action under the control of an executive.

Tim Shallice's 1978 theory focused on conscious selection of a *dominant action system*, a set of current goals that work together to control thought and action. More recently Shallice (1988) modified and refined the theory to accommodate a broader range of conscious functions. Shallice's information-processing system also consists of a very large set of specialized processors, like Johnson-Laird's subsystems and Baars' (1988) specialized unconscious processors. A large set of action and thought schemata can 'run' on these modules. The schemata are well-learned, highly specific programs for routine activities, such as eating with a spoon, driving to work, etc. Competition and interference between currently activated schemata is resolved by *contention scheduling*, which selects among the schemata based on activation and lateral inhibition. Contention scheduling acts only during routine operations. A *supervisory system* modulates the operation of contention scheduling. It has access to representations of operations, of the individual's goals, and of the environment. It comes into play when operation of routinely selected schemata does not meet the system's goals, that is, when a novel or unpredicted situation is encountered or when an error has occurred. Finally, a *language system* can function either to activate schemata or to represent the operations of the supervisory system or specialist systems. More recently an *episodic memory* component with event-specific memory has been added to the set of control processes.

Shallice claims that consciousness cannot reside in any of these control systems taken individually. No single system is either necessary or sufficient to account for conscious events. Consciousness remains even when one of these control systems is damaged or disabled. And the individual control systems can all operate autonomously and unconsciously. Shallice suggests that consciousness may arise when there is concurrent and coherent operation of several control systems on representations of a single activity.

NEURONAL RESONANCE THEORIES

Several brain theories have now been developed. They have so much overlap that we will consider only a few in detail. All brain theories of conscious functions can be broadly characterized as 'neuronal resonance theories'. That is, they propose that in waking consciousness the thalamocortical core of the human brain is continuously cycling neuronal activity between the major thalamic relay nuclei and corresponding regions of cortex, supplemented by corticocortical and cortical-subcortical cycles of activity. When consciousness is at a very low level, as in deep sleep, some comas, deep general anaesthesia, and epileptic 'states of absence', the rapid and irregular electrical field activity characteristic of waking consciousness is replaced by slow, correlated, and high-amplitude waves. At the level of single neurons waking consciousness involves temporally uncorrelated firing, while deep sleep shows repetitive, highly correlated burst-pause firing in large cell populations. These basic facts and their underlying neurophysiology, neuroanatomy, and neurochemistry are so well established that they arouse little fundamental disagreement (e.g. Singer and Gray, 1995; John *et al*., 1997; Edelman, 1989; Tononi and Edelman, 1999; Damasio, 1989). (*See* **Neural Correlates of Visual Consciousness**; **Thalamocortical Interactions and Binding**)

The development of parallel distributed processor (PDP) models is consistent with such large-scale brain models. Grossberg (in press) and Taylor (1992) have applied PDP concepts to aspects of consciousness. Grossberg's Adaptive Resonance Theory (ART) has been applied to specific brain functions including perception, recognition, attention, reinforcement, recall, and memory search. Grossberg writes that 'it is suggested that all conscious states are resonant states', especially those that occur 'between bottom-up and top-down processes as they reach an attentive consensus between what is expected and what is there in the outside world'.

Taylor (1992) also believes that conscious contents are determined by the intermingling of past and present. The reticular nucleus of the thalamus (nRt) appears to control the major sensory highways to cortex, and Taylor has provided a model for intersensory competition based on this evidence. Rather than a simple winner-take-all competition, he suggests that consciousness corresponds to a wave of activity of the coupled thalamic-nRt-cortical system, a multidimensional 'bubble' of neuronal firing patterns. Such a wave will show many regions over cortex that have nonzero activity. Recently Taylor has advocated the possibility that parietal cortex may act as a global workspace in the sense advocated by Baars (above).

Antonio Damasio (1989) suggests a role for consciousness in recognition and recall. Like other authors, Damasio's theory involves looping

feedforward and feedback circuits of neurons, a massive resonant assembly of cells. To this mechanism he adds a specific role for sensory projection areas of the cortex (local convergence zones) and their neighboring higher-order association areas (nonlocal convergence zones). Temporal synchrony is proposed to account for retrieval of information from memory when neuron ensembles are activated in a time-locked fashion in the local and nonlocal convergence zones of cortex. Memories are stored as distributed sets of fragmentary features in large populations of neurons, and are retrieved by means of synchronous activation of related firing patterns in a subset of the same cell population.

CONCLUSION

Although consciousness has only recently returned as a central focus of the brain and cognitive sciences, current proposals capture a good deal of the evidence in a broad way. A critical mass of scientists is now collecting relevant evidence and developing theory. Conscious experience seems to create access to multiple, independent knowledge sources. While there are distinct pros and cons to each theoretical perspective, the general impression is of a surprising degree of convergence. A major goal for the future is to show how neuronal resonance could support the global cognitive functions that require consciousness.

Consciousness, Function of

Intermediate article

Thomas W Polger, University of Cincinnati, Ohio, USA

CONTENTS

To inquire about the function of consciousness is to ask what consciousness does, what it enables us to do that we might not be capable of otherwise, or why some creatures came to be conscious.

INTRODUCTION

Consciousness is perhaps the most salient feature of human mental life. The experience of tasting a red wine differs from the experience of tasting coffee, and from that of reading the label on a wine bottle. Whatever else can be said about these differences, they are manifested in us by different conscious experiences. And this seems to be good for us: different experiences are evidently important in our abilities to discriminate among foods, to avoid injury, to identify potential mates, and so on.

But upon reflection it is less obvious what, if anything, consciousness does, what it allows us to do that we might not be capable of otherwise, or why some creatures – like human beings – have come to be conscious. For it seems that conscious experience is not necessary for the ability to distinguish objects in the world, or avoid injury, or seek a mate. Even if the experience of pain, for example, is important to the way that humans detect and avoid noxious elements in the external environment, it seems that we or other creatures could avoid hazards without the experience of pain, or any conscious experience at all. There is little doubt that mindless mechanical devices can be constructed to detect heat, classify wavelengths of reflected light, or distinguish chemical substances. We do not feel compelled to say that such devices feel pain, see colors, or taste wines. And we need not think only of mechanical devices and the automata of science fiction, for there is ample evidence that biological creatures can evolve fairly sophisticated sensory and motor capacities without having conscious experiences. The natural world is rife with creatures (microorganisms, molluscs, insects, and so on) that interact with their environments effectively, at least some of which may lack conscious experiences altogether.

QUESTIONS ABOUT THE FUNCTION OF CONSCIOUSNESS

The question of the function of consciousness does not have an obvious answer. We are faced not with a single question but with a handful of more or less related inquiries about what consciousness (as a matter of fact) does for human beings, about what if anything consciousness enables us to do that we could not (possibly) do otherwise, and about what capacities consciousness allows that would explain why it should be favored by natural selection: why it would evolve. The question of the function of consciousness is ambiguous, and the ambiguity owes as much to the idea of function as it does to any special considerations having to do with consciousness. Questions about the functions of mechanical artifacts and biological organs meet many of the same problems. (*See* **Consciousness, Philosophical Issues about**)

What Does Conscious Experience Do?

We might ask what abilities consciousness in fact mediates in human beings. In this case we are treating consciousness as a mechanism with certain effects, and we are inquiring about those effects in the same way that we might ask about the function of a carburetor or a heart. Carburetors regulate and mix air and fuel in some combustion engines. Hearts pump blood. Conscious experience allows us to discriminate and identify objects in the environment, to avoid hazards, and so forth. This was the answer that made it at first seem obvious what the function of consciousness is. Such explanations tell us what the 'causal role functions' of carburetors, hearts, and sensations are. A causal role function of a trait or mechanism is an effect of that trait

or mechanism that figures in an explanation of the overall capacities of the system of which it is a part. To explain the capacities of a system in terms of the causal role functions of its parts is to provide a 'functional analysis' of the system (Cummins, 1975). A special subset of causal role functions are those that can be characterized in terms of a computational device, such as a Turing machine.

Is Conscious Experience Necessary?

Even if we have a good explanation for what consciousness happens to do for us, we may still ask what it is that conscious experiences (likewise, carburetors or hearts) allow that could not be accomplished without them. This is not a question only about how human beings and cars are put together and what they are now capable of. It is also a question about how they might have been put together differently and what capacities they would have had under those circumstances. Could there be a car that does not have a carburetor? Certainly. Most automobiles these days use fuel injectors to mix air and fuel, rather than carburetors. Could there be a creature that does not have a heart? Mechanical devices are regularly used to circulate the blood of patients in the operating room. There is no reason to deny that some creature, however unlikely, could circulate its own blood without engaging a heart. So it may be with consciousness. The thesis that consciousness, though it may be crucial to our distinctively human way of interacting with the world, is not necessary for any of our capacities is called 'conscious inessentialism' (Flanagan, 1992).

There are interesting empirical phenomena that have seemed, at least to some, to support conscious inessentialism. Consider, for example, Bejamin Libet's (1985) experiments on the timing of conscious intentions to produce behavior. Libet's results purport to show that the muscular action potential that initiates movement occurs temporally prior to conscious awareness of an intention to move. These results have been interpreted as showing that consciousness does not play a role – or at least not the role traditionally envisioned – in the initiation of behavior. Daniel Dennett (e.g. 1991) has made much of the Libet experiments.

Blindsight is another phenomenon that has seemed, to some, to support some version of conscious inessentialism (e.g. Block, 1995). Lawrence Weiskrantz (1986) aroused the interest of many philosophers with his studies of patients with neural injuries who report no conscious visual experience in parts of their visual fields. Nevertheless, some of these patients perform much better than chance when they are forced to 'guess' about stimuli presented to the blind field. It seems that blindsight patients have residual information processing capacities despite lacking visual consciousness in the area of the scotoma, apparently supporting conscious inessentialism. This sort of phenomenon has led theorists to emphasize the importance of nonconscious visual processing (e.g. Milner and Goodale, 1995). But Weiskranz's results can also weigh against conscious inessentialism. After all, the tasks that blindsight patients perform better than chance – however remarkable that may be – are performed unerringly by normal subjects; and blindsight patients never initiate action based on the stimuli presented to the blind field (Van Gulick, 1985). These considerations suggest that consciousness does play an important role. (*See* **Blindsight**)

If conscious inessentialism is true, then there could be creatures that negotiate the world just as human beings do, but that nevertheless lack consciousness. Despite lacking conscious experience, such creatures (called 'zombies') make the same bodily movements as we do: they avoid fire, behave discriminately towards various wavelengths of light and chemical substances, etc. Sometimes it is claimed that conscious inessentialism entails that consciousness is epiphenomenal – that consciousness does not have any causal powers at all. (*See* **Zombies**; **Epiphenomenalism**)

But this is a mistake: from the fact that a carburetor is inessential to the operation of a car (because it could be replaced by a fuel injector) it does not follow that carburetors have no effects in those cars where they are found. Carburetors mix air and fuel in some cars; fuel injectors mix air and fuel in other cars. Neither a carburetor nor a fuel injector is necessary to the operation of automobiles in general; but carburetors and fuel injectors are not thereby epiphenomenal. (And just as there are reasons for generally preferring fuel injectors over carburetors, visual or painful experience may be better or worse ways of engaging with the world.)

Why Did Conscious Experience Arise?

In asking about the function of consciousness we might want to know not what conscious experiences enable us to do currently, but rather why we have come to be conscious at all. That is, we might be asking about the teleology of consciousness, about the purpose that it serves. If we understand teleology in terms of evolutionary history, then we are asking what the etiological function

of consciousness is. The etiological function of a trait is the effect that the trait had in the ancestors of a creature that provided an adaptive advantage to creatures of that kind, so that evolutionary pressures favored creatures with the trait. The etiological or 'selected effect' function of a trait explains why the trait came to be present or maintained in creatures of a kind, why it was naturally selected (Millikan, 1989; Neander, 1991). (*See* **Evolutionary Psychology: Theoretical Foundations**)

Consider again the possibility of conscious inessentialism. If conscious inessentialism is false – if consciousness is necessary for some human capacities (e.g. detecting wavelengths, avoiding injury) – then it is easy to answer the question of why we are conscious: we are conscious because it is adaptively advantageous (e.g. to detect wavelengths or avoid injury). That is to say, consciousness evolved; the evolutionary history of conscious experience is just the same as that of the capacities that conscious experiences mediate. That history need not be obvious or simple; it may not even be knowable by us: we do not assume that we will know the evolutionary history of every (or perhaps any) biological trait. Further, we should not assume that every trait has adaptive value. Some traits are the result of chance alone – though assuming that particularly complex traits are products of evolution by natural selection may be a reasonable methodological stance (Brandon, 1990; Grantham and Nichols, 1999). Of course the contingencies of organism and environment are such that discrimination of wavelengths and chemicals, avoidance of flames, and so on are not themselves compulsory. But insofar as we could explain why a creature should avoid injury, we would be able to explain why it experiences pain. The research program known as evolutionary psychology proceeds on the assumption that most or all psychological traits are adaptations by natural selection that are required for capacities that would have conferred an advantage on hominids living in the late Pleistocene era (Barkow *et al*., 1992).

On the other hand, if conscious inessentialism is true then the question of why consciousness has come to be is somewhat different. In that case we would need to explain not only why the capacity to avoid injury came to be enabled but also why, in some creatures, conscious experience mediates avoidance of injury. The answer might be that the presence of consciousness is a result of mere chance. That would perhaps be disappointing, but it would not undermine our belief that consciousness in fact has important effects in our lives. In particular, it would not force us to adopt epiphenomenalism. Just as an automobile might be built with a carburetor or a fuel injector, so creatures might evolve conscious experiences or some other mechanisms. Perhaps some forms of conscious experience have interesting evolutionary histories while others arose only by chance. We need not take consciousness to be a single phenomenon in order to meaningfully ask about its function.

CONSCIOUSNESS AND FUNCTIONAL KINDS

One might believe that whatever mixes air and fuel is a carburetor. That is to say, one might adopt a sort of metaphysical functionalism regarding carburetors. On this view, carburetors are functional kinds that are constituted by their capacity to mix air and fuel; thus fuel injectors are carburetors. Likewise one could think of hearts as blood pumps, and one could think of whatever mediates injury avoidance as pain experience. One must then regard the thesis of conscious inessentialism (likewise, carburetor inessentialism) as incoherent. According to a functionalist it would not even make sense to talk about something that did all the things (causal role functions) that pain does in human beings but that does not *ipso facto* have pain experiences. Two popular variations of functionalism about consciousness take conscious mental states to be a subset of representational states (e.g. Dretske, 1995) or to be meta-representations of first-order mental states – the higher-order thought theory championed by David Rosenthal (e.g. 1986). (*See* **Functionalism**)

The theory that consciousness is a functional kind is closely aligned with the view that all the facts about consciousness can be explained by reference to its functional role or roles (e.g. its causal role functions). One reason for holding such a view is general commitment to functionalist explanations, at least with respect to psychology; a widely-held theory is that all properties are causal role functional properties, and thus all explanations are functional explanations (Shoemaker, 1984). But in that case, if we cannot secure functional explanation of consciousness then we will be obliged to abandon the belief that consciousness is a physical phenomenon at all (Chalmers, 1996).

Consciousness, Machine

Introductory article

Keith Gunderson, University of Minnesota, Minneapolis, Minnesota, USA

CONTENTS

The widespread use of computers and robots within research programs in cognitive psychology has stimulated interest in the possibility of machine consciousness. As a result, many unsettled issues in the philosophy of mind and theory of knowledge have been reformulated in terms of, and in turn raised questions about, machine-oriented modeling.

INTRODUCTION

Consciousness is one of the most perplexing topics in the study of mind. There are many controversies surrounding its exact nature and relationship with the physical. For centuries, philosophers and others have argued about whether a machine could be conscious, partly so as to reach a better understanding of human and animal minds.

During the second half of the twentieth century, with the development of the digital computer, the topic of machine consciousness became intertwined with questions about artificial intelligence (AI). Many tasks that once seemed to require human conscious intelligence are now performed by computers. Machines with various kinds of programs and related robotic capabilities have been used to help explain some of the more baffling aspects of human mentality. (*See* **Artificial Intelligence, Philosophy of**)

Such approaches face a variety of problems. What counts as an example of consciousness? Some argue that consciousness is primarily a private (subjective) phenomenon. Nevertheless, attempts to construct machine models that would objectify it continue. Even when such models seem flawed or limited, an understanding of their shortcomings can provide fresh perspectives and stimulate lively debate on thinking, perception, awareness, purposive behavior, and the relationship between the mind and the body. (*See* **Mind–Body Problem**)

HISTORY

Could a machine be conscious? This question was being asked at least as long ago as the seventeenth century. Machines then (as now) were generally assumed to consist wholly of matter. To ask whether we might someday be able to build a conscious machine was one way of asking whether consciousness (animal or human) was made out of matter. The view that it was was called materialism. The view that it was not, and that mind was essentially different from matter, was called dualism. (*See* **Dualism**)

Descartes was dualism's most influential proponent. He regarded the human mind (or soul) as connected to a physical body. This connection, in the case of human beings, made the use of language, and many other activities, possible. A great many of these activities, Descartes felt, could not be explained in a purely mechanical way as matter in motion. On the other hand, he believed that the activities of all nonhuman animals could be explained in a purely mechanical manner. So dualism was not true of animals. Their behaviors, upon close inspection, could be shown to be made up of reflexes, and were instinctual, not guided by reason. Animals were organic machines. They had no thoughts or sensations. This view was called 'animal automatism'. (*See* **Descartes, René**)

Most philosophers found the doctrine of animal automatism too extreme. But some of the arguments in support of it were challenging. Perhaps living organisms were more machine-like than had been previously thought. In the eighteenth century, the simile of the mind being like a machine became popular. The French philosopher La Mettrie tried to turn the tables on Descartes. In his book *The Man Machine*, he first applauded Descartes for being a pure materialist about animals, but then tried to show that Descartes' arguments for animal

automatism could be used to show that human beings were just machines too.

Leibniz held the unusual view that both humans and animals were machines, but immaterial ones. Our bodies were said to be 'divine machines' or 'natural automata'. Human automata possessed the powers of perception and self-conscious memory. Animals had only a limited version of these abilities. Leibniz' doctrine, though odd and ambiguous, illustrates how flexible and abstract the idea of a machine can be. Almost anything, it seemed, might be a machine if it could be broken down into parts that functioned together in organized and predictable ways. (Somewhat surprisingly, Leibniz also claimed that we could never explain our perception in mechanical terms.) Leibniz agreed with the Aristotelean view that living created organisms, unlike windmills or clocks, could initiate purposive movement from within themselves, by virtue of a 'vital force' or 'entelechy'. These movements or activities were sometimes teleological, i.e., directed at ends or goals.

Long after Leibniz, philosophers, psychologists, biologists, and physiologists debated whether such behavior could be explained in purely materialistic mechanistic ways. Those who claimed that it could were called 'mechanists'. Those that claimed that it could not were often called 'vitalists'.

With the development of genetic theory, as well as discoveries about instinct and behavioristic psychology, proponents of vitalism nearly vanished from the intellectual scene. By the 1940s and 1950s, the prevailing view was wholly naturalistic.

The goal of the new field of 'cybernetics' (from the Greek word for 'steersman') was to understand in detail how control and communication worked in human and animal organisms as well as in self-regulating machines. The field was explicitly described as both behavioristic and functional. This meant that the focus of study was on inputs or stimuli from the environment to the animal or machine, together with states in between, leading to behavior. (*See* **Functionalism**; **Behaviorism, Philosophical**)

The centuries-old dream of being able to build a conscious machine seemed closer than ever. And it was at this time that the digital computer began to attract attention. Calculating machines had existed in both design and physical reality since the seventeenth century; but machines that could repeatably make use of their own computations in the production of further ones did not appear until the middle of the twentieth. This 'recursive' power had for some time been of intense logical and mathematical interest. It hinted at the possibility of self-reflection, and represented a new way of thinking about how a machine might be designed to imitate human thought processes.

PHILOSOPHICAL ISSUES ABOUT MACHINE CONSCIOUSNESS

Varieties of Consciousness

There is no tidy or uncontroversial concept of consciousness. But when trying to imagine a conscious machine, at least three (sometimes overlapping) aspects of consciousness should be considered. Firstly, there is the awareness involved in responding with purpose to stimuli from an external environment. Secondly (and often subsumed in the first aspect), there are simple perceptual experiences, such as seeing and touching, and inner thoughts, beliefs, intentions, feelings, emotions, moods, desires, and so on. Some of these mental states are 'about' other things (for example, a thought or belief about a cat). This 'aboutness' is sometimes called 'intentionality'. Other mental states are not about anything: they just are (for example, a visual experience of redness, or a bitter taste, or a sharp pain). Thirdly, there is self-consciousness, or the capacity of minds to reflect on their own conscious states, which might be any of the aforementioned ones. This 'second-order' consciousness is sometimes called 'introspective awareness'. (*See* **Consciousness, Philosophical Issues about**; **Introspection**; **Self-consciousness**)

Many of the aforementioned conscious states can be described as having a character or quality or 'feel' to them, such as 'what it's like' to see something red. These qualities are called 'qualia'. (*See* **Qualia**)

Many philosophers believe that, to some degree, some of these aspects of consciousness already exist in various self-regulating cybernetic mechanisms including computers. But it was the digital computer, with its many different forms of programming, that for many seemed to be the most promising candidate for machine mentality.

The Turing Test

What sorts of beings might be capable of thinking? It is often assumed that only beings with some degree of consciousness can think. It is also often assumed that the best evidence for conscious thinking existing in beings other than ourselves lies in various complex behaviors. The computer has shown impressive potential for performing complex tasks of which only thinking intelligent agents

such as ourselves had previously seemed capable. Thus the question of whether machines can think has attracted much interest since the mid-twentieth century, and with it the question of whether machines could be conscious.

In 1950, the mathematician A. M. Turing, in an interesting 'thought experiment', proposed a test for whether a machine can think. He imagined a game being played (called the 'imitation game'), in which an interrogator asks two concealed participants questions and uses their answers as a means for discovering a hidden aspect of their identities (for example, which one is the man and which the woman). The aim of one participant (A) is to fool the interrogator (C). The aim of the other (B) is to help the interrogator guess the right answer. Turing asked whether a computer might do as well as a human participant A in fooling C. He argued that it could, in the foreseeable future, and by virtue of this ability he felt that such a machine should be credited with thinking. This test later became known as the Turing test. (*See* **Turing Test**; **Turing, Alan**)

Some philosophers, as well as scientists involved in devising programs for modeling psychological processes, gave at least qualified support to Turing's position. Others disagreed. One argument was that a computer might perform a task previously only accomplished by intelligent people, without necessarily being intelligent. Perhaps the computer's performance would simply illustrate that there can be a variety of processes – some conscious and intelligent, others not – that result in the same achievement. Electric eyes, like doormen, may open doors for people, but they don't rely on seeing anyone coming, nor are they polite or concerned in their doing it.

In spite of these objections, Turing's test remained popular. Debates concerning the test's merits and demerits are still continuing.

Early Experiments in AI and some Philosophical Reactions to Them

Some of the most influential work in AI during the 1960s and 1970s concerned computer simulation of cognitive processes (CS). Allen Newell and Herbert Simon and others adopted the following strategy. A simulation of intelligent human mental processes, such as proving a theorem or playing chess, was constructed on the basis of observations of a human problem-solver's behavior. These observations might include verbal reports, jottings on paper, and so on. Attempts would then be made to represent these in the programming vocabulary used for the simulation. When the program was run, a trace of its 'thinking' activity would be printed. This trace would then be compared to some of the general features assumed to be present in the mind or behavior of the human problem-solver. (*See* **Newell, Allen**; **Simon, Herbert A.**)

One would not know with precision beforehand what would result from running the computer program. Nor can one know beforehand exactly what will go on in a human problem-solver's mind. But certain parallels between program and person were pursued. First, the tasks performed by a person were compared to the computer's results (deciding whether it passed the Turing test). Other levels of comparison involved much more guesswork. Although the structure and processes of the computer simulation could be described, it was often far from obvious how much of that description could apply to the human subject. Furthermore, it seemed that whatever objections might be raised to the Turing test in its general form would also be relevant to the specific use of that test in CS contexts.

Nevertheless, there was one important principle that seemed to underly AI research in general. This was what Newell and Simon called the 'physical symbol system hypothesis'. It stated simply that a physical symbol system has all the necessary means for general intelligent action. Whether this hypothesis was plausible or not, it had a bearing not only on CS but on many other related AI projects.

SHRDLU was an ingenious AI project which also incorporated robotic features. SHRDLU was a simulation of a robot that could respond to human commands concerning the construction and manipulation of (imagined) blocks of varying sizes and shapes (cubes, pyramids) and colors in a limited environment, say on a table top. When asked to do something with a block with respect to some present arrangement, not only could SHRDLU comply with the explicitly requested move, but it could calculate and carry out on its own whatever moves had to be made in order to carry out the command. (*See* **SHRDLU**)

SHRDLU could also produce replies to questions about what it was doing. And if a new word was contained in a command to SHRDLU, the program might indicate its unfamiliarity, and acquire the new word.

The environment within which SHRDLU functioned consisted entirely of data structures. These structures were symbolically represented within the computer. This program contained much of psychological and philosophical interest. Here was a buildable mechanical being operating in

three-dimensional space. (Another example of such a system, SHAKEY, was a mobile robot which negotiated its way through 'rooms' towards a goal.) In some sense, SHRDLU seemed to be sensitive to a variety of objects and able to interact with them. Its linguistic competence included an expandable vocabulary. But to what extent did SHRDLU, in its limited little world, reflect and illuminate our real world of perception, problem-solving, and discourse? Hubert Dreyfus has discussed the kinds of question–answer and command 'conversations' that SHRDLU had concerning its own blocky universe. He points out that SHRDLU's test for something being 'owned' is simply whether it is tagged as 'owned'. Dreyfus reminds us that SHRDLU couldn't own anything since it doesn't belong to a community in which ownership makes sense. This is just one example among many of how institutional and cultural facts could restrict how a subject like SHRDLU might act or what it could be 'conscious' of. Some form of embodiment seems to be required. (*See* **Embodiment**)

But questions remain about what SHRDLU can tell us about intelligent understanding, and perhaps about consciousness. At the heart of SHRDLU, as well as of other CS projects, is a program. But how plausible is Newell and Simon's physical symbol hypothesis?

Searle's Chinese Room Argument, and Other Problems for AI

Various AI projects durings the 1960s and 1970s seemed to exhibit some degree of understanding or comprehension (of, for example, language). In 1980, the philosopher John Searle published his famous 'Chinese room' argument, which tried to refute this. Searle claims he can imagine himself functioning just like an AI program. His mimicry consists of using a set of rules (written in his native language, English) whereby he manipulates a set of symbols in a language he doesn't understand at all (Chinese). The rules lead him to produce meaningful sentences in Chinese. Questions in Chinese are passed to him through a hole in the wall and he uses the rules to generate answers, which he passes back. To those outside the room where he is confined it will look as if something in the room is understanding questions in Chinese (about stories in Chinese) and answering them in Chinese. But no such understanding is taking place in the Chinese room. Nor, therefore, is it taking place in any AI program. (*See* **Chinese Room Argument, The**)

Symbol-based AI projects faced other serious problems. Conscious abilities such as recognizing patterns (like a face, or a house) or grouping things into kinds (like cats, dogs, or trees), or quickly sizing up situations, or performing complicated tasks, are often quickly done by people, and may involve many processes going on at once. Symbolic AI systems generally compute things step by step, in a serial way. Perhaps some model of consciousness based on the brain, which seems to carry out many different processes at the same time, would provide a better point of departure. This is called parallel processing. A number of 'connectionist' models have tried to capture this kind of processing. There has been considerable debate in recent years between researchers who favor symbolic AI models and those who favor connectionist ones. Serious philosophical questions arise for either approach to machine consciousness. (*See* **Connectionism**; **Computation, Philosophical Issues about**)

Qualia, Functionalism, Eliminative Materialism, and the Mind–Body Problem

Leibniz imagined a vast machine capable of perceptions, which we could go inside and walk around. No matter how hard we looked, he argued, we would never find anything in its mechanical make-up that would explain or disclose to us its perceptions. Leibniz saw this inevitable lack of disclosure as an important fact about the mind. The very same point could be made about consciousness and the brain. We could never 'see' consciousness displayed in a brain, or in any physical thing.

The philosopher Thomas Nagel has made a similar point by asking: What is it like to be a bat? Bats are very different from us. They are presumably conscious. But we don't know what it is like to be one. Nor would we know the answer to this question even if we knew everything that we possibly could about a bat's physical make-up.

Similarly, Frank Jackson has argued that a person brought up in a black-and-white environment, and thus deprived of any color experiences, might know everything there is to know about the material and functional facts underlying color vision. Nevertheless, when entering a multicolored environment for the first time, that person would be treated to an altogether new fact. The new fact would be what the experience of seeing red was like.

This character, or quality, or 'qualia' of our experiences, or 'what it's like' to have them, seems quite different from anything physical having to do with our brains or behavior. There seems to be a

gap between brains and qualia, between machines and minds. The difficulty of trying to bridge this gap so that we can fit consciousness into a scientific picture of the world is sometimes called 'the hard problem'. In essence it is the mind–body problem itself. (*See* **Explanatory Gap**)

Some say we will never be able to bridge this gap. Others have suggested that it may be possible by some as-yet-unknown means. Or perhaps qualia have a special kind of physical nature, irreducible to other physical things such as brain processes. And some philosophers are not troubled by qualia or subjectivity at all.

All these questions arise in connection with the influential doctrine in philosophy and cognitive psychology known as 'functionalism'. Functionalism claims that what makes a mental state the kind of mental state it is is its function or role in a pattern of causal relations. A pain, for example, is viewed as something caused by an input from the environment, say a brick falling on one's toe. The pain in turn causes other mental states, such as wanting to ease the pain, which then cause certain behavior (the output), such as taking an aspirin, grimacing, moaning, and so on. Anything with this role will be a pain. In conscious human organisms, certain neural states of the brain are thought by many to be what pains are. In other kinds of creatures, physical events other than neural processes may have that same role. For example, some future robot may have a 'brain' made of silicon chips that can produce pain. It is not any specific kind of matter that defines pain: multiple realizations are possible. It is the causal role that determines which mental states are present or absent in the creature under consideration. (*See* **Multiple Realizability**)

If so, then qualia don't seem to matter much. Imagine two different people who have two different color experiences when they look at a fire engine. One sees red; the other sees green. But they talk in exactly the same way about it. They both call it 'red'. They have each learned to use the words 'red' and 'green' in the same way. Their behaviors with respect to fire engines have the same causal relations. (*See* **Inverted Spectrum**)

One would think that the experience of seeing red was a different mental state from the experience of seeing green. But for the functionalist it seems that this is not so. Similarly, if there were a robot that behaved in exactly the same way as a human in the presence of fire engines, it would be, according to the functionalist, in the same mental state as the person experiencing green and the person experiencing red – even if it had no color 'experiences' at all. (*See* **Zombies**)

How do qualia fit into the functionalist's theory of mind? A 'quick fix' to these problems is provided by the doctrine of 'eliminative materialism'. The eliminative materialist suggests that many or most of our ordinary terms for talking about minds are misleading. Terms such as 'thought', 'belief', 'desire', and 'mental image' have been passed on to us as part of our prescientific 'folk psychology'. Perhaps these terms will become obsolete, in the same way that the term 'vital force' became obsolete and was essentially eliminated from the biological vocabulary used to explain goal-directed behaviors. In its most extreme, and least popular, version, eliminative materialism may suggest that the question of whether there is or could be machine consciousness is settled by default, since there is no such thing as consciousness. (*See* **Folk Psychology**)

INFLUENCE OF COGNITIVE SCIENCE ON ISSUES ABOUT MACHINE CONSCIOUSNESS

Since the time of Descartes and La Mettrie, machines have 'evolved'. And in the wake of this robotic 'evolution' have come various bold claims, many made by cognitive scientists, about the potential of physical mechanisms to reflect or even share human mentality and that of other animals. Some philosophers have supported these claims; others have criticized them. The lively dialogue that has ensued has been good for both cognitive science and philosophy. We now have new contexts for asking detailed questions about both mental functions and qualia (the 'hard problem').

Functional problems in modeling constitute what David Chalmers has called the 'easy' problems of consciousness. They include aspects of self-reporting, a system's access to its own internal states, reactions to an environment, categorization, and so on. All these, he and others believe, can be directly approached by the computational and connectionist strategies of cognitive science. Some, however, would claim that the so-called 'easy' problems are not so easy. Certain functional, computational activities that seem at first to be free of qualia may not be so, at least when carried out by human beings. For example, on hearing an ambiguous remark, we may have an awareness, or sense, or 'feel' for what the right meaning for a word in a sentence is. We hear the word 'bank' and we know (or 'compute') that the speaker meant a river bank, not a financial organization. Consciousness (with qualia) may be present in virtually every intentional human activity. So the basic nature – the

metaphysics – of qualia no doubt awaits further clarification.

Even if the 'easy' problems really are easy, we are left with the 'hard' questions – unless we adopt the extreme position of eliminative materialism. Cognitive scientists and philosophers alike want to know how 'outside' things (such as mechanisms, or observed machine behaviors) could ever depict subjective, 'inside' ('what it's like'), nonfunctional, mental features. If we imagine trying to build a machine with perspectives and perceptions step by step from scratch, at what point, if any, might we detect conscious experience entering the picture? Any interesting or useful machine model of consciousness should at least aim to incorporate whatever those features are that make the human mind, or any mind, so puzzling in the first place. Thus the model must be complex enough in what it contains that we are assured that something like the mind–body problem could arise for it. And such a model also needs to be instructive (or transparent) enough to give us some way of seeing through that problem. For suppose the machine model were complex enough to give rise to an analog of the mind–body problem, but it did not make consciousness more transparent than it now is. Then all we would learn from the construction (or imagined construction) of a conscious machine or robot would be that we could create things we didn't understand. We would not know if the machine model was itself a purely physicalistic model, or a dualistic one.

Ongoing attempts by cognitive scientists to model machine consciousness will, hopefully, contribute both to recreating the mind's complexity and to understanding its attendant perplexities. Of course, we cannot say what or 'who' the enhanced or combined 'offspring' of today's programs, robots, and neural networks are likely to be. But they will surely 'embody', as it were, various new research goals and presuppositions in cognitive science concerning mental function, qualia, and consciousness, which philosphers will want to assess.

Consciousness, Philosophical Issues about

Advanced article

Ned Block, New York University, New York, USA

CONTENTS

There are many problems of consciousness, but the most significant of them is: how is it possible to explain consciousness in terms of its neural basis?

THE 'HARD PROBLEM'

There are a number of different matters that come under the heading of 'consciousness'. One of them is phenomenality, the feeling of, say, a sensation of red, or a pain, that is, what it is like to have such a sensation or other experience. Another is reflection on phenomenality. Imagine two infants, both of which have pain, but only one of which has a thought about that pain. Both would have phenomenal states, but only one would have a state of reflexive consciousness. This article will first discuss phenomenality, reflexivity, and one other kind of consciousness, global availability.

The 'hard problem' of consciousness is how to explain a state of consciousness in terms of its neurological basis. If a neural state *N* is the neural basis of the sensation of red, why is *N* the basis of that experience rather than of some other experience, or of none at all? Chalmers (1996) distinguishes between the hard problem and 'easy' problems that concern the function of consciousness. The hard problem (though not by that name) was identified by Nagel (1974) and further analyzed in Levine (1983).

There are two reasons for thinking that the hard problem has no solution. The first is '*actual failure*': the fact that no one has been able to think of even a speculative answer. The second is '*principled failure*': the materials we have available seem ill suited to providing an answer – as Nagel says, an answer to this question would seem to require an objective account that necessarily leaves out the subjectivity of what it is trying to explain; and we do not even know what would count as such an explanation.

PERSPECTIVES ON THE HARD PROBLEM

Of the many perspectives on the hard problem, we will discuss four, all of which comport with a naturalistic framework.

Eliminativism

Eliminativism is the view that consciousness, as understood above, simply does not exist (Dennett, 1979; Rey, 1997). So there is nothing for the hard problem to be about.

Deflationism

Deflationists, also called philosophical reductionists (e.g. Dennett, 1991), move closer to 'common sense' by allowing that consciousness exists, but they 'deflate' this commitment – again on philosophical grounds – taking it to amount to less than 'meets the eye'. One prominent form of deflationism makes a conceptual reductionist claim: that consciousness can be conceptually analyzed in nonphenomenal terms. The main varieties of analysis are behavioral, functional, representational and cognitive.

Pitcher (1971) and Armstrong (1968) can be interpreted as analyzing consciousness in terms of beliefs. One type of prototypical conscious experience, for example of blue, is a matter of an inclination (perhaps suppressed) to believe that there is a blue object in plain view. (See Jackson (1977) for a convincing refutation.) A different kind of analysis appeals to higher-order thought or higher-order perception. Such analyses take the concept of a conscious pain to be the concept of a pain that is accompanied by another state that is about that pain. A pain that is not so accompanied is not a

conscious state (Armstrong, 1968; Carruthers, 1992; Lycan, 1990). (Rosenthal (1997) advocates a higher-order thought view as an empirical identity rather than as a conceptual analysis.) Another deflationist view, compatible with analyses in terms of beliefs, concerns not the states themselves but their contents. Representationism holds that it can be established philosophically that the phenomenal character of experience is its representational content. Many representationists reject conceptual analysis, but still their accounts do not depend on any details of psychology or neuroscience (Harman, 1990, 1996; Dretske, 1995; Lycan, 1996; McDowell, 1994, Tye, 1995). (Shoemaker (1994) mixes phenomenal realism with representationism in an interesting way.) Conceptual functionalists say that the concept of consciousness is analyzable functionally (Lewis, 1994).

According to deflationism, there is such a thing as consciousness, but there is no hard problem, that is, there are no mysteries concerning the physical basis of consciousness that differ in kind from scientific problems about, for example, the physical or functional basis of liquidity, inheritance, or computation.

Inflationism

Inflationism, also called phenomenal realism, is the view that consciousness is a substantial property that cannot be conceptually reduced or otherwise reduced on armchair grounds in nonphenomenal terms. Logical behaviorists think that we can analyze the concept of pain in terms of certain kinds of behavior, but inflationists reject all such analyses of phenomenal concepts in nonphenomenal terms. According to most contemporary inflationists, consciousness plays a causal role and its nature may be found empirically as the sciences of consciousness advance. Inflationism is compatible with the empirical scientific reduction of consciousness to neurological or computational properties of the brain – just as heat was scientifically, but not philosophically, reduced to molecular kinetic energy. (It is not a conceptual truth that heat is molecular kinetic energy.) Inflationism accepts the hard problem but aims for an empirical solution to it (Block, 1995; Flanagan, 1992; Loar, 1997; Nagel, 1974). McGinn (1991) argues that an empirical reduction is possible but that we can't find or understand it. Searle (1992) endorses a roughly naturalistic point of view and rejects armchair reduction of phenomenality, but he also rejects any empirical reduction of phenomenal properties.

The inflationist regards all the deflationist accounts described above as leaving out the phenomenon. Phenomenality has a function and represents the world, but it is something over and above that function or representation. Something might function like a phenomenal state but be an ersatz phenomenal state with no real phenomenal character. The phenomenal character that represents red in you might represent green in me. Phenomenal character does represent but it also goes beyond what it represents. Pain may represent damage but that is not what makes pain painful.

Dualistic Naturalism

Dualistic naturalism is a broad category which includes Chalmers' (1996) view that standard materialism is false but that there are naturalistic alternatives to Cartesian dualism, such as panpsychism. Nagel (2000) proposes that there is a deeper level of reality that is the naturalistic basis both of consciousness and of neuroscience.

AN ATTEMPT AT A DISSOLUTION OF THE HARD PROBLEM

Suppose following a theory of visual experience proposed by Crick and Koch (1990) that corticothalamic oscillation (of a certain frequency) is the neural basis of an experience with phenomenal quality *Q*. There is a plausible argument that seems to solve, or rather dissolve, the hard problem from a physicalist point of view. According to this argument, the hard problem is illusory. One might as well ask why H_2O is the chemical basis of water rather than gasoline or nothing at all. Just as water just is its chemical basis, so *Q* just is its neural basis, and so the original question is vacuous.

This point is correct as far as it goes, but it does not go far enough. It begs another question: how could one property be both phenomenal property *Q* and corticothalamic oscillation? How is it possible for something subjective to be something objective, or for something first-personal to be something third-personal? The problem is not that we cannot find an explanation for this identity; indeed, in a sense there are no explanations for any identities (Block, 1978a; Block and Stalnaker, 1999). The problem is that the claim that a phenomenal property is a neural property seems just as mysterious as – maybe even more mysterious than – the claim that a phenomenal property has a certain neural basis. Explaining an identity is different from explaining how an identity can be true,

where the latter involves removing a sense of puzzlement.

We can even see the same two obstacles stated above reappearing: 'actual failure' and 'principled failure'. In the first place, no one has even a speculative answer to the question of how something objective can be something subjective. In the second place, actual failure does not seem accidental. The objective seems to necessarily exclude the subjective. The third-personal seems to necessarily exclude the first-personal. Further, as McGinn (1991) notes, neural phenomena are spatial, but the phenomenal is prima facie nonspatial.

Thus, the reasons mentioned above for thinking that the explanatory gap resists closing seem to surface in a slightly different form. However, as we shall see, in this form they are more tractable.

AN APPROACH TO THE HARD PROBLEM

We now discuss a possible approach to the hard problem, whose main element is a distinction which is widely appealed to in discussions of Jackson's (1982) famous 'Mary' example. Jackson imagined a neuroscientist of the distant future who is raised in a black and white room but who knows everything scientific there is to know about color and the experience of it. When she steps outside the room for the first time, she learns what it is like to see red. Jackson argued that since the scientific facts do not encompass the new fact that Mary learns, dualism is true.

The most convincing response to Jackson's, argument (which derives from Loar (1990/1997)) involves an appeal to the distinction between a property and a concept of that property (Churchland, 1989; Loar, 1990/1997; Lycan, 1990; Van Gulick, 1993; Sturgeon, 1994; Tye, 1999; Perry, 2001).

A concept is a thought element in a way of thinking, a kind of representation. For our purposes, concepts can be interpreted as symbols in a 'language of thought'. This usage is different from another common philosophical usage in which a concept is something like a meaning. Concepts in our sense are individuated in part by meanings: x and y are instances of the same concept if and only if they are instances of the same representation and have the same meaning. 'Water' and 'H_2O' are instances of different representations, so the concept of water is distinct from the concept of H_2O.

Someone could believe that 'this color' is useful for painting pots but that red is not, even if 'this color' is red. Our experiential concept of red differs from our linguistic concept of red. An experiential concept involves a phenomenal element, a phenomenal way of thinking, for example a mental image that is in some sense of red, or an ability to produce such a mental image, or at least an ability to recognize red – which arguably could not be done without some phenomenal mental element.

Importantly, we can have an experiential concept of an experience (which we can call a phenomenal concept, phenomenal concepts being a subclass of experiential concepts), as well as an experiential concept of a color. And the very same mental image may be involved in both concepts. The difference between the phenomenal concept of the experience and the experiential concept of the color lies in the rest of the concept – in particular, in the way the phenomenal element functions in the concept. This can be a matter of further concepts explicitly invoked in the concept – the concept of a color in one case and the concept of an experience in the other. One type of experiential concept (of a color or of an experience) involves a demonstrative together with a mental image and a language-like representation, e.g. 'that [attention to a mental image] color' or 'that [attention to a mental image] experience' where the brackets indicate the use of attention to a nondescriptive element, a mental image, in fixing the demonstrative reference. Loar (1990/1997) gives an example involving two concepts in which something like a mental image of a cramp feeling is used to pick out a muscular knot in one concept, and in the other concept, the cramp experience itself. In our notation, the two concepts would be 'that [attention to a mental image] cramp' and 'that [attention to a mental image] cramp experience'.

An experiential concept uses a phenomenal property to pick out a related property. For example, an experiential concept of a color can use an aspect of the experience of that color to pick out the color. A phenomenal concept uses a phenomenal property to pick out a phenomenal property. The phenomenal property used in the concept need not be the same as the one picked out. For example, one could have a phenomenal concept of the experience of the missing shade of blue whose phenomenal elements are the flanking color experiences. Or, a phenomenal element involved in one's perception of a color could be used to pick out the experience of the complementary color. Importantly, the phenomenal element in a phenomenal concept need not be, and in general cannot be, conceptualized, at least if the conceptualization is meant to be itself phenomenal. For if a phenomenal concept had to make use of a

phenomenal element via a distinct phenomenal concept of that element, there could be no phenomenal concepts. Thus we can define a phenomenal concept as a concept of a phenomenal property that uses a phenomenal property to pick out a phenomenal property, but not necessarily under a concept of the phenomenal property used.

In these terms, then, Mary acquired a new concept of a property she was already acquainted with via a different concept. In the room, Mary knew about the subjective experience of red via physical concepts. After she left the room, she acquired a phenomenal concept of the same property. So Mary did not learn a new fact: she learned a new concept of an old fact. She already had a third-person understanding of the fact of what it is like to see red. What she gained was a first-person understanding of the very same fact. She knew already that corticothalamic oscillation of a certain frequency is what it is like to see red. What she learned is that 'this [attention to a mental image] experience is what it is like to see red'. So the case does not demonstrate that there are facts that go beyond physical facts.

Recall that there is a principled reason why mind–body identity seemed impossible: that a first-person subjective property could not be identical to a third-person objective property. But the distinction between concepts and properties allows us to see that the above distinction between subjective and objective, and the distinction between first person and third person, are distinctions between kinds of concepts, not kinds of properties. There is no reason why a subjective concept and an objective concept cannot pick out the same property. Thus we can substitute a dualism of concepts for a dualism of properties.

There is another way in which the concept–property distinction helps with the hard problem. We can blame the explanatory gap and the hard problem on our inadequate concepts rather than on dualism. To take a variant on Nagel's (1974) example, we are like pre-Socratics who have no way of understanding how it is possible that heat equals mean molecular kinetic energy, lacking the concepts required to frame both sides of the equation. (Heat was not clearly distinguished from temperature until the seventeenth century.) What is needed is a concept of heat and a concept of kinetic energy that make it conceivable that there is a causal chain of the referential sort leading from the one magnitude to each concept. Or rather, since the phenomenal concept includes a sample of the relevant phenomenal property (on the Humean simplification we are using), there is no mystery about the mental side of the equation. The mystery is how the physical concept picks out that phenomenal property. This is the remaining part of the explanatory gap, which will be closed, if at all, by science. Is there a principled reason to think it cannot be? The hard problem itself does not contain such a reason. Perhaps our conceptual inadequacy is temporary, as Nagel sometimes appears to suppose, or perhaps it is permanent, as McGinn (1991) supposes.

EMPIRICAL FINDINGS ABOUT CONSCIOUSNESS

We will now turn to a discussion of recent empirical findings on consciousness. The most interesting line of experimental investigation of consciousness in recent years uses phenomena in which perception changes independently of the stimulus. One such paradigm uses binocular rivalry. If two stimuli – for example, horizontal and vertical stripes – are presented, a different stimulus to each eye, one does not see a blend, but rather, first horizontal stripes that fill the whole visual field, and then vertical stripes that fill the whole field. Logothetis (1998) trained monkeys to pull different levers for different patterns. They then presented different patterns to the monkeys' two eyes, and observed that, as with people, the monkeys switched back and forth between the two levers even though the sensory input remained the same. Logothetis recorded the firings of various neurons in the monkeys' visual systems. In the lower visual areas (e.g. V1), 80 percent of the neurons did not shift with the percept. But further along the occipital–temporal pathway, 90 percent shifted with the percept. So it seems that later areas in the occipital–temporal pathway (let us call it the 'ventral stream') are more dominantly part of the neural basis of (visual) consciousness than earlier areas. Recent work using imaging has extended and refined these findings. Kanwisher (2001) notes that 'neural correlates of perceptual experience, an exotic and elusive quarry just a few years ago, have suddenly become almost commonplace findings'. And she backs this up with impressive correlations between neural activation on the one hand and indications of perceptual experiences of faces, houses, motion, letters, objects, words, and speech on the other. Although the neural correlates of, say, faces and houses, are somewhat different, both are in the ventral stream, mainly in the higher areas. These results represent a major success: identification of the neural basis of visual consciousness in the ventral stream.

Paradoxically, what has also become commonplace is activation of the very same ventral stream pathways without 'awareness'. Damage to the inferior parietal and frontal lobes has long been known to cause visual extinction – in which subjects appear to lose subjective experience of certain stimuli on one side when there are stimuli on both sides. Extinction is associated with visual neglect, in which subjects do not notice stimuli on one side. For example, neglect patients often don't eat the food on the left side of the plate. Although subjects say they do not see the extinguished stimulus, the nature of the stimulus has various visual effects. For example, if the subject's task is to decide whether a letter string (e.g. 'saucer' or 'spiger') is a word, the subject is faster for 'saucer' if there is a picture of a cup or the word 'cup' in the neglected field, even though they perform no better than chance in guessing what the picture depicts (McGlinchey-Berroth *et al*., 1996). So the stimulus, of which the subject is in some sense unaware, is processed semantically.

Driver and Vuilleumier (2001) point out that the ventral stream is activated for extinguished stimuli (i.e. stimuli that the subject claims not to see). Rees *et al*. (2000) report studies of a left-sided neglect and extinction patient on face and house stimuli. Stimuli presented only on the left side are clearly seen by the patient, but when there are stimuli on both sides, the subject says he sees only the stimulus on the right. However, the 'unseen' stimuli produce a pattern of activation of the ventral pathway that is the same in location and temporal course as the seen stimuli (though lower in magnitude). Furthermore, studies in monkeys have shown that a well-known 'blindness' syndrome is caused by massive cortical ablation which spares most of the ventral stream but not the inferior parietal and frontal lobes (Lumer and Rees, 1999). Kanwisher (2001) notes that dynamic visual gratings alternating with a gray field showed activation for V1, V2, V3A, V4v, MT and MST despite the subjects saying they saw only a uniform gray field.

Zeki and Ffytch (1998) hypothesize that the difference between conscious and unconscious activation of the ventral pathway is just a matter of the degree of activation. But Kanwisher (2001) mentions that evidence from event-related potential (ERP) studies using the attentional blink paradigm show that neural activation of meaning is no less when the word is blinked than when it isn't, suggesting that it is not lower neural activation strength that accounts for lack of awareness. Dehaene and Naccache (2001) note that in a study of neglect patients, it was shown that there is the same amount of semantic priming from both hemifields, despite the lack of awareness of stimuli in the left field, again suggesting that it is not activation strength that makes the difference.

The paradox, then, is that our success in identifying the neural correlate of visual experience in normal vision has led to the conclusion that in masking and neglect, that very neural correlate occurs without, apparently, subjective experience.

What is the missing ingredient *X* which, added to ventral activation, constitutes conscious experience? Kanwisher (2001) and Driver and Vuilleumier (2001) offer similar proposals as to the nature of *X*, namely, that the missing ingredient is binding perceptual attributes with a time and a place, a token event. Rees *et al*. (2000) make two suggestions as to what *X* is. One is that the difference between conscious and unconscious activation is a matter of neural synchrony at fine timescales. This idea is supported by the finding that ERP components P1 and N1 revealed differences between left-sided 'unseen' stimuli and left-sided seen stimuli. Their second suggestion is that the difference between seen and 'unseen' stimuli might be a matter of interaction between the 'visual stream' as we know it and the areas of parietal and frontal cortex that control attention.

Whether or not any of these proposals is right, the search for *X* seems to be the most interesting current direction for consciousness research. For the purposes of the discussion below, we will assume that *X* equals neural synchrony.

PHYSICALISM AND FUNCTIONALISM

There is another, very different, approach to the nature of consciousness. Dennett (1994) postulates that consciousness is 'cerebral celebrity'. What it is for a representation to be conscious is for it to be widely available in the brain. Dehaene and Naccache (2001) say consciousness is being broadcast in a global neuronal workspace.

The theory that consciousness is ventral stream activation combined with neural synchrony and the theory that consciousness is broadcasting in the global neuronal workspace are instances of the two major approaches to consciousness in the philosophical literature: physicalism and functionalism. The difference is that the functionalist says that consciousness is a role, whereas the physicalist says that consciousness is a physical or biological state that implements that role. For example, red may play the role of warning of danger – but green

might also have played that role. The picture of consciousness as role could be characterized as computational in contrast to the biological picture of consciousness as implementer of the role.

Although functionalists are free to add restrictions, functionalism in its pure form is implementation-independent. Consciousness is defined as global accessibility, and although its human implementation depends on human biochemistry, silicon-based creatures without our biochemistry could implement the same computational relations. Functionalism and physicalism are incompatible doctrines, since a nonbiological implementation of the functional organization of consciousness would be regarded as uncontroversially conscious by the functionalist but not by the physicalist. The big question for functionalists is: 'how do we know that it is broadcasting in the global workspace that makes a representation conscious, as opposed to something about the human biological realization of that broadcasting?

The problem for functionalists could be put like this: the specifically human biochemical realization of global availability may be necessary to consciousness – other realizations of global availability being 'ersatz' realizations. The typical response to this 'ersatz realization problem' (Lycan, 1981) is that we can preserve functionalism by simply bringing lower-level causes and effects into our functional characterizations: for example, causes and effects at the level of biochemistry. But this response is inadequate because one can descend the hierarchy of sciences to the lowest level of all, that of basic physics, and find oneself vulnerable to the same point. Putting the point for simplicity in terms of the physics of the 1960s, the causal role of electrons is the same as that of anti-electrons. If you formulate a functional role for an electron, an anti-electron will realize it. Thus an anti-electron is an ersatz realizer of the functional definition of 'electron'. Physics is characterized by symmetries that allow ersatz realizations (Block, 1978b).

We have been talking about the two approaches of functionalism and physicalism as rivals, but we can instead see them as answers to different questions. The question that motivates the physicalist proposal of 'ventral activation plus *X*' is: what is the neural basis of experience? The question that motivates the 'global broadcasting' proposal is: what makes neuronal representations available for thought, decision, reporting and action? The former is a theory of phenomenal consciousness ('phenomenality'), and the latter of 'access consciousness'. (Theorists will differ on whether access consciousness is really a type of consciousness (Burge, 1997).) We can try to force a unity by postulating that it is a condition on *X* that it promote access, but that is merely a verbal maneuver, and only disguises the difference between the concepts and questions involved. Alternatively, we could hypothesize, rather than postulate, that *X* as a matter of fact is the neural basis of global neuronal broadcasting. Note, however, that the neural basis of global neuronal broadcasting might obtain but the normal channels of broadcasting none the less be blocked or cut, and this would again reveal the distinction between phenomenality and access, showing that we cannot think of the two as one. (As an analogy, rest mass and relativistic mass are importantly different from a theoretical point of view despite coinciding for all practical purposes at terrestrial velocities. Failure of coincidence, even if rare, is theoretically critical to the scientific nature of consciousness.)

Many of us have had the experience of suddenly noticing a sound (say, a drilling noise during an intense conversation), at the same time realizing that the sound has been going on for some time even though we were not attending to it. If there was a phenomenal representation of the sound before it was noticed, that is, if the sound was experienced first and noticed second, that state was not broadcast in the global neuronal workspace until it was noticed: there was a period of phenomenality without broadcasting. Of course, this is anecdotal evidence. But the starting point for work on consciousness is introspection, and we would be foolish to ignore it.

If we take seriously the idea of phenomenality without global accessibility, one theoretical option that we should consider is that ventral stream activation is visual phenomenality and the search for *X* is the search for the neural basis of what makes visual phenomenality accessible. The idea would be that the claims of extinction patients not to see extinguished stimuli are in a sense wrong: they really do have phenomenal experience of these stimuli without knowing it. A similar issue will arise in our discussion of the relation between phenomenality and a special case of global accessibility, reflexive or introspective consciousness, in which the subject not only has a phenomenal state but also has another state that is about the phenomenal state, say, a thought to the effect that he has the phenomenal state.

We have drawn a distinction between two concepts of consciousness, phenomenality and global accessibility. We will now add a third, reflexivity.

PHENOMENALITY AND REFLEXIVITY

Consider the 'false recognition' paradigm of Jacoby and Whitehouse (1989). Subjects are given a study list of 126 words presented for half a second each. They are then presented with a masked word, w_1 and an unmasked word w_2. Their task is to report whether w_2 was old (i.e. on the study list) or new (not on the study list). The variable was whether w_1 was lightly or heavily masked, the former presentations being thought of as 'conscious' and the latter as 'unconscious'. Confining our attention just to cases in which $w_1 = w_2$, subjects were much more likely to mistakenly report w_2 as old when w_1 was unconsciously presented than when w_1 was consciously presented. The explanation would appear to be that when w_1 was consciously presented, the subjects were able to use an internal monologue of the following sort (though perhaps not quite as explicit): 'the reason w_2 looks familiar is that I just saw it (as w_1)'. Thus they 'explained away' the familiarity of w_2. But when w_1 was unconsciously presented, the subjects were not able to indulge in this monologue and consequently attributed the familiarity of w_2 to its appearance in the study list.

Any monologue that can reasonably be attributed to the subject in this paradigm concerns why a word (w_2) 'looks familiar' to the subject. For it is only by 'explaining away' the familiarity of w_2 that the subject is able to decide that w_2 was not on the study list. Thus, in the 'conscious' case, the subject must have a state that is about the subject's own perceptual experience (looking familiar), and thus conscious in what might be termed a 'reflexive' sense. An experience is conscious in this sense just in case it is the object of another of the subject's states: for example, one has a thought to the effect that one has that experience. The reflexive sense of 'consciousness' contrasts with phenomenality, which may apply to some states that are not the objects of other mental states. Reflexive consciousness might better be called 'awareness' than 'consciousness'. Reflexivity is phenomenality together with something else (reflection), and there is the possibility in principle of phenomenality without reflection.

What is the relation between reflexivity and the notion of global accessibility discussed in the last section? Global accessibility does not logically require reflexivity, since global accessibility only requires access to all response modes that the organism actually has. (Perhaps a dog or a cat does not have the capacity for reflection.) Reflexivity is a special kind of access, one that requires intellectual resources that may not be available to every being that can have conscious experience.

There is another aspect of the experimental paradigm just discussed which motivates taking seriously the hypothesis that the reflexively unconscious case might possibly be phenomenally conscious. Consider a variant of the exclusion paradigm reported by Debner and Jacoby (1994). Subjects were briefly presented with pairs of words flanked by digits (e.g. '4reason5'), and then given stems consisting of the first three letters of the word ('rea___') to complete. Subjects were instructed to complete the stem, but not with the word that was briefly presented and flanked by digits. There were two conditions. In the 'conscious' condition, they were told to ignore the digits. In the 'unconscious' condition, they were told to report the sum of the digits before completing the stem. The results were that in the 'conscious' condition, the subjects were more likely than baseline to follow the instructions and complete the stem with a word other than 'reason', whereas in the 'unconscious' condition, subjects were more likely than baseline to violate the exclusion instructions, completing the stem with 'reason'. Merikle and Joordens (1997) report corresponding results for the false recognition paradigm with divided attention substituted for heavy masking.

Consider the hypothesis that there was a fleeting phenomenal consciousness of 'reason' as the subject's eyes moved from the '4' to the '5' in '4reason5'. There are two theoretical options that deserve serious consideration: either (1) the 'unconscious perceptions' are both phenomenally and reflexively unconscious (in this case, the exclusion and false recognition paradigms are about consciousness in both senses); or (2) they are fleetingly phenomenally conscious but reflexively unconscious. A third option, that (3) they are phenomenally unconscious but 'reflexively conscious' seems less likely because the reflexive consciousness would be 'false': subjects would have a state 'about' a phenomenal state without the phenomenal state itself. That hypothesis would require some extra causal factor that produced the false recognition, and would thus be less simple. One argument in favor of (2) is that subjects in experiments with near-threshold stimuli often report a 'mess' of partial perceptions that they 'can't hang on to'. Some critics (e.g. Dennett, 1991) have disparaged the idea of fleeting phenomenal consciousness. But they still do not provide a positive reason to think that (1) is the correct view.

It might seem that there is a principled argument that we could never find out about phenomenality

in the absence of reflexive consciousness, for we require the subject's testimony about phenomenality, which requires the subject to have a state that is about the phenomenal state. We can see what is wrong with this reasoning by attention to some potential lines of evidence for phenomenality in the absence of reflexive consciousness.

Liss (1968) contrasted subjects' responses to brief unmasked stimuli (one to four letters) with their responses to longer lightly masked stimuli. He asked for judgments of brightness, sharpness and contrast as well as what letters they saw. He found that lightly masked 40 ms stimuli were judged as brighter and sharper than unmasked 9 ms stimuli, even though the subjects could report three out of four letters in the unmasked stimuli and only one out of four in the masked cases. Liss writes: 'The subjects commented spontaneously that, despite the high contrast of the letters presented under backward masking, they seemed to appear for such brief duration that there was very little time to identify them before the mask appeared. Although letters presented for only 7 ms with no masking appeared weak and fuzzy, their duration seemed longer than letters presented for 70 ms followed by a mask.'

Perhaps the subjects were phenomenally conscious of all the masked letter shapes, but could not apply the letter concepts required for reflexive consciousness of them. (The subjects could apply the concepts of sharpness, brightness and contrast to the letters, so they did have reflexive consciousness of those features, even if they did not have reflexive consciousness of the shapes themselves. There are two kinds of shape concepts that could have provided – but apparently did not provide – reflexive consciousness of the letters: the letter concepts that we all learn in school, and shape concepts of the kind we have for unfamiliar shapes.) In other words, perhaps phenomenal experience of shapes does not require shape concepts but reflexive consciousness, being an intentional state, does require shape concepts, concepts that the subjects seem unable to access in these difficult attentional circumstances. Alternatively, perhaps the phenomenal experience of shapes does involve shape concepts of some sort but the use of those shape representations in reflexive consciousness requires more attentional resources than were available to these subjects.

There is another hypothesis: that the contents of both the subjects' phenomenal states and their reflective states are the same, and include the features 'sharp', 'high contrast', 'bright' and 'letter-like' without any specific shape representation. On this hypothesis, there is no gap between phenomenal and reflexive consciousness. Both hypotheses have to be taken seriously, but the first is superior in at least one respect: anyone who has been a subject in this or in Sperling's (1960) similar experiment will feel that the last hypothesis does not really capture the experience, which is an experience of being able to see more letters than one can categorize.

Rosenthal (1997) defines reflexive consciousness as follows: *S* is a reflexively conscious state of mine if and only if *S* is accompanied by a thought – arrived at non-inferentially and non-observationally – to the effect that I am in *S*. He offers this 'higher-order thought' (HOT) theory as a theory of phenomenal consciousness. Both phenomenal consciousness without HOT and HOT without phenomenal consciousness are conceptually possible. For example, perhaps dogs and infants have phenomenally conscious pains without higher-order thoughts about them. Conversely, imagine that by biofeedback and imaging techniques of the distant future I learn to detect the state in myself of having the Freudian unconscious thought that it would be nice to kill my father and marry my mother. I could come to know – non-inferentially and non-observationally – that I have this Freudian thought even though the thought is not phenomenally conscious. Since there are conceptually possible counterexamples in both directions, the question again is whether reflexivity and phenomenality come to the same thing empirically.

If there are no actual counterexamples, the question arises of why. Is it supposed to be a basic law of nature that phenomenality and reflexivity co-occur? That would be a very adventurous claim that no one is in a position to make. Is it a contingent fact about us but not other phenomenally conscious creatures? Then reflexivity would not provide a basic account of phenomenality. Well then, is it supposed to be a contingent fact that phenomenality and reflexivity are coextensive in all creatures? What would be the evidence for such a far-reaching claim? Further, if phenomenality and reflexivity are correlated, then there must be a mechanism that explains the correlation, as the fact that both heat and electricity are carried by free electrons explains the correlation of electrical and thermal conductivity. But any mechanism breaks down under extreme conditions – as does the correlation of electrical and thermal conductivity at extremely high temperatures. So the correlation between phenomenality and reflexivity would break down too, showing that reflexivity does not yield the fundamental scientific nature of phenomenality.

Alternatively, it might be said that 'consciousness' is a 'natural kind' term, like 'water' or 'heat' or 'light'. We know that water is H_2O, as a matter of empirical fact without having to ask whether there might be a substance in another solar system that has a very different chemical constitution but nonetheless behaves exactly like water. The reason is that as a matter of the semantics of the word 'water', the question of whether there could be a substance that behaved exactly like water but that had a completely different chemical constitution does not matter since it would be wrong to call it 'water'. But this is a poor analogy for two reasons. First, if there are beings in another solar system who have something that feels like phenomenality but without reflexivity, then reflexivity does not capture the fundamental nature of phenomenality, whatever we call what the aliens have. Second, we call anything that feels like phenomenality 'phenomenality', so phenomenality is not a natural kind concept in the sense that 'water' is.

Rosenthal's definition of reflexivity has a number of *ad hoc* features. Non-observationality is required to rule out, for example, a case in which I know about a thought I have repressed by observing my own behavior. Non-inferentiality is required to avoid a somewhat different case in which I appreciate (non-observationally) my own psychic pain and infer a repressed thought from it. But why should the consciousness of a state depend on its causal history? Furthermore, Rosenthal's definition involves a stipulation that the possessor of the reflexively conscious state is the same as the thinker of the thought – otherwise my thinking about your pain would make it a conscious pain. All these *ad hoc* features can be eliminated by moving to the following definition of reflexivity: *S* is a reflexively conscious state if and only if *S* is phenomenally presented in a thought about *S*. This definition uses the notion of phenomenality; but this is no disadvantage unless one holds that there is no such thing apart from reflexivity itself. The new definition of reflexivity, requiring phenomenality as it does, has the additional advantage of making it clear that reflexivity is a kind of consciousness. (See Burge's (1997) critique of our notion of 'access consciousness' as constituting a kind of consciousness.)

We have encountered three concepts of consciousness: phenomenality, reflexivity, and global accessibility. The hard problem arises only for phenomenality. Imaging experiments on consciousness engage phenomenality and accessibility. But many psychological experimental paradigms mainly engage reflexivity. So empirical investigators of 'consciousness' may sometimes be talking at cross purposes.

CONTENTS

Advances in, and links between, neurobiology and psychology as applied in the study of sleep and dreaming compared to the waking state are increasingly revealing significant evidence for the brain basis of consciousness.

CONSCIOUS STATES AND BRAIN–MIND ISOMORPHISM

How can a material structure, like the brain, possibly possess awareness? Philosophers refer to this conundrum as 'the hard problem' and many are deeply pessimistic about its resolution. Countering such pessimism are recent developments in the cognitive neuroscience of waking, sleeping, and dreaming which have made it possible to understand – in considerable detail – how the brain changes its conscious state every day – and every night – of our lives. Even if we cannot yet detail how the brain becomes conscious in the first place, specification of the brain mechanisms responsible for the dramatic changes in consciousness that contrast waking and dreaming constitutes a partial solution of the brain–mind question and points the way to its more complete resolution in the foreseeable future (Hobson, 1999).

That dreaming might provide a privileged access to understanding the relationship of brain and mind has long been recognized by such diverse thinkers as the Enlightenment philosopher David Hartley and the Romantic poet Samuel Taylor Coleridge. Wilhelm Wundt, the father of experimental psychology, astutely speculated that to account for the difference between dreaming and waking consciousness, those brain functions supporting critical thought and self-reflective awareness must be in abeyance (in dreaming) while those supporting internal perceptions and emotions must be enhanced.

In declaring that dreaming was the royal road to the unconscious mind, Sigmund Freud was strongly influenced by his earlier attempt to create a scientific psychology based upon the structures and functions of the 100 billion nerve cells that constitute the brain. Until recently none of these theories could advance because so little was known about the activity of the brain during sleep.

Since the late 1920s brain science has seen dramatic advances that now make a solid neurology of dreaming possible. The first key step in this direction was the discovery of the electroencephalogram (EEG) by Adolf Berger in 1928 and the recognition by him that the pattern of brain waves changed when subjects became inattentive or drowsy. Figure 1 illustrates the normal human sleep cycle as it is understood today.

The idea that the brain waves of the cerebral cortex had to be kept electrically activated to support waking consciousness was crystallized in the discovery of the importance to arousal of the brain stem reticular formation (Moruzzi and Magoun, 1949). Shortly thereafter, it was discovered that the brain was periodically reactivated during sleep and that this activation was associated with rapid eye movements (or REMs) and with intense and sustained dream consciousness (Aserinsky and Kleitman, 1953; Dement and Kleitman, 1957).

It remained to give an account of the mechanisms of electrical activation of the cortex by the brain stem and to distinguish between the brain processes associated with the electrical activation that occurred in waking and in sleep in such a way as to distinguish between dreaming and waking consciousness. These details emerged from studying the animal model of REM sleep provided by the discovery that REM sleep also occurred periodically in the sleep of cats (Dement, 1958).

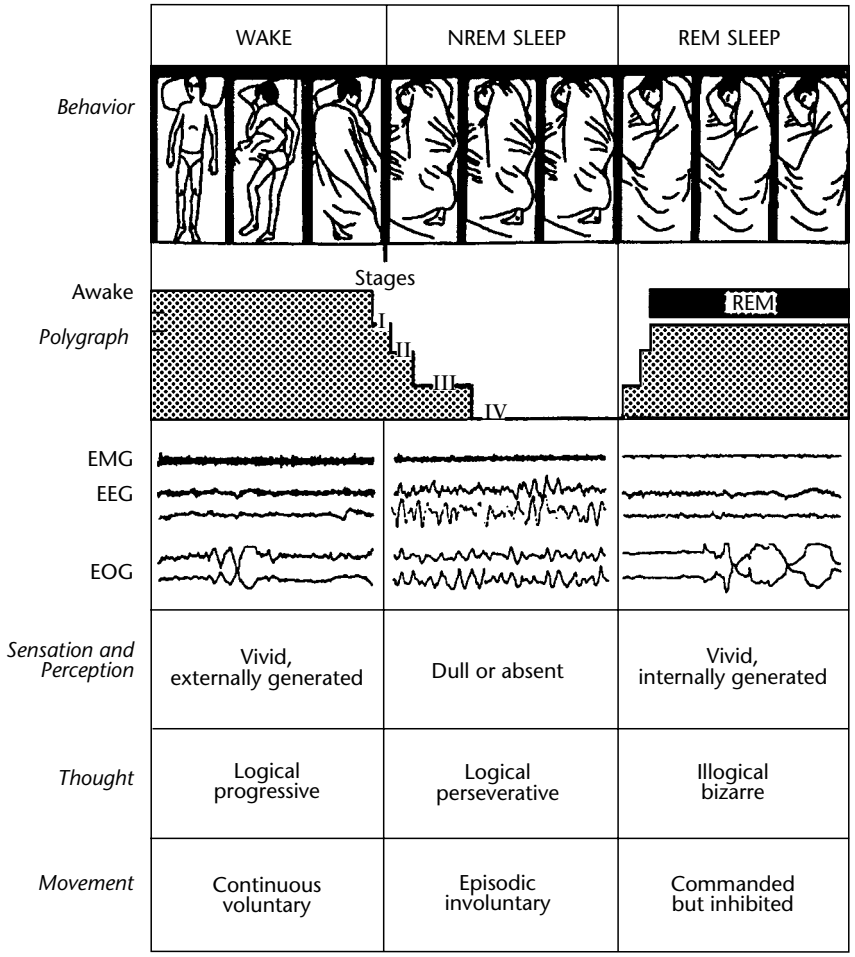

Figure 1. Behavioral states in humans. States of waking, rapid eye movement (REM) sleep, and non-REM (NREM) sleep have behavioral, polygraphic, and psychological manifestations. In the behavior channel, posture shifts (detectable by time-lapse photography or video) can occur during waking and in concert with phase changes of the sleep cycle. Two different mechanisms account for sleep immobility: disfacilitation (during stages I–IV of NREM sleep) and inhibition (during REM sleep). In dreams we imagine that we move but we do not. Sequence of these stages is represented in the polygraph channel. Sample tracings of three variables used to distinguish state are also shown: electromyogram (EMG), which is highest in waking, intermediate in NREM sleep, and lowest in REM sleep; and electroencephalogram (EEG) and electrooculogram (EOG), which are both activated in waking and REM sleep and inactivated in NREM sleep. Each sample record is 20 s. Three lower channels describe other subjective and objective state variables. (From Hobson and Steriade, 1986.)

Working with cats, Michel Jouvet had, by 1959, demonstrated that the brain activation of REM sleep (like that of waking) depended upon the brain stem. That the mechanisms of brain activation were quite different in REM sleep and waking became apparent from Jouvet's discovery that the postural tone of the muscles necessary to support the motor activity of waking was actively abolished in REM. Jouvet also showed that the cerebral cortex was not only activated in REM but received internal stimuli from the brain stem regarding the movement of the eyes. Because these internal visual signals are much stronger in REM sleep than in waking it was possible, for the first time, to imagine how the dreaming brain could produce visual imagery of great intensity entirely on its own (Jouvet, 1962).

All these important discoveries set the stage for the analysis of the cellular and molecular brain processes that mediated the differences between dreaming and waking consciousness. Using the movable microelectrode technique pioneered by the vision specialist David Hubel and the motor expert Edward Evarts, it was possible for Robert McCarley and Allan Hobson to propose a model of reciprocal interaction between two chemically

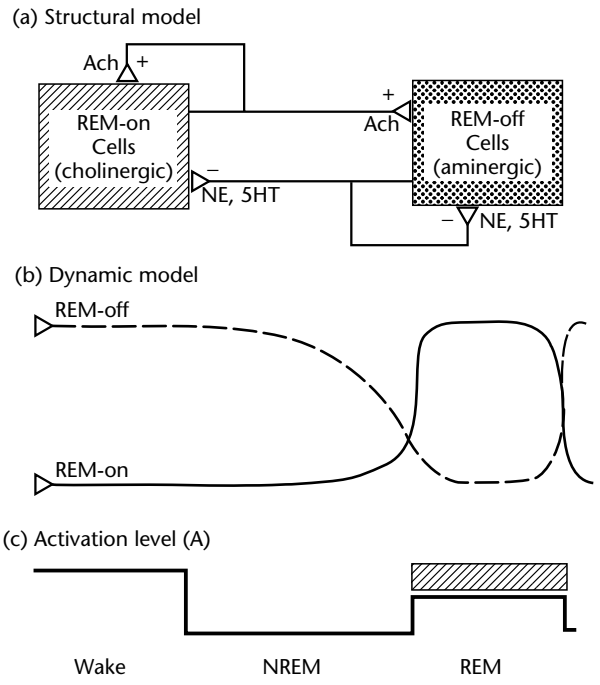

Figure 2. The original reciprocal interaction model of physiological mechanisms determining alterations in activation level. (a) Structural model of reciprocal interaction: REM-on cells of the pontine reticular formation are cholinoreceptively excited and/or cholinergically excitatory (ACH+) at their synaptic endings. Pontine REM-off cells are noradrenergically (NE) or serotonergically (5HT) inhibitory (−) at their synapses. (b) Dynamic model: during waking the pontine aminergic system is tonically activated and inhibits the pontine cholinergic system. During NREM sleep aminergic inhibition gradually wanes and cholinergic excitation reciprocally waxes. At REM sleep onset aminergic inhibition is shut off and cholinergic excitation reaches its high point. (c) Activation level: as a consequence of the interplay of the neuronal systems shown in (a) and (b), the net activation level of the brain is at equally high levels in waking and REM sleep and at about half this peak level in NREM sleep. (Taken from Hobson, 1992.)

distinct brain stem cell groups (Hobson *et al*., 1975; McCarley and Hobson, 1975) and to tie that model to a brain-based dream theory, the activation-synthesis hypothesis (Hobson and McCarley, 1977). Figure 2 illustrates the original reciprocal interaction model and its behavioral consequences, while Figure 3 illustrates the activation-synthesis hypothesis. By integrating these two models with new data, it has recently been possible to elaborate AIM, a three-dimensional state space specifying the major physiological determinants of states of consciousness (discussed below).

FORMAL PROPERTIES OF DREAM CONSCIOUSNESS

Previous approaches to dreaming have reflected the natural tendency to regard dreams as story-like experiences conveying and/or concealing hidden or symbolic meaning. This interpretive tradition is ancient and while it remains humanistically honorable, it has always been scientifically unsatisfactory. Its most zealous modern exponent, Sigmund Freud, understood that a brain-based theory of dreaming was required but, lacking the tools to construct one, he instead created the pseudoscience of psychoanalysis.

Whether dreams are stories or scenarios, and whatever their meaning might or might not be, dreaming is a state of consciousness with distinctive properties that can be defined and measured when the emphasis is placed upon the form of all dreams rather than the particular content of each one. These formal properties of dream consciousness can then be compared with those of waking. Any differences that emerge can then be mapped onto differences between REM sleep and waking state neurobiology (Hobson, 1988).

The emphasis upon the analysis of dream form and the definition and measurement of formal dream properties is every bit as important as the recording of individual nerve cells because it brings subjectivity itself into the scientific arena. In so doing it allows us to describe and quantify

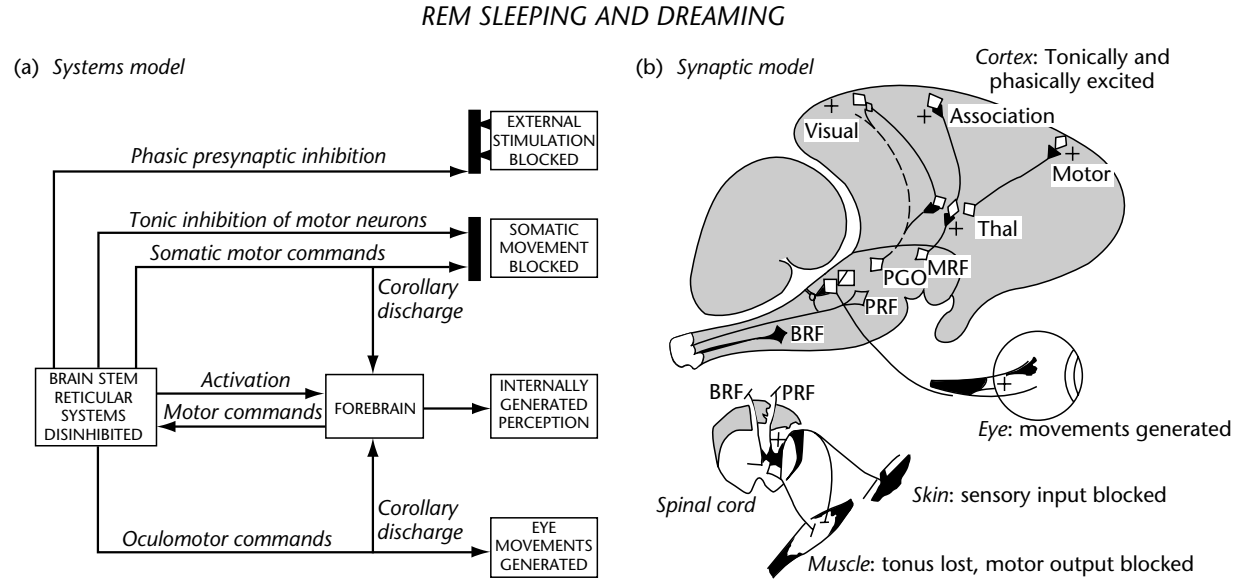

Figure 3. The activation-synthesis model. (a) Systems model: as a result of disinhibition caused by cessation of aminergic neuronal firing, brain stem reticular systems auto-activate. Their outputs have effects including depolarization of afferent terminals causing phasic presynaptic inhibition and blockade of external stimuli, especially during the bursts of REM, and postsynaptic hyperpolarization causing tonic inhibition of motor neurons that effectively counteract concomitant motor commands so that somatic movement is blocked. Only the oculomotor commands are read out as eye movements because these motor neurons are not inhibited. The forebrain, activated by the reticular formation and also aminergically disinhibited, receives efferent copy or corollary discharge information about somatic motor and oculomotor commands from which it may synthesize such internally generated perceptions as visual imagery and the sensation of movement, both of which typify dream mentation. The forebrain may, in turn, generate its own motor commands that help to perpetuate the process via positive feedback to the reticular formation. (b) Synaptic model: the midbrain reticular neurons (MRF) projecting to the thalamus convey tonic and phasic signals rostrally. PGO burst cells in the peribrachial region convey phasic activation and specific eye movement information to geniculate body and cortex (dotted line indicates uncertainty of direct projection). The pontine reticular-formation neurons (PRF) transmit phasic activation signals to oculomotor neurons (V1) and spinal cord which generate eye movements, twitches of extremities, and presynaptic inhibition. The bulbar reticular-formation neurons (BRF) send tonic hyperpolarizing signals to motor neurons in the spinal cord. As a consequence of these descending influences, sensory input and motor output are blocked at level of the spinal cord. At the level of the forebrain, visual association and motor cortex neurons all receive time and phasic activation signals for nonspecific and specific thalamic relays.

universal aspects of conscious experience, leaving aside for the moment individual differences which are more difficult to explain today by a brain-based theory.

The formal psychological feature which has been most extensively analyzed is the bizarreness that makes dreaming so strange, so puzzling, and by turns so amusing and so frightening. To our great surprise, we found that dream bizarreness was reducible to discontinuity and incongruity in the domains of time, place, and person, all three of which are quantitatively more unstable in dreaming than in waking consciousness. And one of them, the tendency of characters to have unstable or hybrid identities, seems to be absolutely unique to dreaming. Only in psychosis do people experience such disturbing phenomena when awake.

Dream consciousness is also characterized by internally generated sensory imagery of hallucinatory clarity and intensity. Dream imagery is predominantly visual, and is associated with the continuous illusion of movement. Dream consciousness is dominated by a false belief that we are awake, which only rarely gives way to the insight (called 'lucidity') that we are actually dreaming. And this delusional belief that we are awake persists despite robust cognitive evidence to the contrary. We simply don't seem to notice that when dreaming we are so disoriented that times, places, and persons change without our notice. Furthermore we cannot direct our thoughts, or our actions, as we do the most improbable or even downright impossible things, such as flying or cycling effortlessly uphill.

It seems probable that one of the most fundamental cognitive features of dreaming is a defect in episodic memory. When we dream we cannot remember prior events or even those that have just occurred in the dream. Furthermore, we cannot remember most of our dreams after we wake up. These perceptual and cognitive peculiarities are most often accompanied by strong negative emotions, such as anxiety, fear, and anger, but pleasantly intense elation may also be prominent. Table 1 summarizes these formal properties of dreaming.

Following Wilhelm Wundt, we agree that any dream theory thus needs to explain two classes of change in the state of consciousness from that of waking: (1) the enhancement of the perceptual and emotional components of consciousness, and (2) the impairment of its orientational, insightful, and memory components. Freud dealt with this dual aspect of dream consciousness by positing a defect in superego and ego functions and a reciprocal increase in instinctual id functions. As will be clear when we discuss new evidence for deactivation of the frontal cortex and a reciprocal increase in subcortical activation during human REM sleep, the new brain-based theory accounts for this kind of duality in a highly specific way.

By demonstrating the automaticity of the REM sleep generator in the brain stem, the activation-synthesis theory (Figure 3) eliminates psychological motives (Freud's unconscious wishes) from the instigation of dreaming. And by demonstrating the neurobiological mechanisms of dream formation, the new theory obviates Freud's disguised censorship hypothesis. It thus greatly weakens the credibility of any interpretative scheme based upon these two erroneous notions.

Before turning to the neurobiology, it is important to emphasize the heuristic value of a brain-based theory of dreams for the scientific understanding of abnormal as well as normal states of consciousness. This is because dream consciousness has so many features of major mental illness. And because it is both hallucinatory and delusional, normal dream consciousness is a psychotic state by definition. But to what abnormal psychosis is dreaming consciousness most similar? Not to schizophrenia where the hallucinations are primarily auditory and not visuomotor. And not to psychotic depression where the most prominent dysphoric emotions are sadness, guilt, and shame – not anxiety, anger, or elation. Because the hallucinations are visual, the thinking undirected, the orientation unstable, and episodic memory badly impaired, dream consciousness is most akin to those delirious states that are associated with toxic conditions which impair the brain organically. Table 2 summarizes these distinct differences between waking and dreaming consciousness.

REM SLEEP NEUROBIOLOGY

We now know that the brain is in an organically altered state in REM sleep. Although it is electrically activated to a level equal to or even exceeding that of waking, the regional pattern of activation is quite different. And because the input–output gates are closed there is no discourse with the outside world. As a result there is no external space–time constancy against which to check the internally generated percepts and emotions. Finally, the percepts and emotions are engendered because of a shift in the chemical balance of the brain which also impairs our memory, our internal

Table 1. The formal features of REM sleep dreaming

Hallucinations – especially visual and motoric, but occasionally in any and all sensory modalities.
Bizarreness – Incongruity (imagery is strange, unusual, or impossible); discontinuity (imagery and plot can change, appear, or disappear rapidly); uncertainty (persons, places, and events often bizarrely uncertain by waking standards).
Delusion – we are consistently duped into believing that we are awake (unless we cultivate lucidity).
Self-reflection absent or greatly reduced relative to waking.
Lack of orientational stability – persons, times, and places are fused, plastic, incongruous, and discontinuous.
Narrative story lines explain and integrate all the dream elements in a confabulatory manner.
Emotions increased, intensified, and predominated by fear anxiety.
Instinctual programs (especially fight–flight) often incorporated.
Volitional control greatly attenuated.
Memory deficits across dream–wake, wake–dream and dream–dream transitions.

Table 2. Cognitive differences between wake and dream states

Function	*Dream compared to wake*
Perception (external)	Diminished
Perception (internal)	Enhanced
Attention	Lost
Memory (recent)	Diminished
Memory (remote)	Enhanced
Emotion	Episodically strong
Orientation	Unstable
Thought	Reasoning *ad hoc*, logical rigor weak, processing hyperassociative
Insight	Self-reflection greatly diminished
Narrative construction	Confabulatory
Volition	Weak

orientational stability, and our ability to think insightfully and critically. Three neurobiological factors affecting consciousness can thus be identified and defined as follows:

1. *Activation (A)*: activating the brain so that consciousness can be at least as intense in REM sleep dreaming as it is in waking is the responsibility of the brain stem reticular formation. This system turns off at sleep onset, allowing the thalamus and cortex to indulge in their own intrinsic rhythmic activity which are seen as the spindles and slow waves of NREM sleep when consciousness abates.
2. *Input–Output Gating (I)*: when the reticular formation turns on again in REM, the brain stem simultaneously inhibits sensory input and blocks motor output so that we do not wake up even though the brain is activated. This input–output blockade is an active process which naturally puts dream consciousness offline, as it were. The eyes move in REM because internal signals are spared the active inhibition that affects the other motor systems of the brain. They arise in the pons whence they are also directed to the upper brain where they stimulate visual and emotional centers in concert with the REMs and thus cause the visuomotor hallucinosis.
3. *Mode (M)*: the internally generated signals emanate from the lateral part of the pontine brain stem where neurons that manufacture acetylcholine are found. Acetylcholine is one of the chemicals involved in learning and memory and it is released in both waking and REM. In waking, the acetylcholine neurons are activated by external stimuli, whereas in REM they become spontaneously active. This is because they are then released from the inhibitory restraint of norepinephrine and serotonin neurons which are active and quell them in waking (see Figure 2). Norepinephrine and serotonin are two other brain chemicals that contribute to attention and memory, and their unavailability in REM contributes to the cognitive deficits in dream consciousness.

The net result of this change in neuronal traffic flow in REM sleep is an electrically activated, offline brain, whose chemical balance has been tipped in the acetylcholine direction. Because the brain is activated it is conscious of its own spontaneous information processing. But because it is offline it is cut off from external reality. Because of the shift in chemical balance, it generates its own signals and interprets them as if they came from the outside world. But the brain is not only deprived of external cues that help to structure waking consciousness. It is also deprived of two of the chemicals that it uses to organize its information in a coherent, logical, and directed manner. This is why dream consciousness is characterized by so much incongruity and discontinuity.

THE AIM MODEL

The perspicacious reader will now realize that the three neurobiological factors we have been discussing collaborate to determine our state of consciousness in the following way:

1. *The Activation level* (A) determines the *intensity* of consciousness. Factor A operates very much in the manner of a power supply. Its value which can be assessed from the EEG, is high in wake and REM but low in non-REM (NREM) sleep.
2. *The Input–Output gating level* (I) determines the source of the information that determines the *content* of consciousness. Its value can be determined by the degree of presynaptic inhibition on the sensory side and by the degree of inhibition of spinal reflex activity on the output side. When the input–output gates are open, as in waking, external information plays a major role in sleeping consciousness. When the input–output gates are closed, as they are in REM, only internal data can be processed.
3. *The Mode* (M) of the brain determines how the internally generated information is processed primarily via its impact upon memory systems. Its value can be determined (so far only in animals) by the ratio of activity of norepinephrine- or serotonin-containing neurons to that of the acetylcholine cells. If the value of M is high, memories will be recorded, but if M is low – as it is in REM – memory will be deficient.

The range of values of A, I, and M can be laid out along the three dimensions of a cube. The resulting cubic space contains and bounds a virtual infinity of possible state points, each of which represents the instantaneous values of A, I, and M. As illustrated in Figure 4(a), the canonical states of waking, NREM sleep, and REM occupy specific

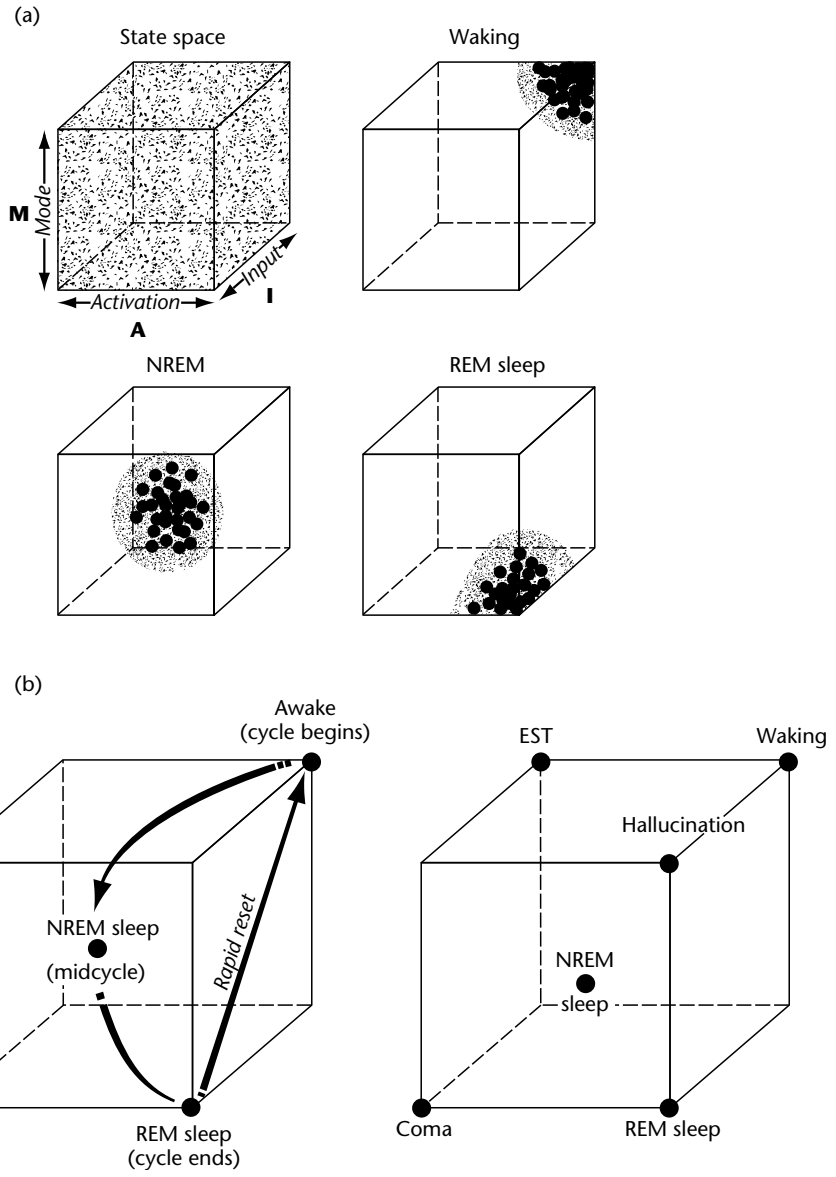

Figure 4. (a) Three-dimensional state space defined by the values for brain activation (A), input source and strength (I), and mode of processing (M). It is theoretically possible for the system to be at any point in the state space and an infinite number of state conditions is conceivable. In practice the system is normally constrained to a boomerang-like path from the back upper right in Waking (high A, I, and M), through the centre in NREM (intermediate A, I, and M) to the front lower right in REM sleep (high A, low I and M). (b) The canonical trajectory of the brain–mind is shown for each cycle of adult human sleep (left box). That this trajectory is an irregular ellipse is in keeping with the cyclical behavior of the brain stem neuronal control system for REM sleep. Besides the canonical states of wake, NREM, and REM, are "forbidden zones" which are only entered under pathological or exceptional normal conditions (right box).

subregions of the consciousness state space. With time as a fourth dimension, the normal diurnal trajectory through this space can be visualized as the sequential points follow a large-diameter elliptical path (representing the circadian rhythm) with smaller dramatic ellipses within it (representing the NREM–REM sleep cycle).

At this early stage, the AIM model is only a heuristic, illustrative construct. But, for the student of consciousness, the three-dimensional model has several advantages over traditional two-dimensional graphic displays of brain–mind state.

The first is its ability to distinguish wake and REM which, despite their identity on the activation

axis, are strongly contrasted along both the I and M axes. This contrast is congruent with the very different formal properties of consciousness in the two states.

The second advantage of AIM is its capacity to accommodate the myriad substates that constitute the conscious vicissitudes of everyday life. These include sleepiness, hyperalertness, fantasy, insomnia, and even creative imagination.

The third advantage of AIM is its recognition of those off-limit sectors of the state space into which consciousness may be pulled – or pushed – when humans suffer from spontaneous dysfunctional states such as epilepsy, schizophrenia, sleep disorders, or the comas that follow head injury. Conceptualization of such abnormal states using the three-dimensional AIM model is illustrated in Figure 4(b).

Finally, the AIM model is at home to the many intentional self-experiments on consciousness performed by humans using and abusing drugs like alcohol, amphetamine, LSD, and cocaine. Its explanatory generosity thus welcomes the vast family of recreational and therapeutic chemicals that play so powerfully – for good and evil – on the modulatory neurons of the brain.

HUMAN NEUROPSYCHOLOGY

Until recently, the experimental study of human REM sleep dreaming has been limited on the physiological side by the poor resolving power of the EEG. Even expensive and cumbersome evoked potential and computer averaging approaches have not helped to analyze and compare REM sleep physiology with that of waking in an effective way. This limitation has probably reinforced the erroneous idea that the brain activation mechanisms of REM sleep and waking are identical, or at least very similar. Fortunately, technological advances in the field of human brain imaging have now made it possible to describe a highly selective regional activation pattern of the brain in REM sleep. At the same time, experiments of nature – in the form of strokes – have allowed the locale of brain lesions to be correlated with the diminution or intensification of various aspects of dream experience in patients (Hobson *et al*., 1998).

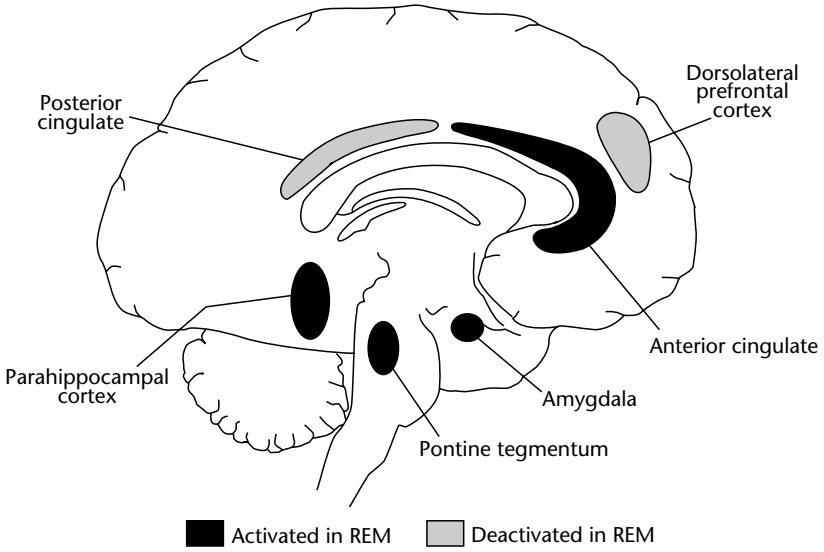

Figure 5. Convergent findings on relative regional brain activation and deactivation in REM compared to waking. A schematic sagittal view of the human brain showing those areas of relative activation and deactivation in REM sleep compared to waking and/or NREM sleep which were reported in *two or more* of the three PET studies published to date (Braun *et al*., 1997; Maquet *et al*., 1996; Nofzinger *et al*., 1997). Only those areas which could be easily matched between two or more studies are schematically illustrated here, and a realistic morphology of the depicted areas is not implied. The depicted areas in this figure are thus most realistically viewed as representative portions of larger central nervous system areas subserving similar functions (e.g. limbic-related cortex, ascending activation pathways, and multimodal association cortex). (Source: Hobson *et al*., 1998.)

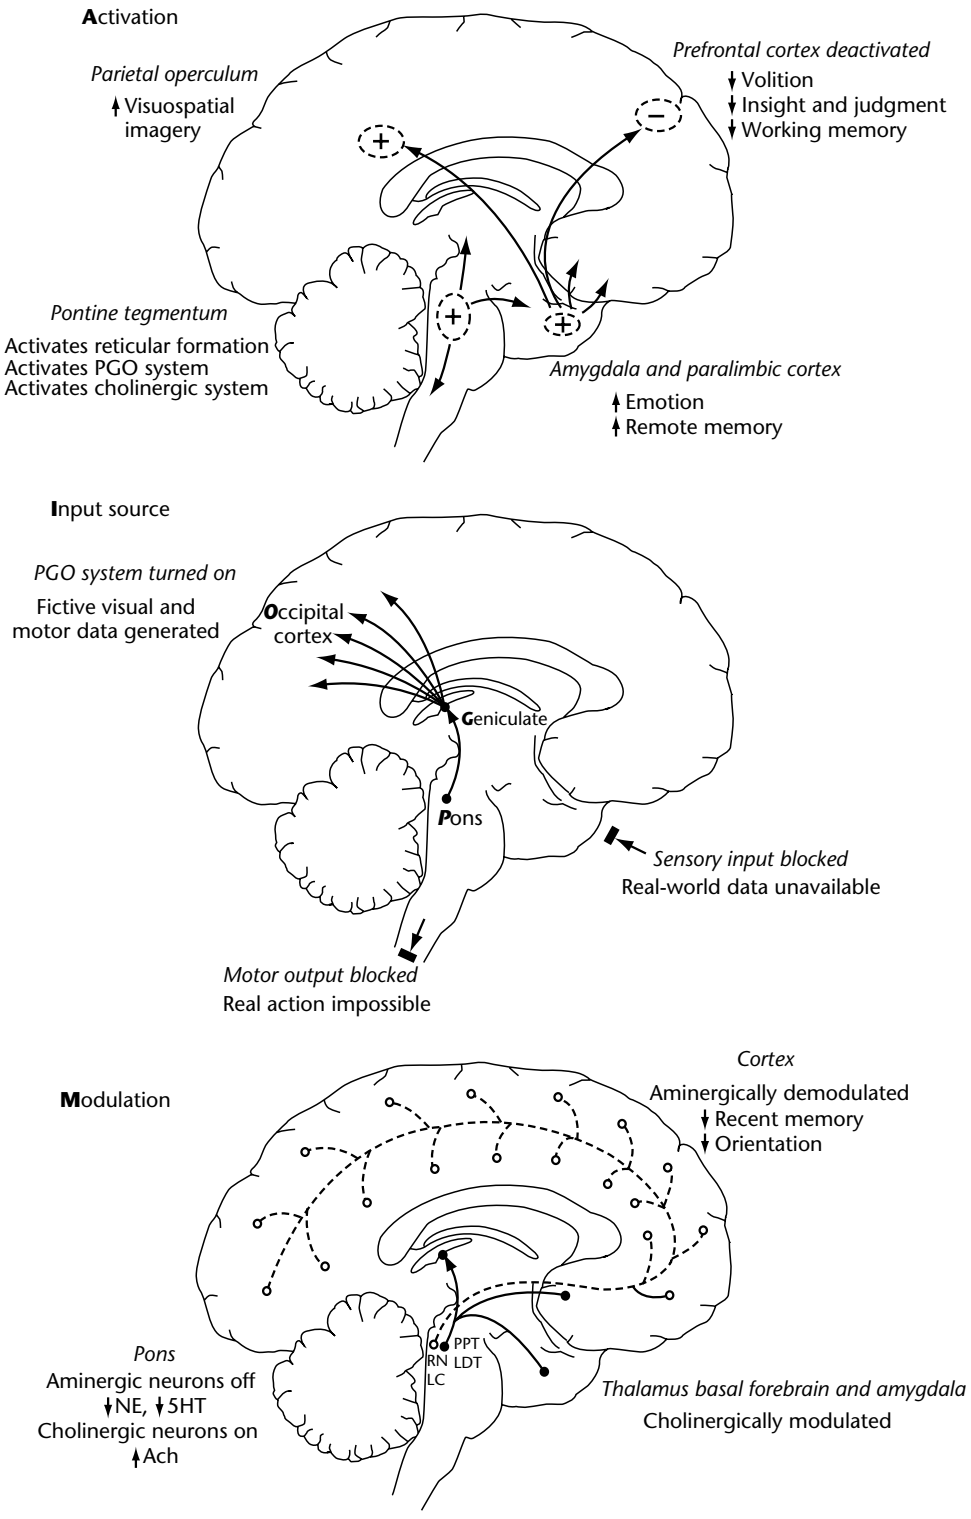

Figure 6. Physiological signs and regional brain mechanisms of REM sleep dreaming separated into the activation (A), input source (I), and modulation (M) functional components of the AIM model. Dynamic changes in A, I, and M during REM sleep dreaming are noted adjacent to each figure. Note that these are highly schematized depictions which illustrate global processes and do not attempt to comprehensively detail all the brain structures and their interactions which may be involved in REM sleep dreaming.

POSITRON EMISSION TOMOGRAPHY IMAGING STUDIES OF REM SLEEP DREAMING

Pierre Maquet and his co-workers at the University of Louvain in Belgium used an $H_2{}^{15}O$ positron source to study REM sleep activation in their subjects, who were subsequently awakened for the solicitation of dream reports (Maquet *et al.*, 1996). They observed a preferential activation of limbic and paralimbic regions of the forebrain in REM sleep (compared to either waking or to NREM sleep). One important implication of this finding is that dream emotion may be a primary shaper of dream plots rather than playing the secondary role in dream plot instigation that was previously hypothesized.

An equally interesting finding, relevant to the cognitive deficits in self-reflective awareness, orientation, and memory during dreaming, is the significant deactivation, in REM, of a vast area of dorsolateral prefrontal cortex. The fact that considerable portions of executive and association cortex are far less active in REM than in waking leads to the idea that in REM sleep there is a specific impairment of executive systems which normally participate in the highest order analysis and integration of neural information. See Figure 5 for results of this study integrated with those of several other recent neuroimaging studies.

LOSS OF DREAMING AFTER CEREBRAL LESIONS

An entirely complementary set of findings and conclusions has been reached following a neuropsychological survey of 332 clinical cases with cerebral lesions by Mark Solms at University College in London, England. The 112 patients who reported a 'global cessation of dreaming' either had damage in the limbic system or the parietal convexity, or suffered disconnections of the mediobasal frontal cortex from the brain stem and diencephalic limbic regions. With respect to the visual imagery aspect, a decrease in the 'vivacity' of dreaming was reported by two patients with damage to the visual associative area in the mediaoccipital-temporal cortex (Solms, 1997).

Taken together, these new neuroimaging and brain lesion studies strongly suggest that the forebrain activation and synthesis processes underlying dreaming are actually very different from those of waking. Not only is REM sleep chemically biased, but the enhanced cholinergic neuromodulation and diminished aminergic modulation are associated with selective activation of the subcortical and cortical limbic structures (which mediate emotion) and with relative inactivation of the frontal cortex (which mediates directed thought). These differences in regional activation obviously force the AIM model to consider still another dimension, that of brain space itself. Figure 6 is an initial mapping of AIM onto patterns of regional brain activation. The regional activation changes could be causally linked to the neuromodulatory dynamics in the following way: those areas which are inactivated in REM are those undergoing aminergic demodulation, while the activated areas are those heavily targeted by cholinergic modulatory neurons.

Whatever the link between the neuromodulatory and regional blood flow data, these findings greatly enrich and inform the integrated picture of REM sleep dreaming as emotion-driven consciousness with deficient memory, disorientation, diminished volition, and impaired analytic thinking. Now that we know that there is a close fit between the animal and human data regarding the mechanism and pattern of brain activation in REM sleep, we are in a much stronger position to strengthen the brain-based theory of dreaming that was first proposed in the early 1980s. And building upon this surprisingly strong base, we can begin to build a general theory of the brain basis of consciousness.

Consciousness, Stream of

Intermediate article

Thomas Natsoulas, University of California, Davis, California, USA

CONTENTS

Except for time-gaps, when the stream comes to a stop and then starts again, a stream of consciousness is constituted, from the Jamesian perspective, of tightly adjacent states of consciousness occurring very briefly one at a time. Unless a second such stream flows in the individual simultaneously, his or her conscious mental life at any instant consists entirely of one integral state of consciousness that typically possesses many intrinsic features.

INTRODUCTION

We commonly speak of someone's being conscious. Also, we often say he or she is conscious *of* something, and we usually specify to some degree the object (or objects) of that consciousness. This object can be an environmental state of affairs or occurrence, the individual himself or herself, or some part of the latter, such as a temporal section of the individual's mental life. Moreover, what one is conscious of can be *merely apparent*: an item, occurrence, or state of affairs having no actual existence, whether present, past, or potentially in the future.

Even if one disbelieves in fire-breathing dragons, it is appropriate to assert, depending on the facts, that someone is undergoing a hallucination and is therein conscious of a fire-breathing dragon. The hallucinatory experiences themselves are certainly real; they are no less real than anything else in the universe. In the example, it is the *object* of the hallucinatory experience that happens to be something unreal, that possesses no kind of existence. Also, hallucinatory experiences may have real objects, such as a long-lost relative. But, of course, the hallucinated presence of real objects in the immediate environment is, with possible exceptions, illusory.

In addition to describing someone as conscious or conscious of something, we may describe certain, or even all, of the mental happenings in an individual as being of the *conscious* kind. Indeed, one sometimes encounters among cognitive scientists the thesis that *all* experiences are conscious in this latter sense. According to this thesis, controversial within cognitive science, to have or undergo any experience is, *ipso facto*, for one to be conscious of it, that is, for it to be an object of 'inner awareness' (Brentano, 1973).

Many cognitive scientists maintain that, in every healthy, intact human being who is functioning normally, there take place both conscious and unconscious mental occurrences. The unconscious mental occurrences are those that cannot be objects of inner awareness; that is, we cannot have first-hand, noninferential apprehension of any instance that transpires of any unconscious mental occurrence. In the case of the conscious mental occurrences, in contrast, all or some of the instances of any one of them are directly apprehended when they occur.

There is scientific disagreement concerning how inner awareness is accomplished. Some cognitive scientists propose that an 'appendage' is required to any mental-occurrence instance that is the object of inner awareness. Thus, inner awareness takes the form of a mental-occurrence instance distinct from the mental-occurrence instance it renders conscious (Natsoulas, 1993b). Other cognitive scientists hold that inner awareness is an *intrinsic* feature of any mental-occurrence instance that is apprehended first-hand. Accordingly, inner awareness is always a dimension of the phenomenological structure of the mental-occurrence instance that is its object (Natsoulas, 1996).

Cognitive scientists are rarely skeptical concerning the reality of conscious mental occurrences as existents in the natural world. They recognize that the pursuit of science itself, among much else in human life and society, *requires* consciousness and necessarily involves the scientist's undergoing mental-occurrence instances with inner awareness. Anyone who may be inclined to cast doubt upon conscious mental occurrences should recall the impossibility of 'mind-blind' science.

Imagine a physical scientist fully capable of perceptual awareness of those molar events in the

environment of interest to his or her science. Now add what is less imaginable: all of the scientist's mental occurrences comprising this perceptual awareness are unconscious. That is, whatever the cause of this condition (of mind-blindness), these mental occurrences cannot be objects of the scientist's inner awareness. A mind-blind scientist could not function as such. It would be, for him or her, as though the environmental events of scientific interest that are objects of his or her perceptual awareness *do not occur*.

Some cognitive scientists attempt to treat of how conscious mental occurrences seem first-hand, to inner awareness, as *illusory* in some respects, although very rarely in respect to their existence. Briefly expressed, here are examples of two such attempts, the second less cogent than the first. (a) Whereas conscious mental occurrences may seem to the person to whom they occur to be mental in the sense of spiritual or nonphysical, they are, in reality, *only occurrences in the brain that*, like the many other kinds of brain occurrences, *possess only physical properties* (Sperry, 1976). (b) Whereas in the large majority of cases, mental-occurrence instances seem to inner awareness to be other than actions or behaviors, they actually are – this includes all of our perceptual experiences and feelings – *forms of self- or other-directed commentary*, either overt, covert, or incipient in any instance (Weiskrantz, 1997). However, cognitive scientists who diverge from the ordinary concept of a conscious mental occurrence do not generally intend thereby to commit a *referential displacement*: that is, to speak of something else, in place of mental occurrences, when they use terms commonly referring to the latter.

Cognitive scientists seldom deny the reality of consciousness, but some argue at length that *unconscious* mental occurrences do not transpire within us at all (e.g. O'Brien and Opie, 1997). In their view, we have brain occurrences that are mental, although not in the spiritual sense; but none of these mental brain occurrences are unconscious in the sense specified above, namely, incapable of being themselves objects of inner awareness. All mental occurrences are *open* to inner awareness, although this does not mean they are actually apprehended on every occasion of their occurrence (Natsoulas, 1995).

The above thesis entails a rejection of Freud's unconscious. According to Freud, an unconscious mental occurrence may 'become' conscious, but conscious only in the sense of evoking a counterpart of itself within a distinct subsystem (called 'perception–consciousness') of the mental apparatus (Natsoulas, 1993a). This counterpart must be of suitable type and instantiate much the same cognitive content as the unconscious mental occurrence. All mental occurrences that take place in the perception–consciousness system are of the conscious variety and, in all instances, are objects of inner awareness. Those mental occurrences that are not conscious transpire in a different subsystem of the mental apparatus in the brain.

The thesis of the nonexistence of unconscious mental occurrences entails, as well, rejection of a large body of contemporary scientific thought. Many hypotheses and theories circulating now inside cognitive science would explain particular instances of behaviors or of conscious mental occurrences by reference to mental happenings to which the person to whom they belong cannot have anything more than inferential access. This is the only kind of access cognitive scientists have to the person's mental life – with the probable exception that, today, some cognitive scientists are applying certain equipment directly to the brain and may be thereby observing mental occurrences by instrument.

The thesis that one's stream of consciousness is the entirety of one's conscious mental life will require modification if people, either normally or under certain conditions, are found to possess more than a single such stream (Puccetti, 1981). Note that the dual-consciousness hypothesis is not equivalent to countenancing the reality of unconscious mental occurrences. One's second conscious stream too would consist of conscious mental occurrences. Admittedly, however, neither of the two streams could have inner awareness of what is transpiring in the other stream and would depend for any information about the latter on inference. For example, the mental occurrences belonging to either stream might ascribe behavior issuing from the one body as causally connected in some instances to a separate consciousness also proceeding in the same body.

HISTORY

Cognitive scientists consider William James's classic contributions to be the most important to date in the history of the concept of the stream of consciousness. If one asks a cognitive scientist about the prevailing concept of the stream, the reply will assuredly contain some mention of James's detailed characterizations. These have a prominent place in *The Principles of Psychology*, in James's famous two-volume masterwork of basic psychology. In many psychologists' opinion, the ninth chapter, 'The Stream of Thought', is an

achievement of great intellectual value and compares favourably to the best analyses of any topic in the scientific psychological literature.

The Principles was published over a century ago and was intended as an introductory textbook for undergraduates. Yet James's phenomenological account of the stream is anything but dated. Indeed, this account would not be out of place if it were included today under 'current work' in a compendium of materials required by anyone seriously interested in consciousness. That James's account of the stream of consciousness is still a central part of our developing scientific thought may be surprising. Its persisting relevance is owed not to cognitive scientists' extending James's empirical observations to any substantial degree. The account itself in its original form still serves to expand the understanding of much about consciousness that lies beyond the merely historical.

This will seem less surprising upon noticing that, soon after James, those who came to control the field of psychology, which James helped found, *refused to acknowledge* the importance of consciousness in psychological functioning. Their refusal to face facts was anti-empirical; their scientific behavior was inconsistent with a true vocation. These academics were motivated by a strong political desire to achieve a broad acceptance for the new psychology as a science among other natural sciences.

To include consciousness as a part of psychology's subject matter would have been, for them, to admit the causal function of something spiritual and to enable thereby religious belief to contaminate their field. The exclusion of consciousness was a joint, systematic, long-term project among people who saw themselves as 'running' the science. And, even with their eventual retirement, their past efforts continued to produce detrimental effects on the science for the remainder of the twentieth century. Beginning in the 1960s, however, it gradually became less difficult to publish scientific articles and books on consciousness and less objectionable to teach the forbidden topic.

The militancy of some psychologists was such that they even denied publicly the existence of consciousness. Others among them, although not expressing such doubts, demanded that all technical concepts be defined in terms only of what could be perceptually observed of the behavior of their experimental or research subjects and the causes of that behavior. Thus, all mental occurrences were to be excluded from playing any role in scientific explanation because they were not in themselves publicly observable. A number of the many psychologists who shared this discredited philosophy of science occupied powerful academic positions and managed to hold back for decades the kinds of research they did not approve of. An indication of their project's success is that, as a whole, James's account of the stream of consciousness has yet to be superseded by a more enlightening account.

THEORETICAL ANALYSES

In describing the stream of consciousness as James conceived of it, one begins traditionally with attention to his metaphor of flowing water. However, a close reading of *The Principles* shows that James's analogy pertains only to how it may well *seem* that one's conscious mental life proceeds. In James's phrase, this life 'does not appear to itself chopped up in bits'. Contrary to some of James's own statements, he did not consistently conceive of the stream of consciousness as a continuous, undivided, internally undemarcated process, albeit subject to stopping and starting. James's more consistent position was, rather, that the stream consists objectively of a succession of *discrete* instances, pulses, or states of consciousness (Natsoulas, 1992–1993).

States of consciousness take place one at a time, and each of them immediately succeeds the one just before it except if there is a 'time-gap' during which the stream goes out of existence sometimes only very briefly. According to James, time-gaps may actually be more numerous than commonly supposed, for they are only inferable, not directly noticeable in his view. However, a temporal section or segment of the conscious mental life that internally involves no time-gaps consists of a succession of pulses of mentality 'with absolutely nothing between'. A state of consciousness lasts very briefly and, thereupon, one's consciousness consists of another such state, and so on. At any moment, one of these states is the entirety of one's consciousness – setting aside the possibility of more than a single stream per person at the same time.

How do the states of consciousness, or basic durational components of the stream, come into existence one after another? Although, according to James, these mental pulses are nonphysical, they are nevertheless the immediate, automatic products of *the total, ongoing brain process*. This said, a major qualification is immediately in order. At different times, the occurrent parts of this completely physical process, which is proceeding in many brain structures, differ in their intensities

and, consequently, are variably determinative of intrinsic features of the pulses that the total process produces.

The stream of consciousness is an accretion of basic durational components, rather than its being an ongoing process of its own whose course is merely influenced by the brain process. In contrast, the latter description is indeed applicable to how pulses of mentality are supposed to affect the total brain process. James's mind–body position expressed in *The Principles* was a dualist interactionism, but the existence of consciousness, of each one of those mental pulses constituting it, was held to depend on the brain. Mind issues from the body rather than the body's having effects on mind. Merely by its occurrence, the total brain process produces as a by-product something new at every point, whereas the pulses of mentality have their direct effects on the brain process as it is already taking place. They can only hinder or further this ongoing process.

Calling the stream's basic durational components 'pulses' of mentality, as James does, may convey the false impression that each of the pulses is proposed to be simple. This is belied by the fact that, soon enough after *The Principles*, James (1899) spoke of the stream of consciousness as consisting of a succession of 'fields' and insisted that these fields are always complex. He stated specifically that most of our concrete states of consciousness contain individually, in different proportions but in some positive degree, all of the following ingredients: sensations from the body, sensations owed to the impact of energies upon sense receptors that are outwardly directed, remembrances of past experiences, thoughts about faraway things, feelings of satisfaction and dissatisfaction, acts of will, desires and aversions, and other emotional conditions. Some of these ingredients are instantiated by a particular state more than by others and seem first-hand to have greater prominence in the state. Thus, although possessing many actual ingredients, one state of consciousness will seem to consist largely of sensation, another largely of remembrance, and so on. James pointed out that, for practical reasons, we tend to classify certain states of consciousness together, calling them states of emotion, sensation, abstract thought, volition, and the like, but a state of consciousness is not equivalent to any of the ingredients mentioned. Rather, these are to be understood as among the intrinsic features of a state, not as parts of it.

Speaking of an image and its 'surrounding' or 'penumbral' content, which is the source of the image's meaning, as though they were two distinct parts belonging to a particular state of consciousness, James in *The Principles* qualified his spatial metaphor in midstream: he described the surround as 'bone of the image's bone and flesh of its flesh'. If the penumbral contents of a state of consciousness had been, in any instance, different, any object of the state would have been taken and understood otherwise. This is not because the penumbral contents are among the causal determinants of a state, but because they are ingredients of the whole unitary, integral state and dimensions of how, specifically, the state apprehends its object or objects.

The ingredients of a single state, pulse, or field of consciousness listed above are not mutually distinct instances of being conscious of something. Such ingredients of a state as sensations, memories, thoughts, feelings, desires, aversions, emotions, and conations are not as they are traditionally considered: separate mental acts. Each state of consciousness is a unitary instance of consciousness. Any object of such a state that may be considered focal is apprehended in relation to all the other objects of the state. The above ingredients are abstractions from the concrete state that contains them. They are features of how the state apprehends its multiple objects together. This makes the ingredients of states no less real, but it does imply that they have no existence outside the states of which they are intrinsic features. For example, no auditory experience exists that is not a feature of one or more states of consciousness.

James found support for his conception of the states of consciousness in an unlikely source: Wilhelm Wundt, the founder of experimental psychology. Wundt assessed his three decades of introspective laboratory work as follows: 'From my inquiry into time-relations, etc. … I attained an insight into the close union of all those psychic functions usually separated by artificial abstractions and names, such as ideation, feeling, will; and I saw the indivisibility and inner homogeneity, in all its phases, of the mental life' (translated and quoted by James, 1899, p. 21). James interpreted the passage in which this sentence appears as a total renunciation of the prevailing conception of the mental life as being made up of 'distinct processes and compartments'.

But James did not also characterize in such terms the neurophysiological source of the stream of consciousness. Although states of consciousness are integral and not compounded of smaller units or acts, the total brain process, which is responsible for the existence of states of consciousness, clearly consists of numerous distinct processes. Indeed,

different sets of brain processes were held by James to be the proximate causes of different states of consciousness. The part-processes that constitute the total brain process of the moment somehow combine together to produce a unitary mental state.

EXPERIMENTAL APPROACHES

Introspection was the empirical ground for James's fundamental conception of consciousness. This conception included: (a) that the whole of one's mental life consists of a stream of consciousness, except insofar as a second stream of consciousness also flows within one; (b) that any stream of consciousness is constituted entirely of a sequence of tightly adjacent states, or pulses, of consciousness, except that the stream does stop and start again, and perhaps very frequently; (c) that each state of consciousness is of an integral character, a unitary awareness albeit often with many objects; and (d) that each such state typically instantiates a complexity of intrinsic features, some of which are traditionally conceived of, wrongly, as distinct mental acts.

The activity of introspecting can be carried out more or less adequately. James sometimes argued against views of consciousness with which he disagreed that these views have their basis in careless or biased introspection. But, in a chapter of *The Principles* devoted to methodology, James stressed that psychologists *always have to rely* on introspection, and that the most basic postulate of psychological science is that people do have inner awareness wherein they distinguish a state of consciousness from what it is about.

When James considered the matter more deeply, he became skeptical concerning our having the ability to apprehend our states of consciousness in a first-hand way. However, this skepticism did not deter him from proceeding on the assumption that the ability to introspect is among our most valuable powers. Indeed, much of what James is known for in psychology involves phenomenological descriptions made possible by inner awareness of his states of consciousness. James came to his skeptical position – which he quickly set aside for evidently practical reasons – as a consequence of introspecting and discovering thereby that inner awareness fails to reveal any spiritual activity at all going on within him.

Before moving on, James contemplated that, in point of fact, we may not have a stream of consciousness as he had been describing it. Better to say, perhaps, that the mental life that we do possess is a stream of 'sciousness' since its components are never objects of inner awareness (cf. Hebb, 1982). Our states of sciousness always have something else as their objects, that is, parts of the environment and body, except insofar as we infer the presence within us of those states from other, observable matters. Thus, states of sciousness may be among the non-immediate objects of some of our states of sciousness.

Although there are inconsistencies in James's reasoning, the only objection to his skeptical view requiring mention here pertains to his implicit notion that one can draw inferences – from perceptual observations to the occurrence of states of sciousness within one – in the complete absence of inner awareness. On James's skeptical view, perceptual awareness transpires not in a stream of consciousness but in a stream of sciousness every one of whose basic durational components are unconscious. The entirety of our mental life is proposed to take place in the 'dark' as we, at most, guess or infer about it. But how can one do any inferring based on the occurrence of a perceptual awareness of which one cannot be aware first-hand? If it is replied that we can know of the perceptual awareness by inference from something we objectively observe, the question is, again, how we can so infer if we cannot have inner awareness of the latter observation either.

More consistently with the skeptical position, which James seems to have preferred, he might have adopted a different methodology than the introspective one that he continued to practice and on whose results he relied for the rest of *The Principles*. This nonintrospective methodology would have him observing his behaviors and their objective context and making inferences about his mental life from what he observed. This is the kind of procedure on which present-day cognitive scientists often rely in studying the mental life of their research subjects, along with putting the latest instruments to use to detect properties of those of their subjects' brain processes that the scientists believe are the mental occurrences of current interest or closely associated with those mental occurrences. Of course, introspection helps them to formulate hypotheses to test experimentally, but they are very restrained in justifying their claims by reference to what they know first-hand by inner awareness.

However, even relying on perceptual observations exclusively – observations of behavior, of its objective context, and (by instrument) of the brain processes that are transpiring at the time – would not mean the cognitive scientist has succeeded in bypassing inner awareness so that inner awareness

forms no part of his or her methodology. The mental processes of a scientist are an essential dimension of any objective methodology; surely, this is an unobjectionable statement. The cognitive scientist cannot proceed to study the states of consciousness of his or her research subjects (or to study anything else for that matter) unless the scientist's mental processes continue to include more than just unconscious mental occurrences. At least some of the scientist's mental states during the experimental researches must be objects of inner awareness; otherwise, the objective observations would be for naught. Although these observations may have unconscious effects upon the researcher, in the absence of all inner awareness of the observations, they cannot be put to use.

In their investigation of states of consciousness, cognitive scientists cannot limit their empirical database to their own introspections. They must seek to determine the properties of states of consciousness more generally, how these states are in other people. For this purpose, cognitive scientists carry out not only programs of objective observation, with some reference to how they find their own states of consciousness to be first-hand. Also, they secure self-reports from experimental subjects concerning their inner awareness of their own respective conscious states, notwithstanding the fact that the causation responsible for self-reports concerning consciousness is not well understood at the present time. Many cognitive scientists remain unwilling to put much evidential weight on such reports, not until cognitive science advances to the point where we know the conditions under which subjects' reports are to be trusted. However, it is important to realize that inference from objective observations to states of consciousness is not any less problematic. The validity of such inference depends on the understanding that we have of the causal relations between these observations and the conscious states that are among the causes of what we are observing about our research subjects.

Consciousness, Unity of

Intermediate article

Tim Bayne, Macquarie University, Sydney, Australia

CONTENTS

Consciousness is unified in various ways, but the nature and basis of its unity remains a matter of intense debate. This debate promises to illuminate the nature of experience, the self, and various pathologies of consciousness.

INTRODUCTION

At any particular point in time you might be enjoying a number of experiences. For instance, you might have the visual experience of seeing these words, the cognitive experience of understanding what these words mean, and bodily sensations of various kinds, such as the feeling of the ground beneath one's feet. These experiences are unified in various ways. In exactly what ways? How can these unity relations be explained and how are they related to each other? In what sense must experiences be unified? What implications might the unity of consciousness have for our understanding of the nature of consciousness and the nature of the self? These are some of the central questions raised by the unity of consciousness.

VARIETIES OF UNITY WITHIN CONSCIOUSNESS

There is no commonly accepted taxonomy for discussions of the unity of consciousness. The following taxonomy is just one path through what is a rather unstructured debate, and the reader is advised that some of the terms introduced below are used in very different ways by other authors.

Subject Unity

Experiences are *subject-unified* when they are had by the same subject of experience. Your experiences are subject-unified in so far as they are yours, while my experiences are subject-unified in so far as they are mine. It is important to distinguish subject unity from the unity of self-consciousness. Subject-unified experiences are had by a single subject of experience, but the subject in question need not be conscious of these experiences as his or her own; many creatures appear to be subjects of experience without being aware of themselves as subjects of experience. Although most mature human beings can – and often do – ascribe their experiences to themselves, this ability seems to be lost, or at least compromised, in certain pathologies of consciousness, such as depersonalization.

Object Unity

A second unity relation in consciousness is *object unity*. Experiences are object-unified when they are about the same object. When I see my dog barking at my neighbor's cat I unify my visual experience of my dog with my auditory experience of him, thus forming a multimodal percept of a single object. Object unity not only extends across perceptual modalities; it also binds perception and action together, as when one when reaches for something that one can see.

Spatial Unity

The intentional content of experience gives rise to a third unity relation, *spatial unity*. When I see my dog chasing the neighbor's cat I experience the dog and the cat as distinct but spatially related objects. Objects of perception are located in egocentric space – 'egocentric' because the structure of this space is given by the structure of one's own body. The experience of one's own body as a unitary physical object enables one to experience one's perceptual environment as a spatially unified domain.

Epistemic Unity

Sometimes a stream of consciousness is said to be unified to the degree that its contents are coherent, integrated, or comprehensive (Shoemaker, 1996).

We might call this form of unity *epistemic unity*. Shoemaker has epistemic unity in mind when he writes that 'perfect unity of consciousness … would consist of a unified representation of the world accompanied by a unified representation of that representation, the latter including not only information about what the former represents, but also information about the grounds on which the beliefs that make up the former are based, and about what the evidential relations between the parts of that representation are' (1996, p. 186). In a related use of the term, the 'unity of consciousness' is also used to refer to the consistency of consciousness. Although one can see the famous duck–rabbit as either a duck or a rabbit, one cannot simultaneously experience it as both – although priming experiments reveal that both interpretations can be simultaneously active (Baars, 1988).

Phenomenal Unity

There is a unity of consciousness that is arguably more primitive than any of the unity relations considered thus far. Consider again the set of experiences that you are currently enjoying: perceptual experiences, cognitive experiences, emotional experiences, and so on. All of these experiences seem to be contained within a single phenomenal field or stream of consciousness. They seem to be conscious together; they seem to be *phenomenally unified*. It has become common to talk about phenomenal unity in terms of the relation of *co-consciousness*. Experiences are co-conscious when they are experienced together: when they have a conjoint phenomenology. My current visual experiences are co-conscious with my current auditory experiences, but they are not co-conscious with your auditory experiences. (Note that psychologists often describe distinct streams of consciousness that concurrently belong to a single organism as 'co-conscious': a very different use of the term.)

Access Unity

A final type of unity of consciousness concerns the relation between consciousness and reportability or accessability. We can describe experiences that are reportable in exactly the same ways as being *access-unified*. My current auditory and visual experiences seem to be access-unified in that I am able to report my auditory experiences in any way in which I am able to report my visual experiences. Note that experiences can be access-unified without being co-reportable; that is, I may be able to verbally report either my auditory experience or my visual experience without being able to report both experiences together.

How are these various forms of unity related? In particular, how are subject unity, phenomenal unity, and access unity related? It is plausible to suppose that experiences can be access-unified or phenomenally unified only if they are had by the same subject of experience. The controversial questions are whether (simultaneous) co-subjective experiences must be phenomenally unified, and whether phenomenally unified experiences must be access-unified. The study of various pathologies of consciousness might help to answer these questions.

UNITY OF CONSCIOUSNESS IN PHILOSOPHY

History

Philosophical reflection on the unity of consciousness dates back at least as far as Aristotle, who argued that there must be a common sense in addition to the specific senses such as sight and hearing. This common sense was thought to be responsible for perceiving the common sensibles – properties such as motion, rest and number – that are perceivable by multiple sense modalities. It was also assigned the role of integrating the contents of the other senses.

In the seventeenth century, philosophical interest in the unity of consciousness shifted focus from what the unity of consciousness might tell us about the structure of the mind to what it might tell us about the ultimate nature of the mind. G. W. Leibniz argued that the unity of consciousness provides support for substance dualism, the view that the subject of experience is an immaterial substance. He argued that if the self is a material entity it must be spatially extended, and hence the different parts of an experience would be had by different subjects. Consequently, there would be no single subject that had the entire experience, as there obviously seems to be. (A similar argument for substance dualism appears in René Descartes' *Meditations*.) Contemporary functionalists respond to this argument by insisting that the subject of an experience is the entire system within which the experience occurs: although a functional system has parts, none of these parts is a subject of experience in its own right.

Another influential seventeenth-century discussion of the unity of consciousness can be found in John Locke's analysis of personal identity. Locke claimed that the identity of a person extends only so far as their consciousness extends. Although

Locke draws an intimate connection between personal identity and the unity (and continuity) of consciousness, he says very little about what the unity of consciousness involves. Most work on Locke's accounts of personal identity has focused on the connection between personal identity through time and the continuity of consciousness; it is only recently that philosophers have begun to explore the relationship between the identity of a person at a time and the unity of consciousness.

Although the notion played little role in his treatment of the unity of consciousness, Locke held that experiences are had by a substantial self. David Hume, in contrast, was positively hostile to this idea. He claimed that since introspection reveals no sign of the self there is no good reason to posit such an entity. Hume claimed that the self is not something distinct from its experiences, something that has experiences, but is, in fact, nothing but a bundle of experiences. In response to Hume, Kant argued that there must be a transcendental ego that is responsible for synthesizing various representations into a unified consciousness. Kant's discussion of the unity of consciousness is notoriously obscure, and there is disagreement both over what Kant meant by the 'unity of consciousness' and over what he explained the unity (or unities) of consciousness in terms of (Brook, 1994; Hurley, 1998). Kant is variously said to have identified the unity of consciousness with, or explained it in terms of: the unity of concepts, the unity of agency, the unity of self-consciousness, and the unity of an objective world. (*See* **Split Brains, Philosophical Issues about**)

Current Issues

Current philosophical interest in the unity of consciousness is particularly concerned with two major questions.

Is consciousness unified?

The claim that consciousness is unified can be taken in a number of different ways. Some take the claim to mean that there is a single anatomical module or site for consciousness. Others take it to mean that co-conscious experiences are always intentionally integrated; that is, epistemically unified. It is doubtful that consciousness must be unified in either of these ways.

A more plausible sense in which consciousness might be unified is that co-conscious experiences must also be access-unified. We can call this the *accessibility thesis*. The accessibility thesis is attractive; indeed, it seems to be presupposed by certain accounts of consciousness (Baars, 1988). But there is reason to think that it might be false. Certain experimental results and pathologies of consciousness (discussed later in this article) suggest that experiences can be phenomenally unified without being accessible to the same report modalities.

Another conception of the unity of consciousness concerns the relationship between subject unity and phenomenal unity. According to the *unity thesis*, (simultaneous) co-subjective states must be co-conscious; that is, any experiences that a subject has at a time must be contained within a single fully unified stream of consciousness. The plausibility of the unity thesis depends in part on one's account of the subject of experience. The unity thesis seems implausible if, as many philosophers argue, subjects of experience should be individuated in biological terms, for it seems quite possible that a single organism might have two experiences at the same time without those experiences being co-conscious. On the other hand, one could also take the plausibility of the unity thesis as an argument against equating the self with a biological organism.

Finally, we can take the claim that consciousness is unified as a claim about the structure of co-consciousness. It is natural to suppose that the relation 'is co-conscious and simultaneous with' is reflexive, symmetrical, and transitive. (A relation R is transitive if, whenever aRb and bRc, then aRc.) Developing an idea that was inchoate in Nagel (1971), Lockwood (1989) suggested that synchronic co-consciousness might not be transitive, and that as a result some streams of consciousness may be only partially unified. If synchronic co-consciousness is not transitive then it would be possible to have three simultaneous experiences, e_1, e_2, and e_3, such that e_1 and e_2 are co-conscious, and e_2 and e_3 are co-conscious, but e_1 and e_3 are not co-conscious. We can call the claim that synchronic co-consciousness is transitive the *transitivity thesis*.

Philosophical debate over the transitivity thesis has focused on the question of whether partial unity might be possible. Most philosophers admit that it is difficult to conceive of what it would be like to have a partially unified consciousness, but they differ over what this might show. Dainton (2000) defends the transitivity thesis on the basis of the inconceivability of partial unity, while Hurley (2002) argues that this line of argument is mistaken. She claims that the 'what it's like' approach is relevant only when it comes to determining the content-based relations between experiences, and since the transitivity thesis concerns the token identity of states neither it nor its denial

could be supported by appeal to phenomenological considerations.

Philosophers have also been interested in whether various pathologies of consciousness, such as those exhibited by split-brain patients, might yield counterexamples to the unity or transitivity theses (see below).

How can phenomenal unity be explained?

There are many accounts of phenomenal unity (or co-consciousness), but no standard way of categorizing them. One useful distinction is between theories that account for phenomenal unity in terms of factors internal to phenomenology (subjective theories) and theories that appeal to factors outside phenomenology (objective theories).

Some subjective theories appeal to introspection in order to explain phenomenal unity. Such appeals can take at least two forms, depending on the account of introspection offered. Introspection can be conceived of as a nonrepresentational act of awareness that unifies various experiences, or it can be thought of as an experience in its own right, a higher-order experience of first-order experiences.

An alternative subjectivist approach is to posit a primitive unity relation for consciousness. Dainton (2000) takes this approach, holding that co-consciousness itself is a primitive unity relation. Bayne and Chalmers (2002) adopt a similar approach, although they take subsumption as their primitive unity relation. (One experience subsumes another when, roughly, the subsuming experience entails the subsumed experience). Dainton's approach is 'bottom-up' – fully unified streams of consciousness are constructed out of particular experiences and relations of mutual co-consciousness – while Bayne and Chalmers take a 'top-down' approach, according to which particular experiences are phenomenally unified by virtue of being subsumed by a single total experience.

Current versions of objectivism tend to be functional in nature. Shoemaker's (1996, 2002) functionalism is a standard personal-level functionalism involving causal relations between content-bearing states, and is in part motivated by his functionalist account of consciousness. Hurley (1998) defends a sub-personal functionalism according to which the unity of consciousness involves a dynamic singularity centered on an active organism.

A number of approaches to the unity of consciousness can be developed along both objectivist and subjectivist lines. Consider, for instance, subject-based accounts of co-consciousness. It is sometimes suggested that experiences are co-conscious simply by virtue of being possessed by the same subject of experience at the same time. This account of phenomenal unity qualifies as a version of objectivism. However, an account which construes co-consciousness in terms of the phenomenology of self-consciousness – that is, in terms of the sense that certain experiences belong to oneself – is a version of subjectivism, for it locates the binding agent of consciousness within phenomenology itself.

It is important to note that objectivism and subjectivism are not mutually exclusive. Indeed, it seems plausible to suppose that a complete account of phenomenal unity will have both subjective and objective components.

UNITY OF CONSCIOUSNESS IN COGNITIVE SCIENCE

History

Cognitive science has had an interest in the unity of consciousness since its beginnings in the nineteenth century. A central strand of this concern has been to examine the conditions under which the human brain achieves perceptual consistency. In this regard, psychologists have devoted much attention to effects such as the phi phenomenon. Spots separated by a small visual angle (up to 4 degrees) that are briefly lit in rapid succession will produce the phenomenal effect of a single spot in motion. The brain assumes that it must be seeing a single source of light in rapid motion rather than two light sources lit in rapid succession. Closely related to the phenomenon of perceptual constancy are intermodal effects, such as the McGurk effect (Stein and Meredith, 1983). When the sound 'ba-ba' is dubbed onto the video of someone who is actually saying 'ga-ga' participants report hearing 'da-da'. Such intermodal effects are common, and reveal that the operations of the various modalities constrain each other in what are often surprising ways.

Object and spatial unity reveal that the brain binds disparate forms of information together. How does it do this? Many early models of integration attributed binding to specialized neurons – so-called 'grandmother cells' – and multimodal association areas. Although some theorists continue to accord such cells a role in binding, it is generally agreed that 'convergence' models are at best a partial solution to the binding problem. At a theoretical level it is hard to see how there could be a particular cell for each possible object of perception, while at a practical level the search for omnimodal cells and association areas has proved

fruitless. Although there are many multimodal areas in the brain, there seems to be no one anatomical site of consciousness on which all information must converge in order to become conscious. Contemporary approaches to integration generally focus on functional integration rather than anatomical convergence.

While neurophysiologists have explored the unity of consciousness via the mechanisms of neuronal interaction, clinical psychologists have examined the unity of consciousness by studying the effects of brain damage and psychopathology. One class of such disorders can be loosely grouped under the heading of 'dissociative disorders': these include the 'hidden observer' effect in hypnosis, fugue states, and dissociative identity disorder (formerly 'multiple personality disorder') (Hilgard, 1986). It is often claimed that dissociative disorders reveal that consciousness is not unified, although the precise meaning of this claim is often unclear. Dissociation clearly involves a lack of integration in the contents of consciousness, but it is an open question whether this disintegration is accompanied by, or results in, multiple (or partially unified) streams of consciousness within the dissociated individual.

Split-brain research raises many of the same issues as do the dissociative disorders, but it has had a far greater impact on discussion of the unity of consciousness within cognitive science. In the mid-1960s surgeons sectioned the corpus callosum, the bundle of fibers linking the two cerebral hemispheres, of a number of patients in an attempt to alleviate their epilepsy. Although the everyday behavior of these patients was largely unaffected by the operation, under certain laboratory conditions these 'split-brain' patients behaved in ways that suggested to many, notably Sperry (1984), that they had two streams of consciousness. If, for instance, 'key-ring' is briefly projected onto the patient's visual field, the patient claims to see only 'ring', but when asked to pick out the object seen from a range of items, the left hand settles on a key (and rejects a ring). The standard explanation for this behavior proceeds as follows. Information concerning the left side of the visual field is conveyed to the right hemisphere of the brain, and vice versa. Further, in most patients linguistic ability is localized in the left hemisphere, and control over each hand is subserved by the contralateral hemisphere. Thus, it is often suggested that the right hemisphere locates a key with the left hand because it is aware only of 'key', while the patient claims only to have seen the word 'ring' because the left hemisphere was conscious only of the information contained in the right visual field. In other words, it has often been claimed that the best explanation of the patient's behavior is to regard each of the hemispheres as independently conscious. (*See* **Split Brains, Philosophical Issues about**)

Other interpretations of the split-brain data are possible. For instance, it might be suggested that at least some split-brain patients have a partially unified consciousness. For one thing, not all split-brain patients are equally split (Moor, 1982). Patients with complete commissurotomies are both tactually and visually split, while patients with central commissurotomies usually are tactually split but not visually split. Furthermore, even patients with complete commissurotomies are not completely split: they retain the ability to integrate certain types of information (e.g., olfactory, proprioceptive, and emotional) between hemispheres.

It is also noteworthy that the degree of disunity that split-brain patients manifest depends on how they are tested. Consider, for instance, the block design task. In the standard task the patient is asked to manually arrange four patterned cubes to match a sample design. The performance of each hand is timed, and the left hand consistently constructs the design much faster than the right hand. Gazzaniga and LeDoux (1978) found that replacing the standard free manipulospatial response with a response in which the patient was visually presented with three possible answers and asked to point to the correct one removed the asymmetry between left-hand and right-hand responses.

Current Issues

Much current research on the unity of consciousness in cognitive science is concerned with two major questions.

What are the mechanisms of integration and binding?

Although there is intensive discussion in cognitive science about the 'binding problem', there is little agreement about how best to approach it, or even what it is (Revonsuo, 1999). A number of binding problems can be distinguished, of which we will consider two. Both problems begin with the generally accepted claim that the mechanisms of consciousness are widely distributed throughout the brain.

The *object binding* problem is this: given that various visual features – colour, shape, location, etc. – are processed in various parts of the brain, how does the brain bind this information together to form a unified visual percept of a single object?

When we look at a Swiss flag, why is that we see a white cross on a red background, rather than a red cross on a white background? The *global binding* problem is concerned with the unity of the entire field (or stream) of consciousness, rather than the unity of individual phenomenal objects. How are various experiences brought together into a single phenomenal field; by what means are they made mutually co-conscious?

Discussions of binding tend to restrict themselves to object binding (and usually to object binding in visual consciousness). As yet there is no commonly agreed approach to object binding. Some (e.g. Barlow, 1995) argue that single neurons play a significant role in object binding; others (e.g., Triesman, 1999) suggest that object binding might be subserved by selective spatial attention; still others argue that synchronized neural activity plays a role in integrating various features into unitary percepts (Crick and Koch, 1990; Engel *et al*., 1999). It is unclear what implications these accounts of object binding might have for the global binding problem. Proponents of the neurophysiological approach sometimes suggest that neural synchrony might hold the key to all forms of phenomenal unity – indeed, to phenomenology itself – but such suggestions are little more than speculation at present.

It is often suggested that there is an intimate connection between the unity of consciousness and the computational architecture of consciousness. Some claim that because consciousness is unified it must be implemented in a serial or 'von Neumannesque' manner, while others claim that since consciousness is implemented in a parallel connectionist network it cannot be unified. Neither inference is unproblematic: there is no obvious reason why unity at a phenomenal level entails seriality in computational structure.

When and how is the unity of consciousness disrupted?

In addition to dissociative disorders and commissurotomy, a number of other 'pathologies' of consciousness seem to involve some form of disunity in consciousness, although it is often difficult to know exactly how consciousness is disunified in these cases.

Patients with anosagnosia fail to fully appreciate that they have an impairment of some kind. For instance, a patient with a paralysed limb may verbally deny that there is anything wrong. Nevertheless, anosagnosics may behave in ways that indicate that they may have 'dim knowledge' of their condition. They may, for example, agree that if the physician had the same complaint he or she would be unable to get out of bed (Bisiach and Berti, 1995).

Marcel (1993) elicited similar dissociations in response from normal subjects. He asked subjects to respond to the onset of a light in three ways: by blinking, by pushing a button, and by saying 'yes'. Marcel discovered that when subjects were asked to give all three responses simultaneously they were often inconsistent. For instance, a subject might give an affirmative response by blinking and saying 'yes' but a negative response by not pressing the button. Even more surprising, subjects were unaware that they had responded inconsistently. Marcel's subjects clearly suffered from a certain disunity of consciousness, but it is an open question how best to characterize this disunity.

Consciousness

Introductory article

Adam Zeman, University of Edinburgh, Edinburgh, UK

CONTENTS

Consciousness refers both to wakefulness and to the contents of our experience. The subjective aspect of consciousness poses a philosophical problem for objective science.

INTRODUCTION

Since the early 1980s there has been a major effort to make better sense of consciousness. The current fascination with the subject flows from several sources: work by neuroscientists is steadily revealing details of the brain processes which make consciousness possible; psychologists have underlined the existence of a wide range of unconscious brain processes which can be contrasted informatively to conscious ones; computer scientists and engineers are designing sophisticated brain-like systems which can rival human intellectual performance, raising the question of whether such systems are conscious. It is clearly time to work out where consciousness belongs in the scientific scheme of things – and many philosophers are trying hard to do just that.

WHAT DO WE MEAN BY 'CONSCIOUS', 'AWARE', AND 'SELF-CONSCIOUS'?

Consciousness

Defining consciousness is tricky, but it is clearly important to clarify what we have in mind before we try to study it. Its linguistic origins deserve a moment's attention. The Latin source of 'consciousness', as of 'conscience', is the combination of 'cum', meaning 'with', and 'scio', meaning 'to know': in Latin 'conscire' meant to share knowledge, often guilty knowledge, with another person. This use was extended, metaphorically, to the sharing of knowledge with oneself. 'Conscientia' was the knowledge shared. In contemporary use, two senses of consciousness are particularly important.

Consciousness as the waking state

In everyday life, and particularly in medicine, if we ask whether someone is conscious we are generally asking whether he or she is awake – as opposed to asleep, anesthetized, very drunk, or in a coma. We are asking, in other words, about his or her 'state of consciousness'. (*See* **Consciousness, Disorders of**)

We tend to assume that if people are awake, they will also be capable of perceiving their surroundings and their bodies, and of interacting and communicating with others and with the environment. We are usually accurate observers of others' states of consciousness, and of the (normally) linked capacities to perceive, interact, and communicate: these are all 'objective' matters. Indeed, doctors use standardized scales, like the Glasgow Coma Scale, to assess patients' states of consciousness (Figure 1). These scales apply objective criteria to the assessment of consciousness, such as whether a a patient's eyes are open, whether he can speak, and his ability to move his limbs on request.

To be conscious in this sense is to be awake or vigilant. While we can usually come to a firm decision about whether someone is awake, asleep, or comatose, each of these states also admits of degrees: we can be wide awake or drowsy, half-asleep or stuporose.

Consciousness as experience

If someone is conscious in the sense of being awake, the person is usually conscious of something. In its second sense consciousness is the content of experience from moment to moment: what it feels like to be a certain person now, in a sense in which we suppose there is nothing it feels like to be a stone or

Figure 1. Glasgow Coma Scale. This scale is widely used in the clinical assessment of consciousness (it is of course fallible: how would someone who is fully conscious but completely paralyzed score?).

in a coma. We can usually be much less sure of the contents of another person's consciousness than we can be that he or she is conscious. This second sense of consciousness is more inward, more subjective, than the first.

We can make several generalizations about the contents of consciousness in this second sense. They tend to be stable over short periods, from a few hundred milliseconds to a few seconds but changing over time; they have a foreground (at present the words in front of you), a background (the pressure of your clothes or the rumble of traffic), and a limited capacity (you can't simultaneously concentrate on Bach's first *Prelude* or Britney Spears' last album and my article on consciousness); they are usually continuous over time, in the sense that memory allows us to connect the consciousness of the present with the consciousness of the past; they have an immense potential range, including information from our senses, and from all our major psychological processes including thought, emotion, memory, imagination, language, and action planning; and, above all, they are personal, conditioned by the perspective which our particular viewpoint supplies.

We all tend to consider ourselves to be experts on our experience: after all, who could know more than you do about the contents of your own consciousness? But perhaps we can be mistaken about what normally passes through our minds. This is an active area of consciousness research. For example, studies which require subjects to give instantaneous reports of their current experience, when a pocket-held buzzer sounds, produce some surprises: it can be difficult to spell out the contents of consciousness; 'inner thought', rather than sensation, tends to dominate awareness, and these thoughts are often clothed in neither images nor words. Other research, exploring our sensitivity to changes in our visual surroundings, suggests that our visual attention is much more narrowly focused than we normally imagine: we completely miss surprisingly large changes in the scene before our eyes unless our attention is on them at the moment they appear. This kind of study is important: it helps to clarify the data which the science of consciousness needs to explain.

Awareness

'Conscious' and 'aware' are used almost synonymously in ordinary speech, with the difference that 'awareness' tends to imply the occurrence of experience. The two words *can* be used to mark any of several subtly different distinctions: for example, wakefulness versus experience, the contents of experience versus the capacity for it, the objective versus the subjective aspects of experience. But these are all rather technical distinctions which should be explained when they are drawn. The two terms are used interchangeably here.

Self-consciousness

'Self-consciousness' is an even more slippery term than 'consciousness' itself. We can mean at least five different things when we say that someone is 'self-conscious'. (*See* **Self-consciousness**)

Self-consciousness as proneness to embarassment

In colloquial speech, if we say that someone is self-conscious we mean that the person is awkward in the company of others because he or she imagines that they are scrutinizing. In other words, we are

self-conscious in this sense when we are excessively aware of others' awareness of ourselves.

Self-consciousness as self-detection

We sometimes say that a man or animal is 'self-conscious' when he detects a stimulus which impinges directly upon him (like an ant crawling over his hand), or when he behaves in a way that suggests an awareness of his own actions (like a dog with its tail between its legs after eating your supper). But this amounts to little more than perceptual awareness, directed towards events brought about by, or impinging directly upon, the creature in question.

Self-consciousness as self-recognition

This sense of self-consciousness was highlighted by the work of Gordon Gallup, in the 1970s, showing that chimpanzees and orangutans can recognize themselves in mirrors, but monkeys cannot. Human children become able to do so at around the age of 18 months. This ability suggests that apes, like small children, have an 'idea of me', a concept of 'self', although probably a very simple one. It is significant that over the few months after they come to recognize themselves in mirrors, children show a growing interest in self-adornment and master the use of the first-person pronoun, 'I'.

Self-consciousness as awareness of awareness

Between the ages of two and five, most children come to realize that they, like others, gain knowledge of the world from limited points of view, forming beliefs which can be mistaken. Their growing understanding of the nature of belief and the possibility of deception has been described as a developing 'theory of mind'. Once you possess this theory, your 'idea of me' has expanded to take in the notion that *you* are not merely a body, capable of reflection in a mirror, but also a mind, a subject of experience.

Self-consciousness as self-knowledge

In its broadest sense, our self-consciousness includes our knowledge of ourselves as members of particular families, schools, professions, social classes, language groups, and nations. We explore our peculiarly human fascination with ourselves in many forms of art: for example in Rembrant's astonishing life-long series of self-portraits.

THE SCIENCE OF CONSCIOUSNESS

Wakefulness

The electricity of the brain

We have learnt a great deal about the neurology of sleep and wakefulness in the past hundred years. In 1929 Hans Berger, a German psychiatrist, reported the first recordings of the electrical activity of the human brain made from the scalp: the 'electroencephalogram' or EEG. Berger and his followers went on to describe a series of brain rhythms (Figure 2) which correlate with states of consciousness: thus beta rhythm predominates while you read this article; alpha rhythm will become prominent if you relax and close your eyes, with increasing amounts of theta and delta if you let yourself drop off to sleep. (*See* **Consciousness, Sleep, and Dreaming**)

Research in the 1950s revealed that sleep itself has a complex structure: on falling asleep, our brain activity descends through a series of stages of deepening sleep, with progressive slowing of the EEG, but after half an hour or so of deep 'slow wave sleep' (SWS) it reascends through these stages. This ascent culminates in a period of

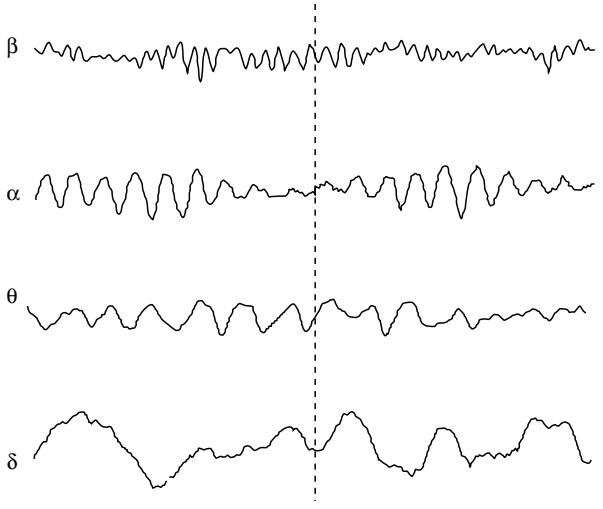

Figure 2. The rhythms of the EEG. This shows the four most commonly recognized EEG rhythms, obtained from four different clinical recordings: beta rhythm (> 14 Hz or cycles/second) characterizes active wakefulness: alpha (8–13 Hz) relaxed wakefulness with the eyes closed; theta (4–7 Hz) and delta (4–7 and < 4 Hz, respectively) occur in sleep and pathological states of depressed consciousness. A two-second period is shown. Reproduced with permission fom Zeman (2001) Consciousness. *Brain* **124**: 1263–1289.

'rapid eye movement sleep' (REM), characterized by EEG appearances similar to those of wakefulness, rapid eye movements, deep relaxation of our muscles, and the experience of dreaming. The cycle is repeated three or four times each night with decreasing amounts of slow wave sleep and increasing amounts of REM in successive cycles (helping to explain why we so often wake in the morning with a dream in the mind's eye).

Since his pioneering work, Berger's technique has been greatly refined. It is now possible to isolate the electrical activity associated with 'mental acts', as he had hoped: electrical correlates of sensation, attention, thought, and intention can all be identified at the scalp. There has been much interest recently in the idea that rapid synchronized activity in the gamma range (25–100 Hz) may be a hallmark of conscious processes.

The control of conscious states

In parallel with the exploration of the electrical correlates of consciousness, a series of discoveries has clarified the brain structures which control our conscious states. Observations of the effects of human brain disease, and experiments with animals, converged on the idea that regions of the brain stem and thalamus contain an 'activating system' that regulates the activity of the cerebral hemispheres (Figure 3).

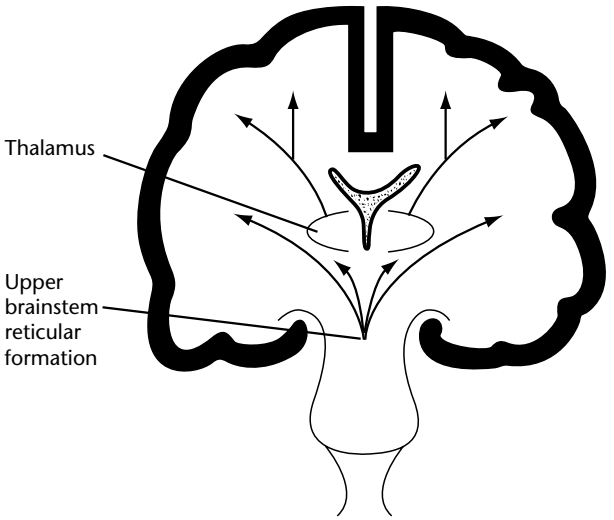

Figure 3. The reticular activating system. This simplified representation makes the points that the upper brainstem and the thalamus play a crucial role in activating the cerebral hemispheres and enabling wakefulness. Reproduced with permission fom Zeman (2001) Consciousness. *Brain* **124**: 1263–1289.

Early models of this 'ascending reticular activating system' supposed that it was a nonspecific mechanism for maintaining wakefulness and alerting the hemispheres to the occurrence of significant events requiring their attention. This picture has been replaced by a much more complex one. It takes account of the existence of several chemical subsystems, employing different neurotransmitters – such as noradrenaline (norepinephrine), acetylcholine, serotonin, dopamine, and histamine – and of regions within the brainstem which serve specific functions, for example inducing REM sleep. But, the broad principle that regions of the brain stem and thalamus orchestrate our conscious states survives within this more sophisticated scheme.

Many details of the signals which switch the brain between wakefulness, SWS, and REM need to be clarified, but neuroscience can now give a plausible account of the neuronal basis of the distinction between wakefulness and sleep. Activating signals from the brainstem to the thalamus fall away as sleep begins, so that the neurons of the thalamus cease to transmit sensory signals faithfully to the cortex (their wakeful 'spike' mode of response). Instead, they enter into a series of rhythmic oscillations, detected at the scalp as the deepening stages of sleep (their 'burst' mode of response). The onset of REM corresponds to a partial reactivation of the thalamus and cortex, giving rise to a 'waking' EEG but with cerebral processing focused on internally generated events. (*See* **Consciousness, Sleep, and Dreaming**)

Pathologies of wakefulness

All the above points to the existence of three principal states of consciousness in health: wakefulness, SWS, and REM. Disease generates a number of further states: these include coma, a state of unresponsiveness resembling SWS but in which the subject is unrousable and the normal cycle of sleep and waking is lost; the vegetative state, a state of 'wakefulness without awareness', in which brainstem mechanisms continue to produce a sleep–wake cycle in the absence of the hemispheric function required to produce experience; and brain death, in which the brainstem is irrevocably destroyed. (*See* **Consciousness, Disorders of**)

Experience

Although brain scientists have sometimes fought shy of consciousness, a great deal of brain research is relevant to the neurology of experience: work exploring brain regions concerned with perception,

attention, memory, language, emotion, and action often reveals correlations between brain events and features of awareness. Some scientists have been working to refine these correlations; others have taken a different, more roundabout, approach to understanding consciousness, by studying unconscious processes. (*See* **Neural Correlates of Consciousness as State and Trait**; **Perception, Unconscious**; **Unconscious Processes**)

Exquisite correlations

Vision is the most intensively studied human brain function and has provided the basis for much of the discussion of the neural basis of consciousness. A series of discoveries this century have revolutionized our picture of the brain events which underly conscious vision. Key findings include the discoveries that: the occipital cortex contains a detailed map of the visual world, in 'area V1'; within this map, cells inspecting each portion of visual space search for the presence of oriented edges; a further 30–40 visual 'maps' surround the primary visual area in the occipital cortex; parallel, though interconnected, streams of visual information flow through these maps, conveying information which defines visual form, color, depth, and motion; two broadly defined pathways fan out from the occipital cortex, an occipito-temporal pathway concerned with identifying objects and an occipito-parietal pathway concerned with visually guided action.

Detailed findings within this program of research have furnished remarkably close correlations between regional brain function and aspects of our experience. For example, human functional brain imaging studies indicate that perception of a colored scene selectively activates a particular region of visual cortex (often called V4); damage in this region can abolish the conscious perception of color. A distinct region plays a comparable role in the conscious perception of movement (V5).

Recently, several scientists have tried to home in on the neural correlate of consciousness (NCC) using a novel strategy. This stems from the thought that correlation need not imply cause: the fact that a brain area becomes active during visual perception does not imply that it causes our conscious experience – it might play some other role in the brain. One partial solution to this problem is to examine changes in brain activity which occur when experience changes without any change in the world. This happens, for example, when we summon up a visual image, or have an hallucination, or switch our attention without moving our eyes, or undergo a switch in the perception of an ambiguous figure. Examination of the neural correlates of these internally driven experiences is at the forefront of the quest for the NCC. (*See* **Neural Correlates of Consciousness as State and Trait**)

Unconscious processes

There is good evidence that our brains can register stimuli which we never consciously perceive, and that these in turn can influence our behavior. Understanding the events in the brain which enable these unconscious processes should help to sharpen the definition of the neurology of awareness. (*See* **Perception, Unconscious**; **Unconscious Processes**)

Conditions under which unconscious perception can be shown to occur include presentation of very brief, faint, or 'masked' stimuli to normal observers; presentation of stimuli to subjects during anesthesia or hypnosis, and neurological syndromes which impair conscious perception, such as blindsight and neglect ('blindsight' is the term given to a range of visually based abilities possessed by subjects who have no conscious vision after damage to area V1; 'neglect' is a disorder in which, most commonly, there is failure to pay attention to the left side of space following damage to the right side of the brain).

The investigation of these unconscious processes is an active area of research. It is too soon to reach firm conclusions about the key differences between conscious and unconscious brain activity. Two main types of explanation for the distinction have been proposed: that unconscious processes result when brain systems which sometimes give rise to consciousness are active at very low levels, and that unconscious processes occur in distinct brain systems, for example subcortical ones, where activity never gives rise to awareness. Recent experiments provide some support for both proposals.

THEORIES OF CONSCIOUSNESS

The data from the developing science of consciousness have spawned a number of overarching theories. They fall into three main types.

Neurobiological Theories

Theories of this type generally assume two broad principles which have emerged from the past century of research: that structures in the upper brainstem and thalamus play a key role in arousal, and that cortical activity supplies much or all of the contents of awareness. They tend, also, to assume that the neural correlate of consciousness will be a more or less extensive network of neurons. These

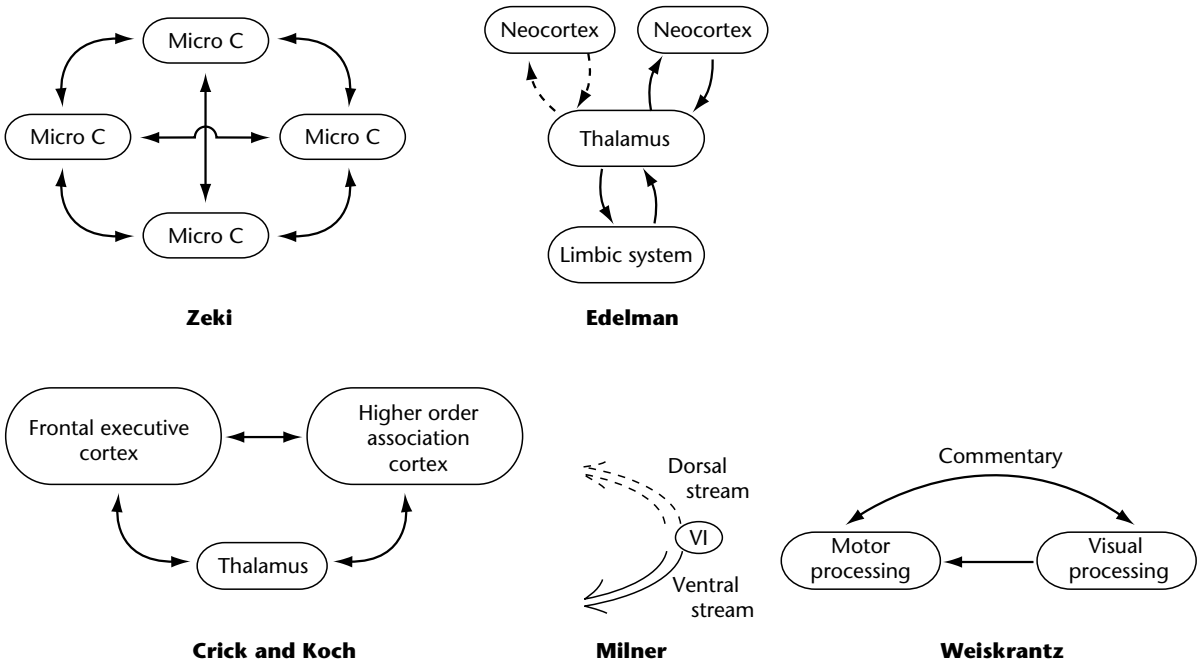

Figure 4. Neurobiological theories of consciousness. This highly schematic figure sketches the outlines of several current theories of consciousness: Zeki's model of interacting 'microconsciousnesses' within the visual system; Edelman's emphasis on interaction between shifting regions of neocortex concerned with perception and the limbic system, via the thalamus; Crick and Koch's proposal that only regions of cortex which 'directly' influence action can participate in conscious processing; Milner's distinction between a conscious 'ventral' and unconscious 'dorsal' stream of visual processing; Weiskrantz's suggestion that consciousness arises from a neural 'commentary' upon otherwise unconscious sensorimotor interactions.

points of agreement leave plenty of scope for disagreement over key details: how large must the network be to give rise to awareness? Need it incorporate particular types of neuron? Need it involve given cortical regions, or possess a particular range of connections with regions elsewhere? Must it engage in any particular pattern or duration of activity? Must it give rise to a certain complexity of interaction?

There is no consensus on these points. Figure 4 sketches a handful of the models currently on offer, underlining their variety. Semir Zeki has suggested that individual visual cortical areas generate their own 'microconsciousness' of color or of movement. David Milner proposes that only the occipitotemporal stream of visual processing is conscious, while the occipitoparietal is involved in action guidance. Gerald Edelman has emphasized the importance of reciprocal interactions between sensory cortical regions, limbic areas concerned with memory and 'value', and the thalamus. Francis Crick and Christof Koch have argued for the role of interactions between sensory areas and motor regions with which they directly interact. Larry Weiskrantz has developed the idea that visual consciousness arises from a secondary 'commentary' on visuomotor processes.

These theories focus mainly on the anatomy of consciousness: it is likely that a certain kind of neural activity is also required for consciousness. Current interest is focused on the role of rapid synchronized gamma-band activity, as there is evidence that this activity is abundant both in states of awareness generally and, specifically, in brain areas which are currently giving rise to experience.

Cognitive and Information-processing Theories

While neurobiological theories consider the nuts and bolts of consciousness, cognitive theories address its functions. Much of what we do, from brushing our teeth to riding a bike, can be achieved with little or no conscious attention. By contrast, novel challenges and unpredictable events force us to mobilize our psychological resources, engaging consciousness.

Cognitive theories take their lead from this everyday observation. Baars, for example, proposes that consciousness allows us to harness the resources

of otherwise independent, unconscious, 'expert systems' in the brain to solve knotty problems as they arise: this sacrifices the high speed and high capacity of automatic 'parallel' processing in the interests of flexible, deliberate behavior. This approach meshes with the widely held idea that consciousness arose in the course of evolution as flexible patterns of learned behavior emerged from the more rigid instinctive patterns of response seen in animals with simpler nervous systems. (*See* **Consciousness, Cognitive Theories of**)

If these theories are correct, they imply that the essence of consciousness lies not in its physical base but in the role it plays in processing information in the brain. If so, it follows that a machine which could reproduce the information flux in the human brain would necessarily be conscious. (*See* **Consciousness, Machine**)

Social Theories of Consciousness

The inspiration for social theories of consciousness is the thought that our awareness of our world and of ourselves is deeply influenced by other human beings: through social interactions from infancy on, through the acquisition of language, the greatest of all our social creations, and through our education in a common culture. In the course of our social development we acquire a 'theory of mind' which, as we have seen, supplies a distinctively human form of self-awareness. Yet while it is clearly necessary to take account of these social facts in giving a full description of human consciousness, it is doubtful whether social theories supply the right level of explanation for the simpler forms of consciousness which we share with animals, for example many of our sensory experiences, desires, emotions, intentions, pleasures, and pains.

THE PHILOSOPHY OF CONSCIOUSNESS

When philosophers discuss the nature of consciousness today, they are continuing an extremely ancient conversation about the relationship between mind and body, subject and object, the realm of experience and the realm of matter. This topic lies at the heart of philosophy: the views philosophers take on it cannot easily be prised apart from their views on a series of other thorny issues, such as the nature of meaning and of knowledge.

Three intuitions lie in the background of much of the philosophical discussion. The first is that conscious experience is 'rich and real': if we are to understand the universe we inhabit fully, we must be able to account for the variety and intensity of our conscious experience, from joy to sadness, from the hues of a sunset to the taste of salt. But, second, experience is clearly bound up with our physical being: everyone knows that fatigue, knocks on the head, too much beer, and countless other physical events can modify the state and contents of our consciousness. Third, we normally assume that awareness makes a difference: if I had not felt hungry, I would not have gone to the fridge. Making sense of the relationship between experience and the brain is difficult because these three intuitions do not square easily with each other.

This becomes clearer on examining three of the more popular philosophical theories of consciousness. One view, 'identity theory', is that conscious events are simply brain events. This idea meshes well with the second and third intuitions: brain events are physical, and well placed to cause our behavior. But does it do justice to the first? Some philosophers think not, arguing that one could know everything there is to know about a brain process and yet lack a full understanding of 'what it is like' to be the creature in whom it takes place. Take the famous example of 'what it is like to be a bat': knowing everything about the bat brain and bat behavior would not tell you what it is like to be a bat engaged in echolocation – or so the argument goes.

A second school of thought, 'functionalism', suggests that the essence of conscious states lies in the functions they serve in our behavior: the essence of vision is that it enables us to control our behavior using our eyes. Understand this control function and you understand visual experience: reproduce this function and you will have created visual consciousness. Once again this approach does justice to the second and third intutions but arguably fails to live up to the first: it is not immediately clear that a 'seeing machine' need be conscious; if it were conscious, it is not clear that its experience would necessarily resemble ours.

The third school of thought, 'dualism', is probably still dominant in our culture. It holds that mental and physical events are of radically different kinds: although the mental and physical realms must be linked in some way, neither can be reduced to the other. This approach appeals to those whose first intuition about consciousness is that it somehow 'goes beyond' the physical: that mental facts are 'further facts' about the world. It can be made compatible with the second intuition, that experience is physical, with the help of 'bridging rules' that link brain events with experience. But it is extremely difficult to see how it can be made

compatible with the third intution, that experience makes a difference to behavior. For if mental events are nonphysical, how can they change the course of physical events?

The difficulty of reconciling these three intuitions calls for radically different ways of thinking about the philosophical problem of consciousness. So, consider two contrasting suggestions to indicate the diversity of current views. Each questions an undeclared assumption of most scientific theories of consciousness.

The first idea is that scientific theories are mistaken in assuming that consciousness *arises* from complexity. Perhaps consciousness is inherent in matter of the simplest kinds, and the complex organization of the brain merely allows this potentiality of matter to emerge and blossom. On this view brain events, in common with all physical events, have inherent mental and physical aspects: any attempt to reduce either aspect to the other would be mistaken. This view, panpsychism, is quite alien to our scientific culture, but it is an understandable response to the problem of explaining how consciousness can be conjured from brain events: on this view there is no need for any magic, as consciousness is present from the start.

The second idea is that we are mistaken in assuming that consciousness arises from the brain. At first sight this idea seems quite bizarre, a denial of the obvious. But it has some powerful backing. The argument runs: when we try to explain consciousness in terms of brain events we are doomed to failure, because we have denied ourselves precisely the resources the explanation requires. We need to expand the limits of our explanation to take in the world we inhabit and the means by which we explore it. For consciousness is a complex kind of interaction with the environment: 'seeing' for example is 'a way of acting'. This approach suggests – and gives reasons for believing – that much of what we take to be 'in our heads' is in fact out in the world, and that our ordinary picture of consciousness, as an internal representation of reality, is mistaken. On this view the brain is not the *source* of consciousness but a device which enables awareness, and awareness is not an invisible process but the use of a set of elaborate skills.

CONCLUSION

There has been huge progress in the scientific study of consciousness over the past century, and there is a growing clarity about the sources of conceptual difficulty in pinning down this elusive prey. The determination of contemporary scientists and philosophers to do justice both to the rich texture of experience and to its intimate relationship to brain events holds out great promise for the years to come.

Direct Reference

Intermediate article

David Braun, University of Rochester, Rochester, New York, USA

CONTENTS

The theory of direct reference says that the meaning of a proper name (such as 'Mark Twain') or indexical (such as 'he') is just its referent.

WHAT IS DIRECT REFERENCE?

The theory of direct reference is a theory about the meanings of two sorts of natural language expressions: proper names (such as 'Mark Twain' and 'Paris') and indexicals (such as 'I', 'today', 'you', 'he', and 'that'). It says (roughly) that the meaning of any such expression is just its referent. The traditional rival to this theory is the view that these expressions have descriptive meanings, in addition to their referents.

The theory of direct reference can be divided into negative and positive parts. The negative part says that the meanings of proper names and indexicals are fundamentally different from those of definite descriptions. Definite descriptions are expressions of the form 'the *F*', such as 'the first Postmaster General of the USA' and 'the even prime number'. A definite description expresses a property (for example, being-an-even-prime-number) which is part of the meaning of the definite description; the definite description refers to the object that uniquely has that property. Thus a definite description refers to an object *indirectly*, by expressing a property that determines its referent.

The negative part of the theory of direct reference says that the meanings of proper names and indexicals are not descriptive in this sense. The meanings of these expressions are not properties; their references are not determined by associated properties, in the way that the references of definite descriptions are; instead, these expressions refer *directly*. The positive part of the theory asserts that the meaning of a proper name or indexical is simply its referent.

One can accept the negative part of the theory without accepting the positive part; indeed, sometimes the term 'theory of direct reference' is used to label just the negative part.

The above description of the theory needs some technical refinements, which are discussed below.

HISTORY

The term 'direct reference' was introduced by David Kaplan (1989) in the 1970s, but the theory is almost certainly ancient in origin. John Stuart Mill was perhaps the first modern philosopher to argue that proper names are directly referring (Mill, 1843); thus, the theory of direct reference for proper names is sometimes called 'Millianism'. Gottlob Frege (1893) and Bertrand Russell (1905) formulated seemingly powerful arguments against the view, and presented alternative theories which were widely accepted in the late nineteenth and early twentieth centuries. Ruth Barcan Marcus revived the theory of direct reference in the 1960s (Marcus, 1961); and from the early 1970s, Saul Kripke (1980), Keith Donnellan (1972), David Kaplan (1989), and John Perry (1977) presented arguments for the theory that persuaded many philosophers of its viability. (*See* **Reference, Theories of**)

Frege's and Russell's arguments against direct reference for proper names turn on certain difficulties which are now commonly called *Frege's Puzzles*. The first puzzle is the *puzzle of informative identities*. If the meaning of a proper name is just its referent, then two proper names that refer to the same thing, such as 'Mark Twain' and 'Samuel Clemens', have the same meaning. It seems to follow that the two identity sentences below have the same meaning:

Mark Twain is Mark Twain. (1)

Mark Twain is Samuel Clemens. (2)

But these sentences seem to differ in meaning:

sentence 1 seems to be uninformative, whereas sentence 2 seems to be highly informative.

The second puzzle is the *puzzle of apparent reference to nonexistents*. If the meaning of a proper name is its referent, then names that refer to nothing, such as 'Pegasus', should be meaningless. Therefore, sentences in which 'Pegasus' appears, such as 'Pegasus flies' and 'Pegasus does not exist', should also be meaningless. But these sentences seem to be meaningful; in fact, the second seems to be true.

The third puzzle is the *puzzle of substitution of coreferring names*. If the meaning of a proper name is just its referent, and we have two names that refer to the same thing, then we should be able to substitute one name for the other in any sentence without changing the meaning of the sentence. Moreover, the substitution should not change the truth-value of the sentence (that is, the sentence should not change from true to false or vice versa). But consider the following two sentences:

John believes that Mark Twain wrote *Huckleberry Finn*. (3)

John believes that Samuel Clemens wrote *Huckleberry Finn*. (4)

It seems possible for sentence 3 to be true while sentence 4 is false. So substitution of coreferring names can change the truth-value of a sentence.

Russell concluded from these puzzles that the meaning of a proper name is not its referent, but is instead descriptive in nature; ordinary proper names are just 'abbreviations' for definite descriptions that speakers have in mind when they use names (Russell, 1905). We can determine the description that a speaker associates with a name *N* by asking the speaker 'Who is *N*?' Thus, for some speakers, the meaning of 'Mark Twain' might be identical with the meaning of 'the author of *Huckleberry Finn*', while that of 'Samuel Clemens' might be 'the person who lives next door'. These descriptions express different properties, and so differ in meaning. Thus sentences 1 and 2 also differ in meaning, and one can be informative while the other is not. 'Pegasus' might mean the same as 'the flying horse'; this description is meaningful even if it fails to refer, so sentences containing it can be meaningful. Sentences 3 and 4 differ in meaning because the names 'Mark Twain' and 'Samuel Clemens' differ in meaning; they differ in truth-value because they attribute different beliefs to John.

Like Russell, Frege also attributed descriptive meanings, which he called 'senses', to proper names (Frege, 1893). Frege's solutions to the puzzles are similar to Russell's. There are differences between Frege and Russell which we ignore here. (*See* **Sense and Reference**)

ARGUMENTS FOR DIRECT REFERENCE

Many of the arguments in favor of direct reference are simply arguments against description theories of proper names.

According to Russell, the meaning for a speaker of a name *N* is the same as that of the definite description that the speaker would provide when asked 'Who is *N*?' Suppose that we ask Fred 'Who is Mark Twain?' and he answers 'The author of *Huckleberry Finn*.' Now consider the following two sentences:

If there is exactly one author of *Huckleberry Finn*, then Mark Twain is the author of *Huckleberry Finn*. (5)

If there is exactly one author of *Huckleberry Finn*, then the author of *Huckleberry Finn* is the author of *Huckleberry Finn*. (6)

The only difference between them is that sentence 6 contains the definite description 'the author of *Huckleberry Finn*' where sentence 5 contains the name 'Mark Twain'. Thus, according to Russell, sentences 5 and 6 should have the same meaning for Fred. But Kripke (1980) and Donnellan (1972) present several reasons for thinking that these sentences do not have the same meaning for Fred.

Kripke points out that sentence 6 expresses a necessary truth. So if sentence 5 means the same thing as sentence 6, then sentence 5 should also express a necessary truth. But sentence 5 clearly does not express a necessary truth; after all, Mark Twain might have died before he wrote *Huckleberry Finn* (as Fred would admit). A similar point would hold for just about any definite description that Fred might provide.

The next argument comes from both Donnellan and Kripke. Imagine that *Huckleberry Finn* was written by Samuel Clemens's cousin, Clyde Clemens, who died shortly after completing it; Twain/Clemens stole the manuscript, passed it off as his own, and since then has been commonly thought to be the author. Now if this is the case, then sentence 5 is false, even as spoken by Fred. But the description theory entails that it is true, for according to that theory, sentence 5 (in Fred's mouth) means the same as sentence 6, which is obviously still true in our imaginary situation. Furthermore, according to the description theory, the name 'Mark Twain' (in

Fred's mouth) refers in this situation to the referent of the description 'the author of *Huckleberry Finn*', which is Clyde. But this is incorrect.

Finally, Kripke notes that Russell's objections take for granted that every speaker who uses the name 'Mark Twain' can formulate a definite description that 'identifies' the referent of the name. But this assumption is incorrect. When asked 'Who is Mark Twain?', some people may answer 'A writer'. This description does not determine a unique referent for the name; yet many of these people may be unable to produce a better identifying description.

Kaplan (1989) and Perry (1977) present similar arguments against description theories of indexicals. Consider the hypothesis that the descriptive meaning of an utterance of 'you' is the same as that of an utterance of 'the person I am addressing now' by the same speaker. Then utterances of the following two sentences by the same speaker should mean the same thing:

> If I am addressing exactly one person now, then you are the person I am addressing now. (7)

> If I am addressing exactly one person now, then the person I am addressing now is the person I am addressing now. (8)

However, sentence 8 expresses a necessary truth, whereas sentence 7 does not. To see that sentence 7 does not, imagine that I utter it while addressing Mary. What I say is true, but it could have been false; for, after all, I could have addressed someone other than Mary, or no one at all.

Examples involving indexicals, like sentence 7, show that we need to distinguish between two different sorts of meaning. Suppose that two different people utter sentence 7 while addressing different people. There is a sense in which the two utterances of 'you' share a meaning, which we may call the *linguistic meaning* of 'you'. But there is another sense in which those utterances differ in meaning: let's say that the two utterances of 'you', and the two utterances of sentence 7 as a whole, differ in *content*. Call the content of an utterance of a full sentence a *proposition*. The above arguments show that the contents of utterances of indexicals are not descriptive. Perhaps the linguistic meanings of indexicals are in some way descriptive, but that is an open question. (*See* **Philosophy of Language**; **Meaning**)

It is now possible to state the theory of direct reference more accurately. According to the negative part, the content of an utterance of a proper name or indexical is not descriptive (is not a property). According to the positive part, the content of an utterance of such an expression is simply the referent of the utterance; moreover, an utterance of a sentence containing such an expression expresses a *singular proposition*: a proposition containing the referent of the expression as a constituent.

PROBLEMS WITH DIRECT REFERENCE

The most important problems for the theory of direct reference are those posed by Frege's Puzzles. Advocates of direct reference have proposed solutions to these puzzles, but whether their solutions are successful is a subject of much current debate.

In response to the puzzle of informative identities, Nathan Salmon (1986), Scott Soames (1987), and other direct reference theorists say that sentences 1 and 2 express the same singular proposition, and, in that sense, mean the same thing. But they say that it is possible for a person to grasp that proposition in distinct ways. Different direct reference theorists have different views about what these ways of grasping propositions are. Some think that they are *mental representations*, and so hold that sentences 1 and 2, and the names 'Mark Twain' and 'Samuel Clemens', are connected with different mental representations in most speakers. This may explain why sentences 1 and 2 seem to differ in informativeness, and why many speakers incorrectly think that they differ in meaning. (*See* **Propositional Attitudes**)

In response to the puzzle of apparent reference to nonexistents, Salmon (1998) claims that names like 'Pegasus' refer to mythical or fictional objects that are created by our story-telling activities.

In response to the puzzle of substitution of coreferring names, Salmon (1986) and Soames (1987) claim that sentences 3 and 4 express the same proposition, and must have the same truth-value. But utterances of them differ in what they suggest about John: sentence 3 correctly suggests that John would assent to 'Mark Twain wrote *Huckleberry Finn*', whereas sentence 4 incorrectly suggests that he would assent to 'Samuel Clemens wrote *Huckleberry Finn*'. This might mislead some speakers into thinking that the sentences themselves differ in truth-value.

DIRECT REFERENCE AND COGNITIVE SCIENCE

The theory of direct reference implies that ordinary speakers are less reliable at judging differences in

meaning than some cognitive scientists may think. For example, most speakers would judge that sentences 1 and 2 differ in meaning; but according to the theory of direct reference, such speakers are mistaken.

The theory also implies that two agents who believe and desire the same propositions may nonetheless behave quite differently. Suppose that John assents to 'Mark Twain is the author of *Huckleberry Finn*' and dissents from 'Samuel Clemens is the author of *Huckleberry Finn*'; suppose Mary assents to both. Now according to Salmon and Soames, John also believes that Clemens is the author of *Huckleberry Finn*, just like Mary (whatever he might say to the contrary). But they might behave differently in similar situations. Suppose, for example, that both assent to 'I want Twain to autograph my copy of *Huckleberry Finn*', and both are told 'Clemens is in the next room.' Then Mary will go next door to get her copy of *Huckleberry Finn* autographed, but John will not. The reason they will behave differently is that John does not believe the proposition in the same *way* as Mary: he believes it in a 'Twain' way, but not in a 'Clemens' way, whereas Mary believes it in both ways. Examples like this lead some philosophers to think that, if the theory of direct reference is correct, then ordinary belief attributions do not provide explanations of behavior of the sort we ordinarily expect; full explanations need to mention the ways in which propositions are grasped.

Dualism

Intermediate article

David Robb, Davidson College, Davidson, North Carolina, USA

CONTENTS

Dualism is the view that the mental and the physical are distinct and mutually irreducible.

WHAT IS DUALISM?

As a candidate solution to the mind–body problem, dualism is opposed to the two main forms of monism: *materialism*, which reduces the mental to some part or aspect of the physical, and *idealism*, which reduces the physical to some part or aspect of the mental. Dualists regard monists of either sort as making the same mistake: conflating domains that are distinct and autonomous.

Dualism is a metaphysical doctrine, a view about the ultimate nature of reality. One often finds it packaged with other philosophical views, but it need not stand or fall with these. For example, while certain versions of dualism are congenial to theism, there is nothing in dualism *per se* that requires the existence of God, or that is committed to any particular religious tradition. Nor does dualism entail the controversial epistemological doctrines that often accompany it. These include the transparency of the mental – according to which the nature of the mind and its states is fully revealed in introspection – and the incorrigibility of first-person beliefs – according to which I am the final authority on the contents of my own mind. Dualism is compatible with the acceptance or rejection of either of these epistemological doctrines.

Even when isolated from these controversial views, dualism – at least in its most radical forms – is largely rejected by the cognitive science community, where materialistic monism predominates. Nevertheless, dualism has never completely disappeared from the intellectual scene, and it is enjoying something of a renaissance. In fact, as we will see, a moderate form of dualism is today widely accepted among cognitive scientists.

VARIETIES OF DUALISM

So far I have referred broadly to 'the mental' and 'the physical', but when dualists distinguish these realms, they normally have entities of a certain sort in mind. Here dualism divides into several related versions: there are dualisms of substances, properties, events, processes, facts, sentences, and more. This article will discuss only substance and property dualism, though much of the discussion applies to other versions as well.

Substance Dualism

A *substance* is a thing or object, something that has properties and persists through time. A substance dualist conceives of the mind as such an entity, one that, moreover, is distinct from the biological body or any part of it, such as the brain.

The most radical form of substance dualism is *Cartesian dualism*, named after its most famous modern defender, René Descartes. Although it has been out of fashion for sometime, Cartesian dualism has a number of contemporary defenders (e.g. Foster (1991)). A Cartesian dualist says that the mind is a nonphysical 'soul' or 'spirit', a substance entirely lacking in physical properties, including spatial location. As Descartes articulated the view, the mind's intrinsic properties are exclusively mental: they are modes (expressions) of consciousness, the essence of minds. By contrast, material substances (bodies) have only physical properties, modes of spatial extension, the essence of bodies.

This difference of essence entails an ontological independence: one kind of substance could exist without the other. Nevertheless, our minds are in fact 'embodied', albeit contingently and only temporarily. Descartes' own views on the nature of this embodiment are obscure; but the relation is often understood causally: for my mind to be embodied

in a particular material substance is for it to have a privileged causal connection with that substance; only my mind can directly (by means of volitions) affect this biological body, and only this body can directly (by means of sensation) affect my mind.

For the Cartesian dualist, then, mind–body dependence is merely causal. But there are forms of substance dualism in which this dependence is much stronger. *Non-Cartesian substance dualists*, while insisting on the strict numerical distinctness of mind and body, allow that the mind has physical properties. Indeed, they claim, its physical properties are just those of the body or brain, for mind and body spatially coincide. E. J. Lowe is a contemporary defender of this more moderate form of substance dualism. He argues that the mind (or self) is a psychological substance, distinct from the body but sharing many of its physical properties (Lowe, 1996). Here the mind–body relation is analogous to the relation between a statue and the lump of clay composing it. Mind and body spatially coincide, but because they differ with respect to certain properties, they are distinct. In a similar vein, those who believe that the mind 'emerges' from the activities of the brain, and those who think that the brain 'constitutes' the mind, would also count as non-Cartesian substance dualists.

Property Dualism

Unlike substance dualists, property dualists need not postulate immaterial substances. They are willing to grant that the mind is nothing more than a complex physical thing. But they still insist that this substance's mental properties are not physical.

In its strongest form, property dualism says that mental properties are fundamentally different from – though they may be lawfully connected to – physical properties. We might call this *radical property dualism*. It is embraced by, for example, Chalmers (1996), at least about qualia. Chalmers believes that the qualitative, categorical features of our conscious experiences are different in kind from any physical properties, which he takes to be exclusively dispositional and structural. *Emergentists* also fall into this category: they take mental properties to be features of physical systems that have achieved a certain level of complexity. Such properties are at best only nomologically or causally dependent on the physical substrate from which they emerge.

Like substance dualism, property dualism exists in a more moderate form, according to which mental properties are not physical, yet always (perhaps necessarily) are realized in or supervene on the physical. The idea here is that mental properties are instantiated at a higher, more abstract level than their physical counterparts. In ascribing a mental property to someone, we abstract away from the physical details that realize, or implement, the mental property in that particular person. For example, in certain versions of functionalism, for a system S to have a mental property M is just for it to have some physical property P_s that within S plays the causal role definitive of M. Since the same M-defining role can be filled by different physical properties in different systems, we cannot identify M with P_s or with any other physical property. Yet there is a clear sense in which, within S, M is determined by, and in fact is 'nothing over and above', its physical realizer P_s. This realization relation is clearly much stronger than the causal or nomic psychophysical relations allowed by radical property dualism. Indeed, the relation here is so intimate that most adherents of moderate property dualism consider themselves materialists. This view is commonly called *nonreductive materialism*, but it is important to remember that it is, strictly speaking, a form of property dualism, since it denies that mental properties are physical.

ARGUMENTS FOR DUALISM

Although dualists have at times appealed to empirical considerations to support their view, the strongest dualist arguments, and those receiving the most philosophical attention, have been *a priori*. In the typical argument, some state of affairs incompatible with materialism is claimed to be clearly conceivable, and so possible. The dualist then moves from this possible state of affairs to a conclusion about the nature of the mental in the actual world.

Arguments for Substance Dualism

The most famous such argument occurs in Descartes' *Sixth Meditation*. A contemporary version proceeds along these lines (here we follow Descartes and other dualists in assuming that I am the same as my mind):

> I can clearly conceive of my existing in the absence of anything physical. (1)

That is, when I consider the matter carefully and rationally, there seems to be no contradiction in the idea of my existing in an entirely immaterial world. From this it follows that:

It's possible for me to exist the absence of anything physical. (2)

(Since what is clearly conceivable is at least possible.) But now note that:

If I am a physical thing, then I am essentially a physical thing. (3)

That is, any physical substance is physical by nature, and so could not exist as an immaterial thing. But then it follows that:

I am not a physical thing. (4)

From the claim of mere possibility in step 2 we have reached a conclusion about what is actually the case, via the linking premise 3.

In spite of its enormous influence among dualists, this argument has been challenged at almost every step. One line of objection faults the inference from step 1 to step 2. Even if I can clearly conceive of myself existing in the absence of anything physical, at most this shows that for all I know (about my nature) it's possible for me to exist in such a state. It doesn't imply that I really can exist in this way. That is, statement 1 at best establishes the epistemic possibility of my existing in an immaterial world, not its genuine, metaphysical possibility. Another line of objection challenges step 3: perhaps I am a physical thing, but not essentially so. Modal intuitions may differ here, but this objection at least puts the burden on the Cartesian to explain why a physical thing cannot be only contingently physical. Yet another line of objection is that the above argument, even if sound, merely establishes the more moderate, non-Cartesian form of substance dualism. That is, perhaps the argument only shows that I am not identical with any physical substance, not that my nature (and all my properties) are nonphysical. This is a delicate question: it turns in part on whether the non-Cartesian can allow for the possibility of disembodied existence. If so, then step 2 would not seem to be strong enough to support a Cartesian reading of the conclusion. (For further discussion of Descartes' argument, see Yablo, 1990.)

In any case, if a substance dualist wants merely to establish the non-Cartesian version, Descartes' modal argument is not required. Since moderate substance dualists claim only that mind and body are numerically distinct, they need only find some property possessed by one but not the other. Since the brain (say) constitutes the mind, the two substances share many of their properties, such as size, location, and so on. But mind and brain do seem to have different persistence conditions: certain kinds of neurophysiological damage, for example, would destroy the mind, but the brain (as a biological substance) would still exist. This difference in properties, the argument goes, entails a numerical difference – the mind is not the brain (or any other part of the body) – but it stops short of Cartesian dualism.

Arguments for Property Dualism

Philosophical arguments for property dualism, at least in its radical form, have also relied heavily on conceivability arguments. One thought experiment features super-neuroscientists able to examine a functioning brain down to the finest physical detail. They would never, it seems, find anything remotely resembling a thought or an experience. So mental properties are fundamentally different from anything physical. (For quite different versions of this argument, see G. W. Leibniz' *Monadology* and Jackson, 1982.) But a materialist might offer the following explanation for why the scientists fail to 'find' the mind: the mind and its contents can be accessed from two perspectives, the introspective, first-person perspective and the observational, third-person perspective. The scientists are in fact encountering mental properties as they observe the brain, but these mental properties aren't recognized as such because they're being accessed from an unfamiliar perspective. The resulting view would be a 'dualism of perspectives', but a materialism of the mind and its properties.

Another thought experiment marshalled in support of radical property dualism features the *zombie*, a being who, in spite of sharing all of the physical properties of a conscious being, is wholly lacking in conscious states (Chalmers, 1996). Such a being seems to be conceivable, yet if it is so much as possible, then our phenomenal properties (an important class of mental properties) are not the same as any of our physical properties. This argument is subject to some of the same criticisms that apply to Descartes. For example, are zombies really possible, or is their apparent conceivability explained by the limitations of our current knowledge? Just as further investigation may reveal, contra Descartes, that my disembodied existence is impossible, so we may eventually learn that zombies are impossible. At this point, however, the materialist can only offer the hope of such a discovery.

Property dualism in its more moderate form – nonreductive materialism – requires nothing as exotic as zombies. Here an appeal to multiple realizability is thought to suffice (Fodor, 1981). Any given mental property can be, and in fact is,

realized by a variety of different physical properties in different species, different individuals of the same species, and even at different times in the same individual. Given that the same mental property is realized by many different physical properties, it cannot be identified with any one of them; hence mental properties are distinct from, though realized in, physical properties. This argument is often used to support certain versions of functionalism against the psychophysical identity theory. (For an identity theorist's response to the argument, see Kim, 1993.)

PROBLEMS FOR DUALISM

However one evaluates the preceding arguments, dualism faces a number of serious obstacles. These range from empirical objections, to the effect that dualism cannot be integrated into cognitive science, to philosophical and conceptual objections. The former are discussed in the final section of this article. Here I discuss the latter.

Charges of Incoherence and Vacuity

One of the reasons why substance dualism fell out of favour is that it seemed incoherent to a number of philosophers. Ryle (1949), for example, accused substance dualists of an egregious conceptual error, that of placing the mind in the wrong ontological category: having a mind isn't a matter of being (or being related to) a substance, immaterial or otherwise. Rather, talk of 'the mind' is merely talk about a set of capacities. Ryle thought that these capacities were exclusively behavioral, but one needn't be a behaviorist to appreciate his insight. A functionalist, for example, may also claim that talk about 'mind' doesn't refer to a kind of substance, but is just a way of describing the causal organization of an organism's mental and behavioral states.

Ryle's objection applies to any form of substance dualism, but there is another charge of incoherence directed specifically at the Cartesian variety: if minds are not located in space, there seems to be no way to individuate them. It is at least logically possible for there to be two qualitatively identical minds, that is, minds which share all of the same intrinsic properties. But by virtue of what, then, are they two minds and not one? Two qualitatively identical material substances can be distinguished by their different spatial locations, but there is no such medium to individuate Cartesian minds. Coupled with the (controversial) doctrine that there can be no entity without clear conditions of individuation, this objection could render Cartesian dualism incoherent. (See Hoffman and Rosenkrantz, 1991.)

Even if substance dualism is coherent, some have objected that as a proposed solution to the mind–body problem, dualism in any of its forms is devoid of positive theoretical content. It seems that dualists can tell us only that the mental is not physical; they can't say anything informative about the intrinsic nature of the mental. This charge of theoretical vacuity is most threatening to radical forms of dualism. Moderate forms – non-Cartesian substance dualism and nonreductive materialism – allow that minds or their mental properties are realized in the physical world, and the nature of this realization might contain enough resources for moderate dualists to say something positive about the mental. But can Cartesian or radical property dualism say anything more about the intrinsic nature of the mind? Perhaps the most obvious option here is also the most promising: discover the positive theoretical content of dualism by appealing to the direct introspective access we have to our own minds and their contents (Foster, 1991). Those who insist on drawing theoretical content only from objective, third-person sources will balk at this move, but the dualist will reply that first-person data cannot be ignored by any systematic study of the mind, at least any study that aspires to completeness.

The Problem of Interaction

The most serious problem for dualism arises from a seemingly undeniable fact: the mental and the physical causally interact. Such interaction is two-way: for example, my decision to get a drink causes me to walk to the refrigerator (mind-to-body causation); and putting my hand on a hot stove causes me to feel pain (body-to-mind causation). Dualists have had trouble integrating these common-sense facts about mind–body interaction into their ontology.

This problem is perhaps most acute for Cartesians, and again the mind's lack of spatial location is the source of the problem. There seems to be no way for a Cartesian mind to causally link to a location in space. Interacting bodies link by spatial contact; yet this mechanical account of the causal nexus cannot work for Cartesian mind–body interaction, since Cartesian minds cannot come into spatial contact with anything. Similar arguments apply in a more recent version of the problem of interaction, the 'pairing problem' (Kim, 2001). Imagine two qualitatively identical minds M_1 and M_2,

and the bodies with which they (allegedly) causally interact, B_1 and B_2. What makes it the case that M_1 is causally paired with B_1, not B_2, and M_2 paired with B_2, not B_1? If these minds were located in space, we might appeal to their different spatial relations to B_1 and B_2 to resolve this question. But this resource is not available to the Cartesian. (For a Cartesian response to the pairing problem, see (Foster, 1991).)

One might think that the problem of interaction doesn't arise for property dualists, who after all can allow that the mind is a physical substance, causally related to the physical world. Yet property dualists face their own problems of causality, for we still would like mental properties to be causally relevant to bodily behavior. We wish, that is, not merely for minds (or mental events) to cause behavior; we wish them to cause behavior by virtue of their mental properties. And it has seemed to many opponents of property dualism that nonphysical properties cannot have a causal effect on the physical world. One much-discussed version of this objection appeals to the *causal closure* of the physical: the causal history of a physical event includes only physical events and their physical properties. At no point, that is, can a nonphysical event or property break into the network of physical causes. Causal closure raises immediate worries for both versions of property dualism: even for nonreductive materialism, since it is not clear that nonphysical properties, even if they are realized in the physical, can be causally relevant without violating closure (Kim, 1993).

Some property dualists cheerfully accept these consequences, thereby embracing *epiphenomenalism* (Jackson, 1982). Here mental properties are demoted to mere 'nomological danglers', properties caused by what goes on in the physical world, but not themselves having any causal efficacy in return. The mind's operations are, therefore, somewhat like the display on a computer's monitor: the changing patterns of colors reflect the internal operations of the computer without having any reciprocal effect on these operations. Epiphenomenalism is attractive for a number of reasons – for example, it allows us to embrace both the irreducibility of mental properties and the causal closure of the physical – yet it too has some obstacles to overcome. Besides being at odds with common sense, epiphenomenalism seems to rob us of an important kind of knowledge: our knowledge of our own mental states. If my qualia, for example, are causally impotent, how could I ever know about their existence and character? Yet first-person knowledge about conscious states is normally thought to be the most secure knowledge we can have. Either epiphenomenalists must bite the bullet and deny that we have such knowledge, or they have to explain how we can know about features of our minds from which we are causally isolated.

DUALISM AND COGNITIVE SCIENCE

What relevance might dualism have for contemporary cognitive science? Cartesian dualism is no longer considered seriously by most cognitive scientists, in spite of its renewed attention from metaphysicians. If cognitive scientists are substance dualists at all, they typically embrace only the non-Cartesian variety: the mind, if it can even rightly be called a substance, is constituted by the body or brain. In spite of this near-consensus, however, it is worth noting that there is nothing in cognitive science *per se* forcing one to reject Cartesian dualism. Most, if not all, theories in cognitive science are neutral with respect to the ultimate nature of the mind. Even psychological theories that 'locate' mental capacities or processes in the brain could be interpreted by a Cartesian dualist as merely revealing their 'neural correlates'. A scientific study of the mind requires systematic (lawful) correlations between mental states and the empirical states of the body and brain. But whether these states are one and the same, and indeed whether the brain is the mind at all, are questions outside the domain of such a study.

However, while empirical theories about the mind are compatible with Cartesian dualism, the progress of cognitive science is making the view less attractive than it was in the seventeenth century. The more cognitive scientists learn about the capacities of physical systems such as the brain, and the more they learn about the dependencies between mental and neural functioning, the less attractive Descartes' theory has become (Damasio, 1994).

In contrast to substance dualism, property dualism is becoming more popular. Indeed, nonreductive materialism is the dominant view in cognitive science, where it is almost taken for granted that mental phenomena exist at a higher, more abstract level than physical phenomena, even if the former are realized in the latter. Some philosophers question whether the hierarchy of 'levels' cognitive scientists speak of really requires a distinct class of mental properties, but this is how such talk is often understood. And while property dualism in its radical form is still a minority view, it has been earning more respect, especially among theorists

of consciousness. Chalmers (1996), for example, believes that nonphysical qualia can be successfully integrated into a science of the mind. He believes that while no physical theory could ever fully capture the nature of our conscious states, cognitive science can fruitfully investigate the laws connecting consciousness with physical systems such as the brain.

Finally, perhaps the most interesting consequences of dualism for cognitive science are not so much metaphysical as methodological. If dualism in any of its forms is true, then any study of the mind is in an important sense an autonomous discipline: theorizing within cognitive science can proceed by and large independently of the physical sciences. As cognitive scientists formulate psychological laws and explanations, they need not await the perfection of, say, particle physics. Among some dualists, this autonomy takes a rather strong form. Descartes thought that the mind was wholly outside the domain of the emerging mechanistic science of his day. And much more recently Davidson (1980) has argued that the form of explanation in psychology is of a radically different sort than that in the physical sciences. Some nonreductive materialists soften this line on autonomy, allowing psychological explanations to be of the same sort as those in the physical sciences. They might even grant that the lower-level physical sciences can illuminate, and put important constraints on, higher-level theorizing about the mind. Yet because, in their view, mental theorizing occurs at a higher level, it will still retain a degree of autonomy.

Dynamical Systems, Philosophical Issues about

Intermediate article

James Garson, University of Houston, Houston, Texas, USA

CONTENTS

Dynamical systems theory provides an alternative to the dominant paradigm in cognitive science that claims human intelligence results from digital computation. The dynamical account of cognition avoids symbolic representation, and stresses the importance of modeling human interactions with the external environment through time.

INTRODUCTION

Dynamical systems theory (DST) has provided a new paradigm for understanding complex systems. The concepts and methods developed to describe nonlinear dynamics have rapidly spread from physics, to chemistry, biology, neurology, ecology, geography, economics, and political science. It is natural to think that the same methods might contribute to cognitive science. The dynamical systems hypothesis (DSH) proposes that the methods and results of DST provide genuine new insights into the nature and explanation of cognition – insights that are missed by the traditional approach in cognitive science, which is to view human intellect as the product of symbolic computation. The differences between the symbolic and dynamical viewpoints raise a number of important philosophical issues. These include the role of symbolic representations, the importance of interaction with the environment, and the way in which time is treated in cognitive models.

WHAT ARE DYNAMICAL SYSTEMS?

Dynamical systems are models of the phenomena of nature that employ the methods of DST. DST is not so much a theory as a body of conceptual and mathematical tools that provide insight into the complex behavior that is generated in nonlinear systems, where solving the equations describing how properties (variables) change through time can be difficult or impossible. DST has developed concepts and graphical techniques for describing the qualitative nature of such systems. Where mathematical solutions for the equations that describe the changes in the variables are unavailable, progress can still be made by simulating a system's behavior on computers and by applying general knowledge drawn from the study of related systems. A main focus of this work is to identify a range of stable and unstable behaviors that the system takes on in responding to forces that affect it. (*See* **Dynamical Systems: Mathematics**)

Phase Space

The concept of phase space (or state space) is a foundational notion in DST. The phase space for a system has a separate dimension devoted to each variable in its equations. For a simple pendulum, for example, the phase space might have two dimensions, one for the position (x) and one for the velocity (v) of the pendulum bob. A phase space describing the brain's neural activity, on the other hand, might include a separate dimension for the firing frequency of each of over 100 billion neurons.

A point in a two-dimensional space indicates a value for each of the two dimensions. For example, the point (x, v) in the phase space for a pendulum might indicate that the position of its bob is x meters away from vertical, and that its velocity is v meters per second. If we give a pendulum bob a push, it will swing back and forth. This oscillating behavior corresponds to a moving point in phase space, with the x and v values of the point changing as the pendulum bob takes on new positions and velocities. The path this point takes is called the *phase trajectory*. Assuming no friction, the trajectory

of a pendulum forms a closed loop. If there is friction, it forms a curve that spirals towards the origin ($x = 0$, $v = 0$), indicating that the pendulum bob is ultimately motionless in a vertical position.

Attractors

Most dynamical systems can be described by 'attractors', which are points, lines or higher dimensional surfaces in the phase space that represent stable motions of the system. A system that is disturbed so that its phase trajectory is moved away from an attractor will soon return to it. There are several fundamentally different kinds of attractors. In the case of a stable attractor, the phase trajectory evolves towards a point in the phase space. The resting position of the pendulum under friction is a good example, for here the system has reached a point of stable equilibrium. A second kind of trajectory is called a limit cycle. In this case, the pathway starting from initial conditions settles into a repeating sequence. For example, the friction-free pendulum traces a limit cycle. A third kind of attractor is the torus, a donut-shaped surface. A phase trajectory on a torus is a curve that may never loop back on itself. 'Strange attractors' are the signature of chaos. These attractors are very complex, and tend to 'fill' large regions of their phase space. Chaotic systems are practically impossible to predict because the slightest deviation in the values of their variables will be quickly magnified into large differences in outcome.

Chaos and Complexity

DST is sometimes called 'chaos theory', but the use of the world 'chaos' is misleading for two reasons. Firstly, it suggests randomness or disorder, yet many chaotic dynamical systems spontaneously create structure. Secondly, chaos is only one of several types of behavior studied by DST. It is not even accurate to refer to a system as chaotic, since chaotic behavior may come and go depending on differences in the system's parameters. Although chaos is not a central feature in most dynamical models of cognition, the possibility of chaotic and near-chaotic behavior has interesting implications.

Dynamical systems described by even very simple equations generally have complex trajectories. Such trajectories display a kind of richness of behavior that defies accurate characterization by any digital program or set of rules small enough to be actually written out or understood by humans. (Although the equations of the system might be easy to state, only an impracticably large and fast digital computer could accurately predict the behavior determined by those equations.) The existence of such chaotic and near-chaotic complex behavior in dynamical systems is an important consideration in understanding the contribution of DST to cognitive science. (*See* **Real-valued Computation and Complexity**)

Self-organization and the Emergence of Order

In nonlinear dynamical systems, an activity that is seemingly disordered at the lowest level can still produce coherent and stable large-scale structures. Chaotic models of Jupiter's famous red spot suggest that such structures can persist autonomously for a long time, and that they do not need any special mechanism to create or maintain them (other than the natural behavior of the system as a whole). Contrary to our intuition that forms of order must always cancel out in a highly energetic and unguided system such as the atmosphere of a gigantic planet, DST shows that structures such as the red spot emerge naturally from the dynamics of gases on the surface of a heavy rotating sphere. It has been proposed that cognition may depend on the same kind of emergent self-organization. (*See* **Emergence**)

WHAT IS THE DYNAMICAL SYSTEMS HYPOTHESIS?

The dynamical systems hypothesis is that cognition is a dynamical system and so is best understood using the concepts and methods of DST. The DSH is often contrasted with the hypothesis that cognition should be modeled on the symbolic operation of a digital computer. The conflict between the two hypotheses centers around the concepts and methods of explanation they advocate. Symbolic modelers attempt to model human knowledge by postulating the existence of symbolic representations in the brain that record information about the external world. They also assume the existence of programs or sets of rules that the brain uses to transform these symbolic data into new forms. These program-guided transformations are thought to account for cognitive processes such as conceptualizing, planning, reasoning, decision making, and eventually action. (*See* **Symbolic versus Subsymbolic**; **Symbol Systems**)

Dynamicists, on the other hand, view the brain as a dynamical system which is continually affected by interaction with its environment. Dynamical representation is not symbolic, but is understood

via the concepts that DST uses to understand structures in phase space, including equation parameters, trajectories or their parts, and attractors.

Levels of Description and the DSH

A common misconception is that the DSH demands that cognitive explanation be carried out in terms of variables for brain features such as the firing rates of neurons, and the strength of the connections between them. Such connectionist models do fall within the DSH. However, dynamical models can also be constructed at higher levels of description. For example, Townsend and Busemeyer (1995) have applied DST to characterize decision making. The variables of their models are clearly cognitive, for they measure the gains or losses expected for the various factors (or dimensions) that are relevant to the decision. (*See* **Connectionism**)

The Role of Representation in the DSH

One of the most important differences between symbolist and DSH approaches concerns the roles that representations play in the two paradigms. The symbolist theory assumes that cognition is correctly described as the execution of programs or subroutines, which are defined over representations. Here representations are directly implicated in a causal explanation of cognitive performance. On the DSH approach, the analogs of programs are the equations that govern the evolution of a system. These equations are not ordinarily defined over representations, but instead over the variables for the system's properties. From the DSH point of view, representations are not essential to an explanation of the mechanisms of cognition, since what matters is the way in which system variables evolve according to the system's equations of motion. Although dynamical explanation may mention representations, these are conceived of as emergent aspects of system activity.

An Illustration of the Difference between Symbolist and DSH Models

An illustration may help to explain the difference between symbolical and dynamical conceptions of representation. Consider two different ways of constructing a thermostat that controls a furnace. The 'symbolic' thermostat would collect temperature information about the outside world with sensors, and convert that information into numbers that are stored in a memory *M* of a small computer. A program running on that computer includes instructions such as 'if the number in *M* is smaller than 20 then turn on the furnace burner'. On the other hand, the 'dynamical' thermostat would consist of a device that connects the furnace to a bimetallic strip in such a way that as air temperature falls, the strip bends, thereby opening a valve that sends more fuel to the furnace's burner.

In the symbolic thermostat, digital representations of the temperature in the room interact with program commands to control the furnace. It would be inappropriate, however, to characterize the dynamical thermostat on the computational model, since no computation over data representing the world is performed. A dynamical model would provide equations describing the interactions between variables for room temperature and valve position. Although one might claim that the amount of bend in the bimetallic strip carries information about (or even represents) the temperature of the room, a satisfactory explanation of how the system works can be made without treating the strip as explicitly representational. The state of the strip is not symbolic data to be processed by a program; it is a part of the mechanism that directly ensures that room temperature and valve opening interact in the right way. Here, in contrast to the symbolist thermostat, we lack any meaningful distinction between the data and the procedures that operate on the data.

Time and Interaction in the DSH

The example of the dynamical and symbolic thermostats helps illustrate other features that distinguish the DSH from the symbolist hypothesis. The DSH promises to provide a richer framework for understanding the evolution of a system through time. The dynamical thermostat can be modeled with a system of equations that specify the relationships between room temperature, the furnace valve position, and its effect on room temperature. These equations specify the rates at which the variables change. A feedback system of this kind displays a rich variety of behavior including oscillations and overshoot when the feedback is too strong or delayed. A symbolist model does not have the well-developed temporal concepts that would explain such dynamic behavior: it does not explicitly treat time as a graded or real-valued quantity. The rate at which quantities change is largely ignored. When time is mentioned at all, it is in description of the sequence of steps a computer performs as it follows its program. Since time is treated as a sequence of discrete moments, rather

than a continuous quantity, symbolist models have difficulty capturing interactions with the environment that depend on how quickly system variables change.

A second difference is that the symbolist has a tendency to view the system as isolated from the environment, being driven by its representations of the world rather than by the world itself. Dynamicists will claim that a better way of understanding cognition is to model the interaction with the world directly.

ARGUMENTS FOR THE DYNAMICAL SYSTEMS HYPOTHESIS

The DSH is in its infancy, and there is not yet conclusive evidence in its favor. However, the available evidence suggests that the DSH is well worth exploring. Firstly, the DSH has a record of success across a wide range of cognitive abilities, including perception, sensorimotor activity, language, attention, decision making, and development (Port and van Gelder, 1995). Secondly, as explained above, the treatment of time and interaction with the environment is richer and more natural in the DSH. Two further arguments for the DSH are worth discussing in detail.

Problems in the Symbolist Paradigm

Certain problems have emerged for the symbolist paradigm. Research programs in artificial intelligence that attempt to symbolically approximate human thought have met with difficulties. The complexity of symbolic programs increases rapidly as rules are elaborated to handle an endless stream of discovered exceptions. Disenchantment with symbolic methods, and interest in alternatives, has arisen from a belief that symbolic methods have failed.

According to the DSH, this failure is a symptom of the fact that the dynamics of the brain embody such complex information processing that even a marginally accurate symbolic approximation would require impossibly complex programs. Although cognition is clearly ordered in many respects, it may be that this order can be expressed in compact form only as 'soft laws' (Horgan and Tienson, 1990). Soft laws incorporate ineliminable exceptions ('*ceteris paribus*' clauses) that reflect the subtlety and flexibility found in human thought. If cognitive regularities are truly soft in this way, then attempts to characterize cognition in the form of programs that embody strict rules are bound to fail.

Even defenders of the symbolist paradigm have voiced doubts about whether symbolist methods can capture higher-level cognition. Given the persistent failure of the symbolist paradigm to present a plausible theory of the flexibility of thought and language, there is every reason to seek an alternative.

The Power of Dynamical Processing

One source of evidence for the DSH comes from the study of dynamical computation (Kauffman, 1993, chapters 5–6). Crutchfield and Young (1990) have examined the computational complexity of high-level system behavior over a range of underlying system dynamics. When a dynamical system exhibits short limit cycles, its computational powers are weak. At the interface between long limit cycles and chaos, the power increases to a maximum, while deeper in the chaotic realm, computational power wanes. Kauffman (1993, p. 221) modeled the evolution of dynamical systems whose survival depends on the ability to solve a simple task. His results lead to a similar conclusion: higher fitness corresponds to complex dynamical behavior at the 'edge of chaos'. Furthermore, he gives evidence that systems evolve more quickly when they operate in this realm.

Work on the superiority of analog over digital computation underscores the potential information processing advantages of dynamical models. Blum *et al*. (1989) have shown that analog computation provides a vast increase in the range of processing available to the brain, and Siegelmann and Sontag (1994) have shown the superiority of analog computation in models of noisy neural networks. Such evidence is far from conclusive, but it suggests that highly complex dynamical processing may account for the intelligent adaptability and avoidance of overly rigid or stereotypical behavior that characterize human cognitive performance.

PROBLEMS WITH THE DYNAMICAL SYSTEMS HYPOTHESIS

Since the DSH challenges an established paradigm, it is not surprising that it faces strong criticism. Some of the main objections are described below.

Problems in Dynamical Modeling

Modeling cognition with DST is not easy. Defining the relevant variables and the dynamical equations that govern them is a daunting task that too often depends on guesswork. Some tools available in

DST allow the researcher to investigate dynamical models even when the actual equations of motion are not known in detail. However, a fundamental problem remains. Even when one has the luck to produce a model that approximates fairly well the behavior to be explained, it can be difficult to determine whether that success is genuine or the result of 'fudge factors' written into the equations.

The 'Wrong Level' Objection

It has been claimed that the DSH attempts to explain cognition at the wrong level. Perhaps DST is useful in giving an account of the behavior of the brain in physical, chemical, or neurological terms, but this does not help us make progress in cognitive science. What is needed is a theory that explains human action in terms of perceptions, memories, beliefs, desires, reasons, plans, and goals. Although some aspects of perception and motor control may be illuminated by DST, the understanding of the central processes that govern human intelligence would seem to require a very different vocabulary from what appears to be available to DST.

One response to this objection has been outlined already, namely that DST is not limited to models framed at the neurological level. Furthermore, work on central processes within DST is in its infancy. Only time can tell whether DST models of a full range of higher cognitive abilities will be successful, either by employing variables for concepts already available in cognitive psychology, or by providing the tools that will allow us to construct more fruitful cognitive-level concepts.

The Systematicity Objection

One of the most widely discussed criticisms of the DSH appeals to the systematicity of higher-level cognitive abilities such as language and reasoning. The systematicity of language means that the ability to produce and understand some sentences is intrinsically connected to the ability to produce and understand others of related form. For example, no one with a command of English who understands 'John loves Mary' can fail to understand 'Mary loves John'.

The systematicity objection proposes that such facts can be explained only by assuming that cognition operates over symbolic strings (such as 'John loves Mary') composed of constituents ('John', 'loves', and 'Mary') that can be combined in different ways. A speaker of English computes the meaning of a string from the meanings of its constituents. If this is so, then understanding 'Mary loves John' can be accounted for as another instance of the same process. Some have claimed that no alternative solution can work, so that symbolic processing of representations with symbolic constituents is required to explain cognition.

It is indeed difficult to explain systematicity without adopting a model that explicitly employs symbolic constituents. Research in DST (van Gelder and Port, 1994) offers some hope that dynamical systems can create the needed combinatorial structures without implementing symbolist structures. However, a convincing response to the systematicity challenge will require more research.

PHILOSOPHICAL ISSUES ABOUT THE DYNAMICAL SYSTEMS HYPOTHESIS

The mission of cognitive science is to explain the highly flexible structure embodied in human intelligence. The DSH requires us to reconsider both the nature of that structure and the methods we use to explain it.

Representation

The DSH undermines common presuppositions about representation in the brain. Symbolists tend to think that having representations of the world is a prerequisite for having knowledge about it. The DSH stresses the idea that intelligence is the result of an ongoing interaction with the world that may not require explicit storage of information. Symbolists tend to think of representations as static entities waiting to be processed by programs. Dynamicists tend to view representation as the product of the system's dispositions to interact with the world as reflected in its attractor 'landscape'. The notion of a phase space in DST provides a framework for understanding the relationships between different representational states. Since representational features are defined in terms of a high-dimensional space, the notion of the distance or similarity between representations is well defined. Within this framework, the features of representations that account for their cognitive roles can be understood in terms of DST concepts that help characterize the similarities and differences to be found in phase space. (*See* **Language, Connectionist and Symbolic Representations of**)

Soft Laws

We tend to expect a science to provide us with the laws of its domain; so that cognitive science should

discover the laws of human thought. But the DSH may require us to revise our understanding of the nature of laws, and hence of the goals of cognitive science. It has been widely noticed that the laws of psychology resist formulation. Some have concluded from this that the study of cognition can never meet the requirements of science; but the DSH suggests that we may need to revise our conception of laws in cognitive science. Soft laws incorporate '*ceteris paribus*' clauses, conceding the existence of exceptions. The DST perspective suggests that such laws may be preferable to hard laws in psychology and other sciences.

The Nature of Explanation in the DSH

The DSH also invites a new conception of explanation in cognitive science. To illustrate this point, let us contrast symbolist and dynamical explanations for how the leopard gets its spots. The symbolist assumes that the genetic code specifies a template for leopard spot patterns that guides the way spots are formed in leopard skin during development. The fetus incorporates a program that reads this template and fixes the colors that fetal skin cells will express. On this paradigm, explaining how the leopard gets its spots amounts to locating the template and the mechanism that reads it. The dynamicist's explanation is very different. The chemistry of fetal leopard skin can be modeled by a nonlinear dynamical system that spontaneously creates spots in leopard-like patterns. So, in a sense, the spot shapes have no explanation apart from the observation that the right dynamical systems make those patterns naturally.

This dynamical explanation may appear vacuous. The symbolist explanation accounts for the mechanism that forces fetal leopard skin to form the right pattern of spots. However, if the dynamicist is right, the project to find a template and program is bound to fail. The lesson of dynamical systems theory is that very complex patterns can emerge spontaneously from the seemingly random interaction of simple units such as skin cells. Patterns may emerge without symbolic guidance.

The same moral may apply to cognition. From the DSH perspective, intelligence is the product of self-organized structures that arise naturally. Searching for programs and data that guide the brain is like searching for a force that keeps objects moving at a constant velocity. No explanation for how cognitive systems behave is necessary beyond merely pointing out that the dynamical systems responsible spontaneously create that behavior.

THE DYNAMICAL SYSTEMS HYPOTHESIS IN COGNITIVE SCIENCE

The relationship between the DSH and alternative paradigms in cognitive science is complex.

Connectionism and the DSH

Connectionism (rather than DST) has so far presented the most popular alternative to the symbolist approach. Connectionists attempt to construct models of interconnected neurons in the brain that are capable of cognitive tasks. While some connectionists accept the thesis that the brain relies on symbolic processing, radical connectionists seek to show that neural networks can produce cognition using non-symbolic methods. Thus both dynamicists and radical connectionists are opposed to symbolism. Furthermore, neural networks are examples of dynamical systems, and some connectionists employ concepts from DST to help understand their behavior.

Symbolism and the DSH

It can be shown that a digital computer can be treated in DST as a special case of a dynamical system. Furthermore, dynamicists typically use digital computers to investigate the behavior of their models, so it may appear that everything they discover also has a symbolist account.

What is Unique about the DSH

However, the fact that symbolist and connectionist models can be treated as dynamical systems does not imply that the DSH is compatible with either paradigm. The main feature that distinguishes the three accounts is found not in *what* they model but in *how* they model. The DSH proposes that the concepts and methods of DST are what is needed to make progress in cognitive science. Symbolism employs entirely different methods and concepts. While some connectionists use tools drawn from DST to obtain insight into the functioning of their neural networks, they differ from dynamicists in their vision of cognition. The DSH views the mind as a structure in constant resonance with changes in the environment. It seeks an explanation for cognition in the complex and often self-organized structures that emerge from systems of nonlinear equations that determine how variables change value smoothly through time. Only time will tell which of these views is the right one or whether

more than one of them may be needed to give a full account of the richness of the human mind.

Eliminativism

Intermediate article

William Ramsey, University of Notre Dame, Indiana, USA

CONTENTS

Eliminativism is the radical thesis that the common-sense conception of the mind is deeply mistaken and that certain mental states posited by it do not exist.

WHAT IS ELIMINATIVISM?

Eliminativism, or eliminative materialism as it is often called, is the thesis that our common-sense conception of the mind is deeply mistaken and that our ordinary notions of mental states will not belong to a scientifically respectable account of cognitive phenomena. Put more simply, it is the view that certain mental states, such as beliefs and desires, do not exist. Eliminativism is one of the most radical and controversial philosophical positions ever held. In many respects, it goes beyond other forms of scepticism since it challenges deep assumptions about the workings of our own minds. In his *Meditations*, Descartes offered a famously extreme form of doubt, questioning many of our beliefs about ourselves and the world. Nevertheless, he insisted that we can at least know with certainty that our minds contain thoughts and beliefs. Eliminativism claims not only that it is possible to doubt the existence of such mental states, but that it is correct to do so.

Eliminativism involves two central and controversial claims. It is worth examining each of these in some detail. For the sake of brevity, much of this article will focus upon our notion of belief, since it figures so prominently in discussions of eliminativism. Many of the arguments concerning belief are thought to generalize to other mental notions as well, especially other propositional attitudes.

Folk Psychology and the Theory Theory

The first claim of eliminativism is that we employ a theoretical framework to explain and predict intelligent behavior. This position is commonly called the 'theory theory', since it maintains that our 'folk' or 'common-sense' psychology is similar to other folk theories that we use to understand a range of different phenomena. As with most theories, folk psychology is assumed to consist of both universal generalizations (or laws) and theoretical posits, with the former capturing the counterfactual regularities found among the latter. For example, a generalization of folk psychology might be something like:

> If someone has the desire for X and
> the belief that the best way to get X is by
> doing Y, then (barring certain conditions)
> that person will tend to do Y. (1)

According to the theory theory, these generalizations function like the laws of scientific theories, though they are learned and used in a far more informal manner.

The theory theory maintains that the posits of folk psychology are the mental states that figure in our common-sense psychological explanations. As theoretical posits, these states account for observable effects (like statements and behavior), but are not themselves directly observed. If we concentrate on our folk notion of belief, the theory theory claims that common sense assigns two sorts of properties to these states. First, there are various causal properties. We assume beliefs are caused in certain circumstances, interact with desires and other cognitive states in certain ways, and bring about certain kinds of behavior. These causal roles help define and distinguish beliefs from other types of mental states. Second, beliefs are essentially about a wide range of different states of affairs. This inherit 'aboutness', or 'intentionality' (also sometimes called 'meaning', 'content', or 'semantic properties'), is commonly regarded as a unique feature of the mind. While conventional signs and linguistic symbols are meaningful, their meaning is derivative, stemming from the stipulations and interpretations of thinking creatures. Only beliefs and other mental representations have what is

called 'original' or 'intrinsic' intentionality: a type of meaning not derived from other sources.

Eliminative Theory Change

The second claim of eliminativism is that folk psychology is severely mistaken about the actual nature of the mind. Eliminativists argue that the laws and posits of folk psychology radically misdescribe our minds; consequently, they denote nothing that is real. To understand eliminativism, it is important to note the difference between two types of theory change: reductive or retentive theory replacement, on the one hand, and eliminative, or ontologically radical, theory replacement, on the other. In the case of the former, the posits of a rejected theory – be it a folk theory or a former scientific theory – find a new home, perhaps with some modifications, in the superseding theory. For example, the notion of a planet survived the transition from Aristotelian physics to Newtonian physics, though it underwent some changes as Aristotle's notion was clearly mistaken in many respects. Despite problems with the Aristotelian framework, we did not conclude that it was so wrong that the notion of planet has no referent.

This can be contrasted with eliminative theory change, where a theoretical posit of an abandoned theory so misses the mark that we conclude that the notion fails to capture anything real. For example, early explanations of strange behavior posited the existence of malevolent spirits that were thought to possess the souls of unlucky individuals. As the theory of demonology was replaced by more sophisticated accounts of mental and neurological disorders, the notion of a supernatural demon was abandoned altogether. Since there is nothing in the new accounts with which demons can be reasonably identified, we have eliminated demons from our contemporary ontology.

Eliminativists predict that this sort of eliminative change will happen with the theoretical posits of folk psychology. The claim is not that mental states, such as beliefs, currently exist but will somehow be abolished as our scientific understanding of the mind grows. The claim is that mental states such as beliefs have never existed; hence, it is the concept of a belief that will be eventually eliminated from our mental taxonomy. There simply are no such things that have the causal and semantic properties we attribute to beliefs.

Eliminativism shares assumptions with both physicalism and dualism. Eliminativists agree with the physicalist claim that the actual causes of behavior are ultimately physical events, taking place inside the brain. However, eliminativists also agree with dualists that the mental states posited by common-sense psychology are not to be identified with anything inside the brain. Of course, whereas dualists hold this view because they think mental states are nonphysical, eliminativists hold this view because they think these states do not exist.

ARGUMENTS FOR ELIMINATIVISM

As one might expect, arguments for eliminativism typically take the form of arguments against folk psychology. By and large, these arguments fall into two groups. The first group involves general theoretical considerations that are relevant to the evaluation of any theory. The second group focuses upon problematic aspects of folk psychology itself.

Most of the arguments against folk psychology based upon theoretical considerations can be found in the writings of Paul and Patricia Churchland, perhaps the two strongest defenders of eliminativism. One such argument starts with the premise that a promising theory should offer a fertile research programme with considerable explanatory power and range. It then notes that folk psychology appears stagnant, making no real progress throughout much of history. Worse yet, there are many cognitive phenomena that folk psychology does not even begin to explain. Important aspects of the mind such as the nature of consciousness, the oddities of mental illness and the actual mechanisms of learning are all left unexplained by folk psychology. These and similar considerations suggest that folk psychology is ripe for replacement. Another argument looks at the track record of folk theories in general and notes how improbable it would be for this one to turn out true. Folk physics, folk biology, folk epidemiology, and so on, all proved to be radically mistaken. Folk psychology concerns a subject that is far more complex and difficult than these others. Hence, it seems implausible that just this one is right (Churchland, 1981).

In response to these theoretical arguments, many argue that folk psychology actually has stimulated a number of fruitful research programs in scientific psychology. Moreover, some of these do help explain a wide variety of cognitive phenomena not directly explained by folk psychology. Furthermore, it is one thing to claim that a folk theory is incomplete or unproductive, but another thing to claim that it is radically false (Horgan and Woodward, 1985). Defenders of folk psychology claim that these theoretical considerations cannot possibly outweigh the evidence provided by the

everyday, ordinary experience of our own minds, which seems to support the reality of beliefs.

Regarding this last point, eliminativists often warn that we should be deeply suspicious of introspective 'evidence' about the inner workings of the mind. Since all forms of observation – including introspection – are, to some degree, 'theory-laden', our folk-theoretical framework may play a larger role in forming the content of our experienced inner lives than actual mental processes. Indeed, there is considerable empirical evidence that we lack reliable access to the actual workings and nature of cognitive processes. Thus, our inner observations of certain mental states may be like the observations of those who claimed to be able to 'observe' demonic spirits.

The second group of arguments looks at features that are unique to folk-psychological posits and challenges the likelihood that these features will be accommodated by a scientific account of the mind. The most widely discussed features are those associated with the alleged linguistic nature of beliefs and other propositional attitudes. Common sense appears to treat these states as having a form similar to public language sentences, with a compositional structure and syntax. For instance, the belief that John loves Mary appears to be composed of the concepts (or mental 'words') 'John', 'love', and 'Mary', and it differs from the belief that Mary loves John by virtue of something analogous to syntactic arrangement. Along with this quasilinguistic structure, beliefs resemble public sentences in another way: they have semantic properties. Beliefs, like sentences, are individuated by virtue of what they are about.

Both of these quasilinguistic features of propositional attitudes – their alleged sentential structure and their semantic properties – have motivated arguments in favour of eliminativism. With regard to the former, some writers have emphasized the apparent mismatch between the sentential form of propositional attitudes and the actual neurological structures of the brain. Whereas the former involves discrete symbols and a combinatorial syntax, the latter involves action potentials, spiking frequencies and spreading activation. It is hard to see where in the brain we are going to find sentence-like structures (Churchland, 1986).

Of course, this argument depends upon a certain view of folk psychology, namely, that it treats beliefs as having a sentential structure. Those who reject that claim, as many have, will not find the argument compelling. Even for those who find this reading of folk psychology plausible, there is a further difficulty regarding the relevance of neuroscience for determining the status of folk psychology. Many have insisted that just as the physical circuitry of a computer is the wrong place to look for computational symbol structures, so too, the neurological wiring of the brain is the wrong place to look for structures that might qualify as beliefs. Instead, the status of folk posits should be decided at a higher, more abstract level of analysis than the neurophysical. For many, the computer model of the mind – where the mind is regarded as the brain's program, abstracted from the neurological details – provides a more appropriate level at which to seek analogs to the posits of folk psychology.

The second type of argument against beliefs – focusing upon their intentional or semantic properties – concludes that folk-psychological concepts are inappropriate for any scientific theory of the mind, including a computational one. The main proponent of this argument has been Stephen Stich (1983). Stich claims that folk psychology individuates beliefs by virtue of their semantic properties; however, there are several reasons for thinking that a semantic taxonomy is ill-suited to scientific psychology. Firstly, because such a taxonomy depends upon matters outside the head, it will individuate mental states differently from other taxonomies, such as those based upon causal roles. Secondly, Stich has argued that the semantic content of a belief is ascribed on the basis of judgements of similarity. Consequently, these ascriptions are vague, and fail with subjects who are too dissimilar from ourselves, such as the very young and the mentally ill. Rather than adopt a folk-psychological ontology, Stich argues a scientific psychology should employ a syntactic taxonomy: one that individuates mental states by appeal to their purely non-semantic properties.

As Stich himself notes, even if folk posits are inappropriate for a scientific psychology, it need not follow that they do not exist. After all, there are plenty of entities that are vaguely defined or demarcated in ways that are inappropriate for science, but are nevertheless real. If our best scientific account posited states that share many features with beliefs, such as similar causal roles, then even if the two taxonomies differed in certain cases, we may still regard folk psychology as, in some sense, vindicated.

To generate a more robust form of eliminativism, we would need to show that there is nothing in our scientific psychology that shares the central properties we attribute to beliefs. In a more recent paper, Ramsey, Stich and Garon (1990) argue that certain connectionist models of memory and

inference could serve as the basis for this stronger eliminativist claim. These connectionist models store information in a holistic, or distributed, manner; thus, there are no causally discrete, semantically evaluable data structures that represent specific propositions. It is not just that these models lack the sentential, compositional representations assumed in more traditional (or 'language of thought') models. Rather, in these networks there are no causally distinct structures that stand for anything specific. Consequently, there do not appear to be any structures in these models that might serve as candidates for the reduction of propositional attitudes. If these connectionist models should prove accurate, they argue, it will show that there are no such things as beliefs and propositional memories. This argument assumes that in a distributed network, it is impossible to specify which bits of information are causally responsible for various acts of cognition. Some have responded by insisting that, with highly sophisticated forms of analysis, it is possible to pick out casually relevant pieces of stored information.

While most arguments for eliminativism focus upon propositional attitudes, it should be noted that one philosopher, Daniel Dennett (1988), has endorsed an eliminativist stance towards a very different class of mental states: those commonly referred to as 'qualia'. Qualia are mental states picked out by virtue of their intrinsic qualitative or phenomenal character, like pain states. Such states seem intuitively to have a number of special features, such as being purely private, immediately perceived, and intrinsically subjective. Dennett discusses several cases – both actual and imaginary – to expose ways in which these ordinary intuitions about qualia are inconsistent. In suggesting that our concepts of qualia are deeply confused, he attempts to cast doubt on the reality of these states as they are commonly understood by folk psychology.

ARGUMENTS AGAINST ELIMINATIVISM

As might be expected of a theory that challenges our fundamental understanding of ourselves, eliminativism has been subjected to a wide range of criticisms. Here we will discuss four such criticisms which have enjoyed particular prominence.

Incoherence of Eliminativism

The first criticism claims that eliminativism is incoherent or in some way self-refuting. The charge is that eliminativism itself presupposes the existence of the very thing it claims not to exist, namely, belief states. A typical way this charge is made is to insist on some cognitive capacity or theoretical principle that is somehow required by eliminativism and yet requires the existence of beliefs. One popular example is the capacity to make an assertion, and that to assert something one must believe it. Hence, for eliminativism to be asserted as a thesis, the eliminativist must believe that it is true. But if the eliminativist has such a belief, then there are beliefs, and eliminativism is thereby proved false (Baker, 1987).

However, it is important to note that the eliminativist thesis itself – that there are no beliefs – is not conceptually incoherent. The criticism is not that eliminativism is self-contradictory, but that the eliminativist is doing something that goes against his or her own thesis. In the above example, this act was the making of an assertion: we are required, it is claimed, to believe what we assert. But this is exactly the sort of folk-psychological statement that an eliminativist would deny: a central tenet of the eliminativist position is that various capacities that we think involve beliefs actually don't. Thus the critic has merely begged the question, since eliminativists reject the idea that various acts (such as asserting a thesis or formulating a theory) require the existence of beliefs.

Misrepresentation of Folk Psychology

The next criticism of eliminativism challenges the way it characterizes folk psychology. This criticism has two distinct origins. The first origin is, at least partly, in the writings of Wittgenstein (1953) and Ryle (1949). According to one version of this view, common sense does not treat mental states, such as beliefs, as distinct inner causes of behavior. Instead, they are treated as dispositional states, which are used to adopt a certain heuristic 'stance' towards rational agents. Hence, ordinary talk about mental states should be interpreted as talk about abstract things that, although real, are not candidates for straightforward reductions to discrete neurophysical states. They serve in many non-explanatory endeavors – for example, they allow behavior to be interpreted as rational – without assigning any specific inner causal structure to the mind. Consequently, discoveries about the actual structure of the mind are viewed as irrelevant to the status of folk mental states (Dennett, 1987).

The second origin of skepticism regarding the theory theory is in contemporary cognitive science,

and stems from a different model of common-sense psychological explanation and prediction. This view, known as the 'simulation theory', maintains that we predict and explain behavior not by using a theory, but by simulating what we would do in a comparable situation. According to this account, we predict an agent's behavior by taking our own information processing mechanisms 'off-line' and giving them data about the agent's background and circumstances including possible beliefs and desires. We then (subconsciously) use our own decision-making mechanisms to generate output which can thereby serve as predictions (and, in other circumstances, explanations) of the agent's behavior. If this account is correct, then no theory of the mind is used to explain and predict behavior. And if there is no theory of the mind, then there can be no false theory of the mind (Gordon, 1986).

In reply to these objections, defenders of the theory theory have turned to empirical work that supports their position. For example, the developmental psychologists Henry Wellman and Alison Gopnik have argued that in explaining and predicting behavior, children go through phases of development roughly analogous to the phases one would go through when acquiring a theory. Moreover, it turns out that children come to ascribe beliefs to themselves in the same way they ascribe beliefs to others. These considerations lend at least some support to the idea that our notion of belief is employed as the posit of a folk theory rather than as input to a simulation model (Gopnik and Wellman, 1992).

Success of Folk Psychology

Even if we allow that folk psychology is a theory, a third argument against eliminativism is that folk psychology seems to offer a fairly accurate account of cognitive processes. Apart from the way introspection appears to reveal beliefs and desires, we also use folk psychology successfully to predict and control the behavior of others. If folk psychology is so wrong then why are we so good at dealing with one another when we use it? The success of folk psychology suggests an 'inference to the best explanation' argument against eliminativism: the best explanation for the success we enjoy in explaining and predicting each other's behavior is that folk psychology is roughly true.

The eliminativist response to this argument is that any theory – especially one as near and dear to us as folk psychology – may appear successful even when it radically misrepresents reality. As philosophers of science often point out, when we are under the influence of a theory we discount the anomalies with which the theory struggles as insignificant, and attribute more power to the theory than it deserves. The degree to which folk psychology misdescribes mental phenomena may not be fully apparent until we have an alternative theory in hand.

Stich's Criticism of Eliminativism

The final argument against eliminativism comes from the recent writings of a former supporter, Stephen Stich. Stich's argument is complex, but we can outline it here. We noted above that eliminativism is committed to the thesis that the theoretical posits of folk psychology fail to refer to anything. But what exactly does such a claim amount to? Stich argues that this question is far more difficult than eliminativists have assumed. For example, we might think that reference failure occurs as the result of a certain mismatch between reality and the theory in which the posit is embedded. But how much mismatch is necessary before we can say that a given posit doesn't exist? For a variety of reasons, Stich suggests that this question has no definite answer. Consequently, the question of whether there really are such things as beliefs has no definite answer either, contrary to the eliminativist view. Of course, this seems to raise problems not just for the eliminativist, but for the folk-psychological reductionist as well. But Stich has presented compelling reasons for thinking that the usual terms of the debate over eliminativism need to be reconsidered (Stich, 1996).

ELIMINATIVISM AND COGNITIVE SCIENCE

Research in cognitive science has had an important influence on nearly all of the major debates concerning eliminativism. Arguments for eliminativism typically depend upon specific claims about the nature of common-sense psychology. Cognitive research is critical for determining the truth of these claims; and empirical work on our conception of the mind, including our introspective access to our own mental states, has played a central role in debates over the plausibility of the theory theory. As this research continues, we should expect to gain a deeper understanding of the nature of folk psychology.

Eliminativism requires that the transition from folk psychology to scientific psychology be of a certain type, namely, eliminative rather than reductive. This would require psychological theories that

are hostile to the posits of common-sense psychology. Until recently, few psychological theories have been of this nature. The traditional computational paradigm which has dominated cognitive science makes explicit use of data structures that are naturally regarded as the scientific counterparts to folk mental states. However, if Ramsey, Stich and Garon are right, connectionist models may, for the first time, provide us with a plausible account of cognition that supports the denial of belief-like states. The future of eliminativism may depend upon which of these two major accounts of cognition proves correct.

The influence eliminativism has had on cognitive science research is less clear. Because so many theories in cognitive science presuppose the reality of folk-psychological states, both as explanatory posits and as phenomena to be explained, there is no doubt that a commitment to eliminativism would require a radical shift in cognitive science research. Of course, without a widely accepted, well-confirmed theory of cognition, we are not yet in a position to judge the status of folk psychology. Indeed, given the amount of speculative forecasting built into many eliminativist arguments, it is reasonable to ask why cognitive scientists should even consider it. The answer is that eliminativism reminds us to reconsider the constraints we intuitively impose on potential cognitive theories, and not to reject out of hand any psychological theory that failed to incorporate folk-psychological states. Thus, eliminativism is not so much a threat to cognitive science, as a view that potentially admits a range of new theoretical possibilities.

Embodiment

CONTENTS

An understanding of how cognition is realized or instantiated in a physical system, especially a body, may require or be required by an account of a system's embedding in its environment, its dynamical properties, its (especially phylogenetic) history and (especially biological) function, and its nonrepresentational or noncomputational properties.

INTRODUCTION

In recent years a number of researchers in cognitive science and artificial intelligence (AI) have criticized many traditional approaches to modeling, building and understanding cognitive systems as not placing sufficient emphasis on the body or physical realization of such systems. Non-embodied approaches to cognitive science typically involve some or all of the following features, to a greater or lesser extent:

- The belief that cognition is computation, and thus can be understood in an implementation-independent way, allowing cognitive science to proceed independently of biology and neuroscience.
- A search for general-purpose cognitive abilities, not relativized to any particular (biological, sensorimotor, physical) context or need.
- A method of analysis, modeling and design that for the most part ignores temporal aspects of cognition, in that it focuses on behaviors (e.g. chess playing) that are evaluated in terms of 'getting the right answer' rather than exhibiting a particular dynamic profile, and sees cognition as a module that mediates between the deliverances of a causally prior perceptual module and the inputs to an autonomous action system.

In contrast, embodied approaches to cognition typically involve some or all of the following features, again to varying extents:

- Acknowledgment of the role that the body and its sensorimotor processes can and do play in cognition. Some aspects of the system that would, on the traditional view, be considered mere matters of implementation, are instead taken to be crucial components.
- Understanding of cognition in the context of its (especially evolutionary) biological function: to support the activities of the body.
- A view of cognition as a real-time, situated activity, typically inseparable from and often fully interwoven with perception and action.

'Embodied' cognitive science or artificial intelligence, then, refers to a range of loosely affiliated philosophies, explanatory frameworks and design methodologies that strive to redress a perceived neglect of the body in cognitive science.

Since the mid-1980s there has been a rapid increase in interest in embodied cognition (and use of the term 'embodiment'), but there are many aspects of cognitive science and artificial intelligence research conducted in the 1960s and 1970s that take embodiment into account.

ISSUES CONCERNING EMBODIMENT

The issue of embodiment is closely related to, though distinct from, several other issues of recent interest in cognitive science.

Embeddedness

Recognizing the role of the body in cognition facilitates an approach that sees cognition as partly constituted by, or in terms of its relationship to, the environment (Clark, 1997). Thus, embodied cognitive science is naturally related to investigations of externalism (the belief that mental states are partially constituted by states external to the cognizer), situatedness (the importance, in cognitive activity, of a cognizer's location in and relations to the environment), offloading (using aspects of the environment, such as numerals when doing long division, to reduce cognitive load), scaffolding (the assistance

a developing infant gains from, e.g. interacting with adults who already have the ability being acquired), and interactivity (cognitive phenomena, such as turn-taking, which depend crucially on the dynamics of interaction between a cognizer and an object or other cognizer).

Noncomputationalism and Nonrepresentationalism

Once one acknowledges the presence of the body, it is possible to use bodily properties, dynamics and configurations to explain some abilities, behaviors and phenomena that previously were thought to require explanation in computational or representational terms (Varela *et al*., 1991). However, it is still unclear whether such explanations which advert to bodily states are themselves noncomputational and nonrepresentational, or whether they instead invoke a new form of computation and/or representation. It certainly seems that an embodied approach need not be anticomputationalist or antirepresentationalist (Clark, 1997).

Dynamics

Many researchers who have taken an embodied approach have found it useful to turn away from discontinuous, nontemporal, logic-based formalisms and instead use the continuous mathematics of change offered by dynamical systems theory as a way to characterize and explain cognitive phenomena (Port and van Gelder, 1995). Again, while there may be natural affinities between embodied cognitive science and these tools, it is certainly possible to have one without the other.

Biology

Perhaps the most obvious connection between the mind and the body is the brain: surely an important part of understanding the mind is to understand the neurophysiology underlying cognition (Churchland, 1986). But there are other connections with biology as well. For example, some researchers have maintained that one can best understand natural cognitive systems in terms of the biological function and purposes that cognitive faculties served in the phylogenetic development of their bodies (Millikan, 1984). This requires understanding not only bodies, past and present, but the evolutionary niches of such bodies as well. An important constraint, then, on models of human cognition will be whether the proposed architecture is an evolvable one: whether it is the kind of architecture that could have been reached through a process of natural selection, given the conditions known to have been in place in our natural history (Sloman, 2001).

VARIETIES OF EMBODIMENT

There are several dimensions of variation in the views and theories of embodiment currently being considered in cognitive science.

Criteria for Embodiment

Perhaps the most important dimension of variation concerns what criteria must be met for something to be an embodied cognizer: what is to count as a body? One can, partly following Ziemke (2001), distinguish a range of views on this question, from the least to the most constraining.

Physical realization

According to one view, to be embodied is just to be realized in some physical substrate. All work in cognitive science is about embodied systems in this sense: even a virtual web agent must be realized in some physical facts at any given time. Only purely mental entities or spirits would lack this kind of embodiment. Thus, even traditional cognitive science is not as disembodied as some have claimed. For example, the influential notion of a physical symbol system (Newell and Simon, 1976) explicitly acknowledges the requirement that a cognitive system be embodied in this (weakest) sense.

Physical embodiment

Physical embodiment requires that the realizing physical system be a coherent, integral system, that to some degree persists over time. This would rule out virtual web agents, the physical realization of which can be radically distributed over the entire planet, but could still include any conventional robot. A tension arises here: if, as some theorists have argued, human cognition extends into the tools and other physical environmental states we exploit, then the localized, biological body is less relevant to cognitive science than the extended, constantly changing, distributed physical system that at any given time includes parts of our environment as well as parts of our bodies. Thus, active externalism (Clark and Chalmers, 1999) may be incompatible with strong notions of embodiment.

Organismoid embodiment

According to another view, the localized physical realization of the system must share some (possibly

superficial) characteristics with the bodies of natural organisms, in terms of form or sensorimotor capacities, but need not be alive in any sense. The most prominent, and perhaps the most complex, examples of organismoid embodiment are humanoid robots such as Cog (Brooks and Stein, 1994) and Kismet (Breazeal and Scassellati, 2000). Work with these robots is based on the view that research in AI and cognitive robotics, in order to be able to investigate human-level cognition, has to deal with systems that have bodies which, although artificial and possibly non-living, have at least some human-like characteristics. For example, Kismet is a humanoid robot that learns how to visually track objects. To do this, a human trainer must move objects of an appropriate size at an appropriate speed at an appropriate distance in front of Kismet's eyes. If the human trainer moves the tracked object too close to Kismet, Kismet responds by raising its eyebrows in a manner which in humans indicates a startle response. This naturally causes the human trainer to startle in return, which prompts a change in the training parameters of speed and distance. Thus, Kismet's organismoid embodiment, in the form of eyebrows and facial expressions, is an integral part of the human–robot training dynamic which should tend towards homeostasis.

Organismal embodiment

The strongest criterion of embodiment is that the body must not only be organism-like, but actually organismal and alive (e.g. Sharkey and Ziemke, 1998). Of course, this raises the question of what is required for something to be alive. Various answers to this question have been proposed, including the ability to metabolize, reproduce, regenerate, or grow; autonomy; and autopoiesis (e.g. Maturana and Varela, 1980; von Uexküll, 1928).

Other Dimensions of Variation

Another dimension of variation is the extent of the domain of cognition that requires an embodied approach. For example, one can ask whether reference to the body is required only for giving an account of low-level, sensorimotor aspects of human cognition, or if it is required for all forms of human cognition, including reasoning, mathematical thought, and language use (cf. the distinction between 'material' and 'full' embodiment in Nuñez (1999)).

Theorists might also disagree on how radical the effect of taking an embodied approach will be on the concepts, theories and methods of cognitive science. Clark (1999) distinguishes between simple and radical embodiment. In simple embodiment, the framework of traditional cognitive science is retained, and facts about embodiment are treated as mere constraints on theories of, for example, 'inner organization and processing'. Radical embodiment is more ambitious, and 'treats such facts as *profoundly altering the subject matter and theoretical framework of cognitive science*' (p. 348, emphasis in original). Radical embodiment is advocated by, for example, Lakoff and Johnson (1999). These authors claim that a central finding of cognitive science is that the mind is inherently embodied, and that this, together with the other two central findings (that thought is largely unconscious, and that abstract concepts are largely metaphorical), force us to reject not just the Western philosophy of mind, but most or all of Western philosophy, including especially Anglo-American analytic philosophy but also including postmodern philosophy. This throws everything into question: the nature of truth, meaning, time, space, language, rationality, and especially the self.

Finally, one can distinguish between epistemological and metaphysical approaches to an embodied cognitive science. An epistemological approach maintains that concepts concerning the body will be required to understand and explain cognition (even if the cognitive system itself is disembodied); a metaphysical approach maintains either that cognitive processes must be realized in a body or that AI should proceed by making embodied robots, but makes no claim as to whether embodiment must be adverted to in explanations of cognitive activity. For example, research involving the robot Shakey (Nilsson, 1984) was metaphysically embodied, but since its design and explanation focused primarily on Shakey's functional, computational aspects (namely, deliberation and planning) and not on Shakey's embodiment, this research was not epistemologically embodied. Conversely, computer simulations are by their very nature not (metaphysically) embodied, in most senses of 'embodiment', yet many researchers use (epistemologically) embodied simulations to model the crucial role a cognizer's body plays in its activity.

PHILOSOPHICAL CONCEPTIONS OF EMBODIMENT

Before the twentieth century, the most influential view of mind in Western thought was dualistic: the mind was regarded as composed of a separate, extensionless, nonphysical substance. This view

led to many insoluble problems, both philosophical and empirical. For example, how do the mental and physical realms interact? How can we scientifically investigate something that is not in the physical world?

Behaviorism rejected dualism, and thereby opened up the possibility of scientific enquiry into an embodied mind, but it left little room for an understanding of the processes underlying much of mentality: it addressed little of what would be called 'cognition' today. Also, it actively avoided explaining or mentioning experience or consciousness (as did many later cognitivists). More promising steps towards an embodied understanding of mind were taken in the first part of the twentieth century: the relevance of von Uexküll's notion of the body has already been mentioned, but there were several other notable thinkers.

For example, in the 1920s Heidegger (1962) developed a phenomenology that understood human activity not as the result of the manipulation of context-free representations of objects, but as the contextualized experience of the body–environment system. Explicit, decontextualized representation of a hammer as an independent object occurs only when there is some kind of breakdown in the system (e.g. the hammer is too heavy). Dreyfus (1992) elaborated this and other aspects of Heidegger's philosophy into a critique of early, disembodied AI work, calling, for example, for systems that react to the particularities of the current perceptual/action situation rather than ones that attempt to create general-purpose, long-term plans. Although heartened by some aspects of neural or connectionist approaches to understanding the mind, Dreyfus provisionally concludes that, like their symbolic predecessors, connectionist models of cognition suffer from their lack of embodiment, in two ways. Firstly, by not being embedded in a real world with actual bodily concerns, most sophisticated connectionist learning must rely on the intervention of a human teacher, which prohibits the connectionist system from developing its own, genuine, meaningful attitude to the world. Secondly, he speculates that connectionist systems will never generalize in a way that we can recognize as being intelligent and meaningful until they have a form of life sufficiently similar to ours – which requires at least a body of some sort, perhaps even a humanoid one.

In the 1930s, Vygotsky (1978) claimed that language is an inherently socially situated activity, and that one can only understand a child's acquisition of language by recognizing this social context. It follows that inasmuch as social activity is embodied, the development and deployment of linguistic faculties will have to be understood as embodied as well.

While placing less emphasis on social embedding, Piaget (1954) was more explicit about the role of the body in the development of cognitive abilities. For example, his accounts typically made essential reference to the notion of a circular reaction, which in its primary form is the repetition of an activity in which the body starts in one configuration, goes through a series of intermediate stages, and eventually arrives at the starting configuration again. Thus, the kinds of abilities that an organism may acquire depend critically on what circular reactions are possible given that organism's body.

In the 1940s, Merleau-Ponty (1962) made the body central to his phenomenology of mind. For example, he claimed that we have intentions that we do not choose to have, by virtue of our bodies being the way they are. Furthermore, the way we perceive an object is determined by the modes of interaction that our bodies, given the nature of the object, allow. (This idea was a precursor of the notion of affordances (Gibson, 1979).) Even more strongly, Merleau-Ponty saw the body as the necessary medium for our having a world at all, with the nature of the activities of the body determining the nature of what could be experienced in our world. Further, the body could be augmented with tools to further develop the elements of our lived world.

Despite the emphasis that these thinkers placed on the body for understanding the mind and behavior, and partly because of their context outside the Anglo-American tradition, it is only recently that the notion of embodiment has had a significant influence on mainstream cognitive science and AI. Instead, these fields were, from their inception in the mid-1950s, dominated by the computer metaphor for mind (not surprising, perhaps, since the notion of computation had for centuries been a concept of the (human) mental activity of symbol and number manipulation). In particular, in the absence of any suggestion as to how they could constrain empirical investigation and modeling, philosophies of embodiment seemed metaphorical or even unintelligible to many cognitive and AI researchers at that time.

COGNITIVE SCIENCE AND EMBODIMENT

The fields of cognitive science and artificial intelligence have played a central role in the development of an embodied concept of mind and

cognition. It was empirical work in cognitive science and artificial intelligence that allowed the development of a more robust and precise notion of embodied cognition to develop.

In particular, work involving mobile robots, at MIT Artifical Intelligence Laboratory and elsewhere, helped to establish the principles and concepts of embodiment and situatedness as the basis of a new approach to artificial intelligence and (later) an embodied cognitive science. For example, Brooks (1991) and his colleagues were able to get robots to perform tasks in the real world in real time that previously could only be done slowly and inflexibly, if at all. They did this by building robot bodies and robot controllers based on a design called 'subsumption architecture'. Rather than trying to graft a domain- and body-independent planning system onto a perceiving and acting robot, the subsumption architecture approach starts with an initial layer of simple perception–action mediation that implements some low-level behavior (e.g. obstacle avoidance). New behaviors (e.g. exploration) are added by adding further layers, which also mediate between perception and action in a simple way, but inhibit ('subsume') the lower layers when necessary to achieve the desired behavior. In such an architecture, there is no central locus of control, no separate planner, and no central model of the world that all processes must write to and read from in order to act appropriately. Communications between processes are not complex symbolic structures, but numerical values. What computation there is in the architecture is distributed, asynchronous, and non-hierarchical.

From an orthodox computationalist perspective, these design features have their disadvantages, but the designs of Brooks and his colleagues exploit the physical properties of the robots to overcome, or bypass, these limitations. For example, although internal communication between processes is limited, the world itself is often used as a medium for communication between the different layers and mechanisms. Much of what traditional thinking would say is required to perform a task is shown to be unnecessary if one takes advantage of regularities and information provided by the body–environment interaction.

The resulting empirical advances in robot engineering served as a springboard for a development and refinement of the notions and philosophies of embodiment. However, the failure of these approaches to quickly scale up to 'higher-level' aspects of cognition has led many to question the ability of the embodied approach to account for conceptual, abstract reasoning and representation. Kirsh (1991) correctly realizes that the issue is not one of representation per se; Brooks concedes that representation is required for some aspects of cognition. The question instead concerns having concepts: 'the ability to find an invariance across a range of concepts', as Kirsh puts it. As we move up a scale of accounting for ever more sophisticated cognitive activities, at what point must we stop limiting ourselves to designs that are tied to the particularities of the body, and begin to use designs that deploy concepts? Brooks (according to Kirsh) says 'almost never'; Kirsh disagrees, saying that much of not only reasoning and abstract thought but even perception and action must be understood in conceptual terms. Perhaps on a strict, rarefied notion of what concepts are, Kirsh is right: the explanation of concept-involving cognition can or must often go beyond what is provided by the body. But perhaps our very concept of concept needs revising (cf. Lakoff and Johnson, 1999); if we can understand how even full concept possession can be the result of being embodied in a particular way, then perhaps embodied robotics can serve as the model for far more of cognition than mere insect-like behavior.

The joint influence of embodied artificial intelligence research and philosophies and concepts of embodiment has prompted researchers to look for and formulate new forms of explanation for natural cognitive phenomena. For example, Thelen and Smith (1994) give an embodied explanation of the development of walking in infants. Rather than attempt to explain changes in gait as the result of changes in plans, rules or representations, Thelen and Smith give an elegant account that emphasizes changes in bodily factors such as the mass of the infant's leg. Such factors are then related to one another in a dynamical-systems framework, the phase transitions of which are used to explain the stage-like developments in infant walking behavior.

While the relevance of embodiment to research in mobile robotics, as discussed earlier, is obvious, some have claimed that concepts of embodiment are required for us to understand non-robotic artificial computational systems as well. Smith (1996) has argued that we will only be able truly to understand what is going on in ordinary desktop computers when we understand how the embodiment (in the sense of being located in space and time, having mass, and so on) of a computer enables it to achieve, for example, various forms of self-reference and even abstract mathematical reference. For example, it is the physically embodied

'two-ness' of a list `L=(a, b)` stored in computer memory that makes it possible for the computer to evaluate expressions such as `length(L)`.

Concepts of embodiment may also be necessary for us to theorize about the representational states of cognitive systems. The traditional means of specifying the content of, say, a belief state, is to provide a 'that' clause: a natural-language sentence that carries the same content as the belief that is being specified, for example, 'the child believes that the toy is within reach'. There are good reasons to believe that many representational contents, such as those of animals, infants, and sub-personal states, cannot be expressed in the conceptual framework of public language. To specify such contents for the purpose of a cognitive-scientific explanation, then, one may have to make essential reference to the body, and in particular the sensorimotor capabilities, of the system being explained (Cussins, 1990; Chrisley, 1995).

Emergence

Intermediate article

Achim Stephan, University of Osnabrück, Osnabrück, Germany

CONTENTS

In ordinary language, to 'emerge' means to 'appear' or 'come into view'; but the technical use of the term is associated with features such as novelty, irreducibility, and unpredictability. The basic idea of emergence is that as systems become increasingly complex during evolution, some of them may exhibit novel properties that are neither predictable nor explainable on the basis of the laws governing the behavior of the systems' parts. Thus, complex wholes can come to have properties that are not reducible to the properties and relations of their constituents.

INTRODUCTION

During the 1990s, the term 'emergence' became widely used in such different fields as the philosophy of mind, self-organization, creativity, artificial life, dynamical systems, and connectionism. The term, however, is not used in a uniform way. It can imply novelty, unpredictability, irreducibility, and the unintended arising of systemic properties, particularly in artificial systems. Thus, it is rather controversial what the criteria are by which 'genuine' emergent phenomena should be distinguished from non-emergent phenomena. Some of the suggested criteria are very demanding, so that few, if any, properties would count as emergent. Others are inflationary, in that they count many, if not all, system properties as emergent. First of all, therefore, one should be clear about the various types of emergence. (*See* **Philosophy of Mind**; **Self-organizing Systems**; **Creativity**; **Artificial Life**; **Dynamical Systems, Philosophical Issues about**; **Connectionism**)

VARIETIES OF EMERGENTISM

Three theories among the different varieties of emergentism deserve particular interest: synchronic emergentism, diachronic emergentism, and a form of weak emergentism. In synchronic emergentism, the relationship between a system's properties and its microstructure (i.e. the arrangement and properties of the system's parts) is at the center of interest. A property of a system is taken to be emergent if it is irreducible, i.e. if it is not reducible to the arrangement and properties of the system's parts. In contrast, diachronic emergentism is mainly interested in predictability of novel properties. Those properties are taken to be emergent that could not have been predicted, in principle, before their first instantiation. Both of these stronger versions of emergentism are based on a common weak theory from which they can be developed by adding further theses.

Weak Emergentism

Physical monism

The first thesis of current theories of emergence – the thesis of physical monism – concerns the nature of systems that have emergent properties or structures. It says that the bearers of emergent features consist of physical entities only. Thus, all substance-dualistic positions are rejected; for they base properties such as being alive or having cognitive states on supernatural bearers, such as an entelechy or a *res cogitans* respectively. (*See* **Dualism**; **Descartes, René**)

Physical monism is the thesis that entities existing or coming into being in the universe consist solely of physical components. Likewise, properties, dispositions, behaviors, or structures classified as emergent are instantiated by systems consisting exclusively of physical entities.

Systemic properties

While the first thesis places emergent properties and structures within the framework of a physicalistic naturalism, the second thesis – the thesis of systemic properties – delimits the types of properties that are possible candidates for emergents. It

is based on the idea that the general properties of a complex system fall into two classes: those that some of the system's parts also have, and those that none of the system's parts has. These latter properties are called systemic or collective properties.

The second thesis is that emergent properties are systemic properties. A property of a system is systemic if and only if the system possesses it but no proper part of the system possesses it.

Both artificial and natural systems with systemic properties exist. Those who would deny their existence would have to claim that all of a system's properties are instantiated already by some of the system's parts. Countless examples refute such a claim, e.g. it is among the properties of a leopard to run, but no part of it (head, heart, nor any cell assembly) can run; and it is among the properties of a connectionist network to recognize patterns, but no single part of it (unit, etc.) has this property.

Synchronic determination

The third thesis specifies the type of relationship that holds between a system's microstructure and its emergent properties. Namely, a system's properties and dispositions to behave depend nomologically on its microstructure, that is to say, on the properties and arrangement of its parts. There can be no difference in a system's systemic properties without some difference in the properties or arrangement of its parts.

Anyone who denies the thesis of synchronic determination has either to admit properties of a system that are not bound to the properties and arrangement of its parts, or to suppose that some other factors, in this case non-natural factors, are responsible for the different dispositions of systems that are identical in their microstructure. One may have to admit, for example, that there may exist objects that have the same parts in the same arrangement as diamonds, but that lack the diamond's hardness. This seems implausible. Equally implausible is the idea that there may exist two physically identical organisms, one viable and the other not. In the case of mental phenomena, opinions may be more divided; but one thing seems to be clear: anyone who believes, for example, that two physically identical creatures could be such that one is colorblind while the other is not, is not a physicalist.

Weak emergentism as sketched so far specifies the minimal criteria for emergent properties. It is the common base for all stronger theories of emergence. Moreover – and this is a reason for distinguishing it as a theory in its own right – it is held not only by some philosophers (e.g. Bunge, 1977), but also by some cognitive scientists (e.g. Varela *et al*., 1991; Rumelhart and McClelland, 1986) in exactly its weak form. Weak emergentism is compatible with current reductionist approaches; and some champions of weak emergentism cite this compatibility as one of its merits compared with stronger versions of emergentism.

Synchronic Emergentism

The essential theses of the two more ambitious theories of emergence are the theses of irreducibility (synchronic emergentism) and of unpredictability (diachronic emergentism). These are closely connected: irreducible systemic properties are *eo ipso* unpredictable before their first appearance. Hence, synchronically emergent properties are also diachronically emergent, but not conversely.

A systemic property is irreducible if it cannot be explained reductively. For a reductive explanation to be successful several conditions must be met: the property to be reduced must be functionally construable or reconstruable; it must be shown that the specified functional role is filled by the system's parts and their mutual interactions; and the behavior of the system's parts must follow from the behavior they show in isolation or in simpler systems than the system in question. (It is an open question whether or not properties exist that demand a construction or reconstruction other than being functional.) If all these conditions are met, the behavior of the system's parts in other contexts reveals what systemic properties the actual system has. (*See* **Reduction**; **Functionalism**)

Since these three conditions are independent of each other, there are three different ways in which systemic properties may be irreducible. Namely, a systemic property is irreducible if: it is not functionally construable (or reconstruable); if it cannot be shown that the interactions between the system's parts fill the systemic property's specified functional role; or if the specific behavior of the system's components, over which the systemic property supervenes, does not follow from the component's behavior in isolation or in simpler configurations. (*See* **Supervenience**)

Thus, we have to distinguish three different types of irreducibility of systemic properties. Their consequences are also different. If a property is irreducible due to the irreducibility of its bearer's parts' behavior we seem to have an instance of 'downward causation'. For, if the parts' behavior is not reducible to their arrangement and the behavior they show in simpler systems, then there

seems to exist some 'downward' causal influence, from the system itself or from its structure, on the behavior of the system's parts.

Such 'downward causation' would not violate the principle of the causal closure of the physical domain. We would just have to accept additional types of causal influences within the physical domain besides the known types of mutual interactions.

Likewise, if it cannot be shown that the interactions between the system's parts fill the specified functional role, it seems that the systemic property has causal powers that the microstructure does not have; hence in this case too there would be some downward causal influence.

In contrast, the occurrence of properties that are not functionally construable does not imply any kind of downward causation. Systems with properties that admit of no functional analysis need not be constituted in such a way that their components' behavior is irreducible. Nor is it implied that the system's structure has a downward causal influence on the system's parts. Thus there is no reason to assume that properties that cannot be analyzed themselves exert a causal influence on the system's parts. Rather, the question is how properties that cannot be functionally analyzed might have any causal role to play at all. And if one cannot see how they might play a causal role, then, it seems, such properties must be epiphenomena. (*See* **Epiphenomenalism**; **Mental Causation**)

Diachronic Emergentism

All diachronic theories of emergence are based on a thesis about the occurrence of genuine novelties in evolution. This thesis excludes all preformationist positions. According to this thesis, in the course of evolution exemplifications of genuine novelties occur again and again. Existing building blocks develop new configurations; new structures are formed that constitute new entities with new properties and behaviors.

However, the thesis of novelty does not by itself turn a weak theory of emergence into a strong one, since reductive physicalism remains compatible with such a variant of emergentism. Only the addition of the thesis of unpredictability, in principle, will lead to stronger forms of diachronic emergentism.

The first occurrence of a systemic property can be unpredictable for at least two different reasons. Firstly, it is unpredictable, in principle, if it is irreducible. This does not mean, however, that further occurrences of the property might not be predicted adequately. Secondly, it can be unpredictable because the microstructure of the system that exemplifies the property for the first time in evolution is unpredictable. Since in the first case the criteria for being unpredictable are identical with those for being irreducible, this notion of unpredictability will offer no theoretical gains beyond those afforded by the notion of irreducibility. Let us focus, therefore, on the second case: unpredictability of structure.

The structure of a newly formed system can itself be unpredictable for two reasons. If the universe is indeterministic, then its novel structures will be unpredictable. However, from an emergentist perspective, it is of no interest if a new structure's appearance is unpredictable only as a result of its indeterminacy – most emergentists claim that the development of new structures is governed by deterministic laws.

Nevertheless, deterministic formings of new structures can be unpredictable in principle if they are governed by laws of deterministic chaos. Against that claim one might argue that a Laplacean calculator could predict even chaotic processes correctly. Whether or not this 'actually' could be the case is not yet settled. It depends mainly on the question of what kind of information we allow such a creature to have. At least we can be sure that creatures of our mental capacities do not have these forecasting abilities, and thus, we can legitimately suppose that where chaos exists, structures exist that are unpredictable in principle.

The thesis of structure unpredictability is that the rise of a novel structure is unpredictable in principle if its formation is governed by laws of deterministic chaos. Likewise, any property that is instantiated by the novel structure is unpredictable in principle.

Although diachronic emergentism with the thesis of structure unpredictability implies the unpredictability of all properties instantiated by systems that emerge from chaotic processes, it does not thereby imply their irreducibility. The unpredictability, in principle, of systemic properties is entirely compatible with their being reducible to the microstructure of the system that instantiates them.

Synopsis

Figure 1 shows the logical relationships that hold between the different versions of emergentism.

Weak diachronic emergentism results from weak emergentism by adding a temporal dimension in the form of the thesis of novelty. Both versions are

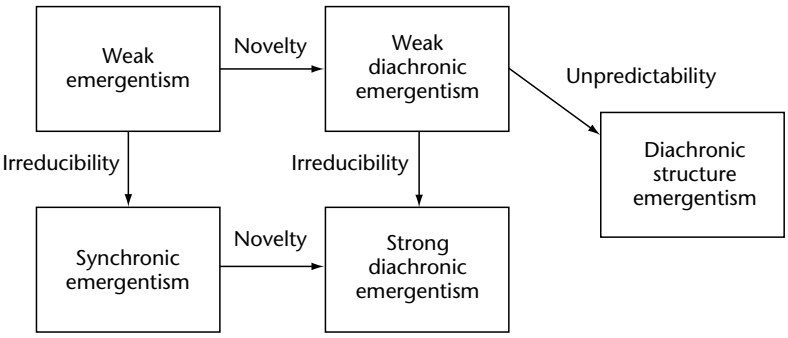

Figure 1. The logical relationships between the varieties of emergentism. Each arrow represents the addition of a thesis to a weaker theory.

compatible with reductive physicalism. Weak theories of emergence are used today mainly in cognitive science, particularly for characterization of systemic properties of connectionist networks, and in theories of self-organization. Synchronic emergentism results from weak emergentism by adding the thesis of irreducibility. This version of emergentism is important for the philosophy of mind, particularly for debating nonreductive physicalism and qualia. It is not compatible with reductive physicalism. Strong diachronic emergentism differs from synchronic emergentism because of the temporal dimension in the thesis of novelty. Structure emergentism is entirely independent of synchronic emergentism. It results from weak diachronic emergentism by adding the thesis of structure unpredictability. Although structure emergentism emphasizes the boundaries of prediction within physicalistic approaches, it is compatible with reductive physicalism, and so it is weaker than synchronic emergentism. Theories of deterministic chaos can be considered as a type of structure emergentism. This perspective is important for evolutionary research. (*See* **Qualia**)

HISTORY

Although some hints of emergentist thinking can be found in the works of Empedocles, Epicurus, and Galen, the proper development of emergentism began in the mid nineteenth century in Britain. George Henry Lewes (1875) introduced the term 'emergent' into philosophy, to distinguish 'emergent' from 'resultant' effects. Here Lewes picked up on John Stuart Mill's distinction between 'homogeneous' and 'heterogeneous' effects: joint effects of causes are called heterogeneous (or emergent) if they are not the 'sum' of their separate effects; otherwise they are called homogeneous (Mill, 1974). Mill's distinction between 'ultimate' and 'derivative' laws was also of great importance for the development of emergentist ideas. Some decades later, C. D. Broad oriented himself by Mill's distinctions and his subsequent considerations about the limits to explanation of psychophysical laws.

In the 1920s, theories of emergence began to attract greater philosophical and scientific interest. In rapid sequence the major works of British and American emergentism appeared: in 1920 Samuel Alexander's *Space, Time, and Deity*, in 1922 Roy Wood Sellars's *Evolutionary Naturalism*, in 1923 Conwy Lloyd Morgan's *Emergent Evolution*, and in 1925 Charles Dunbar Broad's *The Mind and its Place in Nature*.

Most of these philosophers' theories of emergence are reactions to the debate on the nature of life. While vitalists like Hans Driesch and Henri Bergson claimed, for the explanation of vital processes, the existence of supernatural entities such as an 'entelechy' or an *élan vital*, biological mechanists were trying to reduce all phenomena of life to physical and chemical processes without residue. Both positions seem to have implausible consequences: substance-dualistic approaches violate the principle of the causal closure of the physical domain, and it is hard to square them with evolutionary cosmologies; while mechanism does not seem to capture genuine organic and mental processes adequately. The emergentists steered a middle course. They denied both substance-dualistic and reductionist theories: they were nonreductive naturalists.

In the following decades, theories of emergence were much discussed. However, the criticism by Hempel, Oppenheim, and Nagel seemed to put an early end to emergentism, for their analysis led to an uninteresting concept of emergence as meaning nothing but: 'considering all theories we know of, we cannot explain why system *S* has property *P*' (Hempel and Oppenheim, 1948; Nagel, 1961).

With the decline of positivism, interest in metaphysical questions returned. It is the unsettled question about the nature of mental states that has helped emergentism to return to the philosophy of mind. The concept of emergence has also gained ground in such fields as self-organization, artificial life, the philosophy of science, and cognitive science.

EMERGENCE IN THE PHILOSOPHY OF MIND AND COGNITIVE SCIENCE

In different fields of philosophy and cognitive science the idea of 'emergence' has different roles. Thus, within the philosophy of mind, and particularly within the debate about qualia, there is a need for a strong notion of emergence; while within the fields of connectionism and artificial life, weaker notions of emergence suffice.

Emergentism as Nonreductive Physicalism

Within the philosophy of mind, emergentism is the most recent form of what has been called 'nonreductive physicalism' since the 1970s: a doctrine that in one way or other has tried to establish a compromise between physicalist reductionism and various sorts of dualism. First, physicalistic functionalism was seen as a species of nonreductivism because of its violation of biconditional bridge laws of the Nagelian type by its acceptance of multiply realizable mental properties. Subsequently, psychophysical supervenience was thought to be a theory of mind that is essentially both physicalistic and nonreductive. (*See* **Materialism**; **Dualism**; **Functionalism**; **Reduction**; **Supervenience**; **Multiple Realizability**)

Careful analyses, however, particularly by Jaegwon Kim (1993, 1998), revealed that both positions fall short of being what they are supposed to be. Physicalistic functionalism turned out to be reductionistic (it guarantees reductive explanations); and psychophysical supervenience, even in its strong form, turned out to be too weak to establish any specific theory of mind at all. Since even such diverse positions on the mind–body problem as reductive type physicalism and epiphenomenalism entail psychophysical supervenience, theories of supervenience fail to guarantee nonreductivism. In fact, it is synchronic emergentism that comprises the tenets originally associated with supervenience: property covariation and the dependence of supervenient properties on their subvenient bases are captured by the third thesis (synchronic determination) of weak emergentism; irreducibility, of course, is captured by the fourth tenet which is specific to synchronic emergentism. (*See* **Mind–Body Problem**; **Epiphenomenalism**)

Since weak emergentism (like mind–body supervenience) is compatible with both reductionism and nonreductionism, strong emergentism seems to be the only adequate representative of nonreductivism in recent philosophy of mind. An interesting question, however, is whether or not synchronic emergentism really is physicalism. Some philosophers maintain that such a position should be characterized as a kind of dualism, namely property dualism. However, insofar as psychophysical supervenience is regarded as defining minimal physicalism (Kim, 1998), synchronic emergentism can be seen as physicalism, too, and thus be treated as a genuine instance of nonreductive physicalism.

Qualia Emergentism

A case in point for the idea that nonreductive physicalism might be an adequate answer is the problem of phenomenal consciousness. Chalmers, Jackson, and Levine, among others, have argued in various ways that qualitative mental phenomena are not reducible to physical or functional states. If their arguments are sound, they imply strong emergentist positions. Most interesting and powerful seem to be Chalmers's argument for the 'hard problem' of consciousness and Levine's 'explanatory gap' argument. (*See* **Consciousness, Philosophical Issues about**; **Knowledge Argument, The**; **Explanatory Gap**)

According to Levine (1993) and Chalmers (1996), reductive explanations require two stages. The first stage involves the *a priori* process of working the concept of the property to be reduced 'into shape' for reduction by identifying the causal or functional role for which we are seeking the underlying mechanisms. The second stage involves the empirical work of discovering just what those underlying mechanisms are.

Since our concepts of phenomenal qualities do not seem to represent – at least in terms of their psychological contents – causal roles, a failure, in principle, of the first task seems to be unavoidable. Thus, to the extent that there is an element in our concept of qualitative character that is not captured by features of its causal role, qualia are irreducible emergent properties.

Emergence in Connectionism

Connectionism gives rise to emergentist considerations in several ways: trained networks show

cognitive features such as 'rule following', 'schema formation', or 'pattern recognition', that their parts do not have. Thus, the systemic properties that a network acquires are weakly emergent. However, they are not irreducible: they are fully deducible from the network's structure, the properties of its units (their activation formulae), and the properties of their links (the distribution of weights, and the formulae for changing the weights). Thus, systemic properties of connectionist networks are not synchronically emergent.

Connectionists often make use of the word 'emergent' in its ordinary sense, sometimes intermingled with a more technical usage. For example, Rumelhart and McClelland (1986) say that a network's high-level properties 'emerge' from low-level interactions: rules and schemata come into being by themselves without being explicitly fed into the system. However, Rumelhart and McClelland do not thereby subscribe to emergentism. They mainly try to differentiate their position from traditional representationalism, accordingly to which all rules and schemata have to be fed in explicitly. (*See* **Representation, Philosophical Issues about**; **Implicit and Explicit Representation**)

Connectionist networks develop their specific distribution of link weights (their soft structures) in a somewhat evolution-like process. Again, this is not a case of genuine emergence. Since the changes of weights are calculable exactly if we know the initial magnitudes, we should not speak of structure emergence in connectionism. On the other hand, regarding their soft structures, networks show great plasticity, compared with other objects. Chemical compounds, for example, have no freedom to change their internal structure: the diamond's property of being hard is always manifest; it does not emerge.

Emergence of Creativity

The notion of emergence is also of interest in the field of creative cognition. There we seem to face a paradox: how is it ever possible to form a truly creative idea? If we could predict it, it would be determined and not creative. If we could not in principle anticipate it, how could we produce such an idea at all? Some psychologists assume that the cognitive structures involved in creative thinking have emergent properties that could be discovered when those structures are explored, at least some of which could not have been anticipated in advance. This seems like a postulation of unpredictable cognitive features as a result of structure emergence. (*See* **Creativity**)

Emergentism and Artificial Life

Within the field of artificial life, the notion of emergence is central. It refers to adaptive features of artificial systems that result both from 'clever' interactions of many simple components and from couplings between agents and their environments (including other agents). However, the term 'emergence' is not used in its strong sense here, since all phenomena studied in artificial life are reductively explainable, at least in principle. Rather, emergence is associated with behavior that is not centrally controlled and that cannot be reduced to the behavior of single components within hierarchical systems, but is seen as the result of the interactions of multiple simple components or as the outcome of the overall dynamics of the agent and its environment. Thus, the notion of emergence used in artificial life is close to that used in connectionism. (*See* **Artificial Life**)

ARGUMENTS FOR AND AGAINST EMERGENCE

Clearly weak emergent properties exist: indeed, one might ask why such properties should be called 'emergent' at all, and not just 'systemic'. Furthermore, since there are chaotic processes of structure formation, structure emergence exists too. Thus, what is really in question is synchronic emergence. What we need is an argument for the existence of properties that are not and will not be reductively explainable. Many natural scientists deny the existence of such properties, since they do not know of any properties that could not be reductively explained, at least in principle. Without exception, all systemic properties studied in the natural sciences are functionally construable, their functional roles are always filled by the interactions of their systems' parts, and the behavior of the parts of any system always seems to follow from their behavior in simpler systems. Therefore, some critics question whether it is useful to develop the notion of synchronic emergence at all. But, even if it should turn out that all systemic properties studied in the natural sciences are reductively explainable, it is useful to have the strong notion of synchronic emergence. More than any other notion, it can be used to clearly formulate nonreductive positions concerning the mind–body problem.

Whether or not synchronically emergent properties actually exist does not seem to depend on empirical, but rather on conceptual grounds. Among others, Broad, Levine, and Chalmers have argued forcefully that properties such as qualia are not

functionally analyzable. If they are right, then phenomenal qualities may be emergent properties in the strong sense.

If mental properties such as qualia are emergent in the strong sense, then new problems arise. Some philosophers have claimed that irreducible properties necessarily exert downward causation. In the case of mental phenomena, however, this would conflict with the principle of the causal closure of the physical domain.

However, as we have seen above, properties that are irreducible for conceptual reasons do not imply downward causation. Rather, they give rise to another objection: how can properties that escape reconstruction via their causal role play any causal role at all? The reply to this objection mainly depends on our concept of causation. If we think that supervenient causation suffices for causation, then irreducible emergent properties can be causally efficacious. If we think that supervenient causation does not suffice, then irreducible emergent properties do not seem able to play any causal role. But these are still open questions (Kim, 1998; Stephan, 1997). (*See* **Mental Causation**)

Emotion, Philosophical Issues about

Intermediate article

Paul E Griffiths, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

CONTENTS

Philosophers have discussed the nature of emotions with particular reference to whether emotions are feelings, whether they are, or involve, cognitive states such as beliefs, whether they are human universals, whether the category of emotion is a unitary one, and the relationship between emotion and rationality.

CENTRAL PHILOSOPHICAL ISSUES ABOUT EMOTION

Feeling and Cognition

Until the twentieth century it was generally believed that emotions are feelings: subjective states of experience. Darwin carried out extensive empirical investigations of the physiological and behavioral components of emotion but interpreted these as merely external manifestations of the emotions themselves. He regarded emotions as closely akin to bodily sensations such as hunger or pain. Feelings also played a central role in the other important theory of the closing years of the nineteenth century, the James/Lange theory of emotion causation. William James provoked a long and productive tradition of research with his suggestion that emotion feelings are caused by the bodily changes associated with emotion, rather than the reverse. Nevertheless, he took the final stage in this causal sequence, the occurrence of emotion feelings, to be the central feature of an emotion considered as a *psychological* phenomenon.

Predictably, the rise of behaviorism led to the decline of the feeling theory of emotion. Behaviorists in psychology had no difficulty in fitting emotional reactions into their theoretical framework. John B. Watson suggested that all adult emotional reactions were conditioned responses based on three unconditioned reactions present in infants that he termed fear, rage, and pleasure. Behaviorist philosophers such as Gilbert Ryle attempted to analyze the meanings of sentences about emotion so as to eliminate any essential reference to subjective states of experience. The 'cognitive revolution' of the 1960s did not rehabilitate the feeling theory. Philosophers assimilated the new turn in the sciences of the mind by taking existing behavioral definitions of mental states and treating them as implicit definitions of underlying mental states which cause behavior. An emotion is an internal state that mediates causally between sensory inputs and behavioral outputs in a characteristic way. Crudely, anger is an internal state that takes slights as inputs and yields aggression as output. No reference to the quality of feeling associated with anger is required.

The consensus that emerged in the philosophy of emotion in the early 1960s and persists to the present day is that emotions are defined by the cognitions they involve. Later theorists have increasingly allowed feelings a role in emotion, but never one that determines the identity of the emotion. Instead, the role of emotion feelings is to add the 'heat' to 'hot cognition'. A leading contemporary philosopher of emotion, Patricia Greenspan, concludes that emotions are feelings of comfort or discomfort directed towards an evaluative thought about an external (or imaginary) stimulus (Greenspan, 1988). It is the evaluative thought that defines the emotion. Different negative emotions, such as anger and fear, are differentiated only by the evaluative thoughts they involve. Philosophers have generally held it to be a conceptual truth that emotions derive their identities from the thoughts associated with them, and so have not seen empirical results showing the differentiation of states of bodily arousal in different emotions as relevant to their research. Philosophers have, however, cited work on the 'cognitive labeling' of states of arousal as evidence that empirical findings converge on

the same conclusion as their conceptual analyses. Many cite a famous 1962 study in which subjects were induced to describe the effects of identical adrenaline injections as either euphoria or anger (Schachter and Singer, 1962). The experimental design is quite complex, but in essence, some subjects were induced to discount the injection as a cause of their aroused state and these subjects described their state of arousal as an emotion appropriate to whichever cues the experimenters provided them with. (*See* **Cognitive Science: Philosophical Issues**)

Universality of Emotion

Emotions are widely believed to be a critical feature of moral agency, and are even more widely believed to be a critical part of aesthetic response. The claim that all healthy people display, recognize, and respond to the same emotions has been used to support the view that moral and aesthetic judgments can have universal validity. Conversely, if human emotions are as diverse as the concepts embodied in different languages, and if humans can understand the expressive repertoire only of their own cultural group, this would seem to support cultural relativism about ethics and aesthetics.

Until the 1970s there was a fairly solid consensus, based on anthropological fieldwork, that the emotions vary widely across cultures. The work of Paul Ekman and his collaborators has produced an equally widespread consensus that certain 'basic emotions' are found in all human cultures (Ekman, 1972). Ekman revived Darwin's experimental work on human facial expressions of emotion and demonstrated that a range of Western facial expressions of emotion could be reliably classified by members of a visually isolated, non-Western culture, and vice versa. He also reconfirmed many of Darwin's claims about the specific muscles used in these pancultural expressions. Other investigators demonstrated the early emergence of these expressions in human infants and established homologies with facial expressions in non-human primates. The widely accepted 'basic emotions' are fear, anger, surprise, sadness, joy, disgust, and perhaps contempt. (Each emotion term in this list refers to an operationally characterized, brief, involuntary response rather than to the full range of cases commonly referred to by the term.)

Cultural relativism about emotions was revived in the 1980s as part of a broader interest in the social construction of mental phenomena. This led to the first real involvement by analytic philosophers in the debate over universality, since the new arguments for social constructionism were as much conceptual as empirical. One influential argument starts from the widely accepted idea that an emotion involves a cognitive evaluation of the stimulus. In that case, it is argued, cultural differences in how stimuli are represented will lead to cultural differences in emotion. If two cultures think differently about danger, then, since fear involves an evaluation of a stimulus as dangerous, fear in these two cultures will be a different emotion. Adherents of the basic emotions view are unimpressed by this argument since they define emotions by their behavioral and physiological characteristics and allow that there is a great deal of variation in what triggers the same emotion in different cultures.

Social constructionists also define the domain of emotion in a way that makes basic emotions research less relevant. The six or seven basic emotions seem to require minimal cognitive evaluation of the stimulus. Social constructionists often refuse to regard these physiological responses as emotions in themselves, reserving that term for the broader cognitive state of a person involved in a social situation in which he or she might be described as, for example, angry or jealous.

It is thus unclear whether the debate between the constructionists and their universalist opponents is more than merely semantic. One side has a preference for tractable, reductive explanations, even if these are of limited scope, and the other is concerned that science may neglect the social and cultural aspects of human emotion. (*See* **Social Cognition**)

Is Emotion a Natural Kind?

The neuroscientist Antonio Damasio recently defined an emotion as 'a specifically caused transition of the organism state' (Damasio, 1999, p. 282). Confronted by similar definitions, Alan Fridlund has remarked: 'Here, the logical question is what *isn't* emotion. Emotion has, in fact, replaced Bergson's *elan vital* and Freud's *libido* as the energetic basis of all human life' (Fridlund, 1994, p. 185). For many theorists emotion has indeed become synonymous with the whole affective life of the organism and perhaps with motivation itself. Damasio is well aware of this situation and is self-consciously using a familiar term for his own purposes in order to facilitate communication in what he sees as a period of conceptual upheaval (Damasio, 1999, p. 341). He does indeed have a very broad conception of emotion, to the extent that he takes it as

axiomatic that a person is always in some emotional state or other.

Paul Griffiths has argued that the scientific investigation of the domain of affective phenomena has been hindered by a continued belief that 'the emotions' are a unitary kind of psychological state (Griffiths, 1997). Science aims to group phenomena into 'natural kinds': categories about which there are many, reliable generalizations to be discovered. The domain of emotion is so large that it is unlikely that all the psychological states in that domain form a natural kind. Hence there will be few if any reliable generalizations about emotion or, in other words, no theory of emotion in general. Scientific progress would be served by dividing up the domain and investigating groups of phenomena that are likely to form natural kinds, as has occurred in research into memory. Basic emotions theorists may well be investigating one such natural kind and social constructionists about emotion may be examining another – perhaps a certain kind of transient social role. New, more specific concepts will be required to replace the emotion concept, and a central role for philosophers of emotion is to facilitate this kind of conceptual revision.

Most philosophers of emotion see no serious problem with the category of emotion, although they admit that it is vague and covers a diverse range of phenomena. Their concern is with the proper analysis of the concept associated with the word 'emotion' in everyday language. Their analyses of the emotion concept are in reasonable agreement with those produced by psychologists studying the use of the term 'emotion' in Western cultures. There are clear paradigms of emotion, such as love, happiness, anger, fear, and sadness, and most philosophers define emotion so as to include these. Their definitions disagree over the same cases that produce disagreement between subjects in empirical studies, cases such as pride, hope, lust, pain, and hunger. Philosophical definitions include features that psychologists have argued are part of the prototype of the emotion concept in Western culture. Emotions are directed onto external states of affairs, are relatively short-lived, and have an evaluative aspect to them, such that their objects are judged to be either attractive or aversive. Most definitions also provide a role for emotion feelings.

Hence philosophers, like ordinary speakers, can achieve a reasonable level of agreement about what counts as an emotion, as opposed to a mood, a desire, or an intention. Whether the psychological states grouped together in this way form a single, productive object of scientific investigation, and whether other cultures conceptualize emotion in the same way, remains to be seen.

PHILOSOPHICAL VIEWS AND THEORIES OF EMOTION

Propositional Attitude Theories of Emotion

Since the early 1960s the cognitive or propositional attitude school has dominated the philosophy of emotion (Deigh, 1994). The basic commitments of this school are twofold. First, emotions are differentiated from one another by the cognitive states that they involve, as discussed above. Second, the cognitive states involved in emotion can be understood in terms of a *propositional attitude* theory of mental content. Mental states are attitudes, such as belief, desire, hope, and intention, to propositions. The nature of propositions is the subject of complex debate, but for present purposes we can treat them as representations of states of affairs.

The simplest propositional attitude theory is the judgmentalist theory, which identifies emotions with evaluative judgments. A person is angry if he or she has the attitude of belief to the proposition 'I have been wronged'. Other prominent varieties of propositional attitude theory are belief/desire theories, hybrid feeling theories, and 'seeing as' theories.

Belief/desire theories analyse emotions as combinations of beliefs and desires. For example, hope is the belief that some state of affairs is possible and the desire that it be actual.

Hybrid feeling theories, like that of Greenspan discussed above, analyze emotions as combinations of propositional attitudes and feelings. The feeling component is used to differentiate cold cognition from hot (emotional) cognition and in some theories to distinguish positive from negative emotions. The specific identity of the emotion is given by the propositional attitude component.

Finally, 'seeing as' theories have become increasingly popular. These theories cope with various anecdotal objections to earlier propositional attitude theories by noting that a subject's beliefs and desires about an object are not sufficient to constitute an emotion unless the subject 'sees' the object in the right way. A typical anecdote involves a mountain climber who is said to retain the same beliefs and desires as she fluctuates between seeing a climb as terrifying and as exhilarating. Earlier versions of this approach were inclined to treat 'seeing as' as a primitive, following some aspects

of the later work of Wittgenstein. Contemporary versions analyze 'seeing as' in terms of attentional phenomena in cognition. Emotions are then biases in cognition that direct attention at some sources of information rather than others or lead to a higher weighting for one consideration than another, and thus lead to actions that would not have eventuated in the absence of the emotion.

The theories just outlined are primarily intended as analyses of the concept of emotion. They are assessed for their ability to correctly predict the author's intuitions about whether an emotion, or some specific emotion, occurs in an imaginary scenario. Some authors draw extensively on literature for these scenarios, others draw on more or less actual cases from the psychoanalytic literature. Some see their work as assisting the scientific investigation of emotion by more clearly defining its subject matter. Others see their work as complementary and parallel to scientific psychology. Philosophical psychology is often distressingly unclear about the identity of its subject population. It is conventional in the literature to refer to 'our emotions' and to 'commonsense' views about emotion, but it is unclear to what extent these locutions are to be read as limiting the claims made to the author's own community.

The Rationality of Emotions

The prime concern of the propositional attitude school in the philosophy of emotion has been with whether emotions are rational. The feeling theory of emotion is condemned for placing emotions outside the realm of rational evaluation. This is seen as part of a wider and invidious tendency to separate the realm of the moral from the realm of the rational. The attempt to bring these realms together is conceived by some authors as a proposal for the reform of moral discourse and by others as an attempt to do justice to one strain of 'our' everyday practice.

The simplest judgmentalist theory brings emotions back into the domain of reason by identifying them with beliefs. An emotion is rational if the beliefs composing it are justified by the evidence available to the subject. More complex propositional attitude theories give more complex accounts of the rationality of emotions. Belief/desire theories face the difficulty that formal accounts of rationality, such as decision theory, are confined to evaluating the suitability of means to ends and take the ends (desires) as given. So these theories must provide an account of what it is rational to desire. Hybrid feeling theories can evaluate the rationality of having one emotion rather than another, since the identity of an emotion is determined by its propositional attitude component. Whether the state is an emotion in the first place, however, relies on the feeling component, and so hybrid feeling theories must give some account of when it is rational to take one's cognition hot rather than cold. An extensive literature canvasses solutions to these and other difficulties with the project of rationally evaluating emotions. 'Seeing as' theories face their own difficulties, but also have new resources to bring to bear on the rationality question. The cognitive biases that constitute emotions can be evaluated for their heuristic value in generating true belief, successful action, and so forth, and judged rational if they are successful in these respects.

IMPACT OF COGNITIVE SCIENCE ON ISSUES ABOUT EMOTION

Evolutionary Psychology and the Universality of Emotion

Two contemporary schools of evolutionary psychology provide arguments for diametrically opposite views on the universality of emotion. John Tooby and Leda Cosmides urge the application of their well-known blueprint for the evolutionary study of the mind to the domain of emotion (Tooby and Cosmides, 1990). The mind is a collection of highly specialized, domain-specific cognitive devices, or modules, each adapted to a specific ecological problem in our evolutionary past. Existing work in basic emotions research is easily assimilated to this model, and these evolutionists see the six or seven pancultural responses confirmed to date as the first of a much larger number yet to be uncovered. A particularly confident prediction is that there will be a specific module for sexual jealousy. The psychology of emotion in modern subjects is conceived as the result of these many evolved, pancultural modules interacting with the environments found in different societies.

In stark contrast to these ideas, evolutionary arguments are used to support a tradition of emotion research that denies that emotions come in discrete types and emphasizes cultural variation in the psychology of emotion. *Transactional* theories of emotion see emotions as acts of social communication: 'nonverbal strategies of identity realignment and relationship reconfiguration which do not easily translate into the official idea of reasoned argument and information exchange' (Parkinson, 1995, p. 295). A central tenet of this approach is

that emotional behaviors do not express emotions. Rather than being expressed in social interactions, an emotion actually *is* a particular kind of social interaction and emotions thus defined do not stand in a one-to-one relation to underlying psychological processes. The empirical research supporting the transactional view is aimed at showing the effects of social context both on the production of emotional behavior given a particular underlying cognitive state and on whether a given behavior is regarded as expressing an emotion. Transactional approaches naturally tend to be associated with the view that there is extensive cultural variation in emotion, since the forms of social interaction and the functions of emotions within those interactions will differ from society to society. The fundamental mechanisms underlying this variety, however, may be pancultural and subject to evolutionary explanation.

According to Alan Fridlund, the transactional view of emotion is strongly supported by the theories of animal communication found in contemporary sociobiology and behavioral ecology (Fridlund, 1994). Like most authors who have discussed the evolution of emotional expression, Fridlund treats these expressions as conveying information about an animal's motivational state. Organisms who transparently express the internal states that guide their future actions would be unlikely to succeed in evolutionary competition. Instead, he argues, selection would bring any existing signs of emotion under increasing voluntary control, enabling organisms to control the flow of information to their own advantage. Fridlund suggests that an evolutionary psychology of emotion will naturally interpret emotional behaviors not as expressions but as signals produced to manipulate the behavior of others. If we can infer other people's emotions when they would prefer us not to, then this must be the outcome of an 'arms race' between organisms seeking to predict the behavior of others and organisms seeking to manipulate their expectations. Fridlund's argument is certainly in line with the fundamental orientation of the game-theoretic literature on animal communication. However, evolutionary theory is notorious for its inability to predict the course of evolutionary change and it would be a mistake to give this theoretical argument much weight in comparison to empirical studies of the reliability, or lack thereof, with which people recognize one another's emotions. (*See* **Game Theory**)

The obvious objection to a transactional theory of emotion is that it cannot explain asocial emotions, such as fear of an asocial stimulus in a solitary subject. Fridlund has labored to demonstrate experimentally that audience effects play a cognitive role even in asocial emotions: 'What would people think if they saw me?' More fundamentally, however, transactional theorists, like the social constructionists before them, are prepared to redefine the domain of emotion in order to capture what they take to be psychological phenomena of a single natural kind and to exclude phenomena that are of a different kind (Parkinson, 1995, p. 303).

The Frame Problem and the Resurgence of the Feeling Theory

Recent work in cognitive neuroscience has shed new light on the relationship between emotion and cognition and has led to a revival of the feeling theory of emotion. Antonio Damasio has argued that effective reasoning is dependent on the capacity to experience emotion. Patients with bilateral lesions to the prefrontal cortex show both reduced emotionality and a diminished ability to allocate cognitive resources in such a way as to solve real-world problems. They do not, however, have deficits in abstract reasoning ability. Damasio interprets these findings as showing that emotion plays an essential role in labeling both data and goals for their relevance to the task in hand (Damasio, 1994).

Damasio's proposal must be regarded as highly tentative, and faces a number of difficulties (Rolls, 1999); but it has aroused considerable interest amongst cognitive scientists who have seen in 'affective computing' a possible solution to the frame problem: the problem of choosing all and only the relevant data without assessing all the available data for possible relevance (Picard, 1997). Damasio's theory bears a resemblance to some of the philosophical 'seeing as' theories which identify emotions with heuristic biases in cognition. In contrast to those theories, however, Damasio sees emotions themselves as feelings. If emotions function cognitively, then his proposal would be that cognitive priorities are assigned by calculating what is most relevant and important. This would not be a solution to the frame problem, but an instance of that problem. Damasio avoids this trap by using emotion *feelings* to prioritize cognition. He describes a class of 'primary emotions' that bear a strong affinity to Ekman's basic emotions. Damasio envisages emotional development as a process in which the feelings associated with the basic emotions become attached to particular cognitive states, giving rise to cognition/feeling composites that he labels 'secondary emotions'.

Damasio has so far given only a suggestive outline of his theory and it remains to be seen whether

this sketch can be developed into a workable model of cognitive processes. Attempts to expand on Damasio's ideas to date resemble traditional behavior conditioning, with thoughts taking the place of behaviors and emotion feelings acting as reinforcers. The limitations of conditioning models as explanations of complex cognitive performances are well known.

Neurological Support for Twin Pathway Models of Emotion

Another important recent development is Joseph LeDoux's detailed mapping of the neural pathways involved in fear conditioning (LeDoux, 1996). Information about the stimulus activates many aspects of emotional response via a fast, 'low road' through subcortical structures, amongst which the amygdala is particularly important. A slower, 'high road' activates cortical structures and is essential for longer-term, planned, and often conscious responses to the same stimulus.

These findings are consistent with Ekman's proposal that an 'automatic appraisal mechanism' is associated with the basic emotions and operates independently of the formation of conscious or reportable judgments about the stimulus situation. LeDoux's findings also help to explain the experimental phenomenon of 'affective primacy', in which emotional associations with stimuli can be conditioned independently from paradigmatically cognitive responses to the same stimuli, such as recognition or recall.

Twin-pathway models suggest that at least for certain basic emotions the idea that an emotion involves a cognitive evaluation of the stimulus needs to be replaced with the idea that it involves two evaluations, which can conflict and which have complementary but independent cognitive functions. Twin-pathway models also provide some support for the many evolutionary accounts that see the basic emotions as 'quick and dirty' solutions to common survival problems.

CONCLUSION

Perhaps the most pressing philosophical question about emotion is the relationship between the philosophical psychology of emotion and the sciences of the mind. Even the most apparently purely philosophical issue, the rationality of emotion, is now the subject of simultaneous scientific study. A closer examination of the work of philosophers who claim to be concerned only with conceptual issues reveals that few of them fail to take some note of relevant empirical findings. Conversely, the exciting recent work of Antonio Damasio has led him to confront the traditional philosophical questions of the nature of mental representation and of conscious experience. These questions are arguably as much conceptual puzzles as empirical questions. The future of the field seems inevitably to be one of closer interdisciplinary cooperation.

Epiphenomenalism

Intermediate article

William S Robinson, Iowa State University, Ames, Iowa, USA

CONTENTS

Epiphenomenalism is the view that mind does not affect behavior, or does not affect behavior in the ways it is commonly believed to affect it.

WHAT IS EPIPHENOMENALISM?

Epiphenomenalism, in its strict sense in traditional philosophical contexts, is the view that mental phenomena (or certain classes of mental phenomena) make no causal contribution to behavior. In cognitive science contexts, 'epiphenomenalism' is often used in a limited or relative sense. In this usage, mental phenomena are said to be epiphenomenal if they make no causal contribution to behaviors to which they are generally taken to be causally relevant, even if it is admitted that they have *some* effects.

For example, researchers may hold that certain thoughts have no effect on nonlinguistic behavior, even though they allow that those thoughts causally contribute to subjects' reports that they have had those thoughts. This stance makes the thoughts 'epiphenomenal' relative to the nonlinguistic behaviors of interest, and researchers who take such a stance will be regarded as epiphenomenalists, even though their provision for efficacy upon reports implies that they are not epiphenomenalists in the strict philosophical sense.

An often used analogy for epiphenomenalism, taken from Thomas Huxley (1874), compares mental phenomena to steam whistles, which are sounded by the machinery of locomotives, but have no role in moving a train. This analogy suggests arguments that are relevant to both strict and relative epiphenomenalism but actually illustrates only the latter view. Steam whistles do have effects – they vibrate the air and causally contribute to people's getting out of the way of the train; but they are epiphenomenal relative to the behavior of the locomotive, upon which they have negligible effect.

Although a sharp division cannot be made, discussions of epiphenomenalism in cognitive science contexts are often primarily directed at some form of relative epiphenomenalism. Accordingly, this article will emphasize relative epiphenomenalisms. A full treatment of the strict view, which is discussed primarily by philosophers, can be found in Robinson (1999).

HISTORY

The view now known as epiphenomenalism arose in the nineteenth century, often without a convenient name, and sometimes under Huxley's term 'automatism'. Huxley and others (e.g. Hodgson, 1870; Clifford, 1874; Maudsley, 1886), were impressed with 'automatic' behavior. For example, lesioned frogs that were so unresponsive that their consciousness could be reasonably doubted would nonetheless swim perfectly if thrown into water. A soldier who had suffered a head wound in battle suffered periods in which he would carry out extensive routines such as taking a position behind a tree, aiming, and firing – but with only a cane, and no enemy in sight. During these bouts, he was insensitive to pinpricks and shocks, and to many sensory inputs. Interruption of some activities, e.g. removing a piece of paper on which he was writing, would go unnoticed, and he would simply continue his letter on the next sheet. Cases of this kind suggested that consciousness is not necessary for highly organized activity, and the conclusion was drawn that consciousness floats along with underlying brain processes, which are by themselves sufficient to bring about the behavior.

The term 'epiphenomenalism' began to be used in the 1890s and was probably taken over (most likely by William James) from a medical use, in which 'epiphenomena' are symptoms that appear along with those caused by a serious disease, even though they are not actually an effect of the

main disease being treated. The earliest use of the term in its present meaning known to this author occurs in William James's *Principles of Psychology* (1890).

THE CENTRAL ARGUMENT FOR STRICT EPIPHENOMENALISM

Strict epiphenomenalism rests on three premises, of which the first is the causal closure of the physical. This principle says that each physical event has a set of causes, all of which are physical and which, taken together, are sufficient by themselves to cause the event in question. The second premise is the obvious and noncontroversial claim that behavior consists of physical events. Behavior entails either motion of the body, or the holding still of the body (or some of its parts). In either case, behavior depends on contraction states of muscles, and muscles are plainly physical things.

The third premise that is required to lead to traditional epiphenomenalism is the much more controversial assumption that the mental events to which epiphenomenalism applies are not identical with any physical events. This claim must be understood narrowly. In ordinary life, we may view the eating of a red, ripe, sugar-filled tomato as a single event. The redness of the tomato, however, is a different property from its sugariness, and from a nutritionist's point of view, we must distinguish the eating of a red tomato from the eating of a sugar-filled fruit or vegetable. Analogously, it will not be enough to avoid epiphenomenalism if we merely hold mental properties and physical properties to be different properties of the same events; unless the properties themselves are identical, the causal work can be attributed to the physical properties and the mental properties will be as epiphenomenal with respect to behavior as the redness of the tomato is to nutrition.

With these understandings, we can put the argument for strict epiphenomenalism in the following summary way.

(CC) The set of physical events is causally closed. (causal closure)

(PB) Behavior consists of physical events. (physicality of behavior)

(NI) Mental properties of events are not identical with physical properties. (non-identity)

The first two premises tell us that the causes of behavior are exclusively physical events, and this result, together with (NI), leads to the epiphenomenalist conclusion:

(EC) Mental events cause neither behavior, nor any of the causes of behavior.

A very general principle behind this conclusion is that if {C} is a complete set of causes of an event, E1, i.e. a set that is jointly sufficient to bring about E1, then every event that is not in a strong sense identical with some member of {C} is excluded from being a cause of E1.

Many cognitive scientists would hesitate to assert (NI). They may, however, agree that some particular behavior, B1, has a sufficient set of causes, {C1}, and they may apply the general principle just enunciated. Thus, if some mental event, M, can be shown *not* to be a member of a sufficient set of causes {C1}, M will thereby be excluded from being a cause of B1.

DISADVANTAGES OF EPIPHENOMENALISM

Two important objections apply to strict, but not to relative, epiphenomenalism. (1) It conflicts with the deeply entrenched ideology of materialism. Epiphenomenalists respond by focusing on (NI). They note that even if one assumes materialism, one cannot explain how some mental events (e.g. episodes of feelings, e.g. nausea) could be identical with neural events – see, e.g. Levine (1983) or McGinn (1991). They are thus apt to regard denials of (NI) as doctrinaire. Moreover, some criticisms of (NI) are arguably fallacious – see Chalmers (1996). (*See* **Explanatory Gap**)

(2) Epiphenomenalism is self-stultifying. That is, according to strict epiphenomenalism (but not necessarily to relative epiphenomenalism) a report of a mental event is not caused by a mental event. If it is premised that knowingly reporting X requires the report to be causally influenced by X, then the epiphenomenalist's claim to know occurrences of mental events must be counted as false. So, epiphenomenalists who assert that they have mental events that are not causally contributory to any behavior (including reports) will have to be regarded as asserting something that, according to their view, they cannot know. Epiphenomenalist responses to this objection involve arguments against the key premise that knowingly reporting about X always requires causal influence by X on the reporting.

A third objection applies to both strict and relative forms of epiphenomenalism. This objection

affirms that in many cases we have immediate and virtually certain knowledge that our mental events are causally contributory to our behavior. Denials of causal influence in such cases have the appearance of flying in the face of all common sense and reason. Naturally, the force of this objection depends on the particular kind of mental event involved, and we shall consider several cases below. There is, however, a general response that is available to both species of epiphenomenalist: namely that, as Hume (1739, 1748) taught us, causal connection is never simply an object of our experience. Moreover, it is well understood that common effects A and B of an underlying event, C, often falsely appear to us as cases in which A causes B. This is exactly the appearance that epiphenomenalism alleges may occur in cases where A is a mental event, B is behavior, and C is a neural event causing both.

EPIPHENOMENALISM AND COGNITIVE SCIENCE

There are several types of mental phenomena, and one can be an epiphenomenalist with respect to one, or some, of these types without being an epiphenomenalist for all types. This article distinguishes three types of mental phenomena: phenomenal consciousness, thoughts, and will. Arguments or conclusions appropriate to one of these types may or may not apply to other types.

Phenomenal Consciousness

Under 'phenomenal consciousness' we include bodily sensations (pain, itch, nausea, etc.), qualities in perception (colors, tastes, odors, the feeling of warmth, etc.), imagery, and the 'feeling aspects' of emotional states (the way rage, fear, elation, remorse, etc., feel to us). These qualities are often referred to by the terms 'qualia', '(real) seeming', 'sensory consciousness' and many others. They are focal examples of Block's (1995) term 'phenomenal consciousness' or 'P-consciousness'. (*See* **Qualia**)

From a cognitive science point of view, it is a natural (and vexed) question to ask whether phenomenal consciousness has a function, and if so, what this function might be. Evidently, if one accepts (NI), there can be no behavioral function for qualia. But even if one denies (NI), one may worry that, except for reports of occurrences of qualia, qualia have no effect on behavior. (*See* **Consciousness, Function of**)

Several instances of this worry are discussed in a centrally important (and highly controversial) article by Max Velmans (1991). Here is Velmans's own list of areas in which the role of consciousness has been investigated: 'in the analysis and selection of stimuli, in learning and memory, and in the production of voluntary responses, including those requiring planning and creativity' (Velmans, 1991, p. 666).

We may illustrate the way in which doubts about a function for qualia may arise by considering a recent controversy raised by the experimental work of Weiskrantz (1986, 1988) and discussion of blindsight by Block (1995). Blindsight patients have sustained scotoma, i.e. damage to their occipital cortex. When objects are presented in the (distal) region that corresponds to the area of their scotoma, they say they cannot see anything. Nonetheless, when asked to grasp objects in this region (the 'blindfield'), they often form their hands with the correct shape and orientation for grasping the presented object (Marcel, 1983), and, when forced to 'guess' whether an X or an O is being presented, they exhibit above-chance performance. A natural (but hardly uncontroversial – see Dennett, 1991, and the open peer commentaries on Block, 1995) interpretation of these results is that information processing of a kind normally associated with perception can occur in the absence of phenomenal consciousness. If this interpretation is accepted, we must entertain the possibility that phenomenal consciousness has little or no role to play in the information processing that leads to behavioral reactions to perceived objects, even in normal cases. (*See* **Blindsight**)

In his open peer commentary on Velmans's article, Block (1991) points out that it does not follow that (phenomenal) consciousness plays no role in normal cases, even if it is allowed that information processing leading to useful response to inputs *can* be done without phenomenal consciousness. The general point here is well taken: the fact that X can be accomplished by Y does not entail that, in some other particular case, Z is not causally contributory to X. (The fact that hydraulic lifts exist does not show that pulleys can never have the function of raising weights.) However, if it is known that there is an unconscious mechanism that can perform complex information processing in the human brain, we must at least entertain the possibility that that is the mechanism that regularly performs the information processing function. (*See* **Unconscious Processes**)

The claims of such a possibility to be the actual case are strengthened if phenomenal consciousness arises late in cognitive processing. Many of the cases reviewed by Velmans involve temporal

considerations, and give rise to arguments of this form: consciousness arises only *after* certain other important functions (e.g. stimulus selection) have been completed, therefore consciousness was only an accompaniment, and not a causal contributor, to those functions.

Before turning to some further cases, we must note that although many of Velmans's commentators took him to be supporting epiphenomenalism, Velmans himself disavowed such an aim. The explanation is that Velmans assumed a theory that is not widely accepted, and that was not developed in detail in the original, target article. This theory is that causation is relative. In third-person perspective, neural causes that have only late-occurring conscious results are sufficient for information processing that leads to (nonreporting) behavior, and so there is no room for behavioral function for consciousness (save, possibly, in reporting late results). This point is what led many readers to attribute epiphenomenalism to Velmans. His view, however (see author's responses to commentaries, and Velmans, 2000), was that in first-person perspective conscious states *are* regarded as causes of behavior; and, further, the first-person perspective is as legitimate as the third-person perspective. Thus, Velmans himself did not regard it as correct to say that consciousness does not contribute to behavior – it does do so, from the first-person perspective.

There are many cases of implicit processes which, like blindsight, suggest that events that are sometimes taken to be caused by conscious states may have a causal background that bypasses such states. (But see Dulaney, 1997 for an alternative view.) For example, visual extinction patients cannot identify objects in their left visual field when objects are also presented to the right visual field. Some of these patients regard requests to compare left and right presented line drawings as 'silly', saying that only one object has been presented; other patients are aware of something on the left but cannot say what it is. In both cases, however, forced choice judgments as to whether the objects are the same or different range from 88 to 100 per cent correct (Volpe *et al.*, 1979). Prosopagnosics can show skin conductance responses to faces of family members or famous people whom they are unable to identify by name (Tranel and Damasio, 1985). This evidence suggests that our emotional reactions, even in normal cases, may not depend on first consciously (or explicitly) recognizing the people we are seeing. Zajonc's (1980) familiarity effect likewise suggests that preferences are sometimes formed by processes other than the rational considerations we usually suppose to underlie our preference judgments. Amnesics who perform poorly when asked to name words from a studied list nevertheless show robust effects of previous exposure when tested with less direct, implicit tasks such as word-stem completion. (See Schacter, 1987 for review.) This result suggests that consciousness is epiphenomenal for certain aspects of memory. (*See* **Implicit Cognition**; **Prosopagnosia**)

These phenomena and many others of a similar nature (see Reber, 1997; Köhler and Moscovitch, 1997) suggest that, even in normal subjects, responses that are naively attributed to conscious recognition may occur as a result of unconscious processes.

Thoughts

A salient and cherished part of our self conception is our belief that we know the reasons why we think and act as we do. A widely held analysis, explicitly argued for by Davidson (1963), is that, in nondeviant cases, reasons for action are causes of those actions. Similarly, we usually believe that the reasons we might give for our beliefs reflect the actual causes of our holding those beliefs. If we find that reasons that we believe to be our reasons for acting or holding certain beliefs are not causes of those actions or beliefs, those reasons will be relatively epiphenomenal. Our thoughts about those reasons may indeed still causally contribute to our reporting of those reasons; but the reasons we attribute to ourselves will be epiphenomenal relative to the behavior or beliefs for which they are regarded as reasons, i.e. they will in fact not have the causal role they are conceived to have.

It is now widely accepted that under many circumstances people confabulate, that is, they sincerely offer reasons for facts about themselves that can be demonstrated *not* to reflect the actual circumstances that causally determine those facts. For example, Nisbett and Wilson (1977b) manipulated subjects' views about attractiveness of physical appearance, speech, and mannerisms of a videotaped presenter, by varying the style of the presentation between 'warm' (agreeable responses to questions) and 'cold' (rigid, intolerant responses). The causal direction was demonstrably from style difference to attractiveness-judgment difference in both conditions. Nonetheless, subjects who saw the 'cold' version of the presentation were quite firm in their (false) belief that their negative attractiveness judgments had contributed to their disliking of the presentation. In another experiment, Nisbett and

Wilson (1977a) asked a group of subjects to read a text that presented a novelistic scene with high emotional impact. Three other groups read a text that was the same except for the omission of one passage, or another passage, or both passages. Ratings of emotional impact were not significantly different across groups; nonetheless, when asked about the effect of the manipulated passages on their judgments, subjects in groups that had been exposed to them expressed the definite belief that the passages had increased the impact of the text. In still another experiment, subjects erroneously claimed that extraneous noise (from a nearby power saw) had lowered their rating of a film.

Many of the experiments presented or described in Nisbett and Wilson (1977a) demonstrate only failures of ability to report actual causes of behavior or beliefs. Such failures show that very complex cognitive processing can occur without our being aware of it, and thus indirectly support the *possibility* of epiphenomenal thoughts. The examples cited, and other cases reviewed in Nisbett and Wilson (1977a), go further; they are examples of beliefs that do not have the effects on behavior or judgment that their possessors take them to have. They may cause the reports of those beliefs, but they are epiphenomenal relative to their presumed additional effects. (It should be noted that this attribution is ours; the term 'epiphenomenal' does not occur in the cited papers of Nisbett and Wilson.)

There is no suggestion here that all our beliefs about our reasons are epiphenomenal, i.e. that we are always misguided about our reasons. Nisbett and Wilson (1977a) argue, however, that correct apprehension of our reasons depends on factors that are available to observers in general. They hold that introspection unsupported by publicly available knowledge is not a reliable source of knowledge about our own cognitive processes or the causal relations surrounding our reasons.

Decisions

In many cases, having a reason to act in a certain way cannot be taken to be sufficient for producing the action, because the action is deferred for some time. In some of these cases, the action is to be triggered by an expected external stimulus; in other cases, however, precise timing is left indefinite, and is not tied to any definite occurrence. At some point, we decide that the time to act is *now*, and we begin to carry out the action.

These remarks are not controversial. The last mentioned case, however, is one that may suggest to us that our conscious decisions are the causes of the initiation of our actions, and even that we know by direct experience that conscious decisions cause us to act. With these claims, we move into territory that has seen disputation from at least two lines of experimental work.

The older, and now widely known argument stems from investigations by Libet and coworkers of the time at which decisions are made (see Libet, 1985 for discussion and further references). Libet's subjects were free to make a movement (of finger or wrist) when they formed an urge (or desire or intention) to do so. Subjects watched a rotating spot, and reported its clock position (C) when they formed the intention to make a movement. At the same time, Libet used a scalp electrode to measure the time of a 'readiness potential' (RP), which characteristically precedes bodily movements. In brief, Libet found that the onset of RP was about 345 milliseconds prior to the clock position corresponding to the time of the awareness of intention to act. The suggested conclusion is that spontaneous actions are actually initiated by unconscious brain events, with consciousness of intention to act occurring only after the events that bring about the action are already under way. In that case, the sense that it is a conscious intention that initiates the action must be illusory. (*See* **Free Will**)

Two caveats must be entered here. (1) Libet himself allows for the possibility of conscious control in the form of a 'veto' that would occur between 10 and 50 milliseconds before the action (and thus between 60 and 100 milliseconds after the conscious intention). Several of the commentators on Libet (1985), however, have found this allowance arbitrary, and contrary to the main epiphenomenalistic thrust of Libet's results. (2) At the level of precision at which Libet is working, sensory transduction times, neural transmission times, time necessary to shift attention from one item to another, etc., must all be taken into account. Values of these variables are difficult to establish and not always known with exactness. Interpretation of Libet's data is thus an unusually complex matter and is extremely controversial. (See Dennett, 1991, and the commentators on Libet, 1985. Libet has replied to the latter in the author's response section of Libet, 1985.) (*See* **Event-related Potentials and Mental Chronometry**)

A second line of investigation has recently been undertaken by Wegner and Wheatley (1999), who asked a subject and a confederate of the experimenter to place their fingertips on a small board mounted atop a computer mouse. Movement of this apparatus changed the position of a cursor on

a monitor that displayed pictures of a large number of familiar objects. Participants and confederates wore earphones through which they could receive various instructions, and through which participants sometimes heard a word for one of the depicted objects. On a small number of trials (forced-stop trials), confederates received instructions to force a stop on a certain picture; in most trials (non-forced-stop trials) they let participants roam and stop as they would. Participants were given a musical cue to begin an interval at the end of which a stop was to occur. After each stop, participants rated their contribution on a scale from 'I allowed the stop to happen' to 'I intended to make the stop', and confederates pretended to do the same. Participants were *not* instructed to stop on pictures of named objects, and an ancillary experiment showed that hearing the word for a depicted object did not influence participants toward stopping on its picture. The key finding was that participants rated their own participation higher in forced-stop trials when they heard the word for the picture on which the stop was forced 1 or 5 seconds prior to the stop, as compared with forced-stop trials in which they heard the word 30 seconds before the stop, or 1 second after. Wegner and Wheatly (1999, p. 489) report their conclusion in this way: 'Apparently, the experience of will can be created by the manipulation of thought and action in accord with the principle of priority, and this experience can occur even when the person's thought cannot have created the action'. (The principle of priority is that the experience of will requires thought to precede the action at a proper (i.e. small) interval.)

Wegner and Wheatley's result is silent on the matter of whether the experience of will causes the report of such experience, and is thus silent on the question of strict epiphenomenalism. But it does provide experimental support for a relative epiphenomenalism; that is it supports the view that experienced intent need not be a cause of events for which it is taken to be a cause by the participants in whom the experience occurs. Further, the possibility of the illusion that is produced in Wegner and Wheatley's experiment is explainable by a model in which, in normal cases, the thought of an action about to be taken, and the action itself, are co-effects of a common brain event.

CONCLUSIONS

While even relative epiphenomenalism is a controversial topic in cognitive science, there is evidence from several sources that strongly suggests that commonsense views about the causal relations between conscious occurrences and actions or beliefs are overly simple and misleading.

Relative epiphenomenalism does not imply strict epiphenomenalism, so a finding that there are relatively epiphenomenalistic mental phenomena does not directly support strict epiphenomenalism. Nonetheless, strict epiphenomenalists should be interested in the relatively epiphenomenalistic cases that cognitive science at least seems to provide. The relation can be summarized in the principle that 'the enemy of my enemy is my friend'. Nonmetaphorically, the point is that one of the key arguments against strict epiphenomenalism is the apparent introspective certainty of the existence and direction of causal connection between some of our mental phenomena and other mental phenomena or our actions. To the extent that results from cognitive science weaken the appearance that we have such certainty, they weaken an important objection to (even) the strict form of epiphenomenalism.

Epistemology

Intermediate article

Joseph Cruz, Williams College, Williamstown, Massachusetts, USA

CONTENTS

Epistemology is the philosophical study of what is required in order to have rational beliefs and knowledge. Both traditional a priori *methods of philosophy and* a posteriori *methods of cognitive science have been brought to bear on this question.*

WHAT IS EPISTEMOLOGY?

Epistemology answers to a daunting variety of senses in the humanities and the social sciences. Even when we restrict our attention to epistemology as it is understood in contemporary Anglo-American philosophy, the only uncontroversial claim we can make is that epistemology is an attempt to make sense of the possibility, nature, and limits of human intellectual achievement. Typically, the epistemologist does this by trying to illuminate the difference between knowledge and opinion, or the difference between good reasoning and poor reasoning. This project is distinct from merely giving a descriptive account of what people claim to know or to believe reasonably. Instead, epistemologists try to understand what it is really to know or really to believe reasonably, even if people routinely fail to know or are frequently irrational. Moving beyond the descriptive details of knowledge or belief formation to what people ought to believe is a normative philosophical enterprise.

Construed one way, epistemology aims to understand general and ubiquitous elements of human inquiry, such as perceptual knowledge or inductive inference. This project has sometimes been fueled by skeptical doubts about the veracity of our senses or the trustworthiness of our reasoning. Not all philosophers are persuaded, however, that thoroughgoing skepticism allows for, or requires, a response. As a result we often find in contemporary epistemology the attempt to account for epistemic achievements in a way that does not necessarily offer a reply to the skeptic.

Construed another way, epistemology aims to investigate specific domains of knowledge or rational belief. Some aspects of the philosophy of science may thus be understood as constituting a subfield of epistemology. This kind of research may be narrowed to particular sciences, such as the philosophy of psychology or the philosophy of cognitive science (or physics, or biology, to name two more prominent areas). Efforts to understand the nature of explanation in cognitive science ultimately fall under the umbrella of epistemology, though such efforts lie at the intersection of philosophy of science and philosophy of mind and have thereby taken on a robust theoretical autonomy.

Another distinction may be drawn between epistemology oriented towards individuals and epistemology oriented towards social institutions or practices. Some philosophers claim that there are social practices that positively or negatively influence the formation of knowledge or rational belief. A strong version of this view is where knowledge or rationality is exhausted by socially-mediated factors. This position has currency in some fields of the humanities, but the epistemologists who interact most frequently with the cognitive sciences tend to reject the most radical forms of social epistemology.

We shall concentrate on the general construal of individual epistemology and its relation to cognitive science.

Knowledge

What is knowledge? One sort of knowledge is the kind expressed by 'that' clauses. For instance, we may say 'Carlos knows that Oaxaca is in Mexico'. This kind of knowledge is called propositional knowledge, as it is a proposition – in this case, 'Oaxaca is in Mexico' – that is known. Another kind of knowledge is that expressed by 'how to' clauses. Thus, we may say 'Carlos knows how to ride a bicycle'. This second kind of knowledge is called procedural or nonpropositional knowledge. The bulk of attention in contemporary epistemology has been on propositional

knowledge, but this emphasis should not be viewed as making a claim about which kind is more important in human cognition.

Beliefs are thought to be the primary psychological entities that are candidates for propositional knowledge. Of course, not every belief is an instance of knowledge. Carlos may believe that Oaxaca is in Mexico, but his merely believing it does not seem to be enough to make it an instance of knowledge. Carlos cannot know that Oaxaca is in Mexico if it is false that Oaxaca is in Mexico. So one additional thing required for a belief to be knowledge is that the belief be true.

At least since Plato, epistemologists have thought that true belief, while necessary, is still insufficient for knowledge. One way of appreciating this is to note that beliefs that are accidentally true are not knowledge. Suppose that Carlos is guessing that Oaxaca is in Mexico. In that case, his belief does not seem to count as an instance of knowledge. One prominent and historically important way of pursuing the distinction between accidentally true and nonaccidentally true belief is to rely on the goodness of the reasons for the belief. So, if Carlos' belief that Oaxaca is in Mexico is both true and based on his having visited that state, we are likely to have a case of knowledge (assuming, for this example, that his visiting Oaxaca is a source of good reasons). On this conception of knowledge three central projects of epistemology emerge. First, the epistemologist must determine what constitute reasons. Second, she or he must offer a general account of what makes some reasons good. And third, the epistemologist must illuminate the nature of the relationship between reasons and beliefs.

Unfortunately, the 'goodness of reasons' approach to knowledge seems susceptible to a curious kind of problem that shows that true beliefs for which we have good reasons still might not count as knowledge. I may believe and have very good reasons to believe, for instance, that 'Mary owns a Honda'. I could then, for the purposes of teaching a logic course, create a variety of compound sentences involving my belief that Mary owns a Honda. Suppose I propose that 'Mary owns a Honda OR Sally is in Paris' even though I do not have any idea where Sally is. In the normal case, if I know one half of this disjunctive compound sentence, then I know the entire sentence since arbitrary disjuncts cannot change the truth-value of the entire sentence no matter how improbable they are. Now imagine that, contrary to my excellent evidence, Mary does not own a Honda, and, completely coincidentally, Sally *is* in Paris. It then seems that my belief in the whole expression 'Mary owns a Honda or Sally is in Paris' is true (Sally's being in Paris makes it so) and is something that I have good evidence for (since I have good evidence that Mary owns a Honda even though she does not). The problem is that we would not be inclined to attribute knowledge to me, though the three conditions for knowledge – true belief with good reasons – have been satisfied.

This is called the Gettier problem, after the author of the short article that sparked contemporary interest in it (Gettier, 1963). The Gettier problem has inspired many putative solutions, counterformulations, and modified putative solutions. There is no agreement on how the Gettier problem is to be solved within the goodness of reasons approach, but many epistemologists think that what the problem reveals is that there must be some fourth condition to ensure that truth and good reasons will be tied together in knowledge. Alternatively, the puzzle may show that the concept of knowledge is ill-defined. The Gettier problem has by no means crippled epistemology. Even if knowledge is not a concept that epistemologists can characterize in any simple way, issues in epistemology having to do with the nature of reasons and belief remain.

We shall turn to these issues shortly, but first it should be noted that there are accounts of knowledge that do not rely on the goodness of reasons approach. Some of these are pursued because they seem to offer a way to avoid the Gettier problem, while others seem to hold greater promise in defeating skepticism. We can divide these accounts of knowledge that do not rely on the goodness of reasons into two categories. One is where beliefs are calibrated to the truth in a way that can be characterized by epistemologists even though the relation between belief and truth may not involve reasons (Nozick, 1981). The knower does not have knowledge by virtue of having reasons for a belief; rather, a belief is an instance of knowledge if certain metaphysical or logical facts about the relation between belief and truth are satisfied.

The second category is *contextualism*, which maintains that the truth of attributions of propositional knowledge vary from context to context (DeRose, 1995). For instance, we may properly claim that Carlos knows that Oaxaca is in Mexico in mundane conversational contexts while the same claim would be improper in the rarified context of a university seminar on skepticism. Developing contextualist theories of knowledge requires an elaboration of what makes some contexts more demanding than others as well as a systematic treatment of changes in context.

Justification, Rationality, and Warrant

So far we have been identifying epistemology with the elucidation of knowledge. Being an instance of knowledge, however, is not the only epistemically positive characteristic a belief might have. We may be interested in having good reasons for our beliefs without insisting that such beliefs be instances of knowledge. The possibility of independently exploring epistemically positive beliefs that fall short of knowledge was implicit above when the three central projects regarding reasons (their nature, what makes some good, and what their relationships are) were proposed. In spite of their potential independence from knowledge, though, all three of these projects are typically conceived against the background of treating truth as the fundamental aim of epistemic reasoning. Good reasons are therefore often understood in the first instance to be reasons in favor of taking a belief to be true. Maintaining a close link between the goodness of reasons approach and truth is a deep commitment in epistemology, and explains the confidence in the connection between rationality and knowledge. Still, some epistemologists have offered accounts that sever the link by treating good reasoning as wholly unconnected to the truth.

The most prominent properties of epistemically positive beliefs discussed by philosophers are justification and rationality. These labels carry with them some connotative differences. Except where the distinction is crucial, in this essay we will read 'justification' and 'rationality' as synonyms. *Warrant* also has some currency in describing what a belief must have, in addition to truth, in order to yield knowledge.

How should we undertake evaluations of beliefs in terms of justification or rationality or warrant? The goodness of reasons strategy for investigating knowledge again affords a persuasive framework. We may study the reasons for a belief in order to make some judgment about whether that belief is epistemically positive. Furthermore, if rationality or warrant are graded notions, the strategy may allow us to advance a scale that appeals to the comparative goodness of the reasons for a belief. Thus, we may account for judgments of 'more rational' or 'more warranted' belief.

There seems to be an immediate problem, though, with employing the strategy of reasons for assessing epistemically positive belief along the dimensions of justification or rationality. A belief will inherit the epistemic status of the reasons for it, so we must in turn determine whether the reasons for a belief are themselves rational or justified. This threatens a regress of reasons that must be resolved. Responding to this regress has been instrumental in crystallizing issues in the recent history of epistemology, even if the regress problem no longer occupies the most crucial role in contemporary epistemological research. Deflecting the regress of reasons argument does not by itself answer the question of what makes a reason justified or rational. An answer to the structural question seems like a necessary first step, but it cannot be a complete theory of epistemically positive beliefs.

The structure of the belief corpus: foundationalism and coherentism

Two responses to the regress problem that differ on the structure of the belief corpus are foundationalism and coherentism. The foundationalist claims that there is a set of basic beliefs that do not require reasons to explain their epistemically positive nature because of some special characteristic(s) that they have. The epistemic credentials of beliefs that are not foundational are due to a traceable lineage through reasons, from basic beliefs via a basing relation that must be illuminated by the foundationalist. Thus, the justification relationship in the foundationalist picture is asymmetrical.

Foundationalists have attempted to develop axioms of goodness for foundational beliefs. Candidates for axioms include the claim that beliefs about how things appear are intrinsically epistemically positive. In a like fashion, foundationalists will need to provide enough axioms for foundational beliefs to account for the credentials of all epistemically positive beliefs.

Modulating the claim that the regress of reasons must end in intrinsically epistemically positive beliefs can complicate the foundationalist picture. It is an open question whether reasons for beliefs must themselves be beliefs. If not, then it is possible that the foundational reasons are other cognitive states such as perceptual states or memory states.

In contrast to foundationalists, coherentists maintain that no beliefs are intrinsically epistemically positive (Bonjour, 1985). By their lights, every belief relies on other beliefs for its epistemic status. One (controversial) argument for coherentism is that the foundationalist's putative axioms of goodness require an argument to show that they are good, and any such argument will rely on further beliefs, indicating that the axioms are not foundational after all. On one reading of coherentism, beliefs are epistemically positive based on a lineage of reasons in a structure that may ultimately loop back onto itself. There may be no need, however, to

trace reasons in a way that is circular. One might instead claim that a belief is epistemically positive in the case of its being a member of a coherent belief corpus without pursuing particular reasons in a linear fashion.

Coherentists discharge the task of revealing what makes some reasons good by claiming that cogent arguments can be given for the high epistemic credentials of beliefs, and further arguments can be given in favor of the cogent arguments.

Epistemic internalism

Despite their differences on the structure of the belief corpus, the foundationalist and coherentist strategies traditionally agree on a different issue: reflective, careful agents are able to make assessments of their own beliefs in order to determine whether they are epistemically positive. This is called the *internalist* conception of epistemic justification or rationality.

In order to defend internalism in detail, the epistemologist needs to specify what is meant by the claim that agents can determine whether there are good reasons for their beliefs. A number of interacting but independent issues arise here. One challenge is deciding whether the epistemic agent must be able to determine that reasons are *good*, versus the less strict demand that the agent merely be able to determine what the reasons *are*. Another challenge is whether the agent must be able to determine *what* her or his good reasons are for a belief, versus the much less demanding constraint that the agent must be able to determine *that* she or he has good reasons for a belief. A third challenge is deciding what sort of effort on the part of the agent will be consistent with the claim that agents can access their reasons. Most of the combinations of answers to these challenges have been defended in the internalist literature.

Internalism originates in three related concerns. First, one of the projects that sometimes accompanies an assessment of epistemically positive belief is to illuminate how one might improve one's beliefs. If improvement is to be possible, it needs to be possible to determine which belief among many candidate beliefs is most epistemically positive, and it has seemed that the epistemic agent personally needs to be able to make the judgment. Second, justification (though not rationality) has often been viewed as at least partly a matter of fulfilling a distinctly epistemic duty. Fulfilling a duty seems to require that one be able to do the things that duty requires. In order to secure the means to an intellectual duty, an epistemic agent will need to be able to reflect on her or his condition and on the resources available. Third, recall that the ability to answer the skeptic is sometimes thought to be a crucial component of epistemology. The only answers that the epistemic agent can give, though, are ones that are available on reflection.

Epistemic externalism

Thinking of the epistemic agent as able to determine when beliefs are epistemically positive is not demanded by the overarching goal of epistemology. Though the philosopher may state the conditions that must be met for a belief to be epistemically positive, the epistemic agent may not be able to make assessments of particular beliefs. Thus one might reject internalism and not expect the right philosophical account of epistemically positive belief to enable meliorative, duty-oriented, or skeptic-answering evaluations to take place. This is the *externalist* view in epistemology.

For example, *process reliabilism* – the best-known externalist view – to a first approximation claims that what confers positive epistemic status on a belief is that it be produced by a psychological process that reliably produces true belief (Goldman, 1979). Though the reliability of a psychological process is often opaque to the person employing that process, process reliabilists think that the reliability of belief-forming processes can be uncovered by cognitive science or by other kinds of empirical inquiry.

The motivations for defending an externalist position are diverse. One simple motivation is the impulse to tie justification and rationality directly to truth via an appeal to truth-sensitive properties such as reliability. In this connection, the externalist's commitment to truth as the central goal of justified belief looms large. Externalist theories can be neutral on the question of the structure of the belief corpus, and instead attempt to tackle more directly the issue of epistemically positive belief.

Another motivation that is prominent in discussions of externalism is the role of causal factors in belief formation. It has seemed to many epistemologists that, in order to be justified or rational, a belief has to have both an evidential and a causal relation to the reasons for it. Incorporating this causal element seems to require some of the specialist's insight into the causes of our beliefs, and that is in tension with the internalist's impulse to insist that it is the epistemic agent personally who is in a position to determine the epistemic status of her or his beliefs.

The Methods of Epistemology

In traditional epistemology, the standard of correctness for epistemological questions appeals to intuitions about epistemic methods or particular cases of belief. For example, that beliefs formed under favorable perceptual conditions in a healthy observer are justified is a principle that we may intuitively certify. So, a non-skeptical account of justification should in this view be designed to accommodate intuitions about beliefs formed under favorable perceptual conditions. Alternatively, a theorist may take particular instances of an intuitively epistemically positive belief – the belief that *this* shiny Macintosh apple is red, for instance – and attempt to build a theory that respects this intuition. A successful theory of justification will yield the result that such beliefs are justified unless there is some other overriding consideration that would result in the retraction of the judgment that the belief is justified. Such beliefs are called 'prima facie justified' in order to highlight the fact that new information about the situation might change intuitions about the justifiedness of the belief in question. Many epistemologists have exploited both kinds of intuition by seeking to balance methods and cases.

There are reasons to be dissatisfied with the methodology of epistemology, not the least of which is that the use of intuitions alone can seem to be a precarious or even spurious basis for theorizing. Intuitions might be thought to be too subjective or theory-laden. There was a period in Anglo-American philosophy when philosophy was viewed as wholly conceptual (*a priori*) analysis. The strong commitment to that position has long since passed. Intuitions ground philosophical inquiry in our pre-theoretic understanding of epistemic concepts, and allow a bridge to the long history of philosophical theorizing on the same topics. But intuitions may need to be adjusted in light of other considerations. There is much debate as to what the other sources of constraint may be. It is within a particular answer in this debate that there is the most cross-fertilization between epistemology and cognitive science.

EPISTEMOLOGY AND COGNITIVE SCIENCE

Some epistemologists maintain that a sensible division of labor in understanding justification and rationality is that philosophers investigate the normative elements of belief formation, while cognitive scientists study how we actually form beliefs. To the extent, however, that philosophical intuitions about epistemic concepts need to be constrained by the empirical (*a posteriori*) details of belief formation, cognitive science will play a significant role in epistemology. Theories of rational belief that incorporate a significant empirical component are categorized under the label of 'naturalized epistemology'.

Naturalized Epistemology

Cognitive science gives epistemologists detailed and empirically robust accounts of the origins of belief. This is relevant to epistemology if we are persuaded that a belief is rational only if it bears the right causal relation to the reasons for it. Empirical details will also be important in part because philosophical intuitions are likely to be misleading with respect to the nuances of belief formation. For example, intuitively it seems that inductive reasoning on the basis of small samples would not be a method for forming epistemically positive beliefs. It has been argued, however, that induction on the basis of small samples is epistemically defensible in reasoning involving natural kinds (Kornblith, 1993). It is only through the insight of cognitive scientific accounts of how reasoning interacts with kind concepts that this unintuitive method will appear epistemologically sound. Other insights from cognitive science that have been relevant in epistemology include vision research, research on deductive reasoning, and research on memory.

Process reliabilism advocates a proprietary role for cognitive science in epistemology. Once causal factors are deemed relevant in understanding justification, and once it has been determined that justified beliefs are the product of reliable psychological processes, cognitive science enters into epistemology to provide the details of psychological processes in terms of their reliability (Goldman, 1986).

Naturalized epistemology is often identified with externalism. Depending on how issues of access to reasons are resolved, though, it is possible to maintain an internalist theory that carves out a role for empirical research on belief formation. Artificial intelligence models of cognition have been employed in epistemology to investigate how complex patterns of reasoning interact in order to yield intuitively justified beliefs (Pollock and Cruz, 1999; Thagard, 2000). The rules or norms of reasoning at each step of reasoning may be unintuitive owing to their complexity, but the whole reasoning process may be counted as rational because it yields an intuitively justified conclusion. This position can

be internalist by maintaining that epistemic agents will be able to determine in their own cases whether their reasoning is good, even though the norms of reasoning generally will be inscrutable.

The Cognitive Science of Epistemology

Finally, we consider another way to conceive of the relationship between epistemology and cognitive science. Cognitive science may step back from philosophy and investigate epistemology itself. There are two plausible targets of investigation: concepts and methods. First, cognitive science might investigate how people employ the concepts of justification, knowledge, or good evidence in the same way that nonphilosophical concepts are studied (Goldman, 1992). Drawing conclusions from such research is a delicate matter, however, since it has seemed to philosophers that there is no way to uncover the genuine normative character of epistemological concepts by merely studying their psychological status.

Second, cognitive science might investigate the method of employing *a priori* intuitions to address epistemic questions. A specific instance of this suggestion is that we should think of epistemic intuitions as analogous to grammaticality judgments in linguistics (Pollock and Cruz, 1999). Reasoning on this view is the product of an underlying rational competence, but actual cases of reasoning might go wrong due to resource constraints. If the analogy could be successfully developed, it would help explain the difference between merely describing how people reason (which would always be particular performances of reasoning) and the normative account of how people ought to reason. The explanatory credentials of this account appeal directly to its success in linguistics and related areas of psychology and artificial intelligence research.

Ethics

Intermediate article

CONTENTS

Ethics is the philosophical study of standards of conduct and value. Such inquiry often encounters questions regarding human motivation, affect, and cognition that can be addressed by empirical and theoretical work in the cognitive sciences.

INTRODUCTION: WHAT IS ETHICS?

Contemporary philosophical ethics is customarily divided into three subdisciplines, here ordered by increasing theoretical abstraction: applied ethics, normative ethics, and meta-ethics (see Darwall, 1998 for a useful survey).

Applied ethics addresses concrete ethical problems in areas such as law, medicine, business, and agriculture. While work in applied ethics may involve the advocacy of particular positions, philosophers often aim only to clarify, through philosophical methods of argumentation and analysis, the issues surrounding such controversial topics as abortion, euthanasia, capital punishment, and the development of genetically modified organisms.

Normative ethics investigates obligation, virtue, and value; very often, work in this area consists in attempts to adduce general claims about the sorts of things that are morally valuable and general principles for the regulation of conduct and choice. In contemporary normative ethics, three approaches are especially prominent. Proponents of virtue ethics, inspired especially by Aristotle, maintain that human excellence is the fundamental evaluative consideration; conduct is to be judged by reference to such virtues as courage and temperance. Consequentialists and Utilitarians, working in the tradition of Bentham and Mill, argue that right actions are those that, of the options available, maximize the total quantity of a valuable end such as pleasure or happiness. Followers of Kant, or Kantians, argue that an act is morally permissible only in so far as it proceeds from a principle that could coherently serve as a law governing the choice of all rational agents.

Meta-ethics concerns the structure of moral reasoning and justification, the sources of moral motivation, and the nature of moral concepts. Perhaps the most persistent issue in meta-ethics concerns the objectivity of ethical inquiry. Is ethical discourse merely the statement or expression of preference or emotion, as various brands of skepticism about moral objectivity maintain? Or is there some method for discovering objectively true answers to ethical questions, or conferring rational justification on ethical judgments, as moral realists have argued?

THE RELATION OF COGNITIVE SCIENCE TO ETHICS

Historically, many moral philosophers have been skeptical about the relevance of the sciences to ethics. In the spirit of Hume (1978/1740, p. 469), it is argued that because scientific inquiry is primarily descriptive or factual and ethical inquiry is primarily prescriptive or normative, there is an unbridgeable 'logical gap' between the *is* of the sciences and the *ought* of ethics. However much the sciences may tell us about human beings, how the beings in question should comport themselves remains – to borrow an influential formulation of Moore's – an open question. For example, contemporary life science has discovered much about the development and functioning of the fetus, yet this has, in the eyes of many, done little to resolve the abortion controversy.

But there have always been those who viewed this gap between *is* and *ought* as illusory, and much recent philosophical work suggests that the barrier between description and prescription may not be as impermeable as followers of Hume and Moore suppose (Railton, 1995). Certainly moral philosophers often offer arguments – such as those

regarding the nature of moral motivation and cognition – whose presuppositions appear amenable to empirical investigation. In so far as this is the case, cognitive science bears a strong prima facie relevance to ethics. Accordingly, we will not attempt to adjudicate the continuing philosophical controversy regarding the relation of scientific to ethical inquiry, but will instead identify interfaces between cognitive science and ethics that merit further empirical study and philosophical discussion.

APPLIED ETHICS

Many issues in applied ethics raise important epistemological questions – questions about what people can and cannot be reasonably expected to know. Other issues raise closely related questions about what people do and do not understand. The cognitive sciences have produced empirical findings relevant to such questions, and these findings often play a central role in debates in applied ethics. In this section we will give two brief illustrations.

One of the first domains in which experimental psychology was applied to an important ethical issue was the debate over reliance on eyewitness testimony in legal proceedings. Traditionally, the identification of a defendant by an eyewitness to a crime has played a central role in Anglo-Saxon law. However, almost 100 years ago, Munsterberg conducted a number of dramatic, though poorly controlled, experiments in which many eyewitnesses to a staged 'crime' gave seriously inaccurate reports of what they had seen. In a book that generated considerable controversy in the legal profession and beyond, Munsterberg (1908, p. 194) argued that it is 'astonishing that the work of justice is ever carried out in the courts without ever consulting the psychologist and asking him for all the aid which the modern study of suggestion can offer'.

More recent work, using much improved methods, has demonstrated that people's memories of events can be affected in dramatic and disquieting ways by information (or *mis*information) that they encounter after the event. In one experiment, conducted in train stations and other naturalistic settings, Loftus (1979) and her students staged a 'robbery' in which a male confederate pulled an object from a bag that two female students had temporarily left unattended and stuffed it under his coat. A moment later, one of the women noticed that her bag had been tampered with and shouted: 'Oh my God, my tape recorder is missing.' She went on to lament that her boss had loaned it to her and that it was very expensive. Bystanders, most of whom were quite cooperative, were asked for their phone numbers in case an account of the incident was needed for insurance purposes. A week later, an 'insurance agent' called the eyewitnesses and asked about details of the theft. Among the questions asked was 'Did you see the tape recorder?' More than half of the eyewitnesses remembered having seen it, and nearly all of these could describe it in detail – this despite the fact that *there was no tape recorder*! On the basis of this and other experiments, Loftus concludes that even casual mention of objects that were not present, or of events that did not take place (for example, in the course of police questioning), can significantly increase the likelihood that the objects or events will be incorporated into people's memories. Other studies have shown that people are often mistaken when they identify someone as a participant in an event that they witnessed, and that both white and black subjects are considerably less accurate at identifying people of the other race (Loftus, 1979; Lloyd-Bostock and Clifford, 1983; Wells and Loftus, 1984).

Findings like these, along with a number of highly visible cases in which people have been convicted of crimes they did not commit on the basis of eyewitness testimony, have led one leading legal scholar to recommend that judges should be required 'to direct the jury that it is not safe to convict upon eyewitness evidence unless the circumstances of the identification are exceptional or the eyewitness evidence is supported by substantial evidence of another sort' (Devlin, 1976). Though this recommendation has not been widely accepted, the recent use of DNA testing to reverse wrongful convictions that were often at least partially based on unreliable eyewitness testimony has once again focused attention on the need for reform. Although some philosophers have questioned the wisdom of relying on empirical studies in this context (Coady, 1992), the research raises an important and troubling question: when, if ever, is it ethically defensible to allow legal decisions to be influenced by such an empirically suspect source of evidence?

Another area of research in cognitive science that has important implications for the legal system, and also for issues about medical and academic decision-making, focuses on the reliability of predictions about an individual's future behavior based on interviews and 'clinical' judgments. In some American states, interviews with parole board members play a central role in deciding whether an offender will be granted a parole. In one state system, for example, interviewers are

asked to make a prediction of the risk that the offender will commit another crime. A study by Carroll *et al*. (1988) showed that psychologists who had never spoken with the prisoners could make much more accurate predictions by using purely statistical 'actuarial' methods and basing the prediction entirely on a few background factors, such as number of previous convictions. This finding is one of well over 100 studies comparing clinical to actuarial methods for predicting a wide range of behavioral phenomena, from academic success to the prognosis for patients admitted to a mental hospital. In just about all of these studies, actuarial methods are at least as good as clinical prediction, and often they are much better. These findings have led to considerable discussion about *why* the human cognitive system does such a bad job on these tasks, despite the often powerful conviction on the part of 'expert' judges that their professional experience enables them to make better predictions (Nisbett and Ross, 1980; Dawes, 1994). Though we do not currently have a good understanding of the mechanisms that give rise to clinical predictions, their unreliability raises serious questions about the moral justification for using such predictions in making important decisions.

NORMATIVE ETHICS

Making defensible moral judgments requires a sensitivity to ethically salient features of the environment: one is not likely to act compassionately if one is oblivious to suffering, nor is one likely to act justly in complex circumstances without some awareness of what justice requires. It appears as though individuals vary on this dimension; just as some are especially attuned to the dictates of etiquette or fashion, others seem especially attuned to the demands of morality.

This sort of observation has been prominent in philosophical thought regarding the virtues, or excellences of character. According to Aristotelians such as McDowell (1979), virtue involves a 'reliable sensitivity' to ethically salient considerations. The requisite sensitivity must be both *reliable* and *robust*; while even morally mediocre people may manifest ethical sensitivity in particular instances, the virtuous person manifests appropriate ethical sensitivity in all circumstances where she can reasonably be expected to do so, regardless of whether this exercise is difficult or easy.

However appealing the foregoing view may be, experimental social psychology suggests that ethical sensitivity is typically far from robust. A large body of research indicates that people's moral judgments and behavior are extraordinarily sensitive to features of the situation in which they are embedded, including many features that most people would agree are morally irrelevant. (See Doris (2002) for details and references.) Experimental studies of helping behavior provide some particularly disconcerting examples. Finding a bit of change or hearing the noise from a lawn mower can make the difference between helping and not – results that likely would have astounded Aristotle. In a classic demonstration by Darley and Batson, subjects performed tasks at two separate sites. The behavior of interest occurred when subjects walked from one site to the other, passing the experimenters' assistant slumped in a doorway, apparently in some distress. Before leaving the first site, subjects were told either that they were running late ('high hurry'), were right on time ('medium hurry'), or were a little early ('low hurry'); thus members of each group experienced a different degree of time pressure while travelling from one site to the next. Helping behavior varied markedly with degree of hurry: 63 per cent offered help in 'low hurry', 45 per cent offered help in 'medium hurry', and only 10 per cent offered help in 'high hurry'. Evidently some subjects wanted to help but reluctantly ceded to the demands of punctuality, while for others (more germane here), time pressures muted their sensitivity to ethically salient stimuli – in some instances subjects stepped unconcernedly over the stricken 'victim', apparently without registering the scene. There is no reason to think that the subjects in these studies were aberrant in their sensitivity to situational factors; it is quite reasonable to suppose that most people exhibit very substantial situational variability in their moral judgments and behavior, whatever we are antecedently inclined to say about their character.

These empirical issues do not by themselves show that a conception of virtue as involving a robust and reliable ethical sensitivity is of no use to ethics. Perhaps virtue is to be understood, as some philosophers have suggested, in terms of a rarely attainable ideal that serves to focus people's ethical aspirations (Blum, 1994, pp. 94–6), or perhaps the empirical findings do not unsettle a suitably sophisticated moral psychology of virtue. Or perhaps, as others have argued, results such as those just recounted suggest major revisions for philosophical thinking on virtue and character (Doris, 1998, 2002; Harman, 1999). It remains to be seen how compelling these alternatives are, but it is obvious that virtue ethics is in a fertile tension with empirical work.

META-ETHICS

Meta-ethics is concerned, in part, with the nature of moral concepts, the structure of moral reasoning, and the nature of moral motivation, and there are many ways in which the findings and theories in cognitive science are relevant to these concerns. In this article we have space for only a single example.

As we noted earlier, the Kantian tradition in moral philosophy emphasizes the role of reason in ethics, and many Kantians have invoked reason to explain why people should be motivated to act morally. The explanation they propose is that it would be irrational not to be motivated to do what one morally ought to do (or what one believes one morally ought to do), in much the same way that it would be irrational not to believe the conclusion of a sound argument (Nagel, 1970, p. 3). One famous obstacle to proposals of this sort is suggested by Hume's (1777/1966, pp. 282ff) hypothetical example of the 'sensible knave' – a person who recognizes that it is morally wrong to be dishonest in a situation where he would benefit from dishonesty, but who is not moved at all by this judgment. More recent writers have urged that Hume's sensible knave is more than a philosophical fiction since there actually are psychopaths who know the difference between right and wrong but simply have no motivation to *do* what is right.

Those who wish to defend the link between reason and moral motivation have adopted two quite different strategies, both of which appear to make substantive empirical assumptions of the sort that cognitive science might test (Nichols, 2002). The first strategy relies on a claim about our ordinary concept of moral judgment: the concept of moral judgment entails that 'agents who make moral judgments are motivated accordingly' (Smith, 1994, p. 66). Philosophers who adopt this strategy recognize that psychopaths may *say* that something is 'morally required' or 'morally wrong' and that they may be quite sincere. But if psychopaths are not motivated in the appropriate way, their words do not mean what non-psychopaths mean by these words and the concepts they express with these words are not the ordinary moral concepts that non-psychopaths use. This strategy only works, of course, if it is true that our ordinary moral concepts *require* that people to whom the concepts apply have the appropriate sort of motivation. And, for two quite different reasons, it is far from clear that this is the case. First, there is considerable disagreement in cognitive science about whether and how concepts are structured, and about how we are to determine when something is built into or entailed by a concept (Margolis and Laurence, 1999). Second, there has been almost no serious empirical work aimed at uncovering the structure of ordinary people's moral concepts. There has, however, been work on ordinary people's epistemic concepts, and that work suggests that people in different ethnic and socioeconomic groups use significantly different epistemic concepts (Weinberg *et al*., forthcoming). If the same is true for moral concepts, it will pose a serious challenge for the conceptual approach to the problem posed by sensible knaves and psychopaths.

A second strategy for defending the connection between reason and moral motivation takes the link to be empirical rather than conceptual. Those who adopt this approach maintain that it is an empirical fact that the faculty of reason, when functioning normally, generates motivation to do what one judges one ought to do, just as it is an empirical fact that the faculty of reason generates an inclination to believe the conclusions of arguments one judges to be sound. If psychopaths fail to have the appropriate moral motivation, it is argued, then there must be something wrong with their reasoning faculty. But is this true? The answer is far from clear.

Blair (1995) has shown that psychopaths *do* exhibit surprising deficits on a cluster of cognitive tasks that have been used frequently by psychologists who study moral development. In these tasks subjects are presented with descriptions of various transgressions such as a child hitting another child, or a child leaving the classroom without the teacher's permission. In the moral development literature, transgressions of the first sort are labeled 'moral' while those of the second sort are labeled 'conventional'. From quite early on in childhood, normal children distinguish moral from conventional transgressions on a number of dimensions: they view moral transgressions as more serious, they explain why the acts are wrong by appeal to different factors (harm and fairness for moral transgressions, social acceptability for conventional transgressions), and they understand conventional transgressions, unlike moral transgressions, to be dependent on authority. If the teacher says there is no rule about leaving without permission, children think it is OK to leave without permission. But if the teacher says there is no rule against hitting other children, they do not think that hitting is acceptable. What Blair found was that incarcerated psychopaths do not draw the moral/conventional distinction. Though normal children and normal adults (including a control group of non-psychopath prisoners) have no

trouble classifying new cases in one category or the other, psychopaths fail to do so.

These results might well give some support to the hypothesis that psychopaths have a reasoning deficit, and thus that they do not pose a problem for those who maintain that a properly functioning reasoning faculty always generates some motivation to do what one believes one ought to do. But, as Nichols (2002) has pointed out, the issue cannot be so easily resolved, because psychopaths have also been shown to have affective responses that are quite different from those of normal subjects. When shown distressing stimuli (e.g. slides of people with dreadful injuries) and threatening stimuli (e.g. slides of an angry man wielding a weapon), normal subjects exhibit much the same suite of physiological responses. Psychopaths, by contrast, exhibit normal physiological responses to threatening stimuli, but abnormally low physiological responses to distressing stimuli (Blair *et al*., 1997). Thus, Nichols argues, it may well be that what is wrong with psychopaths is not that their reasoning system is abnormal, but that their affect system is abnormal, and that it is their affective abnormalities that are responsible for their inability to draw the moral/conventional distinction. If that is the case, then Hume's challenge continues to pose a major problem for those who think there is a link between reason and moral motivation. Resolving this issue will require conceptual clarification on how to draw the boundary between reason and affect, and on what counts as an *abnormality* in each of these domains. It will also require much more empirical work aimed at understanding exactly how psychopaths and non-psychopaths differ. Clearly, this important issue in meta-ethics cannot be addressed responsibly without taking account of the increasingly rich body of empirical findings generated by the cognitive sciences.

THE METHODS OF ETHICS

'Intuition pumps' or 'thought experiments' are among the most prominent elements of philosophical method. The technique is to present a hypothetical example and attempt to elicit some philosophically telling intuition; if the 'experiment' is successful, it may be concluded that competing theories must account for the resulting intuition. In such cases, those forwarding the thought experiment insist that for a theory to be viable, it must be consistent with the intuition elicited by the hypothetical example; if the theory is inconsistent with the intuition, the hypothetical is supposed to be a counterexample to the theory. This is a central rhetorical strategy in ethics, as evidenced by debates over Utilitarianism. Consider, for example, an influential intuition pump proposed by Williams (1973, pp. 97–100), who asks us to imagine the following circumstances: George, a new PhD in chemistry in dire need of a job to support his family, is offered a chance at a job researching chemical and biological weapons (CBW). George is strongly opposed to CBW research, but if he does not take the job, it is likely to go to a man with rather alarming enthusiasm for CBW research. Williams maintains that Utilitarians are bound to say that George should take the job, presumably because doing so will both help his family and hinder CBW research, thus maximizing total available welfare. But Williams argues that 'many of us would certainly wonder whether … that could possibly be the right answer at all'. Williams apparently thinks that in this case people will conclude that the Utilitarian prescription does not properly account for the value of George's 'integrity', a commitment to principle that would be undermined if he took the job.

In response, the Utilitarian may deny that ethical theory should be constrained by intuitions. But this is a rather unappealing expedient; a theory that makes no reference to intuitions risks becoming divorced from the experience of ethical life. On the other hand, it is also perilous to deploy intuitions as a constraint on ethical reflection. Given the ubiquity of moral controversy, cultures and individuals may vary dramatically in their moral intuitions; how is it to be decided which intuitions, and whose should serve as constraints? For example, Haidt *et al*. (1993) found evidence suggesting that Americans' ethical intuitions varied with their socioeconomic status. Returning to George the chemist, is Williams right to suppose that 'many of us' value integrity over food on the table, or is this intuition limited to the 'many of us with sufficiently high socioeconomic status'? A further look at cognitive science presses this question still harder: experimental work suggests that even within a single individual, moral intuitions may vary in quite arbitrary ways.

In an important study, Tversky and Kahneman (1981) presented a group of subjects with the following problem:

> Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:

> If Program A is adopted, 200 people will be saved.
>
> If Program B is adopted, there is a 1/3 probability that 600 people will be saved, and a 2/3 probability that no people will be saved.

A second group of subjects was given an identical problem, except that the programs were described as follows:

> If Program C is adopted, 400 people will die.
>
> If Program D is adopted, there is a 1/3 probability that nobody will die and a 2/3 probability that 600 people will die.

On the first version of the problem most subjects thought that Program A should be adopted. But on the second version most chose Program D, despite the fact that the outcome described in A is identical to the one described in C. The disconcerting implication of this study is that the moral decisions we make are strongly influenced by the manner in which the options are described or *framed*. The general worry is that ethical intuitions may be determined by features of thought experiments that are quite ethically irrelevant. To return once more to George the chemist, are responses to the thought experiment determined by reflection on the ethical substance of the case, or by ethically irrelevant features of the richly textured example? Until we can say with confidence how a given ethical intuition is generated, we should be hesitant to rely on it in argument.

This suggests a dilemma for philosophical ethics: it must either eschew appeal to thought experiments that have not been evaluated empirically, or eschew appeal to intuitions altogether. As we've already said, the abolition of intuitions is a problematic solution: it threatens to distance philosophical ethics from the experience of ethical life, and thereby alienate the study of ethics from the concerns of actual ethical agents (see Williams, 1985, pp. 93–119, esp. 116–119). But continued reliance on intuitions in the face of the difficulties just surveyed presents its own difficulty: intuitions, and the thought experiments generating them, must be subjected to systematic empirical scrutiny before they can be appealed to in adjudicating theoretical disputes. In other words, if practitioners of philosophical ethics wish to rely on intuitions, they must work to develop a cognitive science of ethics. If we are right, the implications of this are radical: philosophers must either depart from the traditional methods of ethics by abandoning the use of intuitions, or depart from the traditional methods of ethics by pursuing experimental work in cognitive science.

Explanatory Gap

Intermediate article

Joseph Levine, Ohio State University, Columbus, Ohio, USA

CONTENTS

The explanatory gap concerns the problem of explaining the qualitative character of conscious experience by reference to underlying physical and computational processes.

WHAT IS THE EXPLANATORY GAP?

The explanatory gap is a fundamental aspect of the mind–body problem, the problem of determining the relation between physical and mental phenomena.

We commonly explain the behavior of the people around us by appealing to their beliefs and desires, along with their sensory experiences. In our own case we know that there is something particular that it is like to smell a rose, taste coffee, or see a sunset. We have fairly direct knowledge of what we believe, desire, hope and fear. It is almost unimaginable to abandon this conception of ourselves and our fellow human beings (and many higher animals) as possessing mental lives that play a central role in determining behavior.

On the other hand, we also know that we are physical creatures. We have bodies that are subject to the laws of physics, and, more specifically, to the laws of biology. So the question naturally arises: how do these two sets of phenomena relate to each other? Are mental states and events just identical to certain physical states and events – in particular, to states and processes in the brain? Or are mental states and events somehow distinct from, metaphysically independent of, though perhaps causally connected to, processes in the brain?

Materialism is the doctrine that mental phenomena are a species of physical phenomena. Whether the precise relation between mental properties and neurological properties is identity, or instead something like constitution or realization, is a further question. What unites all versions of materialism is the idea that mental phenomena are part of the physical, natural order. This is where the problem of the explanatory gap enters. If we accept this basic tenet of materialism, it seems reasonable that we ought to be able to explain why it is that certain neurological states constitute the mental states they do. We ought to be able to say why having these neurons fire the way they do amounts to believing that $2+2=4$, and why having these other neurons fire the way they do amounts to having a visual experience of red. The problem of the explanatory gap is that, at least for states like visual experiences of red, there seems to be a deep problem about how to explain their character by reference to the physical states that allegedly constitute them.

Mental states fall roughly into two groups: cognitive states and experiential states. Cognitive states involve representing the world in some way and taking an attitude towards the situation represented. Experiential states are those for which it makes sense to talk about 'what it is like' to have them: for example, visual sensations and pains. These are states that have a 'qualitative' character; and their qualitative properties – such as the way a toothache feels, or a red rose looks – are called 'qualia'. While many philosophers agree that progress has been made towards explaining how physical phenomena could represent, there is much less agreement that we have any clear idea how physical phenomena could amount to conscious experience. What is it about certain neurological processes that explains why it is like what it is like to undergo them? Here the explanatory gap seems to many to be as wide as ever.

HISTORY

The term 'explanatory gap' was introduced by Levine (1983), but the idea is older. John Locke (1690/1975) distinguished ideas of primary qualities from ideas of secondary qualities. Primary qualities are essentially the basic physical properties of matter, which Locke thought to be size, shape, and bulk. Secondary qualities are properties like color and taste. On Locke's view, when our

sensory systems are affected by certain physical stimuli, our minds react by forming certain ideas, such as experiences of color and taste, and these are our ideas of secondary qualities. According to Locke, there is no intelligible relation between the configuration of primary qualities in the perceived objects and the ideas of secondary qualities that interaction with them gives rise to. Ideas of red could just as easily have been associated with green objects as with red objects. God just happened to pick one scheme of association rather than the other. Thus, on Locke's view, the reason why there is an explanatory gap between the description of the physical interaction taking place during perception and the description of the experience is that there really is no explanation of the latter in terms of the former. God arbitrarily decreed that these experiences should be the result of those particular physical interactions.

The other important historical antecedent is Leibniz (1840). Leibniz asks us to imagine a brain expanded to the size of a factory. We could enter and look around at all the physical interactions among the various parts of the brain. Where, Leibniz asks, would we see sensations of blue, pains, or thoughts? His point is that we cannot see how physical interactions of this sort could amount to experience.

Among modern philosophers, the most famous expression of the problem of the explanatory gap is by Nagel (1974). Nagel argues that physicalism can never make sense of the relation between physical processes and conscious experience because we can only understand physical phenomena from an objective point of view, whereas our conception of conscious experience is essentially subjective. For example, while we could understand everything there is to know about the workings of the bat's perceptual system of echo location, we could not thereby know what it is like to perceive as a bat does. But if we could really explain what it was like on the basis of the relevant neurology and information processing, we would be able to know what it was like. Thus our ignorance in this case is a direct reflection of the explanatory gap.

ARGUMENTS FOR THE EXPLANATORY GAP

There are three forms of argument that support the existence of the explanatory gap: the conceivability argument, the knowledge argument, and an argument connected with the problem of other minds.

The Conceivability Argument

The conceivability argument is a well-known argument against materialism, due to Descartes but revived recently by Kripke (1980), and even more recently by Chalmers (1996). We begin with the premise that it is at least conceivable that a creature could share all of my physical traits (or, if the argument is employed against functionalism – a particular version of materialism – all of my functional traits) and yet have different qualia or no qualia at all. That is, we can conceive of a creature that is physically like me but for whom there is nothing that it is like to be that creature, or for whom experiences are very different from what they are like for me. We now add the premise that if such a situation is conceivable – we can find no contradiction or incoherence in its supposition – then it is genuinely possible. But if it is possible to have A without B, then it follows that A and B are not identical. Therefore, qualia are not identical to physical (or functional) properties.

One response to the conceivability argument is to deny the second premise: that conceivability entails possibility. But for the advocate of the explanatory gap this doesn't matter. Even if we grant that, merely from the fact that we can conceive of a creature physically like me, but without consciousness, it does not follow that such a creature is indeed possible, still, the fact that such a creature is even conceivable demonstrates the explanatory limits of materialist theory. For if we really could explain why someone had the qualia they had by appeal to their physical (or functional) structure, then, it is argued, the creature in question would not be conceivable. We would see why having this physical structure necessitated having the conscious experiences it has. The fact that we find no problem conceiving a physical duplicate for whom there is no experience, or very different experiences, is a sign of the explanatory gap between the physical and the mental.

The point is best made by contrasting the mental–physical case with other instances of theoretical reductions. We know that water is composed of H_2O molecules. Certainly it is conceivable that this could have not been the case: the world could have been as Aristotle thought it to be, with water a basic element. However, it does not seem conceivable that there are H_2O molecules obeying the laws of chemistry and physics that apply to our world, and yet not manifesting the various superficial, high-level properties by which we normally identify water. In other words, it does not seem conceivable that, with all of our chemistry and physics in

place, masses of such molecules should not freeze and boil at the appropriate temperatures, or not allow light to pass through, or not supply an essential ingredient to plants and animals. We can see how the laws of chemistry and physics necessitate these high-level phenomena.

However, when we turn to the relation between qualia and the neurological states that underlie them, the situation seems different. It is not difficult to imagine how, from a sufficiently detailed description of the underlying neurology, one might be able to infer the structure of the functional, or information processing, relations among mental states. At least such a derivation seems possible in principle. But no similar derivation seems possible from neurological phenomena to conscious, qualitative phenomena. For any proposed neurological correlate of a conscious experience, such as a visual experience of red, it always seems at least conceivable that the neurological state might obtain without the experience: either because we can conceive of a different sort of experience going with that state, such as an experience of green instead, or because we can conceive of there being nothing that it is like to occupy that state.

The Knowledge Argument

The 'knowledge' argument is due to Jackson (1982). He asks us to imagine Mary, a super-scientist of the future who knows everything there is to know about the physical and functional structure of color vision, but who, because she is imprisoned in a black and white environment, has never seen color herself. When she emerges from her black and white world for the first time and sees a ripe tomato, it seems plausible that she will learn something new: namely, what it is like to see red. But if she already knew everything there was to know about seeing red, why would there be anything left for her to learn in this situation? Thus, all the physical and functional facts together fail to encompass all the facts, and therefore materialism is false.

As with the conceivability argument, it is possible to disagree with Jackson's conclusion that materialism is false, but still use the argument to establish the explanatory gap. A standard materialist reply to Jackson is as follows. The fact that Mary will seem to learn something new upon seeing a ripe tomato for the first time does not show that the facts about conscious experience are distinct from the facts about what is going on in her brain. It could be that she is not learning new facts, but rather learning to represent them in a new way, using new concepts.

Nevertheless, one can reply that if the physical and functional theory really explained the qualitative character of visual states, Mary should be able to tell in advance what the experience would be like. Yet it seems plausible that if, instead of a ripe tomato, she were presented with a flat rectangular patch of red immediately after leaving her black and white prison, she would not know what color she was looking at. In other words, all the physical and functional descriptions of color experience do not allow her to predict its qualitative character – and this is precisely the situation we would expect if they do not explain it.

The Problem of Other Minds

Traditionally, the problem of other minds concerns our basis for attributing mental states to anyone but ourselves: how do I know that others have real experiences and are not just automata? We will not address this question here, but a related problem. First, let us distinguish between our functional structure and our physical structure. The former has to do with the causal pattern of interacting states that mediate between environmental stimuli and behavior. In principle, this same pattern could be realized, or implemented, in creatures with significantly different physical structures, provided that their internal physical states followed the requisite pattern of interactions. Functional structure admits of various levels of description. For instance, it is possible for two creatures to both satisfy the same generalizations concerning their ability to discriminate among colors, and to generally agree on their judgments of the relative similarity of colors, but to differ in the details of the algorithms for computing color information that are implemented by their visual systems. So at the more superficial level they would count as functionally identical with respect to color vision, but at a deeper level they would not.

Thus, creatures with a prima facie claim to mental lives can differ from us in two ways: with respect to (at least) deeper-level functional structure, and with respect to physical structure. Here the problem of other minds arises. Just how much, and in which ways, can a creature differ from us and yet still provide us with sufficient reason to attribute conscious experiences to it (or, experiences qualitatively like ours)? Notice that the problem is not one of ignorance, or at least not obviously. Let us imagine that we know all there is to know about the ways in which our candidate creature is functionally and physically like us, and the ways in which the creature differs from us. The

question remains: does this creature have conscious experiences, and, if so, what are they like? It is not clear how we could decide the matter.

However, if we had an adequate explanation of what it is about either our physical or functional structure that is responsible for our experience being like what it is for us (or being like anything at all), then, it seems, we would have a sound basis for making this decision with respect to other types of creature. We could just look for those features, at whatever level of description, that explain the nature of our experience. The fact that we do not know how to solve this problem about alien creatures demonstrates that we do not really know what explains experience in our own case. We do not know what level of functional or physical detail makes the difference.

ARGUMENTS AGAINST THE EXPLANATORY GAP

There are various ways for a materialist to respond to the explanatory gap. The most straightforward way is simply to deny it exists. Denial of the explanatory gap can take three forms: appeal to future science, conceptual reductionism, and eliminativism.

Appeal to Future Science

One might argue as follows. At present we do not have an adequate understanding of how conscious experience arises from the neurological processes of the brain, but this is no different from many other instances of current scientific ignorance. We also do not have an adequate understanding of memory, problem-solving, or many other psychological capacities that do not involve qualia. So those who attribute special urgency to the explanatory gap are just exhibiting unwarranted impatience with the progress of science.

The problem with this line of response is that it is not easy to imagine how future research could bridge this particular gap. In the case of psychological capacities like memory or problem-solving, while it is true that we do not know much about how these tasks are accomplished, still it is clear that the tasks themselves could be understood in terms of the implementation of a causal role. Now, either conscious experience can be conceptualized in similar terms or it cannot. If it can, then it is that analysis that is doing the principal work of bridging the gap (see below). If it cannot, then discovering more details about how the brain implements the various causal roles involved in information processing is not going to solve the problem. But what else can neuroscientific investigation yield except a theory of the implementation of the relevant causal roles?

Conceptual Reductionism

A fairly direct way to argue against the explanatory gap is to adopt a conceptual reductionist position (White, 1986). On this view, our idea of what it is to experience a certain quale is explicated in terms of a state's causal role. For example, we might think that to have a reddish experience is to be in a state that is normally caused by seeing red things, is judged similar to experiences of other red things, and normally leads to verbal reports like 'that's red'. If this is what we have in mind by an experience of red, then there is no problem explaining its qualitative character by reference to neurological processes. As long as we can see how the relevant process plays the requisite role, we have the explanation we are looking for. This position rules out the conceivability of a creature that satisfies the physical but not the mental descriptions true of us; it entails that Mary does not learn anything new when she emerges from the black and white room; and it gives us the principle we need to determine when physically diverse creatures share our experiences.

Eliminativism

To the extent that one finds the arguments for the explanatory gap convincing, one will take them as evidence that the 'causal role' analysis of our concept of conscious experience is inadequate. Another way to deny the explanatory gap, while admitting the inadequacy of a causal role analysis, is to endorse eliminativism (Dennett, 1991). According to the eliminativist it is true that we cannot analyze our idea of qualitative experience in causal role terms, but that is because our pretheoretic conception of conscious experience is confused and does not correspond to any real phenomenon. There is no explanatory gap because the phenomenon allegedly left unexplained by materialist theories – conscious experience – does not really exist.

Put that way, eliminativism seems absurd: feelings of pain, visual experiences of color, itches and tickles somehow do not really exist; they are mere illusions. However, there are two considerations that help to relieve the apparent absurdity. First, eliminativism seems more plausible after one has surveyed all the other attempts to deal with the explanatory gap and other problems posed by

conscious experience. If the advocate of the explanatory gap is right that we have no clear idea even where to look for a solution, it seems appropriate to consider the hypothesis that the reason we cannot find a solution is that there is something seriously wrong with the question.

Second, eliminativism is often associated with a positive account of why it should seem to us that we do have the sort of experience we think we have (Dennett, 1991; Rey, 1995). Something is indeed going on in us when we apparently experience qualia; but it is not what we think. To the extent that such positive accounts successfully explain our tendency to describe our experience in the way we do, the apparent absurdity of denying reality to that description is diminished. However, while some of the adherents of these positive accounts conjoin them with an eliminativist position, most do not.

ACCOUNTS OF THE EXPLANATORY GAP

Non-deflationary Accounts

The most direct account of the explanatory gap is the one that accepts it at face value: we cannot explain qualitative experience in terms of physical or functional mechanisms because conscious experience is not a physical phenomenon. According to Chalmers (1996), there is a basic law of nature – basic in the same way that the fundamental laws of physics are basic – that connects certain functional states with certain conscious states. Since this is a basic law, there is no way to explain the correlation in more fundamental terms. Qualia appear brute and inexplicable because they are.

Another approach is what may be called the 'mysterian' view. McGinn (1991) provides perhaps the clearest account of the mysterian position. On McGinn's view, conscious experience is in fact a material phenomenon, so he departs from dualists like Chalmers. However, there is an explanatory gap because we humans have limited conceptual resources: we cannot form the concepts needed to appreciate the connection between underlying physical processes and conscious experience. Nagel (1974) also thinks that the problem can only be solved with concepts we do not possess, though he is less pessimistic about our ability to develop such concepts.

McGinn and Nagel also offer more specific accounts of where the conceptual gaps lie. For McGinn, the problem largely has to do with our restriction to spatial concepts in scientific explanations, and the unsuitability of a spatial framework for our concepts of qualia. For Nagel, the problem has to do with the objective point of view adopted in scientific explanations and its inability to capture phenomena, like conscious experience, which can only be fully appreciated when apprehended as well from a subjective, first-person point of view.

Deflationary Accounts

A deflationary account of the explanatory gap is one that accepts its existence but does not see it as either threatening to materialism or demonstrating any deep mystery. There is a family of such accounts (e.g. Loar, 1997), all of which share two basic components. First, they appeal to the distinction between concepts and properties. Second, they appeal to some distinctive feature of the way we gain cognitive access to our own conscious experiences. The basic idea is that the explanatory gap is real, but merely reflects certain (explicable) features of our cognitive organization; so that on the proper materialist theory the explanatory gap is to be expected.

The idea behind the concept–property distinction is that properties are objective, mind-independent features of the world, and concepts are mental representations, or modes of presentation, of properties. It is possible to have more than one concept for a given property. For instance, the concept expressed by 'temperature' and the concept expressed by 'mean molecular kinetic energy' are distinct but they pick out the same objective property of objects. Similarly, it may be that our normal concepts for experiences and the scientific concepts derived from psychology and neuroscience, though distinct, nevertheless pick out the same properties.

Merely making the concept–property distinction is not sufficient to deflate the explanatory gap. In other cases of scientific reductions we deal with distinct concepts and yet do not face an explanatory gap. This is where the second component of the deflationary account is needed. The idea is that the concepts involved in our everyday thoughts about our experiences stand in a very special computational relation to those experiences, a relation that makes it difficult to combine them with our concepts for objects and properties other than our mental states. It is this incommensurability between our first-person concepts for our experiences and other concepts that makes the relation between physical and qualitative properties unintelligible to us. Accounts differ as to precisely how first-person

concepts of experience are distinguished from other concepts.

THE EXPLANATORY GAP AND COGNITIVE SCIENCE

For the most part, research in cognitive science can proceed without concern for the explanatory gap. We can investigate the computational basis of language acquisition and processing, visual processing, problem-solving, and the like – indeed, the entire domain of information processing psychology – without encountering the question of what it is like to occupy these various information processing states. Most of the states involved are not conscious anyway, since most of the processing underlying perception and thought occurs below the level of conscious awareness. Furthermore, even those states and processes that are conscious can be investigated to a great extent without regard to their qualitative character.

However, as long as we have not bridged the explanatory gap, or deflated it, cognitive science will face a fundamental limitation on its explanatory reach. There seems to be more to us than how we process information: there is what it is like to be us. Whether theories in cognitive science are likely to successfully bridge the gap in the near future is a matter of controversy.

Externalism

Intermediate article

Robert A Wilson, University of Alberta, Edmonton, Canada

CONTENTS

Externalism is the view in the philosophy of mind that an individual's social or physical environment is partly determinative or constitutive of that individual's mental states.

WHAT IS EXTERNALISM?

The debate between individualists (or 'internalists') and anti-individualists (or 'externalists') is sometimes glossed in terms of whether psychological (or mental) states are 'in the head'. At first sight, that is likely to seem a trivial question: of course mental states are in the head ('Where else could they be?', as Robert Stalnaker (1989) asked). So we must first articulate a version of the issue that makes it clearer why externalism is a substantive, and thus potentially controversial, claim about the nature of the mind; we will then show why the (sometimes rarefied) debate over externalism has some important implications for how the mind should be studied with the cognitive sciences.

Consider the question of whether the character of an agent's environment plays some crucial role in determining or fixing the nature of that agent's mind. A natural thought (one, in fact, common to those who disagree about the answer to this question) would be that agents causally interact with their world, gathering information about it through their senses, and so the nature of their minds, in particular what their thoughts are about, is in part determined by the character of their world. Thus, the world is a causal determinant of one's thoughts, and hence one's mind. That is, the world is a contributing cause of the content, or intentionality, of one's mind, that is, what one perceives and thinks about. This is just to say that the content of one's mind is not causally isolated from one's environment. Individualists and externalists in the philosophy of mind agree on this much. What separates them is the question of whether there is some deeper sense in which the nature of the mind is determined by the character of the individual's world. It is this 'deeper sense' of world–mind determination that we need to articulate.

We can approach this task by extending the brief discussion above of the idea that the content of the mind is in part causally determined by the agent's environment to explore the conditions under which a difference in the world implies a difference in the mind. Individualists hold that this is so just in case that difference in the world makes some corresponding change to what occurs inside the boundary of the individual; externalists deny this, thereby allowing for the possibility that individuals who are identical with respect to all of their intrinsic features could none the less have psychological or mental states with different contents. And, assuming that mental states with different contents are *ipso facto* different types or kinds of states, this implies that an individual's intrinsic properties do not determine or fix that individual's mental states.

This provides us with another, more precise way of articulating the difference between externalism and individualism about the mind. Individualists claim, and externalists deny, that what occurs inside the boundary of an individual metaphysically determines the nature of that individual's mental states. The individualistic determination thesis, unlike the causal determination thesis, expresses a view about the nature or essence of mental states, and identifies a way in which, despite their causal determination by states of the world, mental states are autonomous or independent of the character of the world beyond the individual. What individualism implies is that two individuals who are identical in all their intrinsic respects must have the same psychological states. It is the modal aspect to this implication that makes supervenience an appropriate concept to use in stating individualism more precisely: an individual's psychological states must supervene on the intrinsic physical states of that individual.

This implication, and indeed the debate over externalism, is often made more vivid through the fantasy of doppelgangers, pairs of individuals identical at the molecular level, and the corresponding fantasy of 'Twin Earth'. We will return to these fantasies later in this article.

HISTORY OF AND ARGUMENTS FOR EXTERNALISM

Hilary Putnam's paper 'The meaning of "meaning" ' (1975) introduced both of the above fantasies in the context of a discussion of the meaning of natural language terms. Putnam was concerned to show that 'meaning' does not and cannot jointly satisfy two theses that it was often taken to satisfy by then-prevalent theories of natural language reference: the thesis that the meaning of a term is what determines its reference; and the thesis that meanings are 'in the head', where this phrase should be understood as making a claim of the type identified above about the metaphysical determination of meanings. These theses typified descriptive theories of reference – first formulated by Frege and Russell – according to which the reference of a term is determined by the descriptions that a speaker attaches to that term. In attacking this view and its presuppositions Putnam focused on terms denoting natural kinds, such as 'water' and 'tiger', but he intended his attack, and his subsequent alternative theory of natural language reference, the causal theory of reference, to be more general than this.

Consider an ordinary individual, Oscar, who lives on Earth and interacts with water in the ways that most of us do: he drinks it, washes with it, and sees it falling from the sky as rain. Oscar, who has no special chemical knowledge about the nature of water, will associate a range of descriptions with his term 'water': it is a liquid that one can drink, that is used to wash, and that falls from the sky as rain. In a descriptive theory of reference, these descriptions determine the reference of Oscar's term 'water'. That is, Oscar's term 'water' refers to whatever it is in the world that satisfies the set of descriptions he attaches to the term. And since those descriptions are 'in the head', natural language reference on this view is individualistic. But now, to continue Putnam's argument, imagine a molecule-for-molecule doppelganger of Oscar, Oscar*, who lives on a planet just like Earth in all respects but one: the substance that people drink, wash with, and see falling from the sky is not water (i.e., H_2O), but a substance with a different chemical structure, XYZ. Call this planet 'Twin Earth'. This substance, XYZ, is called 'water' on Twin Earth, and Oscar*, as a doppelganger or twin of Oscar, has the same beliefs about it as Oscar has about water on Earth. (Recall that Oscar, and thus Oscar* has no special knowledge of the chemical structure of water.) Twin Earth has what we might call 'twin water' or 'twater' on it, not water, and it is twater that Oscar* interacts with, not water – after all, there is no water on Twin Earth. Given that Oscar's term 'water' refers to or is about water, then Oscar*'s term 'water' refers to or is about twater. That is, they have natural language terms that differ in their meaning, assuming that reference is at least one aspect of meaning. But, by hypothesis, Oscar and Oscar* are doppelgangers, and so are identical in all their intrinsic properties, and so are identical with respect to what is 'in the head'. Thus, Putnam argues, the meanings of the natural language terms that Oscar and Oscar* use are not metaphysically determined by what is in the head of the individual using those terms.

Putnam was attacking a tradition of thinking about language which was, in terms that Putnam appropriated from Carnap's *Aufbau*, 'methodologically solipsistic': it treated the meanings of natural language terms, and language more generally, in ways that supposed that the world beyond the individual language user did not exist. Since Putnam's chief point is one about natural language terms and the relationship of their semantics to what is inside the head, one needs at least to extend his reasoning from language to thought to arrive at a position that denies individualism about the mind itself. But given the tradition to which he was opposed, such an extension might be thought to be relatively easy, since in effect those in the tradition of methodological solipsism – from Descartes to Brentano, to Russell, to Husserl, to Carnap – conceived of natural languages and their use in psychological terms.

The term 'individualism' itself, as well as a series of thought experiments which made a case for externalism and in some ways parallelled Putnam's 'Twin Earth' thought experiment, was introduced by Tyler Burge in his paper 'Individualism and the Mental' (1979). Burge identified individualism as an overall conception of the mind prevalent in modern philosophical thinking at least since Descartes, and argued that our commonsense psychological framework for explaining behavior, our 'folk psychology', was externalist. Burge was explicit in making a case against individualism that did not turn on any controversial claims about the

semantics of natural kind terms: he developed his argument using agents with thoughts about arthritis, sofas, and contracts, so did not presuppose any type of scientific essentialism about natural kinds. Like Putnam's argument, however, Burge's argument does presuppose some views about natural language understanding. The most important of these is that we can and do have incomplete understanding of many of the things that we have thoughts about and for which we have natural language terms.

VARIETIES OF EXTERNALISM

Putnam's externalism is sometimes characterized as a form of 'physical' externalism, in contrast to Burge's 'social' externalism. According to Putnam, the character of the physical world (e.g. the nature of water itself) in part metaphysically determines the content of one's mind; while according to Burge the character of the social world (e.g. the nature of one's linguistic community) does so. While these terms may serve as a useful reminder of one way in which these two views differ, we should also keep in mind the 'social' aspect of Putnam's view of natural language: his linguistic division of labor. Important to both views is the idea that language users and psychological beings depend and rely on one another in ways that are reflected in our everyday, common-sense ways of thinking about language and thought. Thus, on both views, there is a social aspect to the nature of meaning and thought. This is partly what justifies the label anti-*individualism* for both of them.

There is another division between varieties of externalism that turns on their relationship with the cognitive sciences. Taking their cue from the linguistic emphasis of the Putnam–Burge arguments for externalism, some externalists, such as McDowell (1986) and Pettit (1983), have developed their views within a broadly Wittgensteinian tradition of thinking about the mind, one that views externalism as latent in our ordinary language and the 'language games' that we play with mental terms. But other philosophers, such as Segal (1989), Egan (1992, 1995) and Shapiro (1993, 1997), locate the debate between individualists and externalists within the areas of the philosophy of science that concern cognition. These philosophers have probed general notions, such as that of computation and mental representation, central to understanding cognition, as well as exploring specific research programmes within cognitive science for their relationship to the externalism debate.

EXTERNALISM AND COGNITIVE SCIENCE

At around the time when individualism was coming under attack from the externalism of Putnam and Burge, it was also being defended (e.g., by Fodor (1980) and Stich (1983)) as a view of the mind particularly apt for a genuinely scientific approach to understanding the mind, especially of the type that was being articulated within the nascent interdisciplinary field of cognitive science. For these defenders of individualism, there was something suspiciously unnaturalistic about the Putnam–Burge arguments, as well as something about their conclusions that seemed anti-scientific. Part of the defence of individualism and the corresponding attack on externalism turned on what we may call the 'cognitive science gesture': the claim that, as contemporary empirical work on cognition indicated, any truly scientific understanding of the mind would need to be individualistic, and thus could not be externalist.

Common to both Fodor's and Stich's views of cognitive science is the idea that an individual's psychological states should be *bracketed off* from the environments beyond the head in which individuals find themselves. Unlike Putnam and Burge in the papers discussed above, Fodor and Stich have focused on the relevance of individualism to psychological explanation, and have used their respective principles to argue for substantive conclusions about the scope and methodology of psychology and the cognitive sciences. Fodor (1980) contrasted a 'methodologically solipsistic' psychology with what he called a naturalistic psychology, and argued that since the latter (in which he included J. J. Gibson's approach to perception, learning theory, and the naturalism of William James) was unlikely to lead to reliable research in psychology, methodological solipsism was the only fruitful psychological framework for understanding cognition (see also Fodor, 1987). One implication of Fodor's position is that the relevant notion of content for cognitive science is *narrow content* (White, 1991). Stich (1978) argued for a syntactic or computational theory of mind that made no essential use of the notion of intentionality or mental content. Thus he deployed individualism in defence of an eliminativist view of content (see also Stich, 1983).

Although the 'cognitive science gesture' is a gesture rather than a solid argument that appeals to empirical data, it is not an empty gesture. Although Fodor's and Stich's arguments have not won widespread acceptance either by philosophers or by

cognitive scientists, they have struck a chord with the latter, perhaps not surprisingly since the dominant research traditions in cognitive science have been at least implicitly individualistic. Relatively explicit commitments to an individualistic view of aspects of cognitive science include Chomsky's (1986, 1995) use of the distinction between two conceptions of language (the 'I'-language and the 'E'-language, for 'internal' and 'external' respectively), Jackendoff's (1991) related, general distinction between 'psychological' and 'philosophical' conceptions of the mind, and Cosmides and Tooby's (1994) more recent emphasis on the constructive nature of our internal, evolutionary-specialized cognitive modules.

Two further points in brief. First, there is a large literature that discusses Marr's (1982) theory of vision in connection with externalism, beginning with Burge (1986), which raises and discusses many issues relevant to assessing the relevance of externalism for cognitive science (see Wilson, 2002). Second, an important way to develop the externalist view of the mind is to pursue its connection to 'embodied' or 'embedded' approaches to cognition (e.g. Clark, 1997; Hutchins, 1995; McClamrock, 1995). These approaches question business as usual in cognitive science, and their development is likely to be fruitful for the study of cognition.

PROBLEMS FOR EXTERNALISM

Two important problems for externalism, especially for practicing cognitive scientists, are its perceived incompatibility with the insights of the computational and representational theories of mind. The former of these theories holds that mental processing is a form of computation. The latter theory holds that we interact with the world perceptually and behaviorally through internal mental representations of how the world is (as the effects of perceiving) or how the world should be (as instructions to act). Provided that the appropriate internal representational states of the organism remain fixed, the organism's more peripheral causal involvement with its environment is irrelevant to cognition, since that involvement cannot alter the internal mental states that represent that environment. Wide computationalism (Wilson, 1994 and 1995) is one response to the first of these problems; Burge's (1986) interpretation of Marr's theory of vision is one response to the second. (For replies, see Segal, 1989 and 1998, and Matthews, 1988.)

Externalism has also been thought to give rise to various related, but more purely philosophical, problems; for example, by failing to make sense of the notion of mental causation (e.g. Block, 1986), or misconstruing the role of causal powers in psychological taxonomy (Fodor, 1987). Connecting such objections of individualism with the methodological formulations that have influenced cognitive science, it has been claimed that individualism provides a minimal constraint needed to arrive at psychological explanations that locate the mind suitably in the physical world, a psychology that taxonomizes its entities by their causal powers.

A further philosophical problem for externalism concerns its compatibility with a cluster of related epistemological issues: those concerning self-knowledge, a-priori knowledge, and scepticism.

Basic to self-knowledge is knowledge of one's own mind, and traditionally this knowledge has been thought to involve some form of privileged access to one's own mental states. This notion of epistemic privilege has been developed in a number of ways, all of which share the idea that there is an asymmetry between knowledge of one's own mind and knowledge of the minds of others and of other things in the world. (Indicative of the depth of these asymmetries in modern philosophy is the fact that an introduction to epistemology that reflects on skepticism will likely introduce the *problem of other minds* and the *problem of our knowledge of the external world*, but not the corresponding *problem of self-knowledge*.) Skepticism about one's own mind has seemed to be precluded by the very nature of self-knowledge.

Individualistic conceptions of the mind have seemed well suited to making sense of first-person privileged access and the asymmetry between self-knowledge and knowledge of the mental states of others. If mental states are individuated in abstraction from the environment 'beyond the individual', then there seems to be no problem in understanding how the process of introspection – turning our mind's eye inwards, to use a common metaphor – reveals the content of those states. To invoke the Cartesian fantasy in a way that brings out the asymmetry between self-knowledge and other forms of knowledge: even if there were an evil demon who deceived me about the existence of an external world – including the existence of other people with mental states like mine – the one thing that I could be sure about would be that I am having experiences with a certain content. As it is sometimes put, even if I could be deceived about whether there is really a tree in front of me and thus about whether I am actually seeing a tree, I can't be deceived about whether it seems to me that I am

seeing a tree. Thus individualism seems to confer a certain epistemic security on first-person knowledge of one's own mental states which the corresponding third-person knowledge lacks.

Externalism, by contrast, poses a *prima facie* problem for even the more modest forms of first-person privileged access, and has even been thought to call into question the possibility of any form of self-knowledge. For externalism claims that what mental states are is metaphysically determined, in part, by the nature of the world beyond the boundary of the subject of those states. Thus it would seem that in order to know what one is thinking (that is, to know the content of one's mental states), one would have to know something about the world beyond one's self. But this would be to assimilate our first-person knowledge of our own minds to our knowledge of other things, and so to deny any privileged access that self-knowledge might have. It implies that in order to know my own mind I need to know facts (perhaps difficult to discern) about the nature of the physical or social world in which I live; and so also suggests that in a range of ordinary cases where we might unreflectively attribute self-knowledge, I don't actually have self-knowledge.

We can express the problem in another way, which abstracts away from the differences between specific accounts of privileged access and specific accounts of externalism. Knowledge of one's own mental states, whether it be infallible, incorrigible, self-intimating, introspective, or a priori, has a special character. Knowing one's own mental states involves, *inter alia*, knowing their contents. Now, according to externalism, the contents of a subject's mental states are metaphysically determined, in part, by facts about his or her physical or social environment. Knowledge of these facts, however, does not have this special character. How is the special character of self-knowledge compatible with the non-special character of worldly knowledge, given the dependence of the former on the latter?

The problem can be represented as a supposedly inconsistent triad of propositions (see also McKinsey, 1991). Let *P* stand for the contents of our mental states; let *E* stand for facts about the environment; and let 'by introspection' stand for the special character of self-knowledge.

We know *P* by introspection. (Self-Knowledge) (1)

P are metaphysically determined in part by *E*. (Externalism) (2)

E are not known by introspection. (Common Sense) (3)

The claim is that one of these three propositions must be rejected. If we reject Self-Knowledge, then we give up on the idea that we have privileged access to our own minds; if we reject Externalism, then we return to individualism; and if we reject Common Sense, then we make a strange and implausible claim about our knowledge of the physical or social world.

Folk Psychology

Intermediate article

Shaun Nichols, College of Charleston, Charleston, South Carolina, USA

CONTENTS

Folk psychology is the body of information people have about the mind. It is often regarded as the basis for our capacity to attribute mental states and to predict and explain actions.

INTRODUCTION

In its broadest sense, folk psychology is the information that lay people have about the mind. Although the scope of folk psychology is thus vast, contemporary discussion of folk psychology in philosophy and cognitive science focuses mainly on the portion of folk psychology that guides the prediction and explanation of actions. This portion of folk psychology plays a central role in our everyday lives where folk-psychological prediction and explanation abound. We engage in such prediction for mundane tasks, like trying to figure out what the baby wants, what your peers believe about your work, and what your spouse will do if you arrive home late. Folk psychology is also involved in loftier endeavors, like trying to understand Descartes' reasons for thinking that many ideas are innate. So pervasive is the role of folk psychology in our lives that Jerry Fodor has remarked that if folk psychology should turn out to be seriously mistaken, it would be 'the greatest intellectual catastrophe in the history of our species' (Fodor, 1987, p. xii).

HISTORY

The idea that lay people have views about beliefs and desires and that people believe that actions result from beliefs and desires is hardly new. Indeed, Descartes would never have denied that people have such information. However, according to Descartes, the core information about the mind comes from introspection, which he regarded as an infallible source. Since introspection reveals the truth about the mind to each of us, for Descartes, the somewhat pejorative qualifier 'folk' is unnecessary: folk psychology *is* psychology.

In the twentieth century, two developments led to a revolutionary new picture of lay views of the mind. The first development was the challenge to introspection as a source of knowledge about the mind. This challenge occurred in both psychology and philosophy. In the early part of the century, psychologists advocating methodological behaviorism maintained that introspection was scientifically disreputable and could not be a source of knowledge about the mind. In effect, they forswore all talk of mental states in scientific psychology. In philosophy, Ryle (1949) launched a more sweeping attack. In his view, sometimes labeled 'logical behaviorism', it is a mistake to think that there are beliefs and desires inhering in an unobservable mind. Unlike the methodological behaviorists, though, Ryle was not against using terms like 'belief' and 'desire'. Rather, he maintained that such terms refer not to internal mental states, but to publicly observable phenomena, in particular, to dispositions to behave in certain ways under certain conditions. One important consequence of Ryle's view is that, since beliefs and desires are not internal states, they cannot possibly be revealed by introspection. Suspicions about introspection have exercised a powerful hold over psychology and the philosophy of mind ever since, even among those not sympathetic to logical behaviorism.

The second development occurred in the wake of the first. If we cannot rely on introspection to provide us with knowledge of the mind, then we need a new account of the source of our knowledge about the mind. Wilfrid Sellars (1956) developed what has turned out to be the most influential alternative to the introspectionist account of lay knowledge about the mind. Rather than maintain that the mind reveals its secrets to itself through introspection, Sellars suggests that lay people have a *theory* of the mind. Sellars proposes a myth about the origins of our common-sense view. He suggests that in the distant past, our ancestors never spoke of internal mental states like beliefs and desires.

Rather, these 'Rylean' ancestors only spoke of publicly observable phenomena like behavior and dispositions to behave. They even lacked terms for inner mental states. Then one day Jones, a great genius, arose from this group. Jones recognized that positing inner states like *thoughts* as theoretical entities provided a powerful basis for explaining the verbal behavior of his peers, and Jones developed a *theory* according to which such behavior is indeed the expression of internal thoughts. Jones then taught his peers how to use the theory to interpret the behavior of others. We are ultimately the beneficiaries of Jones' genius, since we still use his theory to interpret others' behavior.

Although Sellars explicitly presents this origin story as a myth, the point is that the myth allows us to see clearly a new picture of the nature of our common-sense views about the mind. In this picture, the common-sense view is a theory of mind, and this theory posits inner mental states, like thoughts, that are not publicly observable. So, the myth can be seen as one possible (and surely false) account of the origin of the theory. Sellars has provided us with an alternative account of common-sense psychology that does not rely on introspection. Nor, however, does it adopt the logical-behaviorist view that terms like 'thought' refer to publicly observable phenomena. This idea that folk psychology is a theory, whatever its origins, has come to be known as the 'theory theory' (Morton, 1980). Not only does the theory theory provide a new way to construe commonsense psychology once introspection had been displaced, but Sellars's account provides a new way to construe introspection itself. For Sellars suggests that the common-sense theory of mind is what we use to attribute mental states to ourselves as well as others.

FOLK PSYCHOLOGY AND THE SCIENTIFIC VIEW OF THE MIND

The very possibility that the theory theory might be correct requires us to be explicit about the potential gap between folk psychology and the scientific view of the mind. For if lay views about the mind derive, not from (infallible) introspection but from a common-sense theory, then they may well not cohere with mature scientific views of the mind. It now becomes a question of some moment whether folk psychology adequately characterizes the mind.

In order to address this question, one needs to know much more precisely what folk psychology is. In philosophy, one prominent way of characterizing folk psychology is to say that it consists of ideas or platitudes that everyone accepts, such as 'Persons in pain tend to want to relieve that pain. Persons who feel thirst tend to desire drinkable fluids. Persons who are angry tend to be impatient' (Churchland, 1988, pp. 58–59). According to Churchland, among others, the collection of all such platitudes constitutes the folk theory of mind that guides the prediction, explanation and interpretation of behavior. If one assembled such a list, one might then determine whether individual items on the list are corroborated or refuted by mature science.

Here the most prominent theme in philosophical discussions of folk psychology emerges. For, some suggest, if the folk account diverges widely from the scientific account, then we should conclude that the folk theory is wrong. Indeed, it may turn out that the folk theory is so thoroughly wrong that we must reject the theoretical posits of 'belief' and 'desire' and acknowledge that beliefs and desires don't really exist. This is the position of 'eliminative materialism': the folk theory is so far off the mark that we need to uproot the ontology of folk psychology entirely, just as we have uprooted the ontology of the supernatural. Eliminativist arguments have been developed in two rather different ways. Some, like Stich (1983), maintain that folk psychology will be at odds with a mature scientific psychology and that for this reason we may need to reject the folk ontology of beliefs and desires. Others, like Churchland (1981), see neuroscience as the proper scientific approach to the mind and argue that folk psychology will be at odds with a mature neuroscience; therefore, the folk ontology should be rejected in favour of a neuroscientific ontology.

Evaluating eliminative materialism is a complex undertaking. Eliminativist arguments typically depend on important assumptions about reference, reductionism, and other controversial issues in metaphysics (see, e.g. Lycan (1988), Stich (1996)). The eliminativist claim of primary interest here, though, is that folk psychology is a fundamentally mistaken theory. This has been a subject of much recent debate. Eliminativists like Churchland (1981) bemoan the explanatory failures and limitations of folk psychology, and maintain that these shortcomings indicate that mature science will be at odds with it. Others, however, like Fodor (1987), have celebrated the success of folk psychology. Indeed, Fodor maintains that folk psychology is much better at predicting behavior than contemporary scientific approaches, and that this predictive success suggests that the folk theory is roughly right and hence will be compatible with a mature cognitive science.

FOLK PSYCHOLOGY AS TACIT KNOWLEDGE

While philosophers have debated the continuities between science and folk psychology and the consequences that would follow from various scenarios, cognitive scientists have been concerned with exploring more systematically the nature of the capacity to attribute beliefs, desires, and emotions, and the capacity to predict and explain behavior. It has become increasingly clear that the 'platitude' view of folk psychology does not suffice to explain the lay capacity for psychological attribution, prediction, and explanation.

To take a simple example, people are quite good at inferring others' emotions on the basis of facial expressions. Very small differences in muscular activity in the face determine the emotion we attribute, and people do not seem to be able to articulate the principles behind these attributions. Indeed, some of these processes occur outside conscious awareness. For instance, subjects are more likely to judge a neutral face as sad if they have just been subliminally exposed to a smiling face (Underwood, 1995). Similarly, the attribution of goals from motion cues seems to exceed the informational resources of the available platitudes. In a famous study, Heider and Simmel (1944) showed subjects geometric objects moving around in a two-dimensional scene. Almost all subjects attributed goals to the geometric objects, and there was a good deal of consistency in subjects regarding certain events as chasing, fighting, and trying to get out of a box. What is guiding subjects' judgments here? Certainly we have no platitudes about the likely goals of geometric objects. The judgments seem to be guided instead by low-level motion cues. Determining which motion cues tend to produce which judgments is an area of active research, and the details are far from worked out. But there are a number of cues that seem to contribute to judgments of intention in geometric displays, including relative speed following a position change, orientation of the object relative to direction of motion, and the turning axis of the geometric object (see, e.g., Scholl and Tremoulet (2000)). It seems very unlikely that the final account of the motion properties that elicit judgments of intention will correspond with folk platitudes.

Such experiments suggest that the mechanisms underlying folk-psychological capacities are more intricate than is suggested by platitude accounts. Prediction, explanation and attribution are unlikely to be a matter of applying platitudes to instances. As with other interesting cognitive capacities (such as language comprehension and production and folk physics), we can expect that much of the information underlying the capacity is not consciously accessible. This does not refute the theory theory, of course, since one can simply adopt the view that the folk-psychological theory is at least partly 'tacit'. Indeed, that has long been the prevailing assumption in empirical research on folk psychology.

By far the most extensive empirical research on folk psychology has been focused on charting the development of folk-psychological capacities in children. This research illustrates in a dramatic way the central role that folk psychology plays in our everyday lives. The distressing social deficits of children with autism have been linked to a breakdown in their capacity for folk psychology (Baron-Cohen, 1995). Furthermore, an analysis of everyday speech in normal children indicates that from a very young age, they talk a great deal about beliefs, desires, intentions, and emotions (Bartsch and Wellman, 1995). And this is not just talk. Experimental evidence indicates that children are good at predicting a person's behavior on the basis of that person's beliefs, desires, and emotions (Gopnik and Meltzoff, 1997). Some important capacities emerge at a surprizingly early age. For instance, there is evidence that 18-month-old children can attribute desires on the basis of facial expressions (Repacholi and Gopnik, 1997). Most researchers in the field agree that these capacities depend on a tacit theory of mind. In view of the early emergence of folk psychology in normal children and its breakdown in autism, many researchers maintain further that the tacit folk psychology theory has an innate basis. However, even among those who agree that folk psychology is a tacit theory with an innate basis, there is much disagreement about the nature of the tacit theory. On one account, this body of information is very much like a scientific theory, and the process of development is really a process of theory revision, much like the process of theory revision in science (see, e.g. Gopnik and Meltzoff (1997)). On another account, the tacit theory is not at all like a scientific theory, but rather is represented in an innate module with restricted information flow to other parts of the mind. This module does have to develop, but its development is a constrained process of maturation rather than an open-ended theory revision process (Leslie, 1994).

SIMULATION THEORY

While theory theorists debate among themselves the nature of the folk theory, there is a major

challenge to the theory theory, the 'simulation theory'. According to the simulation theory, one does not use a psychological theory in predicting a person's behavior; rather, one pretends to have the mental states of the person and then runs one's own decision-making mechanisms 'offline' using these inputs. The resulting decision is then used to predict what the person will do (Gordon, 1986; Goldman, 1989). This approach is a departure from the theory theory since it explains important folk-psychological capacities by appealing to something other than a tacit body of knowledge about the mind. In fact, the simulation theory has made the very term 'folk psychology' problematic since this term is usually associated with the theory theory. As a result, 'mindreading' is often used as a more theoretically neutral term for the cluster of capacities we have for attributing mental states and predicting and explaining behavior.

The simulation theory has one overriding virtue. It gives an elegant explanation of the remarkable success of lay prediction of thought and action. Typically, when I am trying to guess what a target person is going to do, it's plausible that the target and I share similar cognitive mechanisms. So if I use my own cognitive mechanism to run a simulation, it's likely that the outcome of that simulation will be very much like what the target's analogous mechanism will actually do. This virtue of the simulation theory is illustrated well by an example from Paul Harris (1992). Harris asks us to imagine a psycholinguistics experiment in which we are to predict the grammaticality judgments of another English speaker on a set of sentences. It seems likely that we would be reasonably accurate at such a task. How is it that we would do so well? A simulation-theoretic explanation is that we use our own mechanisms for judging grammaticality and then we attribute the output to the subject. So, if our own mechanisms produce the judgment that a sentence is grammatical, we attribute that judgment to the subject. Given that the mechanisms that produce judgments of grammaticality are extremely complex, to explain success in this task, a theory-theoretical account would have to appeal to an improbably vast amount of tacit knowledge about how people make grammaticality judgments. The simulation-theoretic alternative is almost certainly a better explanation.

It is important to note that in Harris's example, no pretense is involved; so the example is not entirely parallel to the 'offline simulation' account. But the example succeeds in showing that prediction of behavior will at least sometimes rely on resources that go beyond a tacit theory of psychology, and that in some cases at least, we use a simulation-like process to predict others' behavior.

Thus, simulation (or simulation-like) processes plausibly play some role in mindreading. How much of a role does simulation play? One proposal, 'radical simulation', is that simulation explains everything that the theory theory purported to explain, including all attribution of mental states, prediction of behavior, and explanation of behavior (see, e.g. Gordon (1986 and 1996)). This radical view led some simulation theorists to suggest that there *is* no folk psychological theory. It was noted above that even Descartes would not have challenged the claim that people have a body of information about the mind. But radical simulationists challenge precisely that claim. This would imply that the debate over eliminativism needs to be overhauled. For if there is no folk-psychological theory, it cannot be the case that the theory is false.

However, the radical simulation theory has few advocates. One problem for radical simulation is that there are many cases in which we are very bad at predicting what people will do, and simulation theory has difficulty explaining our failures in these cases (Stich and Nichols, 1992). There is a large body of literature in social psychology documenting situations in which subjects behave in ways that seem surprising to common sense. For example, in an experiment demonstrating the 'endowment effect', Kahneman *et al*. (1990) gave a coffee mug to subjects in one group, the 'endowed' group, and then offered the subjects the opportunity to trade the mug for various amounts of cash. Another group of subjects, the 'unendowed' group, was not given the mug but was allowed to choose between the mug and various amounts of cash. Subjects in the endowed group tended to place a much higher cash value on the mug than subjects in the unendowed group. Most people find this result interesting, and part of the reason it's interesting is because it's surprising. Yet if simulation theory explained all of mindreading, it's puzzling why we are surprised by the result. For we should be able to imagine ourselves in the endowed subject's situation and let our own cognitive mechanisms determine what value we would place on the object. Indeed, recent research confirms that we are not successful at this imaginative exercise. Loewenstein and Adler (1995) explored whether subjects would be able to predict the value they themselves would set on an object if they were endowed with it. They handed subjects a coffee mug and asked the subjects to imagine that they owned the mug and to indicate how much they

would be willing to sell it for if they owned it. After they had completed this part of the task, they were told that they could in fact keep the mug – it was theirs. Then they were once again asked to indicate how much they would be willing to sell it for. It turned out that subjects were bad at predicting their own judgments. They tended to want significantly more money when they were endowed with the object than when they were merely imagining that they were endowed with it. If we made judgments like this using simulation, one would expect subjects to be very good at this sort of task. And this is only one example among many similarly surprising results from social psychology. Indeed, if the simulation theory accounted for all of our mindreading capacities, one would expect social psychology to be a radically different discipline, with few surprising results. The theory theory, by contrast, can provide a natural explanation of these folk mistakes by maintaining that the body of information that guides our judgments in these cases is incomplete. The tacit theory is missing information in crucial places, and the absence of this information leads to the mistakes in our predictions.

A second problem with radical simulation is that for many normal, successful attributions of mental states, it is difficult even to devise a simulation theory that would explain how we arrive at the mental state attributions. This point is perhaps clearest in the case of attribution of perception. You know that if you are sitting at the dinner table, the person opposite you can see your face but not your knees. But if she puts her head under the table, then she may well be able to see your knees. It is not at all clear how pretending to have the mental states of the other person is going to tell you whether she has visual access to your knees. By contrast, the tacit theory approach suggests an obvious answer. You calculate information about the opacity of the table, the line of sight, the amount of ambient light, and so on, and from this information the tacit theory of mind (which would presumably have information about when a subject is likely to see something) produces a perceptual attribution.

Although radical simulation currently has few advocates, the simulation theory has considerably altered the landscape of folk psychology. Researchers from both sides of the simulation debate have mostly converged to the view that a full explanation of the capacities for attribution, prediction and explanation will require a hybrid account, appealing both to simulation processes and to tacit knowledge about mental states (see, e.g. Goldman (2000); Nichols and Stich (forthcoming)). Simulation theory requires a significant revision of the idea that lay understanding of other minds derives from a folk-psychological theory, and this has implications for both cognitive science and philosophy. Firstly, it suggests that the capacity for mindreading cannot be entirely captured by traditional cognitive models. The kinds of mechanisms exploited in mindreading will be very different from the kinds of mechanisms exploited in, say, folk physics and folk biology. Secondly, if simulation processes play an important role in mindreading, much of the eliminativist debate is too crude. For a large part of our mindreading capacity may be insulated from the eliminativist critique. On the other hand, in so far as the success of mindreading depends on simulation-like mechanisms (as opposed to tacit theory), the success of mindreading cannot be casually used to support the claim that the folk-psychological theory is largely true.

INTROSPECTION REVISITED

A second major challenge to the theory theory emerges from a reassessment of the capacity for introspection. One of the historical precursors of the theory theory was the repudiation of introspection as a reliable source of information about the mind. However, introspection fell into disrepute largely under the influence of behaviorism. It is not clear that the reasons for renouncing introspection are still decisive for cognitive scientists who reject behaviourism.

Many cognitive scientists, in fact, still maintain that the available evidence indicates that the only way to access one's own mental states is via the theory of mind (e.g., Nisbett and Wilson (1977); Gopnik (1993)). This view effectively embraces Sellars's early suggestion that the folk theory of mind is essential not only for attributing mental states to others but also for attributing mental states to oneself. Although the theory-theoretical approach to introspection is still very influential, some researchers have recently begun to defend alternative cognitive accounts of introspection according to which access to our own minds does not depend on the theory of mind (Goldman, 1993; Nichols and Stich, 2002). Goldman suggests further that introspective access might provide the basis for our concepts of belief and desire. In this case it might turn out that the theory of mind depends on introspection rather than the reverse.

The question of the nature of introspection and its possible role in generating our understanding of others' minds is far from settled. But whatever the outcome of this debate, there is every reason to

think that our capacity for mindreading is subserved by a diverse and intricate set of mechanisms. Although it is likely that the theory theory explains part of that capacity, it probably cannot provide a complete account. Rather, our capacity for mindreading probably also depends on simulation-like processes and perhaps even introspective mechanisms that are independent of the theory of mind.

Free Will

Intermediate article

David Hodgson, Supreme Court of New South Wales, Sydney, New South Wales, Australia

CONTENTS

The expression 'free will' has been understood as a capacity of human beings to engage in voluntary conduct in accordance with their own unconstrained choices. The questions of how such capacity could relate to causation as understood by the physical sciences, and whether human beings do have such capacity, have not yet been decisively answered.

INTRODUCTION

Problems associated with the correct understanding of the concept of free will, and with the existence and exercise of the human capacity for voluntary conduct, have been debated since the time of the Greek philosophers. Developments in science, particularly during the last four centuries, have tended to support the universal applicability of laws of nature, apparently leaving little scope for any capacity for voluntary conduct that is not itself entirely subject to and determined by the same laws. However, scientific understanding of consciousness is still very limited, and there are reasons to think that consciousness may play a role in human behavior that is not entirely governed by or explicable in terms of the operation of laws of nature upon physical systems. Accordingly, there are still questions concerning free will that are far from settled.

THE CONCEPT OF FREE WILL

The expression 'free will' refers to a capacity or power, supposedly possessed by human beings, to engage in voluntary conduct in accordance with their own unconstrained choices. The questions whether or not human beings do have such a capacity, and if so, how it works and what is its significance, depend in part on what the concept itself is taken to involve.

Most would agree that the concept involves an ability to act consciously, rationally, and without constraint. The word 'will' refers to the capacity for volition, in the sense of the initiation and execution of voluntary conduct; and voluntary conduct is understood as requiring consciousness and control of the conduct in question. The word 'free' carries the notion that the conduct is the result of a choice unconstrained by matters outside the control of the person acting. Control of conduct and choice themselves presuppose some minimum rationality.

Associated with the concept of free will is the concept of *responsibility*: human beings are widely regarded as being responsible for their voluntary actions, precisely because these actions are considered to be under their control. Accordingly, it is widely regarded as appropriate to praise or blame, or reward or punish, a person for voluntary conduct, to an extent that is in some sense proportional to the merit or demerit of the conduct. This is reflected in criminal law, which includes quite elaborate rules for determining whether persons are to be considered responsible for conduct that is objectively in breach of the law.

A central problem concerning the concept of free will is how it relates to theories of causation. One common view of causation is that for an event A to be caused by prior events B, C, D, etc., those prior events must amount to sufficient conditions for the occurrence of event A. For free will to make sense, it would seem that a person's voluntary conduct would have to be caused by the person's exercise of the capacity to engage in such conduct; but what then causes the exercise of the capacity? On this view of causation, there must have been prior sufficient conditions for this, and further prior sufficient conditions for those prior sufficient conditions, and so on.

Associated with this issue is the relationship between free will and *determinism*. If all events are caused by prior sufficient conditions, it would seem that any event that occurs, including any human action, must be determined, indeed

predetermined, by its causal antecedents. Another way of putting much the same idea is to say that any event that occurs is uniquely determined by prior conditions and laws of nature.

One controversy concerning free will is whether the concept of free will should be understood in a basic sense, according to which free will is not excluded even if all choices and exercises of control are themselves predetermined by prior sufficient conditions outside the control of the person acting; or whether it should be understood in a strong sense, as attributing to human beings a power to choose, the exercise of which is not itself entirely predetermined by prior conditions outside the control of the person acting.

The other main controversy concerning free will is whether or not human beings really do have free will, particularly if it is understood in a strong sense.

HISTORY

The history of ideas relevant to the relationship of free will to the cognitive sciences can be seen as one of continuing assaults on the strong sense of free will.

Although there were significant discussions of free will by Greek and medieval philosophers, a convenient starting point for the history of issues relevant today is the seventeenth-century philosopher René Descartes (1986). His famous dualist view of the human mind as an immaterial substance distinct from the material body was significant at the time, not so much because he asserted that there was a free-willing 'ghost' affecting the operation of the human brain, but because he asserted that there were no such ghosts anywhere else. His dualism thus legitimized the application of the physical sciences to everything apart from the human mind: all systems other than the human mind were conceived of as changing or developing over time in accordance with impersonal laws of nature, thus excluding even from animals any conscious control of their actions that was not simply a working out of causation amenable to the physical sciences.

Later in the seventeenth century came the physics of Isaac Newton. Newton's three laws of motion were proposed as applying without exception to all physical matter, and they asserted that, given the mass, position, and motion of any piece of matter at one time and the forces acting on it over a period following that time, its positions and motion during that period were uniquely determined; and Newton's law of gravitation gave rules determining the quantity and direction of the force of gravity at any point. Newton himself did not spell out what that might mean for the physical matter of the human brain or for the dualism of Descartes, but the eighteenth-century French mathematician Pierre Laplace pointed out that, under the Newtonian scheme, initial conditions plus laws of nature determined the future, which could thus be exactly calculated by a being with sufficient information and intelligence; and Laplace made no exception for the human brain, and left no room for any independent efficacy of free will.

Also in the eighteenth century, the British philosopher David Hume (1888) made a further assault on the strong sense of free will with his philosophy of causation and action. Causation, according to Hume, was simply a matter of the regularity with which one type of event followed another type of event; that is, at bottom, the succession or unfolding of events over time conformably with regularities that could be expressed as laws. Hume thereby denied any significant causal role to the efficacy which humans seem to experience in their own voluntary actions and choices.

On the other hand, the German philosopher Immanuel Kant (1956) defended the strong sense of free will by distinguishing between the operation of causation in the realm of phenomena (things-as-they-appear-to-us) and that in the realm of noumena (things-as-they-really-are-in-themselves); and suggesting that, while deterministic law-governed causation operates in the former realm, it does not or need not do so in the latter. Thus, he said, human beings as noumena can be free, although as phenomena they are subject to deterministic causation. Few today find this a satisfying resolution to the problem.

During the nineteenth century, progressive scientific developments gave further support to the view that all matter behaved wholly in accordance with impersonal laws. Two were of particular significance: James Clerk Maxwell showed how the forces associated with electromagnetic radiation, including visible light, could be calculated by reference to mathematical rules, analogous to Newton's law of gravitation; and Charles Darwin's theory of evolution provided an explanation both of how the huge complexity and variety of life could have arisen from simple beginnings by the operation of impersonal laws of nature, and also of how animals and humans could have come to give the appearance of making choices, even if they were in reality only operating as determined by the impersonal laws.

The twentieth century saw further developments challenging the strong sense of free will. Albert

Einstein's theories of relativity appeared to support and advance the view that there are universal laws of nature governing all systems: his special theory, among other things, provided for a modification to Newton's mechanics so as to achieve full consistency with Maxwell's theory; and his general theory offered a deeper explanation of the gravitational force, and also accounted for certain observations which could not be accounted for by Newton's theory. The work of Sigmund Freud directed attention to the fact that much human motivation is unconscious or barely conscious; and since then, it has been impossible to maintain a view of human agency as a matter of wholly conscious decisions based on wholly conscious motives.

The invention of quantum mechanics (QM) in the 1920s challenged the determinism of the classical physics of Newton, Maxwell, and Einstein; but the only indeterminism postulated by QM was *randomness*, so that QM did not directly support the strong sense of free will. In other ways, QM tended to confirm the universal application of laws of nature: it showed how events at the atomic level could be explained by laws that also accounted for the substantial accuracy of classical physics at larger scales; and it also provided the basis for Linus Pauling's explanation of the chemical bond in terms of quantum physics, showing how chemical properties of matter could be explained by basic physics.

In the second half of the century, Crick and Watson's discovery of the structure of DNA showed how life itself could be explained by the laws of physics and chemistry. And the advance of the cognitive sciences has enabled more and more aspects of the working of the human brain to be understood in terms of the operation of laws of nature on physical systems. (I will look in more detail at this below.) However, there is still little understanding of consciousness in general, and its role in voluntary conduct in particular; so that, as considered in the final section, the problems of free will cannot be considered solved.

DIFFERENT VIEWS AND THEORIES OF FREE WILL

Compatibilism

Most people accept that human beings have a capacity to engage in voluntary conduct, in accordance with their own unconstrained choices; but on the other hand, many think it implausible to suggest that human voluntary conduct somehow stands outside the causal order studied by the physical sciences. Accordingly, a popular theory of free will is that free will is compatible with that causal order. In substance, this is taken as meaning that free will is compatible with determinism, because the proponents of this view assume that any indeterminism suggested by QM does not relevantly affect the causation of actions, so that for all practical purposes associated with problems of free will, even QM can be considered deterministic; and compatibilism is sometimes called *soft determinism*.

This theory adopts the basic sense of free will introduced in the opening section, and claims that this sense captures all that is important in the concept (Dennett, 1984). Human beings have freedom and responsibility just because they are free to act in accordance with their own choices and to do whatever it is they most want to do; and it does not matter that their choices and their wants may themselves be determined by prior circumstances and impersonal laws. Furthermore, it is said, our choices can be rationally based on our beliefs and desires, even if they are at the same time causally determined by them or by their neural correlates. Compatibilism is also expressed in terms of one's ability to have done otherwise than one actually did *if* one had chosen or wanted to do otherwise, with this ability or freedom (and its associated responsibility) not being excluded even though it is the case that one *could not in fact* have chosen or wanted to do otherwise.

Compatibilism correctly asserts that determinism is not the same as *fatalism*: while fatalism suggests that what will be will be, no matter how much or how little we deliberate over alternative courses of action or strive to achieve goals, determinism can accept that deliberation and striving do make a difference. And compatibilism correctly asserts that determinism does not entail *predictability* of human conduct.

Some compatibilist thinkers have gone so far as to say that determinism is necessary for free will: following Hume, they have asserted that, if there were any indeterminism in human conduct, this would mean that actions arose from something other than a person's character, beliefs, and desires, and would not be under the person's control (see Hobart, 1934).

Another strand of compatibilist thought, again following Hume, is that the imposition of rewards and punishments makes sense only if they have consistent effects, in accordance with ordinary notions of causation; and that, quite independently of any strong sense of free will, punishment is justified by its consequences, and it is appropriate to limit punishment to voluntary conduct because for

the most part it is only voluntary conduct that can be deterred by threats of punishment (see Hart, 1968).

Hard Determinism

Another theory of free will agrees with compatibilism in holding that human actions are caused deterministically, but departs from compatibilism by asserting that this means that human beings do not have free will in any substantial sense. That is, it says that the basic sense of free will adopted by compatibilism does not capture what is important in the concept, and that determinism is both true and incompatible with free will as properly understood. This theory has been called *hard determinism*.

A central argument for the view that determinism is incompatible with free will is the 'consequence argument', which has been stated as follows by an opponent of determinism:

> If determinism is true, then our acts are the consequences of the laws of nature and events in the remote past. But it is not up to us what went on before we were born, and neither is it up to us what the laws of nature are. Therefore the consequences of these things (including our present acts) are not up to us. (van Inwagen, 1983, p. 16.)

Hard determinists can support many of the compatibilist ideas outlined above. The real difference is that they say there can be no such thing as genuine free will and responsibility. One variant of the consequence argument, which highlights the basic dilemma of responsibility, has been put as follows:

> (1) There is a clear and fundamental sense in which no being can be truly self-determining in respect of its character and motivation in such a way as to be truly responsible for how it is in respect of character and motivation.
>
> (2) When we act, at a given time, the way we act is, in some quite straightforward sense, a function of the way we then are, in respect of character and motivation. We act as we act *because of* how we then are, in respect of character and motivation.
>
> (3) It follows that there is a fundamental sense in which we cannot possibly be truly responsible for our actions. For we cannot be truly responsible for the way we are, and we act as we act because of the way we are. (Strawson, 1986, pp. 311–12.)

So according to hard determinists, free will and responsibility are illusions, and it is best to fashion our interpersonal relationships and our legal systems in the light of this reality.

Libertarianism

The third main theory of free will has been called *libertarianism*: it asserts both that free will is incompatible with determinism, and that human beings do have free will, so understood.

Libertarianism meets the dilemma of responsibility by accepting that nothing a person does or can do *at the time of any choice or action* can make the person responsible for the way the person then is, in respect of character and motivation – but claims that the way the person then is, in respect of character and motivation, does not predetermine what the person does. It only predetermines what the alternatives are and how they appeal, and provides the capacity to choose between them; so that the person can be responsible for *the way the person exercises the capacity to choose*. That responsibility may be greater or less, by reason of the nature of the choice posed by the way the person now is – the harder it is, by reason of the person's inclinations, for the person to make the 'right' choice, the less blameworthy will be the 'wrong' choice – but on this view, normal adult human beings always have some responsibility for their choices and voluntary actions. And this means in turn that the person may have some responsibility *through prior choices* for the way the person now is in respect of character and motivation, and thus for presently operating reasons and the way they appeal (see Hodgson, 1999).

One variety of libertarianism supports what is called *agent causation*, the view that the causation of human actions is a special kind of causation; in that while ordinary events are caused by other prior events, human actions are caused not by prior events but by the human agents who perform the actions. This view faces the difficulty that events do seem to have an important role in the causation of human behavior, and so it is very hard to explain just how agent causation could work.

Although libertarians recognize that the randomness of QM cannot directly support the strong sense of free will, some do see three features of QM as providing indirect support: (1) its indeterminism, leaving room within which free rational choices could be made; (2) its nonlocality, suggesting the possibility of global influence from combinations of events in extended regions of the brain; and (3) its reference to observation, suggesting that participation of conscious observers may be as fundamental as laws of nature in the operation of the universe (Hodgson, 1991, 1996, 1999, 2002).

BEARING OF COGNITIVE SCIENCE ON FREE WILL

As noted earlier, the advance of the cognitive sciences has enabled more and more aspects of the

working of the human brain to be understood in terms of the operation of laws of nature on physical systems. It has thereby apparently further reduced the scope for any independent operation of human free will.

As considered in detail in other essays in this encyclopedia, much is now known about the operation of the brain as a physical system. At the level of the individual neurons of the brain, a great deal is now known about what causes them to fire or not fire; how electrical signals are transmitted within neurons and then passed across the synapses to other neurons by means of chemical transmitters; and how all this is affected by the chemistry of the brain. Much is also known about the patterns of connections between the neurons of the brain, and what regions of the brain are involved in particular cognitive functions and behaviour.

Along with physical investigation of the brain's operation, the cognitive sciences have thrown light on its functional organization, giving insights into how the physical processes of the network of neurons can give rise to sensation, perception, memory, problem-solving, emotions, and actions. The brain is considered as an information-processing system, which takes the information from sensory inputs, processes it in various ways, and gives out various kinds of outputs – generally resulting in physical actions, such as walking or speaking. Brain processes are sometimes considered analogous to those of a computing machine. This idea has its basis in the Church–Turing thesis, to the effect that anything that can be computed or calculated can be computed, given enough time, by a general purpose machine. There has been much theoretical and practical work on the idea that human cognitive performance (sensation, perception, reasoning, execution of decisions, etc.) can be reproduced or simulated by computers.

Efforts are being made to identify the brain processes involved in voluntary action, with some success, albeit without much understanding of the role of consciousness in these processes. Three other areas of investigation are of particular relevance to free will, suggesting that our conscious processes may be considered a tip of a cognitive iceberg, arguably having little if any role in determining what it is that we say and do: (1) investigations into the prodigious cognitive abilities of unconscious processes – for example, investigations into the pre-conscious information processing necessary for perception and for language use; into the so-called 'sleep-on-it' phenomenon, where an answer to a problem suddenly occurs to a person some time after ceasing to think consciously about it; and into the calculating and other capabilities of some savants, suggesting that all of us may have similar capabilities inaccessible to consciousness; (2) investigation of the nature and extent of unconscious motivation, not merely confirming that much of our motivation is unconscious, but also suggesting that we are adept at *rationalizing* our conduct by (unconsciously) fabricating, and then believing, plausible but untrue stories to explain why we did what we did (Gazzaniga, 1988; Wegner, 2002); and (3) investigations suggesting that consciousness comes too late for real-time control of actions.

One set of experiments in the third area (Libet *et al*., 1979) has suggested that there is a delay of about half a second between the arrival at the brain of a novel sensory stimulus and its experience in consciousness; and another (Libet *et al*., 1983) has suggested that, when actions are initiated, there are pre-conscious preparations over a similar time before the instant noted by the person acting as the instant of initiating the action. However, these results do not exclude conscious control in *shaping* voluntary conduct: in a concert performance by a pianist, consciousness comes too late to direct fingers to the right keys, but not necessarily too late to shape the performance in response to heard sounds and felt emotions. Also, as Libet himself pointed out, the results do not exclude a conscious veto exercisable right up to the instant of initiating an action. And they say nothing about considered decisions.

RELEVANCE OF FREE WILL ISSUES IN COGNITIVE SCIENCE

The fact remains that human brains seem to be adapted, at some cost in terms of complexity and energy use, to support conscious processes, suggesting that conscious processes must contribute significantly to survival and reproduction. And it is plausible that any such contribution would be by way of determining what voluntary conduct is undertaken – that is, how free will is exercised. The cognitive sciences have yet to explain how such a contribution could be made, in terms of the operation of laws of nature on physical systems.

Libertarians see an analogy here with the inability of logicians to explain human rationality in terms of the application of rules to premisses or data. 'Plausible reasoning' has yet to be justified by reference to rules of logic or probability or mathematics or any other rules of reasoning or information processing that human beings have discovered or devised: there is an element of

judgment in plausible reasoning that has not yet been, and perhaps cannot be, reduced to compliance with rules (Hodgson, 1991, 1995). One of the challenges to the cognitive sciences is to explain plausible reasoning in terms of rules, in a manner that is not self-defeating or circular, or alternatively to explain it in some other way – and any other way might well be consistent with strong free will.

Consciousness involves two tricks that do not appear to be performed by computers, and that have no known function in information processing as presently understood: I call them the *qualia trick* and the *chunking trick*. The former is the trick of associating types of physical processes in the brain with types of qualitative experience (or 'qualia') such as seeing blue or feeling pain; and the latter is the trick of chunking particular instances of these general types of experience into particular whole experiences of a person. This second trick is associated with what is called the 'binding problem' of consciousness, concerning how information carried in distinct parts of the brain (such as 'seeing red' and 'seeing circle') is brought together into a unitary conscious experience (such as 'seeing a red circle'). The cognitive sciences have had some success in identifying physical brain processes involved in both these tricks, but virtually none in explaining their functional role. And the understanding of these tricks at present falls far short of enabling the creation of an artificial system that could perform the tricks, or of stating what would distinguish such a system from one of similar information-processing power that could not perform them.

As one who prefers the libertarian view of free will, I believe that the two tricks may possibly be understood as having a function in combination with a third trick that they make possible, what I call the *selection trick*, involving the capacity to make selections between alternatives thrown up by unconscious information processing. On this view, unconscious information processing gives rise to alternatives available for selection, provides reasons on the basis of which a selection between them can be made, and determines the intensity with which such reasons are felt; and also gives rise to whole experiences having unique qualities with which general laws of nature cannot engage, but to which the person having the experiences can respond rationally in making the selection (see Hodgson, 2001).

This is a vision of free will that I believe could be usefully addressed by the cognitive sciences, particularly as they continue to investigate the unsolved problems associated with voluntary action, plausible reasoning, the qualia trick, and the chunking trick.

Frege, Gottlob

Introductory article

Jason Stanley, University of Michigan, Ann Arbor, Michigan, USA

Gottlob Frege (1848–1925) was a German mathematician and philosopher widely credited with discovering modern quantificational logic.

Gottlob Frege (1848–1925), a German mathematician and philosopher, did not receive much recognition during his lifetime. However, Frege is now recognized as one of the greatest logicians since Aristotle. Frege's contributions to mathematical logic did not, like those of, say, Georg Cantor or Kurt Godel, consist of proofs of startling new results. Rather, Frege, in his 1879 work, *Begriffsschrift*, introduced the concept of a formal system, in which mathematical proofs could be carried out rigorously and precisely. The theory developed in the *Begriffsschrift* was what would now be called second-order quantification theory, in which there are quantifiers ranging over objects and quantifiers ranging over properties (Frege's 'concepts'). Indeed, Frege is rightly described as the person who discovered modern quantification theory.

Frege's purpose in carrying out proofs within a formal system with clear axioms and rules of inference was, in the first instance, to demonstrate the truth of logicism. Logicism is the doctrine that arithmetic is a branch of pure logic, a view which had been contested by the philosopher Immanuel Kant. For logicism to be true, each arithmetical theorem must be derivable from axioms that are purely logical, together with rules of inference that are justified by reason alone, without appeal to psychological intuition. By couching the proofs of the axioms of arithmetic within a formal system, Frege believed he could ensure that no nonlogical step entered unnoticed into his proofs. Frege's great work, *The Foundations of Arithmetic*, was devoted to an extended philosophical introduction and defense of the thesis of logicism, as well as an informal sketch of the derivation of the axioms of arithmetic; part II of the *Grundgesetze* contains his actual attempted proofs thereof.

Unfortunately, the theory that Frege took to be logic turned out to be inconsistent, a discovery made by the philosopher and logician Bertrand Russell, and communicated to Frege in June of 1902. The problem lay with the fifth axiom of Frege's theory in the *Grundgesetze*. This axiom entailed that to every predicate, there corresponded the set of all and only those things of which that predicate was true. This principle leads directly to Russell's paradox, which involves the predicate 'is a set that does not contain itself'. Frege's Axiom 5 entails that there exists a set of all and only those things of which this predicate is true. However, the question arises whether this set is a member of itself, and either answer leads to a contradiction. Over the years, various repairs and modifications of Frege's system have been proposed, but the general consensus is that no repair of Frege's system yields a theory the axioms of which are all plausibly logical.

Despite the failure of logicism, Frege's technical writings have borne rich fruit. Frege's *Begriffsschrift*, the formal language in which his theories are couched, despite some notational complexities, clearly reflects the quantifier-variable reasoning that has now become so familiar. In the language, *n*th order universal quantifiers are the quantificational primitives, and they also function as devices for binding variables, as in standard contemporary formulations of the language of the predicate calculus. So the idea of a quantifier as a device for binding variables, so influential in linguistic theory and logic, is clear in Frege's work. But so too is the understanding of quantifiers as denoting 'second-level functions', in particular functions from properties to truth-values. This treatment of quantifiers has proven of great value in the semantics of natural language. Furthermore, his sophisticated discussion of the semantics of his formal system in part I of *Die Grundgesetze der Arithmetic* laid some of the groundwork for formal semantics, both in logic and linguistics.

Frege's defense of logicism raises important issues in epistemology. According to logicism, arithmetic is analytic, its propositions derivable from logic and definitions alone. Adherents to the positivist school of philosophy, such as Rudolf Carnap, took logicism to entail that arithmetic was devoid of substantive content. However, this is not how Frege construed logicism. In *The Foundations of Arithmetic*, Frege argues that analytic judgments can lead to substantive extensions of our knowledge. But analytic judgments, by their

nature, seem empty of content. So, one might think that any consequence of them would lack substantive content. The position that logic together with definitions can lead to substantive extensions of our knowledge is a bold anti-empiricist position in epistemology, one that has attracted considerable attention in recent years.

In addition to his work devoted to defending logicism, Frege made many other significant contributions to philosophy and cognitive science. In his 1892 paper 'On sense and reference', the defining paper of the analytic tradition in philosophy, Frege introduced the distinction between sense and reference which was to have a profound influence on future discussions of linguistic and mental intentionality. Other important notions, such as the discovery of the negation test for semantic presuppositions, appear for the first time in this work. In his 1918 paper, 'The thought', Frege had a sophisticated discussion of the content of indexical expressions such as 'I' which prefigured later work in the philosophy of language and mind on the ineliminable nature of indexicality.

Frege's nontechnical writings are best known for his distinction between sense [*Sinn*] and reference [*Bedeutung*]. In 'On sense and reference', Frege argues that two names that refer to the same object in the world, such as 'Mark Twain' and 'Samuel Clemens', may nevertheless present that object in different manners. So, while it is uninformative to be told that Mark Twain is Mark Twain, it can be quite informative to be told that Mark Twain is Samuel Clemens; similarly, one might believe that Mark Twain was a writer without believing that Samuel Clemens was a writer. According to Frege, this is because the names 'Mark Twain' and 'Samuel Clemens', while having the same reference, are associated with different senses. So, we may think of a term such as 'Mark Twain' as having a reference, namely the famous author, as well as a sense, such as that expressed by 'The author of *Huckleberry Finn*'.

The distinction between sense and reference also helped Frege address a problem about how to individuate mental states. Consider verbs such as 'believes', 'fears', and 'expects', which take sentences (sometimes headed by 'that') as complements. Such verbs appear to express relations between persons and the contents of their sentential complements. So 'John believes that Mark Twain is Samuel Clemens' expresses a relation between John and the content of the sentence 'Mark Twain is Samuel Clemens'. If the only notion of the meaning of a lexical item were the entity in the world it denoted, then it would seem that believing that Mark Twain is Mark Twain is the very same mental state as believing that Mark Twain is Samuel Clemens. For if the only notion of the meaning of a lexical item were its reference, then the content of the sentence 'Mark Twain is Mark Twain' would then be the same as the content of the sentence 'Mark Twain is Samuel Clemens'. However, it seems that someone may believe that Mark Twain is Mark Twain, without thereby believing that Mark Twain is Samuel Clemens. This suggests that the mental state of believing that Mark Twain is Samuel Clemens is distinct from the mental state of believing that Mark Twain is Mark Twain. If, following Frege, we take the content of a sentence (as used in a particular context) to be determined by the senses (rather than the references) of the terms that compose it, then we can explain the intuition that the belief that Mark Twain is Mark Twain is a distinct mental state from the belief that Mark Twain is Samuel Clemens. For on Frege's theory, the belief that Mark Twain is Mark Twain has a different content than the belief that Mark Twain is Samuel Clemens, since 'Mark Twain' and 'Samuel Clemens' have different senses.

Frege's distinction between sense and reference has had a profound influence on subsequent research into linguistic meaning. The idea that a theory of meaning for a natural language needs to have recourse to a more 'fine-grained' notion than that of reference proved to have wide applicability. For example, though Frege himself never took seriously talk about the modal properties of thoughts, later research by Rudolf Carnap and Alonzo Church (among others) into the semantics of modal discourse was influenced by Frege's discussions, since here too a more fine-grained notion than mere reference seems required to address the complexity of the phenomenon. Indeed, the term 'Fregean' is now used in the philosophy of language to refer to any position according to which names are semantically associated with something in addition to their referents.

Frege's view of the nature of senses (and hence of thoughts – the senses of sentences) was that they were abstract, mind-independent entities, much like numbers or sets. In entertaining a thought, one is in a relation to one of these abstract entities. This 'Platonist' conception of thoughts played a role in Frege's arguments against psychologism, the doctrine that thoughts were composed out of subjective, mind-dependent ideas. Frege was led to his Platonist conception of thoughts by his insistence on the publicity of content. If psychologism were true, then thoughts would not be communicable or shareable. Yet two people seem to be able to

share the same thought. Furthermore, by uttering a sentence, one seems to give voice to the thought it expresses. But if thoughts were composed out of subjective ideas, then a hearer could not grasp the thought someone expressed by her utterance of a sentence. The tension Frege recognized between psychologistic accounts of the contents of mental states and the apparent publicity of these contents remains an important issue for cognitive science today.

Functionalism

Intermediate article

David Braddon-Mitchell, University of Sydney, Sydney, New South Wales, Australia

CONTENTS

Functionalism is the view in the philosophy of mind that that what makes some state of some system a mental state is what that state does in the system.

INTRODUCTION

Functionalism is an influential doctrine in the philosophy of mind, which in various ways provided the philosophical impetus for early work in artificial intelligence and cognitive science. This article gives a characterization of the various forms of functionalism, where they come from and what their strengths and difficulties are. It concludes with a brief discussion of the connections between functionalism and cognitive science.

WHAT IS FUNCTIONALISM?

Functionalism about the mind is the view that what makes some state of some system a mental state is what that state does in the system – not, for example, what it is made of or any other purely intrinsic features of the state. This kind of view is familiar in other contexts. What makes something a thermostat is what it does: it turns heating or cooling on and off in a way that keeps temperature stable. The thermostat is multiply realizable: while an explanation of how a particular thermostat works may appeal to the differential coefficient of expansion between copper and iron strips welded together, there are other ways of building a thermostat (e.g. with an electric charge passed through a mercury column) that would produce something intrinsically different, but functionally the same. The mercury-column device is still a thermostat, despite its intrinsic difference from the bimetallic strip, because of the role it plays in the heating or cooling system as a whole.

Functionalism is compatible with dualism, since logically there might be nonphysical systems that count as minds in virtue of what they do rather than what they are made of. However, in this article we will concentrate on cases where there is something about what a physical system and its physical states do in virtue of which it has mental states. A functionalist about the mind thus looks for a specification of what a system comprising a body and a brain does in virtue of which it counts as having mental states.

Multiple realizibility is a necessary condition shared by anything that can be called functionalist. Once we have specified what a system must do so as to have mental states, realizing the system with different methods or materials will, according to functionalism, make no difference.

Most functionalists agree that the way to characterize what the state of a system does is by specifying the relations between its inputs, outputs and internal roles. Thus, for example, a belief that 'ice cream is near' might be characterized in part as the state of a system which is typically caused by ice cream, makes the system (a person) move towards ice cream in combination with a desire for ice cream, and so on.

There is, however, considerable disagreement between functionalists on a range of issues. These include: how we may discover the theory of inputs, outputs and internal roles that determines whether something is a mind; what kinds of inputs and outputs count; and even whether what something does is a matter of its causal influence on the world.

VARIETIES OF FUNCTIONALISM

At the highest level of abstraction there is a distinction to be drawn between 'analytic' (or 'commonsense') functionalism and 'empirical' functionalism.

Analytic Functionalism

According to analytic functionalism, we already possess the right theory of the inputs, outputs

and internal roles, in virtue of our mastery of mental-state language. We are able to attribute mental states to others from observations of their behaviors and the events happening to them, together with some very thin assumptions about how they work (such as that there are internal states causing the behavior, and they are not just puppets controlled from elsewhere). Because of this mastery we are able to predict and explain behavior in mental-state terms. The theory is said to give the meaning of such terms. What belief, desire, and so on, mean depends on their place in the theory that our predictive and explanatory practices reveal that we know. We cannot write down such a theory: it is very complex and difficult. But nonetheless it is held to be tacitly known, since if it were not then we could not explain the relatively widespread agreement in mental-state attributions given similar behavioral evidence. A useful analogy is with grammar. We are said to know grammar tacitly, as this explains our grammatical competence. Nonetheless, it takes an expert linguist to attempt to write down the theory, and even then there is vast room for disagreement.

Thus, the inputs and outputs that analytic functionalism takes to be definitive of mental states (but not the internal roles) must be environmental inputs and behavioral outputs, since these inputs and outputs are all we can directly observe in everyday life. And behaviors must be understood as typical effects on environments: hailing a cab is to be understood in terms of making cabs more likely to stop, rather than, say, intentions to do so, since the environmental effects are observable but the intentions are not.

There need be no commitment in all of this to the discreteness of mental states. The theory may reveal that a person is held to be in a mental state which believes that *P*, *Q*, *R* and so on, and desires that *A*, *B*, *C* and so on. It does not follow, though, that any of these individual beliefs or desires can be identified with some physical or architectural part of the system. The only commitment is to the possibility in principle of a system undergoing some (possibly small, and possibly holistic) change which would be enough to change just one of the beliefs or desires.

Empirical Functionalism

Empirical functionalism, on the other hand, denies that we already know in any sense the right theory of inputs, outputs and internal states that gives the meaning of mental-state terms. Rather, this theory has to be discovered by empirical investigation. (Nevertheless, something like the tacit theory of analytic functionalism may be used to select the paradigmatic mental beings – other humans in our case – for something must tell us what to empirically investigate; to unleash the cognitive sciences on glaciers would be futile. See Braddon-Mitchell and Jackson, 1996, Ch. 5.)

This leaves open the question of how best to characterize in different ways the level at which to look for inputs, outputs, and internal roles. For example, empirical study might reveal that the outputs, rather than being typical effects on the environment, are classes of motor responses of the body, or neural inputs and outputs at the periphery of the central nervous system or even of the brain. This last conception of the 'right' kinds of inputs and outputs is sometimes called 'psychofunctionalism'. (Block, 1991).

Another kind of empirical functionalism is concerned less with inputs and outputs than with more or less abstract specifications of what goes on inside the brain. While such theories retain the generic specification of functionalism as being concerned with what is done, this is not understood as what the system does to the world and what the world does to it. Rather, it is understood as what is going on internally, in a sufficiently abstract sense that there are various ways of making physically different systems that count as 'doing the same things' internally.

Functionalisms of this sort will tend to specify a kind of cognitive architecture or hypothesis about internal organization (e.g. Fodor's 'language of thought' hypothesis (Fodor, 1976, 1987)) which captures what it takes to have mental states. Extreme versions may specify something as abstract as a machine table, which can in principle be mapped onto many obviously non-mental physical systems. (*See* **Language of Thought**)

HISTORY

Functionalism has two fairly distinct historical roots, and this is partly why there are such different varieties of functionalism. Analytic functionalism is essentially a response to behaviorism, allowing mental states to be the hidden causes of behavior. J. J. C. Smart's materialism (Smart, 1959) is sometimes seen as opposed to functionalism. But in fact Smart emphasizes the 'topic-neutrality' of the analysis of mental states: the meaning of mental-state terms is given in part by the roles invoked by functionalists, and indeed his work foreshadows analytic functionalism. Armstrong's causal theory of the mind (Armstrong, 1968) is near to analytic

functionalism, and David Lewis (Lewis, 1972) is a standard reference. (*See* **Behaviorism, Philosophical**)

Empirical functionalism arose as a criticism of a certain understanding of an unrestricted type–type identity theory of the mind according to which any given type of mental state is unrestrictedly identical to some type of physical state. In Putnam (1975, p. 335), something like a nonreductive functionalism is seen as opposed to reductive physicalism. Sometimes in the work of Putnam, and in the tradition that follows, the sort of similarity that is relevant is thought to be discovered by uncovering empirically what the significant abstract features of the state are. Early work in computational artificial intelligence made it seem natural that the relevant abstract state might be something like 'the program that is being run', regardless of how it is connected to the world. Combined with philosophical interest in the 'necessary *a posteriori*' arising from, for example, Saul Kripke's work (Kripke, 1980), this made it seem plausible to many that the investigation of actual paradigmatic minds might reveal hidden internal features that are essential to having minds. (*See* **Mental Causation**)

Contemporary views, including perhaps Fodor's architectural model of the mind and the very different views of dynamical systems theorists, insist that there are internal, architectural features that account for mentality in a way which is undetermined by actual and counterfactual behavior.

ARGUMENTS FOR FUNCTIONALISM

Functionalism is popular partly because it is consistent with physicalism, while avoiding some of the problems associated with other physicalist views. It avoids the worst problems of behaviorism – especially its failure to provide behavioral analyses of individual beliefs – while allowing that mental states are the causes of behavior. It also avoids the main problem of the unrestricted type–type psychophysical identity theory: functionalism insists that some features of a physical system – even the substance of which it is made – may be irrelevant to mentality.

Functionalism provides the best explanation for the multiple realizability of minds. Furthermore, the different kinds of functionalism give us positive accounts of what the relevant features are, together with arguments to establish their relevance. Analytic functionalism – and the kinds of empirical functionalism that refer to the so-called folk roles – also explain how we are able to attribute mental states to entities from behavioral evidence.

Apart from the positive arguments for functionalism, there is the following negative argument: dualism (for independent reasons) and the remaining physicalist theories are ruled out, leaving functionalism as the remaining contender. The strength of this argument will depend on the strength of the objections to functionalism.

PROBLEMS FOR FUNCTIONALISM

Many objections to functionalism have been raised. Some of these are worse for some varieties of functionalism than for others.

Certain traditional arguments have involved imagining functional duplicates of human minds realized in ways that appear intuitively not to count as mental. These include John Searle's 'Chinese room' (Searle, 1980) and Ned Block's 'China brain' and 'Block head' (Block, 1981).

Searle asks us to imagine that we have written out in English the program that is realized in people who understand Mandarin, and in virtue of which they understand it. It is written down in a series of books, and we suppose that a monolingual English speaker is in a closed room with the books. He first receives a text in Mandarin, and he then receives questions – also in Mandarin – designed to test his comprehension of the text. He uses the books to perform (from his perspective) purely symbolic manipulations. He performs a huge number of line-by-line calculations, running the program written down in the book very slowly in his head, in the way that a computer programmer might try to mentally check a short piece of code. This process is repeated with the comprehension questions, and finally the English speaker, following the English directions, will draw certain Mandarin characters and place them in the 'out' slot. These will be good answers to the test, and might persuade those outside the room that there is some understanding of Mandarin, but in fact he understood nothing of it. In this example, understanding stands in for mentality, but appropriate variations could be devised (e.g. the English speaker has no beliefs about the propositional content of the story).

The severity of this problem depends on the kind of functionalism: the example assumes that the right understanding of functional duplication is at the 'program' level. Analytic functionalism, which specifies inputs and outputs not symbolically but in terms of typical environmental effects, may be unaffected, since the example does not provide a functional duplicate of a Mandarin speaker at that level: the outputs are not the typical effects of

understanding Mandarin. And empirical functionalisms that stress the importance of the mental architecture can reply that although the individual in the room fails to understand, there may be a virtual machine running on his or her wetware that does.

A variation of Ned Block's 'China brain' has much the same structure: we imagine a functional duplicate of someone's brain, made by equipping everyone in China with mobile phones and with instructions to make calls to certain numbers on receiving calls from certain numbers in a pattern that duplicates the brain's neuronal firing pattern. The intuition is supposed to be that there is functional duplication with no mental duplication.

One response is to deny this 'intuition' (no one phone caller has the mental states of the original person, but nor does any one of our own neurons have a mental state: this does not mean that the whole system does not). Another response is to note that, again, analytic functionalism is not affected, unless we connect the whole system to a robot capable of having the right environmental effects, and ensuring that the states in the simulation are suitably affected by environmental influences. But then the 'intuition' becomes even less plausible.

The idea behind the 'Block head' argument is to imagine a being programmed so that its interactions with the world are indistinguishable from those of a real thinker, but in such a way that, once we knew it, we would deny that the being had mental states. The suggestion is, roughly, that this could be achieved by prerecording sensible responses to all possible eventualities in a tree-like structure that would ensure that the responses produced at any time and under any circumstances are consistent with previous behavior.

The example, originally intended as an argument against behaviorism and for psychologism, appears to be a counterexample to analytic functionalism, since empirical functionalism requires that the only correct way to duplicate mentality is to duplicate the way we do it, where the internal roles are specified by more that just what it takes to account for behavior. We do not operate in this way, and presumably we will not deny our own mentality by discovering how we in fact function.

Analytic functionalists can reply that if we are able to recognize on inspection that the way the Block head works is not enough to ensure mentality, then it must be something that we know *a priori*. It is not an empirical claim by Block that such creatures do not have mental states. Block's example simply makes explicit what we tacitly know, and in that case it must already be part of the analytic-functionalist theory of the mind that a mental system cannot be organized in that way. The lesson for analytic functionalism is that there are some constraints on internal structure that are stronger than merely how that structure must affect and be affected by the environment.

Qualia and Consciousness

Some forms of functionalism have difficulty accounting for phenomenal experience – the 'raw feelings' of color, sound and touch, and other more subtle qualitative phenomena. (*See* **Qualia**)

An important objection is the so-called inverted spectrum problem (Shoemaker, 1975). If there were two individuals whose color experience was inverted – one saw yellow when the other saw blue, and so forth – but whose color language and other behavioral effects were the same, then they would be functionally indistinguishable. The invert, who saw yellow as blue, would nonetheless use the word 'yellow' for the blue experiences he would have of the yellow things. Thus he would agree that the sun is yellow, that it is the same color as the Bondi sand, and so forth.

This seems problematic for analytic functionalism because the states that mediate between inputs and outputs in this case play identical mediating roles, and hence must be classified as identical in a functional classification. Yet by hypothesis they are distinct qua qualitative experiences – and hence different mentally. This seems to refute the idea that mental classifications are functional classifications.

One response is to 'bite the bullet' and insist that this is a metaphysically impossible scenario. It appears to be conceivable because we appear to have a grasp of the essential intrinsic nature of color experience, but this is an illusion. A softer response is to acknowledge that a partial inversion might be possible: perhaps all the color language might be the same but other functional effects might be different. These might include, for example, the effects of colors on hunger, anger, and intermodal judgments (how similar colors are to certain sounds or sensations). In such a case there would be functional differences between the so-called invert and a normal individual. This partial inversion is genuinely conceivable, and it generates the illusion of conceivability of total inversion. Many, however, still claim to find total systematic inversion conceivable even after distinguishing it from partial inversion.

Empirical functionalism can avoid this problem more easily: color experiences may be identified

with particular neural states that typically play certain roles. Inversion could be explained by the state that typically plays the 'yellow' role taking on, in a rare case, the 'blue' role, and vice versa. The problem lies in justifying the claim that the state has that experiential quality: this will be untestable, since testing will be by the kinds of functional roles specified by analytic functionalism (for example, verbal outputs if we ask people about their phenomenal experience).

The Knowledge Argument and Conceivability Arguments

Frank Jackson's 'knowledge argument' against physicalism (Jackson, 1982) can also be deployed either as an argument against physicalism, and hence against physicalist functionalism, or (with a minor modification) against functionalism in general.

This style of argument proceeds via a thought experiment in which we are asked to imagine someone who knows all the physical facts about color vision, experience and so forth (in the variation, read 'functional facts' for 'physical facts') but has never actually had an experience of, say, redness. She has not been in the physical (or functional) state that is purportedly the one of experiencing redness, but knows everything about it. We then suppose that she actually sees something red. Intuitively it seems that she now learns a fact about that state which she did not know before: what it is like to see something red. But she knew all the physical (or functional) facts before, so if she has learned something new, then it must be some nonphysical (or nonfunctional) state fact that she learns. Therefore, physicalism (or functionalism) is false.

There is a considerable, and growing, literature on this argument. Most responses try to show either that the person would not learn any new fact (even if she acquires new abilities or know-how) or that if it is a fact, she must have known it all along in some way. Most physicalists and functionalists agree that something is wrong with the argument, but there is little consensus on what. Currently a popular idea is that conceivability and thought experiments are no guide to metaphysical possibility.

There are themes in common between this argument and the conceivability argument of David Chalmers (Chalmers, 1996), which has reinvigorated the discussion. Chalmers asks us to imagine functional duplicates of ourselves, which are in fact qualitatively dead. Allowing conceivability to be a guide to possibility, we discover that there could be (perhaps only if the laws of nature were different) functional duplicates that entirely lacked qualia. If so, then qualia do not supervene on functional states in the way required by functionalism. The legitimacy of the conceivability claim is bolstered by arguments that we fix reference on qualitative states in the first place via acquaintance with their phenomenal nature.

Again, replies often depend on separating conceivability and possibility. One reply is as follows. Even allowing conceivability to be a good guide to possibility, it is not clear what we are conceiving, for it may be part of our concept of experience that the nature of experience depends on what we discover about metaphysics. If we are in fact living in a dualistic world, then our concept connects us to something whose essence we grasp directly through experience; but if we are in fact living in a physicalistic world then the thing picked out by the concept of qualia is functional, and the thought experiment fails. The intuitive appeal of the experiment would be explained by our proper acknowledgement of our uncertainty about our world, and thus of what our concept of qualia picks out.

Chauvinism Arguments

'Chauvinism' arguments are directed against empirical functionalism. The idea is that in specifying the functional roles required for mental states by reference to an examination of how we are in fact built, we thereby rule out the mentality of any beings who are built differently internally. If there were apparently intelligent life elsewhere, with an internal architecture different from the most explanatorily salient features of our own, it would not count as mental – and this, it is argued, is unacceptably chauvinistic. The point can be made more dramatic by supposing that the Alpha Centaurans made contact with Earth before the development of the cognitive sciences. If the subsequent philosophical consensus in philosophy of mind conferences (attended by both species) was for empirical functionalism, then it would be features in common between humans and Centaurans that would be regarded as definitive. So the account of the mental under empirical functionalism depends on accidental features of the available paradigms at the time of investigation. One response to this argument is to look for empirical features which are very abstract and can be expected to obtain in all nomologically possible beings that behave intelligently.

FUNCTIONALISM AND COGNITIVE SCIENCE

Functionalism arose at the same time as early work in artificial intelligence, one of the disciplines that helped form cognitive science. Functionalism seemed to justify the claims of artificial intelligence researchers that the creation of genuine artificial intelligence was possible. Analytic functionalism underwrites cognitive science inasmuch as it justifies the claim that a full cognitive account of how we work, if appropriately embodied so as to enable causal connection with the world, would be sufficient for mentality.

Empirical functionalism makes the further claim that duplicating the most salient cognitive features of how we in fact work is also necessary for mentality.

The difference is in how philosophically deflationary an understanding of completed cognitive science is meant to be. Analytic functionalism says that philosophy is the tool for an understanding of what is required for mentality; whereas cognitive science tells us about the nature of our own version of mentality, gives us explanations about how our own mentality works, and gives us tools to potentially duplicate our mentality.

Empirical functionalism assigns to cognitive science the role of establishing the essential nature of the mental itself. According to this doctrine, what mental states are essentially depends on how they actually are in us. Some versions of empirical functionalism which concentrate on 'architectural' features – the so-called program that is running on the brain – assign to cognitive science an autonomous role studying the nature of the mental at a level less abstract than behaviorism or analytic functionalism, but more abstract than various lower-level ways of studying the neural chemical or physical nature of the brain. Thus, according to most kinds of empirical functionalism, cognitive science will be the final arbiter of whether, should we succeed in making contact with extraterrestrials, we would be communicating with other thinkers, or merely with zombies produced by a freak of alien evolution.

Implicit and Explicit Representation

Intermediate article

David Kirsh, University of California, San Diego, California, USA

CONTENTS

The degree to which information is encoded explicitly in a representation is related to the computational cost of recovering or using the information. Knowledge that is implicit in a system need not be represented at all, even implicitly, if the cost of recovering it is prohibitive.

INTRODUCTION

During the brief history of cognitive science, disputes have often arisen over how explicitly certain types of information (or knowledge) are represented in human cognitive systems, and what it means for information to be explicitly rather than implicitly represented in a system. Every few years it seems that new ways are discovered to build information into architecture, internal dynamics, and agent–environment interaction. Information that was stored in 'software' becomes integrated into 'hardware' in the next generation of systems, and then becomes integrated into a new 'architectural' design in the following generation. This seems to hold whether the software is made out of computer programming languages or malleable neural connections, whether the hardware is silicon or organic, and whether the architecture is a computer system or an anatomical plan that only changes across generations. When information is no longer encoded in distinct data structures with definite location and form, should we say that the information is still there, but represented in a more implicit form?

Questions about how information may be embedded in systems, how it may exercise a causal influence over processes, without being easily identifiable with a recognizable state, structure or process, make problematic the analysis of representation, and especially the analysis of what it means for information to be explicitly, as opposed to implicitly, represented in a cognitive system. There is a temptation to simply dismiss the matter as being of purely philosophical, or even semantic, interest. But the questions remain important because any hope of understanding how information enters into causal accounts of cognition must eventually explain the relation between the information attributed to a system, and appealed to in explanatory models, and the underlying states, structures or processes that serve as the vehicles for that information, and which are closer to the level of purely causal or neurophysiological explanation. Since there are many explanatory models in cognitive science that refer to information that is only implicitly present, it is important to clarify what implicit representation means and how it enters into underlying causal interactions.

EXPLICITNESS AND SYMBOL-PROCESSING MODELS

According to the symbol-processing view, all higher-order cognition, and most lower-order cognition too, is a computational process in which syntactically structured representations – such as sentences in an internal language of thought (Fodor, 1975; Pylyshyn, 1984), algebraic or graph structures (Chomsky, 1980; Minsky, 1975), or matrices of numbers (Marr, 1982) – are systematically transformed in a rule-driven or algorithmic manner. To understand, and therefore explain, a cognitive process, it is necessary to track the trajectory of informational states that the host system follows as it moves towards an explicit answer to a computational problem: for example, determining the meaning of an utterance, the implication of a previous thought, or the shape and visual appearance of an external object.

Since a cognitive system, on this view, is a mechanism for applying rules to structured

representations, it is natural to regard information as explicitly encoded if the structured state, process or form – the symbol structure – representing that information can be interpreted according to a well-behaved theory of content, such as a truth or model theory. We can then point to any given structured representation and say 'that form explicitly encodes this content'.

Although the data structures and representations involved in the various symbol-processing models (lattices, matrices, graph structures, extended first-order predicate calculus) go well beyond the structures we typically see in everyday life, this idea of 'implicit' and 'explicit' representation remains close to the everyday meaning of the terms used when discussing natural language. In ordinary parlance, we regard a fact to be 'explicitly' stated if it is expressed literally and unambiguously in a well-formed sequence of words, a sentence. Something that must be inferred from the sentence – because, for instance, it is presupposed, or because it is a consequence of the meaning of the words – is not explicitly stated; it is implicit in the meaning and context of utterance. Thus, when someone says 'when did you stop being a bachelor?' we take them to be explicitly asking a question about a date or time, but implicitly asserting that we no longer are a bachelor (the major presupposition), that we now have a wife (a consequence of the meaning of 'bachelor'), that we know when our marriage took place (a presupposition of the 'when' question), and so on.

On this account, information is 'explicitly' encoded if it can be read directly off a sentence without more inference than is required to understand the meaning of the words and their structure; while information is 'implicitly' encoded if additional inference or semantic processing is needed to recover it.

Using this intuitive analysis, Dienes and Perner (1999) have presented a theory of implicit and explicit knowledge that attempts to integrate and relate the divergent uses of the implicit–explicit distinction in different research areas, such as implicit and explicit memory, blindsight, automatic and controlled action, and development. They offer an explanation of why discussions of explicit and implicit knowledge are so often tied to concepts like consciousness, volitional control, and verbalizability.

Any theory about the nature of explicit and implicit representation based on our intuitions about what is explicit and implicit in natural language can be generalized to other declarative representations discussed in symbol-manipulation models: matrices, connected graphs, vectors, etc. But our intuitions about explicitness, even in natural language, are not complete. For instance, the sentence 'police police police police police' is grammatical and unambiguous. This sentence may be paraphrased as 'policemen who are policed by policemen also police policemen'. Since it has a unique syntactic and semantic identity it should qualify as an explicit representation. One need only understand the meaning of the words and their structure. Yet few people can actually recover this meaning because too much computation is involved in determining which sense of 'police' is being used in each position. Because of the computational complexity of interpreting the meaning of the sentence, the meaning is not easily recovered, it is not on the surface, and cannot be directly accessed. Consequently, we have conflicting intuitions about whether to say its meaning is explicitly encoded. On the one hand, it satisfies the basic truth-theory intuition 'here is the representation, there is the meaning', since it is well formed and unambiguous, so it is explicit on that criterion. On the other hand, few people can actually recover the information in the representation, so it ought be implicit on that criterion. Thus it seems that the intuitive theory is incomplete.

Such concerns about the computational processes involved in understanding the meaning of a representation suggest that a theory of implicit and explicit representation should be based more on the way representation and computation interrelate.

EXPLICITNESS AS A COMPUTATIONAL PROPERTY OF REPRESENTATIONS

One such theory involves measuring the computational effort required to extract, use, or interpret the information encoded in a representation (Kirsh, 1991). The computational complexity of the process of interpretation determines where on the continuum of explicit to implicit a given representation lies. If the interpretative process implements a constant-time algorithm, or extracts the content quickly and without substantial involvement of the rest of the cognitive system, then the information it extracts is directly available and hence explicitly encoded. For instance, the numeral '5' encodes the number 5 in English more explicitly than $\sqrt[5]{3125}$, even though both designate 5, because the value 5 can be read off directly from '5' by English speakers without performing lengthy computation.

It is assumed here that a representation is a well-defined state, structure or process, in a causal

system; that it encodes a specifiable informational content that can be harnessed by the causal system of which it is a part; and that it is possible to use techniques of computational complexity theory to measure the computational effort involved in recovering the information, providing we have a theory of the processes that use or extract that content.

So to determine how explicitly or implicitly a piece of information is represented, we need a substantive theory about the functioning of the different parts of a cognitive system. This must include how the system identifies the state, structure or process carrying the information, and how it exploits the information.

A plausible consequence of this approach is that individual capacities for memory, learning and other cognitive skills can affect how explicit a representation is. For one person, a certain representation may be identified and grasped directly. For another, the representation cannot be grasped without substantial computation. This conforms to both intuition and science. We now know a good deal about the computational costs associated with different neural-network methods of identifying and individuating states (structures or processes). It is known that there are computational trade-offs between the number of perceptron-like connections reaching out into a region where neural states encode information (the spatial complexity of the identifying process), and the amount of later processing required to correctly identify the state (the time complexity of the identifying process) (Minsky and Papert, 1969). Consequently, a neural state that in one person may be immediately identified – because identified in a highly parallel manner – and so meet the identifiability condition of explicitness, for another person may not be immediately identifiable – because, for example, this person has not yet developed efficient recognition methods, and so will take much longer to identify the information-bearing state and access the information contained therein. For a lengthy discussion of these points see Kirsh (1991).

IMPLICATIONS

By treating explicitness as a computational property of a representation, we have a method for deciding the point at which we can say that information or knowledge is so deeply embedded in hardware, architecture or agent–environment interactions that it is no longer a causally active agency and no longer represented, even implicitly. It is the point where the cost to the cognitive system of recovering the information would be so great that there are no connections or accessing procedures that can reliably make use of the information. Since a representation is a mechanism for reliably carrying information across space or time, it is best to say that the information is so implicitly built into the cognitive system as to no longer be represented in it. At the other end of the continuum, information that is encoded in well-defined states, structures or processes, which the cognitive system can immediately identify and use, is explicit.

A further consequence of tying the implicit–explicit distinction to computation is that we have a method for distinguishing different types of explanation in cognitive science. Not all explanations of behavior and design are mechanistic. We accept this in other design sciences, where discussions of design rationale and historical evolution help us to understand why a particular design is a good one. The same should hold true when we discuss the 'implicit theory of the world' built into a system or process.

Although sometimes such claims point the way to a computational explanation, we should not assume that every implicit theory implies that there are counterpart representations in the system. For instance, a vision module designed to extract a three-dimensional shape from two stereoscopic images works rapidly if it is equipped with an algorithm that differentiates. Such an algorithm will work if the assumption about the world that objects change in shape smoothly and continuously is true. Smoothness is a 'success condition' of the algorithm, and any designer who wishes to determine the algorithm's reliability will need to know how often the assumption is correct. But the algorithm may not implicitly represent the assumption. The assumption will not be recoverable by the system itself if the representational vocabulary of early vision does not include terms such as 'smoothness'. The assumption of smoothness serves as a powerful constraint on the design space of useful algorithms and representations; but it is not implicitly represented.

Thus, theoretical assumptions, such as smoothness, generativity, conformity to a truth theory, adherence to a formal linguistic theory, and so on, may guide the design of algorithms or the architecture of a system; they may figure in discussions of implicit knowledge or of the evolutionary fitness of a creature; but they need not figure directly in discussions of the computational mechanism. Depending on the cost of using those assumptions directly, they may be best understood as nonmechanistic explanations.

Implicit Cognition

Intermediate article

Eyal M Reingold, University of Toronto, Ontario, Canada
Colleen A Ray, University of Toronto, Ontario, Canada

CONTENTS

'Implicit cognition' refers to unconscious influences reflecting perception, memory, and learning, without subjective phenomenal awareness.

TERMINOLOGY AND DEFINITIONS

Since the 1970s, the 'implicit–explicit' distinction has become the dominant terminology under which experimental cognitive psychology has investigated unconscious influences on behavior and thought. Historically, the relation between consciousness and cognition has been one of the most controversial areas of investigation in psychology. This controversy can be traced back to the association of the conscious–unconscious distinction with psychoanalytic theory. Many experimental psychologists have regarded the unconscious as an unsuitable topic for scientific inquiry. But related phenomena have been empirically investigated under a variety of alternative terminologies. Terms such as 'incidental', 'pre-attentive', 'inaccessible' and 'covert' were used to avoid the unwanted associations of the terms 'unconscious' or 'unaware'. The term 'implicit' is a more recent, and perhaps more successful, example of such terminological camouflage. The implicit–explicit distinction was introduced in the mid-1980s in the context of the study of unconscious or unaware memory. This shift in terminology is illustrated in Figure 1, which plots the number of abstracts in the PsycINFO database from 1985 to 1999 that employed the term 'implicit' to refer to unconscious perceptual or cognitive processes. Figure 1 also displays the number of abstracts referring specifically to implicit memory. The sharp increase in the popularity of this terminology is particularly apparent in the area of memory research.

Given the dominance of the 'implicit–explicit' terminology, it is instructive to consider how these terms are typically defined. For example, Graf and Schacter (1985, p. 501) stated that 'implicit memory is revealed when performance on a task is facilitated in the absence of conscious recollection; explicit memory is revealed when performance on a task requires conscious recollection of previous experiences'. More recently the distinction has been extended to the study of conscious versus unconscious perception, as exemplified in the following definition by Kihlstrom *et al*. (1992, p. 22): 'Explicit perception refers to the person's conscious perception of some object or event in the current stimulus environment. … By contrast, implicit perception is demonstrated by any change in experience, thought or action that is attributable to some event in the current stimulus field, even in the absence of conscious perception of that event'. Similar definitions have also been proposed for implicit and explicit knowledge. As described by Berry and Dienes (1993, p. 2), 'explicit knowledge is said to be accessible to consciousness, and can be communicated or demonstrated on demand, whereas implicit knowledge is said to be less accessible to consciousness, and cannot be easily communicated or demonstrated on demand'. Finally, in reviewing the implicit learning literature, Shanks and St John (1994, p. 368) pointed out that 'different authors have used a variety of definitions to capture the fine detail of the explicit–implicit learning distinction, but the key factor is the idea that implicit learning occurs without concurrent awareness of what is being learned, and represents a separate system from that which operates in more typical learning situations, where learning does proceed with concurrent awareness (i.e. explicitly)'. Thus, with respect to recollection, perception, knowledge, and learning, implicit processes are invariably defined by the absence of consciousness or awareness. Given this observation, it is unclear what is gained by the 'implicit–explicit' terminology. Such proliferation of terminology is problematic in that it obscures the historical link between related ideas and findings.

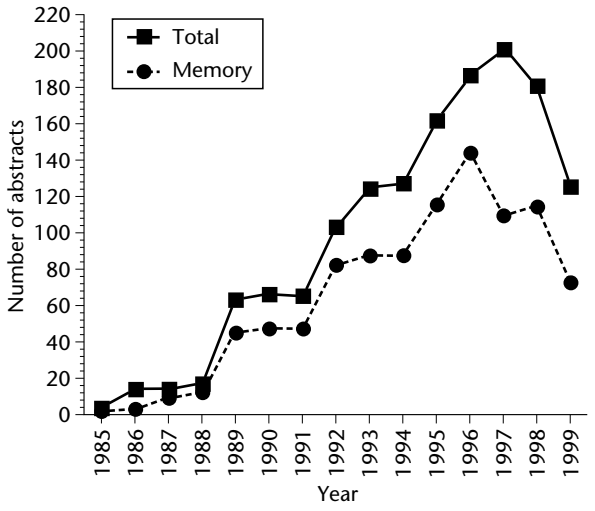

Figure 1. The number of abstracts in the PsycINFO database from 1985 to 1999 that employed the term 'implicit' to refer to unconscious perceptual or cognitive processes. The dotted line shows the number of abstracts referring to implicit memory.

THE DISSOCIATION PARADIGM

Regardless of the terminology used, most studies investigating perception, learning or memory without awareness have employed the 'dissociation' paradigm. This paradigm establishes three prerequisites for demonstrating unconscious cognition:

1. A valid measure C of cognitive information available to consciousness must be selected, and compared with another measure X of cognitive processing.
2. $C = 0$. The measure of conscious awareness indicates null sensitivity, or null awareness.
3. $X > 0$. The second measure of cognitive processing must be shown to have greater than zero sensitivity.

To illustrate the dissociation paradigm, consider the following purported demonstrations of perception and memory without awareness. In all of these examples, the measure of conscious awareness C, was 'claimed awareness' thus $C = 0$ if participants reported an absence of subjective phenomenal awareness.

Perception in the absence of claimed awareness is a very robust phenomenon that can be used as a classroom demonstration. Consider the famous experiments by Sidis (1898). In these experiments, Sidis showed each observer a card containing a single printed digit or letter. 'The subject was placed at such a distance from the card that the character shown was far out of his range of vision. He saw nothing but a dim, blurred spot or dot. … The subjects often complained that they could not see anything at all; that even the black, blurred, dim spot often disappeared from their field of vision'. When Sidis asked the subjects to name the character on a card, their responses were correct considerably more often than would be expected on the basis of purely random guessing, even though many subjects expressed the belief 'that they might as well shut their eyes and guess'. On the basis of these and similar findings, Sidis concluded that his experiments indicated 'the presence within us of a secondary subwaking self that perceives things which the primary waking self is unable to get at'. Thus, in Sidis' experiments, a 'forced choice' identification measure demonstrated the availability of perceptual information concerning stimulus identity (i.e. $X > 0$), whereas subjective report indicated null awareness for such information (i.e. $C = 0$).

An even more dramatic example of perception in the absence of subjective confidence was obtained by studying brain injury patients with lesions in their visual cortex that result in scotomas (blind regions) in their visual field. Case studies of such patients document that they perform perceptual discriminations (e.g. detection, location, orientation) concerning stimuli presented in their blind field at a level well above chance (i.e. $X > 0$), while at the same time claiming to be purely guessing (i.e. $C = 0$). This phenomenon has been called blindsight. For example, Weiskrantz *et al*. (1974, p. 721) described the verbal report of one such patient as follows: 'he was at a loss for words to describe any conscious perception, and repeatedly stressed that he saw nothing at all in the sense of "seeing", and that he was merely guessing'. Thus, just like the participants in Sidis' experiments, blindsight patients report an absence of subjective phenomenal awareness of perceiving, coupled with indirect behavioral evidence of perceiving (i.e. better than chance perceptual discrimination).

When participants' subjective report is used to index their phenomenal awareness of remembering at the time of retrieval, there is ample evidence for unconscious or implicit influences of previously encoded information on cognition and behavior. This was illustrated in the work of one of the founders of the modern empirical study of human memory, Hermann Ebbinghaus. Ebbinghaus (1885) memorized lists of nonsense syllables, and then relearned them at a later time. He quantified the saving in relearning (i.e. the reduction in time or in the number of repetitions required for a perfect recall of the list) as an indirect measure of retention. This paradigm came to be known as the saving method. Ebbinghaus also varied the 'retention interval', that is, the time interval between the

original learning of the list (the study phase) and the relearning of the list (the test phase). Being a subject in his own experiments, Ebbinghaus was able to report that following long retention intervals he observed savings in the relearning of items (i.e. $X > 0$) for which he had no conscious awareness of having studied before (i.e. $C = 0$). In fact, in developing the saving method, Ebbinghaus intended to measure, not only recollection accompanied by the subjective experience of remembering, but also the retention of experiences that are not accessible to introspection, but which nevertheless influence behavior. He stated that 'most of these experiences remain concealed from consciousness and yet produce an effect which is significant and which authenticates their previous experience'. Ebbinghaus advocated a much broader definition of memory than many subsequent memory researchers and lay people who view memory as necessarily involving the subjective experience of remembering.

As Figure 1 shows, there has been a renewed interest in the study of retention in the absence of the subjective phenomenal awareness of remembering. Currently, implicit memory is one of the most actively studied areas of human memory. This is largely due to the development of numerous indirect or implicit memory tasks. In all of these tasks, participants are not instructed to refer back to the original study phase; rather, the experimenter tries to disguise the link between the study and test phases of the experiment. A typical example of an implicit memory task is word stem completion. In this task, participants are given word stems (e.g. *bra_ _*) and are instructed to complete them with the first word that comes to mind. In an earlier phase of the experiment, participants are exposed to words that are potential completions for some of the stems (e.g. *brave*). Typically, stem completion is presented as a new and unrelated task, in order to disguise the link with the earlier study phase of the experiment. Memory for words presented in the study phase is measured as an increase in the tendency to produce these words (as opposed to other possible completions such as *brain*, *braid*, *brake* or *brass*) as responses to the stems. This effect is referred to as 'priming'. Performance on implicit or indirect memory tasks is often compared with performance on explicit memory tasks, such as recognition and recall. In explicit or direct memory tasks, participants are instructed to refer back to the study phase and to retrieve study items.

One of the most important antecedents to the renewed interest in the study of unconscious memory was the observation of memory dissociations in amnesic patients. The amnesic syndrome provides a dramatic demonstration of retention in the absence of reported subjective phenomenal awareness of remembering. In one famous case, HM became amnesic after an operation was performed to alleviate his epilepsy attacks by bilaterally removing parts of his temporal lobes. As a result of his surgery, HM became severely amnesic and seemingly unable to commit new material to memory. For example, after his operation, he was very poor at learning the names or recognising the faces of people he met, or remembering the contents of an article he had read just hours before. However, upon closer examination, HM was found to have retained information for experiences that occurred following his surgery. This preserved learning capacity included, for example, the ability to learn the mirror-drawing task. In this task, the participants must carefully trace the outlines of shapes (e.g. stars) while viewing their hands and the shapes through a mirror. HM performed this task on consecutive sessions. Although at the beginning of each session he denied having performed this task before (i.e. $C = 0$), his performance improved across sessions (i.e. $X > 0$). Similarly, when performing on implicit or indirect memory tasks, such as word stem completion, amnesic patients often demonstrate normal levels of retention ($X > 0$), while reporting no memory for the study episode (i.e. $C = 0$).

OBJECTIONS AND DEBATES

The above examples of dissociation with normal participants and with blindsight and amnesic patients clearly demonstrate that when conscious awareness is defined and measured on the basis of subjective report, there is ample evidence for unconscious or implicit perception and memory. However, despite the intuitive appeal the dissociation paradigm, the study of unconscious or implicit cognition remains highly controversial. We will now outline some of the issues underlying the controversy (for a more thorough discussion, see Reingold and Merikle, 1990 and Reingold and Toth, 1996).

The most important source of controversy is the absence of a general consensus as to what constitutes a valid measure of consciousness or awareness. For example, some critics of the study of the unconscious challenge the validity of the subjective report as a measure of awareness. They argue that requiring a subjective report of awareness of seeing or remembering transfers the responsibility for defining awareness from the experimenter to the

participants, who may vary in the criteria or concepts of awareness they employ as the basis for their report. For example, some participants who report null awareness may discount conscious access to partial or degraded information regarding a stimulus or an event, while other participants may use such information as the basis for reporting awareness of perceiving a stimulus or remembering an event. Furthermore, participants may tend to respond on the basis of what they perceive to be the goals or expectations of the experimenter. This tendency is referred to as 'demand characteristics'. It is therefore likely that subjective report, at least on some occasions, may fail to reflect all of the relevant information that is accessible to consciousness. Thus, the validity of the subjective report as a measure of awareness depends on our ability to distinguish between the participants' response bias, affected by factors such as preconceived notions and demand characteristics, and their subjective phenomenal experience. Given the difficulty of this, many investigators prefer an approach to the measurement of conscious awareness based on objective task performance rather than subjective report. This is referred to as the 'objective' approach, and the use of subjective report has been termed the 'subjective' approach.

Proponents of the objective approach employ tasks such as stimulus detection, identification, and forced choice discrimination to measure perceptual awareness, and explicit memory tasks such as recognition and recall to measure conscious recollection. Null awareness is then defined as chance performance on these discrimination tasks. Unconscious or implicit cognition is inferred when null awareness is coupled with evidence of above-chance performance on indirect or implicit tasks. The most important problem with the objective approach to the measurement of awareness is the implied one-to-one mapping between tasks and processes. It is assumed that performance on explicit or direct tasks reflects explicit or conscious cognition, while performance on implicit or indirect tasks reflects implicit or unconscious cognition. The fact that the 'explicit–implicit' terminology is used to refer to both tasks and processes may foster such an unwarranted assumption. In fact, performance on implicit and explicit tasks may reflect conscious, unconscious, or both conscious and unconscious processing. For example, if the discrimination task used to measure conscious awareness is actually sensitive to both conscious and unconscious information, then requiring above-chance performance as a prerequisite for demonstrating implicit cognition may lead, at best, to underestimating the magnitude of unconscious influences or, at worst, to denying their existence.

Clearly, neither the subjective nor the objective approach to the measurement of awareness can be justified *a priori*. Given that the dissociation paradigm depends critically on the availability of a valid measure of conscious awareness, its use in the absence of such a measure is problematic. Thus, any approach to the measurement of conscious awareness must be validated by converging empirical evidence. Another problem with the dissociation paradigm is that it reflects a preoccupation with trying to prove or disprove the existence of the unconscious. Progress in the study of the relation between consciousness and cognition will require going beyond existence proofs and towards the development of multiple conceptual and methodological frameworks in order to explore this complex and controversial topic in a satisfactory way.

Indexicals and Demonstratives

Intermediate article

Maite Ezcurdia, Universidad Nacional Autónoma de México, Mexico City, Mexico

CONTENTS

Indexicals are expressions that vary in reference according to the context in which they are used. They are of two sorts: pure, and impure or demonstrative. Unlike pure indexicals, demonstratives require an extralinguistic element, like a demonstration or an intention of a certain sort, in order to refer.

WHAT ARE INDEXICALS AND DEMONSTRATIVES?

Indexicals are expressions that vary in reference according to the context in which they are used; and they do so in virtue of their semantic rule or rule for referring. For example, 'I' is an indexical. Its semantic rule states that it refers to the utterer in a given context. Hence, for 'I' to vary in reference, the contexts in which it is used must vary with respect to the utterer. Any other variation in the context of use will be irrelevant to the reference of 'I'. In the case of 'today', the relevant variation in context will be in the day of use, because its semantic rule states that it refers to the present day or day of utterance.

'I' and 'today' are examples of pure indexicals. But there are also impure indexicals or demonstratives. These include 'that', 'this', 'that person in the corner', 'these houses', 'you', 'she', and so on. Impure indexicals differ from pure ones in that they require an extralinguistic act or element in order to generate a semantic rule. If I uttered 'that' without producing the extralinguistic element, it would not be possible for it to refer. (Given the contrast between 'that' and 'this', it would have to refer to something that is at a certain distance from me; however, there are a great many properties and objects that are at a certain distance from me.) A semantic rule for 'that' which just stated that it refers in a given context to an object or property if and only if it is at a certain distance from the speaker would be insufficient to determine any object or property as the referent. What is required to complete the semantic rule is an extralinguistic element supplied by the speaker. Three candidates have been offered for such completion: demonstrations, like pointings and overt gestures (Kaplan, 1989a); salience (Kaplan, 1989a, pp. 490 and 527); and certain sorts of intentions (Kaplan, 1989b), namely, intentions to refer to an object that is presented in a certain way to the speaker in a given context.

Not all indexical expressions can be straightforwardly classified as demonstratives or pure indexicals. Such is the case with 'here' and 'now'. In their pure use they refer, respectively, to the place and time of utterance. However, there are also demonstrative uses of them: for example, when I say 'we are here' pointing at a place on a map, or 'we don't do that now' meaning that we no longer do something that was done at the time of the Aztecs.

Furthermore, some personal pronouns, like 'he', 'she' and 'it', do not always behave as demonstratives. They sometimes behave as anaphora, as in 'Every girl thinks she is going to the party' (where 'she' is anaphoric on 'every girl'), or in 'Mark came to the dinner; he enjoyed it' (where 'he' is anaphoric on 'Mark').

Indexicals, like proper names, are referring expressions, or singular terms. Phrases such as 'every man', 'some cats', 'most fences', and even 'the dog in the corner' are general or nonreferring. Referring expressions, unlike non-referring ones, require that for an utterance of a sentence containing a referring term to express a proposition, that term has a referent.

ACCOUNTS OF INDEXICALS AND DEMONSTRATIVES

Indexicals and demonstratives have been the source of much debate among competing semantic theories. There are two main issues: how to give an adequate account of the meaning and reference of indexicals; and whether it is tokens (e.g., inscriptions on a blackboard or piece of paper), utterances of indexicals, or indexical types relative to certain contexts, that do the referring. These issues may be related. For example, Reichenbach (1947) called

indexicals 'token-reflexive expressions', and claimed that their meaning would be given by making reference to a token produced by the speaker. The meaning of 'I' would be given in terms of 'the person who utters this token', and the meaning of 'now' in terms of 'the time at which this token is used'.

Within a Fregean semantics – that is, of a theory that recognizes the semantic levels of sense and reference – Evans's (1981) account of indexicals is the best offered so far. The sense of an expression involves a mode of presentation of its referent. Sense also determines an expression's reference, so that if two expressions have the same sense (e.g., 'cat-like' and 'feline') they must have the same reference. Because an indexical may vary its reference across contexts, it cannot always express the same sense; and because the semantic rule of an indexical is what remains constant across all its uses, senses cannot be the semantic rules in accordance with which an indexical varies in reference. For Evans, sense determines reference only because sense is itself determined by the context of utterance. Context, together with the sense type, determines a sense, which in turn determines the reference. The sense of 'I' when uttered by me differs from the sense of 'I' when uttered by you, although their sense type is the same (and remains constant across all uses of 'I'). If anything, the sense type can be taken to be the semantic rule.

Furthermore, since for the Fregean propositions have only senses as constituents, the account of indexicals as referring expressions depends on the nature of the constituent senses. For Evans, referring expressions, unlike nonreferring ones, express object-dependent senses, senses that entail the existence of their referents. So a referring term that lacks a referent lacks a sense, and the utterance that contains such a term fails to express a proposition. On this account, an utterance of a sentence containing 'you' (unlike an utterance of 'some dogs') requires there to be a referent of 'you' for it to express a sense and, therefore, for a proposition to be expressed.

It is, however, the work of Kaplan (1989a, 1989b) that has been most influential on current research on indexicals and demonstratives. Kaplan argues that if we are to develop a semantics and logic of demonstratives, then the bearers of reference should be the indexical types relative to contexts of use. These contexts are represented as ordered sequences of the following sort.

$$(\text{User},\ \text{time of use},\ \text{place of use},\ \text{actual world},\ (d_1, \cdots, d_n)) \quad (1)$$

where the last member is an ordered n-tuple of possible referents of demonstratives. In terms of these contexts, and of the notion of circumstances of evaluation, Kaplan develops a semantic theory that includes three levels: character, content, and extension. The character of a sentence is both its semantic rule and its linguistic meaning (that is, the part of meaning that remains constant across all uses); its content is the proposition it expresses; and its extension is its truth-value. Character can be represented as a function from contexts of use to content, and content as a function from circumstances of evaluation to extension. A circumstance of evaluation is a possible situation, actual or counterfactual, with respect to which the truth-value of a sentence is evaluated.

Relative to the context of use in which Tony Blair is the user of 'I am in London', the character of 'I' yields Tony Blair as part of the content of that sentence, and it is with respect to Tony Blair that the truth of that sentence in context will be assessed. An indexical may vary in reference with respect to a variation in context, but since relative to a particular context its contribution to the content of a sentence is just its referent, it does not vary in reference with respect to possible circumstances of evaluation. Because the contribution of an indexical to the content of the sentence in which it occurs is (if any) its referent, if the indexical did not have a referent there would be no content or proposition expressed by the sentence containing that indexical. This is as required by the condition for referring expressions namely, that a sentence (in context) containing a referring expression expresses a proposition only if that expression has a referrent. In contrast, a nonreferring expression like a definite description contributes to content a descriptive condition, which in different circumstances of evaluation may determine different extensions or none at all.

INDEXICALS AND DEMONSTRATIVES AND COGNITIVE SCIENCE

We may understand cognitive science roughly as the collection of disciplines whose aim is to study human cognition in any of its forms and at any of its levels. Indexicals, being terms of the languages that we use, are within the scope of linguistics, philosophy, and cognitive psychology. Topics of study include, amongst others, the semantics of indexicals, how they are learned, how they are processed, and how the cognitive abilities which we employ in understanding a use of an indexical or demonstrative involve taking contexts into

account (for a general attempt at this, see Sperber and Wilson (1986)). Moreover, we can obtain special insights into our cognitive abilities from consideration of indexicals; these insights are of particular interest in the philosophy of mind and in cognitive psychology. They concern indexical or demonstrative thoughts – that is, psychological states or processes whose content is most adequately reported in public language with the use of an indexical.

Perry (1979) points out that there are thoughts of certain types that are essential for action and that are reported in public language with the use of 'I', 'now', and 'here'. Suppose I believe that Maite must start writing her paper in Room 105 on the 15th of February at 10 o'clock. This belief, though a true belief about myself, may not give me a reason to act if I am amnesic and do not know I am Maite, or if I do not know that it is 10 o'clock on the 15th of February, or that I am in Room 105. It may, however, give me a reason to act if it is accompanied by the beliefs that I am Maite and that it is now 10 o'clock on the 15th of February and that I am in Room 105. What 'I', 'now', and 'here' thoughts do for the subject is locate the subject, the time, and the place in a way that connects with the subject's abilities to perceive, think, and move. There has been some discussion of the nature of such thoughts, and the necessity and nature of mental representations corresponding to indexicals in public language (Cussins, 1990; Millikan, 1990).

Other abilities associated with the use of indexicals and demonstratives give rise to what Kaplan has called 'cognitive dynamics'. These abilities relate to the sorts of psychological processes involved in tracking a specific object, time or place through space and time. In order to refer to the 15th of February on the 14th, for example, I may use 'tomorrow', but in order to continue to refer to the same day on the 15th I have to use 'today', and on the 16th 'yesterday'. Evans (1981) thought that these uses of different indexicals all expressed the same sense, for underlying such uses was a single ability in the subject to track a particular day. Study of the nature of such tracking abilities with respect to time and with respect to objects throughout space has given rise to discussions on the relation between demonstrative thoughts based on perception and the representational character of the psychological processes underlying those abilities, in particular on whether or not they are conceptual (Cussins, 1990; Evans 1982).

One of the most important topics in the philosophy of mind, and in current research in cognitive psychology, concerns the various kinds of consciousness. The indexical 'I' is of particular importance to studying one such kind, namely, self-consciousness. The focus of such research is on a subject's ability to think of or refer to himself or herself in thought. Upon having an 'I' thought, one is presented to oneself in a special way (in which one is presented to no one else). But if the semantic rule of 'I' is to refer to the speaker, then the semantic rule itself will not give us that special way of being presented. Recent attempts to account for the ability to think of oneself have concerned the way we are aware of our own bodies (proprioception) and of our own thoughts (introspection) (Evans, 1982; Bermúdez, 1998).

Innateness, Philosophical Issues about

Intermediate article

Fiona Cowie, California Institute of Technology, Pasadena, California, USA

CONTENTS

Philosophical problems about innateness cover conceptual and empirical issues regarding the claim that concepts or beliefs are innate, inborn, or genetically determined.

INTRODUCTION

Many different kinds of traits are claimed to be innate in us and other animals. We speak of a termite's innate nest-building behavior, a llama's innate hairiness, a Golden Retriever's innate tendency to hip dysplasia, a person's innate beauty. Philosophical interest in innateness, however, has centered around the innateness or not of various mental properties. Probably because of the issue's traditional connections with epistemological problems like justification and a priori knowledge, philosophical attention has focused on the innateness (or not) of our 'ideas' or representations (e.g. concepts and beliefs) and, to a lesser extent, our cognitive abilities (e.g. mechanisms of learning). This article, too, will focus on the innateness of mental items (ideas or capacities) rather than physical features or behaviors.

The first known philosophical claims about the innateness of concepts and beliefs were made by Plato (428–348 BC) in his dialogues *Phaedo* (74b–75e) and *Meno* (80d–e). (See Grube, 1997.) He argues (in the voice of Socrates) that since some of the concepts and knowledge we possess could not have entered the mind through sense experience or as a result of teaching, they must be innate, that is acquired by our souls prior to our birth. So-called learning, he argues, is really a process of recollection: our experience reminds us of things we already know but have forgotten. Later defenders of the view that certain ideas are innate include the philosophers René Descartes (1596–1650), Gottfried Leibniz (1646–1716), and Immanuel Kant (1724–1804). Notable critics of their 'innateness hypotheses' have included the historical figures Aristotle (384–322 BC), John Locke (1632–1704), and David Hume (1711–1776). Most recently, two cognitive scientists, the linguist Noam Chomsky and the philosopher Jerry Fodor, have taken up arms under the nativist banner: Chomsky defending the notion that our knowledge of language is substantially innate, and Fodor arguing that the vast majority of our concepts are innate (e.g. Chomsky, 1986, 1990; Fodor, 1981, 1998).

CENTRAL PHILOSOPHICAL ISSUES ABOUT INNATENESS

The central philosophical question – indeed, the central question – about innateness is: what, if anything, is innate? To aid in answering this question, philosophers have asked a prior question: what is innateness and why should we care about it? Then, to help in answering this question, they have further inquired: what do particular nativists (i.e. defenders of an innateness hypothesis) mean when they call some idea or capacity 'innate'? Thus, the three main philosophical issues about innateness are:

1. the interpretive issue: what do nativists mean by the claim that such and such mental item is innate?
2. the explanatory issue: what is innateness, and what does an idea's being innate enable us to explain?
3. the factual issue: which ideas (concepts, beliefs, knowledge) and cognitive or behavioral capacities are innate?

The interpretive issue arises because it is frequently very difficult to tell exactly what a person means when she claims that certain ideas are innate. People often appeal to metaphors and analogies in explaining what innateness is, and these often support conflicting interpretations. For example,

Descartes sometimes says that concepts or beliefs are innate in the same way that certain diseases (like gout) are innate in certain families (Descartes, 1985). This argument, together with the fact that many of the concepts and beliefs he discusses are not possessed by babies or very small children, suggests that in his view, innate concepts or beliefs are not present at birth but exist as potentialities or dispositions to acquire ideas during the course of development. (See Stich, 1975.) Chomsky, by contrast, claims that principles of Universal Grammar (UG) are innately represented in the human 'language organ' and are crucially implicated in the process of language acquisition. This assertion suggests that, for Chomsky, innate knowledge of UG is no mere disposition but is encoded in the brain at birth in a robust and causally efficacious form. Fodor (1981), to take another example, has likened innate concepts to imprinted behaviors, suggesting that for him, innate ideas are not learned but are merely 'triggered' by some appropriate releasing stimulus. It is unclear that the same or even a similar notion of innateness is at work in these three authors, and the interpretive problem only increases as the work of additional nativists is examined. (See Cowie, 1999, ch. 1, for more on the interpretive issue.)

While it is, of course, important to understand what theorists (past or present) have thought about innateness, the interpretive issue is primarily of interest to cognitive science because it bears on (2), the explanatory issue. Innateness is most commonly invoked to explain how an idea was acquired: Meno's untutored slave knows Pythagoras's theorem because it is innate; we know that $2+2=4$ because we have innate knowledge of mathematics; people believe in God because of an innate concept of the deity. The fact that innate ideas are often contrasted with those that are learned or otherwise acquired as a result of experience has led to the notorious 'nature versus nurture' debate about whether our genes or our experience are responsible for our mental lives. This debate is generally fruitless for two reasons. First, everyone knows that both experience and the genes are implicated in cognitive development: the opposition between nature and nurture is overstated. Second, participants in nature versus nurture debates often talk past one another, simply because there are so many different understandings of innateness at play in the literature. In order to avoid such unproductive arguments, therefore, is vital to be very clear about what notion of innateness is being used in a specific discussion. For example, it would be a serious mistake to read Fodor's claim that most concepts are innate as asserting (in Cartesian vein) merely that we have dispositions to acquire concepts during the course of development. The latter claim, while true enough, trivializes what is meant to be a substantive – indeed, radical – claim about concept acquisition, because it is quite consistent with the typical empiricist's view that concepts are learned. ('Empiricist' is the name given to opponents of innate ideas.)

The explanatory issue thus arises in part because the interpretive issues are not clear. In discussing the innateness of various concepts, beliefs, or capacities we need to be explicit about what notion of innateness we are invoking. We also need to be clear about why that notion is important: we need to understand what innateness, so understood, explains. For too often it is assumed that the innateness of a trait has implications which, upon examination, it does not have. Herrnstein and Murray (1994), for instance, argue that IQ is substantially innate and that certain ethnic groups are inherently deficient in intelligence, concluding thence that social and educational programs aimed at those groups are ineffective. But as Block (1995) has responded, since 'innate' for Herrnstein and Murray means something like 'highly heritable', this conclusion does not follow even if the facts are as they claim. For the heritability of a trait is a measure of the extent to which variance in the trait in a population is correlated with genetic (as opposed to environmental) variation, and high heritability does not imply imperviousness to (or even difficulty of) change by means of environmental manipulations. In the next section of this article, we will look at a number of different notions of innateness used in the contemporary and historical literatures and examine their explanatory abilities.

Once one has clarified one's explanatory goals and chosen an appropriate notion of innateness, the question arises: what traits, if any, are innate (in that sense)? This is the third, the factual issue, about innateness with which philosophers have been concerned. In the final section, we will look at what sorts of evidence bear on this factual question, focusing in particular on the ways in which cognitive science plays a role in determining which of our ideas are innate.

THEORIES OF INNATENESS

Philosophical investigations of innateness have revealed that there are about as many different things meant by the claim that an idea is innate as there are theorists making such claims. In this section, we will survey some of these different

notions of innateness and see what sorts of explanations they figure in.

'Innate' Means 'Built In' or 'Inborn'

When the person in the street talks of hearts or hands or hemophilia being innate, what she often means to indicate is that those features are 'built in' or present at birth, the intended contrast being with traits that are acquired as a result of our postnatal experiences in the world. Arguably, some mental capacities (e.g. some perceptual and inferential abilities) must be innate in this sense, or we would have no mental lives at all. However, there is room for considerable controversy about what else may be inborn. For example, Locke (1975) famously argued (contra Leibniz, 1981) that no beliefs are inborn, since infants are not conscious of them and cannot make use of them, but must rather learn them as a result of experience. Currently, cognitive scientists are debating the extent to which knowledge of language is inborn (see Pinker, 1994; cf. Cowie, 1999), and neuroscientists are debating the extent to which the organization of the brain is inborn rather than being fixed by experience (e.g. Quartz, 2002).

'Innate' Means 'Genetically Determined'

Since the discovery of genes as the mechanisms of inheritance, talk of innateness has sometimes been code for the genetic determination of traits. When we say that a tendency to violence, or dyslexia, or the capacity for shared attention is innate, we may mean that it is under the control of one or more specific genes. Here, the aim is to explain such facts as why some traits seem to run in families, and/or why they seem to develop reliably under many different circumstances, and/or why they seem independent of other cognitive capacities, and/or why they seem impervious to ordinary environmental interventions (e.g. coaching or therapy). A major problem with the use of 'innate' in this sense, whether in cognitive science or elsewhere, is that the concept of genetic determination on which it is based is itself extremely unclear. If, for instance, a trait counts as genetically determined so long as there are genetic necessary conditions for its development, then arguably all traits are genetically determined, hence innate. If, instead, genetic determination requires that there be genetically sufficient conditions for the trait, then arguably nothing is genetically determined, since the survival of any organism requires certain environmental conditions to obtain. If genetic determination is relativized to a certain class of environments (by saying, e.g. that a trait is genetically determined if, given a normal environment, its development is controlled by the genes), then its meaning changes as the class of relevant environments does. And if genetic determination requires that there be particular genes which are 'the cause of' or are 'responsible for' a given trait, then it is at least unclear that many traits – especially those of interest to cognitive science – would be candidates for innateness. First, many genes are implicated in the development of many different traits – regulatory genes are one example; certain hox genes, which are expressed in both the fore- and hindlimbs of tetrapods are another. Second, the development of most traits requires the coordinated activity of many different genes. So while development can certainly be disrupted by 'knocking out' one or more of these genes (as, e.g. deletion of the ultrabithorax gene in fruitflies causes two copies of the second thoracic segment, including wings, to develop), it cannot be inferred from this that those genes are the 'causes of' the trait in any more robust sense than ambient oxygen is 'the cause of' a wildfire. (See Davidson, 2001; Block, 1995; Kitcher, 1985 for more on genetics and genetic determination.)

'Innate' Means 'Has a Flat Norm of Reaction'

One way of making more precise the idea that innate traits are those which are genetically determined is by invoking the notion of a norm of reaction. A norm of reaction is a function which describes how a phenotypical property, P, varies in response to environmental variation in organisms with a given genotype, G. P is said to have a 'flat' norm of reaction when there is little or no change in P across different environments, and this is of interest because the traits we call 'genetically determined' or 'innate' often display this feature. Thus, for instance, hair is both innate and (pretty much) inevitable in mammalian genotypes, as are feathers in avian ones, and backbones in vertebrate ones. It is not clear, however, that this is a useful sense of innateness when speaking of ideas. There are many ideas which are inevitable, yet not innate, being a result rather of ubiquitous features of the environment. For instance, overwhelmingly, most people who survive at all have the concept 'water' and the belief that night follows day.

'Innate' Means 'Canalized'

A related way of making the notion of innateness more precise involves the biological concept of canalization. A trait is said to be canalized when

its development is buffered against certain environmental and genetic variations (Waddington, 1942). Brains, for example, have this feature: most mutations and most environmental changes do not prevent their development. The philosopher Andre Ariew (1996, 1999) has argued that the best account of innateness holds a trait to be innate (in a given range of environments) to the extent that its development is canalized (in that range). Innateness in this sense, as he notes, enables us to explain why certain traits appear so reliably in a population. What is problematic for this proposal, however, especially as an account of what 'innate' might mean for cognitive scientists, is that many ideas seem to be canalized without being plausibly called innate. Again, the belief that night follows day and the concept 'water' are examples.

'Innate' Means 'Genetically Entrenched'

Another philosophical account of innateness is due to the philosopher William Wimsatt. He argues (e.g. 1986, 1999) that innate traits are the ones that are highly 'generatively entrenched'. Generative entrenchment is a measure of what one might call 'ontogenetic necessity'. The more entrenched a property or process is, the more disruptive to subsequent development is its absence or modification:

> to be innate is to be deeply generatively entrenched in the design of an adaptive structure – to be a functional part of the causal expression of that system…upon which the proper operation of a number of other adaptive features depends. (Wimsatt, 1999, p. 153)

Thus, having a brain is in his view a deeply entrenched or innate property: modifications to that organ cause a cascade of other developmental effects. Some problems with this account of innateness are (i) it does not capture the opposition with learning that is so crucial to many discussions of innate ideas, since learned ideas can be highly entrenched precursors to the acquisition of other adaptive cognitive structures; (ii) it apparently counts environmental features as innate if it turns out that they are necessary to further development. (For example, having edges or lines of different orientations in the visual environment would be an innate trait of Hubel and Wiesel's famous kittens, since normal visual development was found to be contingent on experience of those stimuli.)

'Innate' Means 'Developmentally Constrained'

Elman *et al*. (1996) have proposed that innateness be understood in terms of the notion of developmental constraints. In their view, ideas and behaviors count as innate to the extent that there are constraints on (i) the representational systems they involve, and/or (ii) the architectures that implement them, and/or (iii) the timing of their development. The more constraints there are operating at any of these levels, the more the trait counts as innate. Elman *et al*. maintain that their notion of innateness is of interest to cognitive science because it recognizes the complex interplay of genome and environment during development, thus avoiding spurious arguments about 'nature versus nurture'. However, it is difficult to see what innateness, so understood, explains. Since the development of every trait is multiconstrained, not just by environmental conditions and genes of various sorts but also by myriad other factors (such as the laws of physics and chemistry, the plasticity of the relevant portion of the genome, the existence and fitness of alternative phenotypes), all traits would appear to be to some extent innate, in this view.

'Innate' Means 'Triggered' or 'Not Learned'

The philosopher and cognitive scientist Jerry Fodor seeks to import the notion of triggering (Lorenz, 1965) into discussions of innate ideas. He argues (1981, 1998) that most concepts are innate in us in the same way as imprinting is innate in ducklings: just as a duckling's attachment to its mother is triggered by its first visual and auditory experiences of her, our concepts are triggered by our experiences of their instances. Here, the intended contrast is with learning: just as ducklings do not learn to love their mothers, we do not learn concepts – even concepts like 'train' and 'rose' are unlearned, in Fodor's view. A problem with this proposal is that triggering is in most cases a poor model for the process of concept acquisition. First, the connections between releasing stimuli and triggered behaviors are set up by natural selection, but natural selection has not had time to set up connections between many concepts (e.g. 'train') and the world. Second, whereas there is typically a critical period for the development of triggered responses, there appears to be no critical period for the acquisition of concepts like 'train'. Finally, and because behaviors and releasing stimuli are paired by natural selection, the stimuli for triggered behaviors are arbitrary in a way that the experiences leading to acquisition of a concept are not. There is no intrinsic connection between red spots and sex, yet natural selection has recruited red spots as a trigger for mating behavior in stickleback fish. In contrast,

there is an intrinsic connection between concepts and the experiences that cause their acquisition: 'rose' is acquired as a result of seeing, or hearing talk about, or reading about roses.

IMPACT OF COGNITIVE SCIENCE ON ISSUES ABOUT INNATENESS

It remains to consider the factual issue about innateness, and this is where the various branches of cognitive science play a crucial role.There are three main types of argument used in support of innateness hypotheses. These are:

- Transcendental arguments.
- Poverty of the stimulus arguments
- Impossibility arguments.

The soundness of these arguments clearly depends on what sense of 'innate' is being invoked. Transcendental arguments (Antony, 2001) concern innateness in the sense of 'inborn' or 'present at birth'. They point out that in order for learning from experience to be possible at all, something must be there already. Even the most extreme empiricists accept the conclusion of transcendental arguments; where they differ from nativists is in their accounts of what is inborn. Empiricists like the behaviorist B. F. Skinner think that all that is innate are dispositions to emit certain behaviors as a result of certain environmental stimuli, together with a disposition to modify the strength of these stimulus-response connections in response to reinforcement. In contrast, a nativist like Chomsky thinks that knowledge of UG is inborn. This is a much stronger innateness hypothesis than Skinner's, since it requires that there be inborn syntactic representations. Cognitive science contributes to this debate primarily by clarifying the processes of cognitive development. For it is only when we know what the mechanisms of learning and development are, that we will be in a position to identify their inborn precursors.

Poverty of the stimulus arguments contend that a given idea (a belief or a concept) must be innate (again in the sense of 'inborn') because the environment does not provide enough information to enable it to be learned. For example, Chomsky has argued that since the information about language available to children is so meager, knowledge of language must be substantially innate – in particular, he argues, a representation of Universal Grammar, a theory describing the features shared by all human languages, is an inborn feature of the 'language acquisition device' (e.g. Chomsky, 1965, 1993). Poverty of the stimulus arguments rely on four crucial empirical premisses: (i) people do in fact possess the idea in question (e.g. people have knowledge of a generative grammar); (ii) the available information is of such and such kinds (e.g. children do not get evidence about what *not* to say); (iii) the available learning mechanisms are of such and such types (e.g. language learning, if it occurred, would proceed by hypothesis testing); (iv) the available information is not sufficient to enable the idea to be learned by that learning method. Cognitive science will be critical in verifying all these premisses. For example, psycholinguistic theories of the processes of language production and comprehension will be the ultimate arbiters of Chomsky's claim that language use and understanding involve knowledge of a generative grammar; developmental psychology will tell us what information, as a matter of fact, children learning language have access to; and cognitive psychology or cognitive neuroscience, perhaps, will tell us what are the learning methods available to them. Only then will it be clear whether innate knowledge of UG is required for language acquisition.

A third kind of argument for innate ideas claims that since learning a certain idea is literally impossible, that idea must be innate. Fodor is the contemporary champion of this form of argument, contending that since concept learning is impossible, concepts must be innate. Fodor's impossibility argument starts with a transcendental point. Since learning a concept involves formulating and testing hypotheses about what it means, we must already have some representations available to use in stating our initial semantic hypotheses: unless some concepts are innate, concept learning could never get off the ground at all. Fodor's impossibility argument then continues as follows. Successful learning of a concept involves finding the correct hypothesis about what it means. This requires that we find, in effect, the definition of the concept: we have learned the concept 'dog' when we know that dog applies to a thing if and only if that thing is F, where F specifies the necessary and sufficient conditions for doghood. However, Fodor contends that, since most concepts do not have definitions (in the sense that we cannot specify their necessary and sufficient conditions, except circularly, by using the very concepts at issue), most concepts could not be learned. Concept learning is (in most cases) impossible, so most concepts must be innate.

It is still unclear exactly what 'innate' means in the context of Fodor's impossibility argument – there is still a serious interpretive issue here (see

Cowie, 1999, ch. 4). However it is clear, whatever 'innate' turns out to mean for Fodor, that cognitive science has an important role to play in establishing the soundness this argument. First, by developing alternatives to the hypothesis-testing model of concept acquisition, cognitive science may undermine the transcendental argument with which Fodor's argument begins: maybe concept learning does not require that we already have representations (though it may require that we have, say, a neural network with a certain kind of distribution of initial weights and a certain learning algorithm). Second, the development of alternatives to Fodor's account of concept possession may undermine his argument from the indefinability of concepts to their unlearnability. If having a concept is not necessarily a matter of knowing the necessary and sufficient conditions for its application (as, e.g. Prinz, 2002, argues), then the indefinability of concepts is no bar to their being learned.

In sum: claims about the innateness of ideas are often ambiguous. In order to assess such claims, then, it is necessary to understand what sense of 'innate' is being used and to be clear about what innateness, so construed, can explain. Claims about the innateness of ideas are also subject to empirical test, and this is where cognitive science comes in. When the processes of learning and development are better understood, we will be in a better position to know what is innate, and what implications this might have.

Intention

Intermediate article

Élisabeth Pacherie, Centre National de la Recherche Scientifique, Paris, France

CONTENTS

The concept of intention is used to characterize both actions and states of mind. To a first approximation, we classify actions as intentional if they are both purposeful and voluntary and we say that someone intends or has the intention to do something if he is settled on so acting.

INTRODUCTION

The notion of intention lies at the intersection of the two domains of action theory and philosophy of mind. On the one hand, the concept of intentional action is at the heart of action theory. Providing an analysis of the distinction between intentional and non-intentional action is one of its main aims, with important consequences for work on moral and legal responsibility. On the other hand, the notion of intention is also a central element in the web of concepts used to characterize the mind and the various kinds of states and attitudes that belong to the mental realm.

It is not surprising that intentions figure so prominently in both fields of inquiry. A capacity for intentional behavior is the mark of intelligent agency. Intentional behavior is behavior the correct explanation of which cannot be purely mechanistic but requires us to make reference to the agent's attitudes, beliefs and desires, and reasons for acting in a certain way. There is little doubt, therefore, that there is a close connection between intentions and intentional action. Yet, what exactly an intention is, what qualifies as an intentional action, and what is the connection between the two, are all matters of considerable philosophical debate.

ARE THERE SUCH THINGS AS INTENTIONS?

On one simple and prima-facie plausible view, the connection between intentional actions and intentions is to be construed as follows: someone does something intentionally if and only if he or she has the intention to do it and that intention causes him or her to do it. Yet this simple view can be criticized in a number of ways. One objection that can be raised is that it involves the unnecessary postulation of intentions as distinctive states or events. The philosophers who raise this objection (Anscombe, 1963; Davidson, 1980, essay 1) consider that for an action to be intentional is for it to be explainable by reasons the agent has for acting that way. In other words, an action is intentional if it is explainable in terms of beliefs and desires of the agent, typically a desire for, or more generally, a 'pro' attitude towards, a certain outcome and a belief that acting in such or such a way would promote attainment of this outcome. On this view, to say that someone acts intentionally or with an intention is simply to say that some appropriate relation obtains between the agent's beliefs and desires and the agent's actions. Talk of intentions as distinct states or events is therefore superfluous.

This relational analysis of intentions has in turn been criticized. As several philosophers, including Davidson himself, have pointed out (Davidson, 1980, essay 5; Bratman, 1987; Harman, 1986; Velleman, 1989), this analysis is inapplicable to intentions concerning the future, intentions that, although we may now have them, are not yet acted upon, indeed might never result in action. Acknowledging the existence of future-directed intentions forces one to admit that intentions can be states separate from the intended actions or from the reasons that prompted the action. But, as Davidson notes, once this is admitted there seems to be no reason not to allow that intentions of the same kind are also present in all or at least most cases of intentional actions. Once intentions are acknowledged as separate mental states and not just relational constructs, a new issue arises. Can these states be given a reductive analysis – are they assimilable to complexes of desires and beliefs, to

special kinds of beliefs or judgments – or do they form a *sui generis* and irreducible class of mental states?

BELIEFS, DESIRES AND INTENTIONS

Although they acknowledge the existence of states of intending, a number of philosophers want to resist the idea that intentions constitute some new, irreducible kind of attitude. They see beliefs and desires as the two fundamental kinds of mental state and think they can provide an analysis of intentions that remains within the bounds of the belief–desire framework. These elaborations of the belief–desire model have taken several forms.

One approach sees intentions as reducible to combinations of beliefs and desires. It is commonly admitted that intentions have both cognitive and motivational components. Belief–desire reductionism about intentions suggests that the cognitive component of an intention can be identified with a belief and its motivational component with a desire. In particular, it stresses the link between an intention to perform an action and a belief that one will, and claims not only that intending to do something entails believing that one will do it but that the intention consists in this belief. Yet, not all our beliefs about our future actions constitute intentions: some may simply be predictions. A proponent of this view must therefore introduce further constraints that beliefs should meet to qualify as intentions. Here, the motivational component of intentions becomes highly relevant. Thus, Davis (1984) suggests that an agent's intention to *A* consists in believing that the agent will *A* because he or she desires to *A*, together with believing that this desire will motivate him or her to *A*. Alternatively, Velleman (1989) identifies intentions with self-fulfilling beliefs that are motivated by a desire for their fulfilment and that represent themselves as such.

Another approach, advocated by Davidson (1980, essay 5), rejects this belief–desire reductionism. In particular, Davidson does not accept the claim that intending to *A* entails believing that one will *A*. Yet, his approach maintains a close correspondence between intentions, beliefs and desires. According to Davidson, intentions should be viewed as a special kind of evaluative judgment different from the evaluative judgments that correspond to desires to act. Desires to act are what Davidson calls 'prima-facie' judgments, judgments that actions of a certain kind are desirable insofar as they have a certain attribute. As such, prima-facie judgments are not directly associated with actions, for it is not reasonable to perform an action on the sole ground that it has some desirable feature. By contrast, an intention to act is what Davidson calls an 'all-out' judgment, an unconditional judgment, made in the light of one's beliefs, that a certain action is desirable. In making an all-out judgment as opposed to a prima-facie judgment, we settle on a course of action. Intentions are thus associated with actions in a way that mere desires are not. This analysis of intentions introduces a new element, an all-out judgment in the belief–desire framework, yet it avoids having to postulate a completely *sui generis* kind of mental entity. Intentions, together with other pro attitudes, are deemed to belong to the general class of evaluative judgments.

Each of these proposals has encountered specific objections. For instance, it is not clear how, on Davidson's view, an agent would decide between two courses of action that are equally desirable all things considered but are not mutually compatible. It is also disputed whether intending to *A* need always entail believing that one will, not to mention whether it consists in this belief. A more general criticism of such analyses is that they are too backward-looking. They focus on how intentions are arrived at, and therefore fail to appreciate important aspects of the role of intentions.

THE FUNCTIONS OF INTENTIONS

Opponents of reductive approaches to intentions tend to emphasize a number of functions plausibly attributed to intentions. They argue that intentions have their own complex and distinctive functional role that warrants considering them as forming an irreducible kind of psychological state, on a par with beliefs and desires. Among these functions are some that are most apparent when one considers future-directed intentions and the way they function in practical reasoning. Philosophers pursuing this line of inquiry (Bratman, 1987; Harman, 1986; Mele, 1992) propose to articulate what is at stake in being settled on or committed to some course of action as a result of having formed or acquired an intention. Thus, Bratman stresses three aspects of the roles played by intentions in the period between their initial formation and their eventual execution. First, intentions have a characteristic stability or inertia: once we have formed an intention to *A*, we will not normally continue to deliberate whether to *A* or not; in the absence of relevant new information, the intention will resist reconsideration. Second, during this period between the formation of an intention and action, we will often reason from such an intention to

further intentions, for example, reasoning from intended ends to intended means or preliminary steps. Third, this intention will itself often be an element in a larger plan: it will constrain the other intentions we may form and will help us achieve both intrapersonal and interpersonal coordination.

The role played by intentions in practical reasoning is especially salient when we consider future-directed intentions. The executive aspect comes to the fore when we concentrate on immediate intentions. Here the philosophical focus is on the role of the intention in the production of the corresponding action (Brand, 1984; Mele, 1992). This role is both cognitive and motivational. Many philosophers agree that intentions are motivating causes of actions. Furthermore, this role as motivators is not only to trigger or initiate the intended action but to sustain it until completion. If, say, while on my way to my office, I ceased to intend to go my office, this would bring my action to a halt. Intentions also involve the guidance and monitoring of action. The cognitive component of an immediate intention to *A* incorporates a plan for *A*-ing, a representation or set of representations specifying the goal of the action and how it is to be arrived at. Moreover, intentions may be assigned a monitoring function, a capacity to detect progress towards the goal or to detect and correct deviations from the course of action as laid out in the guiding representation.

An exclusive focus on the practical reasoning aspect of future-directed intentions may give the impression that only agents endowed with sophisticated cognitive abilities may be capable of intentional actions. Yet, some philosophers think that it would be unduly restrictive to limit the sphere of intentional actions to premeditated or planned actions. They are ready to accept that some actions that we perform relatively spontaneously and without prior deliberation, or some actions performed by creatures devoid of the sophisticated capacities necessary for forward planning, still qualify as intentional actions. Concentrating on the executive aspect of immediate intentions may be a way to make sense of this idea. We will return to this question, after considering one further idea related to the executive aspect of intentions.

ARE INTENTIONS SELF-REFERENTIAL?

Reflection on the executive functions of intentions has led some philosophers (Harman, 1986; Searle, 1983) to claim that intentions involve a kind of causal self-referentiality. Put very simply, the self-referentiality thesis is the thesis that an intention to *A* is the intention that this very intention be the cause of the agent's *A*-ing. Two main considerations may be adduced in favor of this thesis.

First, if one accepts a causal analysis of intentional actions according to which an action's being intentional depends on its being appropriately caused by a corresponding intention, one must find a way to exclude cases of deviant causal chains. An example, adapted from Harman, may illustrate the nature of the problem. Mabel may intend to kill Ted by running him over in her car. Ted happens to be walking by when she backs out of her driveway and she runs him down, killing him without even seeing him. Here, although Mabel intended to kill Ted by running him over and killed him in this way, her action is not intentional: although her intention plays a causal role in her running over Ted, it is not the causal role specified in the content of the intention itself. The suggested moral is that for an act of *A*-ing to be intentional, it is not enough that it be caused by an intention to *A* or even an intention to *A* in a certain way, but the intention must be an intention that this very intention lead one to *A* in a certain way.

This conclusion has been challenged by Mele (1992), who argues that what accounts for Mabel's action being unintentional may be a function of the plan component of her non-self-referential intention. For instance, he would say that Mabel's action is not intentional because her intention did not incorporate a plan to run down Ted while backing out of her driveway. Mele insists that it not enough for an action to be intentional that it fits some intended plan; it must be guided by the plan. It is unclear, however, what is involved in the notion of guidance and whether it can be defined so as to exclude causal deviance without invoking the idea of causal self-reference of intentions.

A second kind of consideration supporting the self-referentiality thesis refers to the conditions of satisfaction of intentions. Searle (1983) argues that the conditions of satisfaction of an intention include that the intention itself play a causal role in bringing about the rest of its conditions of satisfaction. Moreover, Searle claims that this causal self-referentiality condition is internal to the content of the intention. Thus, the content of my intention to raise my arm should include that I raise my arm as a result of this very intention.

This construal of the self-referentiality thesis has also been challenged. It has been objected that, even if self-referentiality is part of the conditions of satisfaction of intentions, there is no obvious reason

why this condition of satisfaction should be reflected in the content rather than attached to the psychological mode itself or considered part of the background conditions. It has also been objected that Searle's account of self-referentiality is psychologically implausible in requiring of the intenders unrealistically strong cognitive and conceptual capacities. Recently, attempts have been made to dispel the charge of conceptual oversophistication by showing how self-referentiality can be construed as an implicit element of the content of intentions, reflecting architectural and circumstantial facts about how the intention connects with action (Pacherie, 2000; Roth, 2000).

THE CONNECTION BETWEEN INTENTIONS AND INTENTIONAL ACTIONS

The discussion of self-referentiality above raised the question whether it is sufficient for an action of *A*-ing to be intentional that the agent have the intention to *A* or whether it is furthermore required that the intention be self-referential. We can also ask the converse question, namely whether it is always necessary for an action of *A*-ing to be intentional that the agent intends to *A*. In other words, are our folk-psychological notions of intention and intentional action sufficiently univocal that philosophers may hope to provide a unified analysis of their connection? We will now examine three kinds of cases that seem, in different ways, to shed light on the connection between intentional actions and intentions.

Expected Side-effects and Responsibility

Both Harman (1986) and Bratman (1987) have argued that certain actions we perform are intentional despite not being intended because they are expected side effects of some (larger) action we intend to do. For instance, Bratman claims that if someone intends to run a marathon and believes that he will thereby wear down his running shoes, his action of wearing down his running shoes is intentional despite not being intended. Similarly, Harman suggests that in firing his gun to try to kill a soldier, a sniper who knows that he will thereby alert the enemy to his presence does not intend to alert the enemy, yet does so intentionally. If this analysis is accepted, we are forced to conclude that there is a gap between intentions and intentional actions. One way to try to avoid this conclusion, suggested by Mele and Moser (1994), involves drawing a threefold distinction among intentional actions, unintentional actions and non-intentional actions. Since the sniper does not unknowingly or accidentally alert the enemy, the action is not unintentional, but since, on the other hand, alerting the enemy was not a goal or aim of the agent, nor is it intentional. Non-intentional actions would then constitute a middle ground between intentional and unintentional actions.

However, as both Bratman and Harman note, the tendency to consider an expected side effect as an intentional action depends on the significance of the action and on the reasons one might have not to do it. We can contrast alerting the enemy with another expected side effect of firing the gun, such as thereby heating the barrel. Although we have no inclination to say that the action of heating the barrel was intentional, we may want to say that alerting the enemy was intentional insofar as the sniper had reasons not to want to alert the enemy and yet chose to do so. Here the topic of intentional action becomes entwined with issues of responsibility and moral assessment. Maintaining that an action was intentional may justify holding the agent responsible for it. At the same time, maintaining a distinction between intentional actions that are intended and intentional actions that are not may also make an important difference for moral or legal purposes.

Goals, Plans, and Skills

We have considered cases where one might be said to act intentionally in *A*-ing despite not having *A*-ing as a goal, and thus not having the intention to *A*. Conversely, there are cases where one does *A*, one has *A*-ing as a goal and in this sense an intention to *A*, and yet it is unclear whether the *A*-ing qualifies as an intentional action.

Take the following example adapted from Mele. Tom, who has never handled a gun before but is offered a large prize for hitting the bull's-eye on a distant target, aims carefully, fires and hits the bull's-eye. Does he do it intentionally? Here, intuitions diverge. Some philosophers consider that Tom intentionally hits the target, others deny it. Those (Velleman, 1989; Mele and Moser, 1994) who deny that the action is intentional typically insist that in this and similar cases, successfully *A*-ing is not sufficiently within the control of the agent because he lacks a reliable plan for or sufficient skill at *A*-ing and because there is therefore an important element of luck involved in the action resulting in success of failure. Yet, in Tom's case, even philosophers who would deny that the action

was intentional accept that the action was done for a reason – Tom wanted the prize money and thought that to win it he had to hit the bull's-eye – and that in this sense he acted with the intention to hit the bull's-eye. Velleman sees such cases as proof of a fundamental ambiguity of the term 'intention', which is used to denote both plan states and goal states. It would seem that those who think that Tom's and similar actions qualify as intentional actions have intentions as goal states in mind, and those who deny this think of intentions as plans or representations that guide and control the action.

Yet Velleman's distinction may still not fully capture the complexity of our intuitions. Take the following more extreme example, borrowed from Mele and Moser. Lisa selects a sequence of six numbers to win a fair Florida instant lottery, and, as it happens, she wins the lottery. Here, it seems that we would not want to say that Lisa wins intentionally, and that we would also be reluctant to say that she acted with an intention to win, despite the fact that she chose the numbers out of a desire to win the lottery. Our unwillingness to consider the action as intentional is not motivated by Lisa's lack of skill or the frailty of her plans. Assuming that the lottery is fair and that there is no way to win by cheating, Lisa has done all that was in her power to win the lottery. The difference between the Lisa and Tom cases lies in how much the successes of their actions, considered as types, can in principle depend on the agents' skills or planning abilities.

It seems, therefore, that to account for our intuitions a threefold distinction is needed. At one extreme are actions over which the agent has a sufficient degree of control, and which are therefore uncontroversially intentional. In the middle are actions over which the agent could in principle have a sufficient degree of control (as witnessed by the fact that some other agents do exhibit such control – for instance expert marksmen), and which can be deemed intentional in a weaker sense (Tom's case). At the other extreme are actions over which we could not in principle have sufficient control, because there is some important element of luck on which their outcome depends essentially (Lisa's case).

Sudden, Impulsive, and Subsidiary Actions

Some philosophers (Searle, 1983; Wilson, 1989) argue that sudden and impulsive actions can be intentional despite being performed without the agent's forming, either consciously or unconsciously, a prior intention to do them. Thus, if a pile of books on my desk starts to topple, I might suddenly reach for the pile to keep it from collapsing; or, frightened by an earth tremor while in California I might impulsively throw myself under a table; acting in both cases intentionally. Similarly, Searle claims that even in cases where we have a prior intention to do something, there are often many subsidiary actions that are not represented in the prior intention and yet are intentionally performed. I might have a prior intention to type a certain sentence, without the intention representing the key pressings that must be performed for the sentence to be typed. It may be thought that sudden and impulsive actions are too fast for there to be time to form an intention. It may also be pointed out that such actions do not meet the strong consistency requirements that are distinctive of actions done in conformity with a prior intention. Typically, they are performed with no regard for their potential side effects or for their general coherence with the agent's other beliefs and goals.

On Searle's account, these actions are intentional despite the absence of a prior intention because they involve an 'intention-in-action'. In his terminology, a prior intention is an intention that is formed prior to the action and that represents and causes it as a whole. Thus, both future-directed and immediate intentions are prior intentions. An intention-in-action is the mental component of the action itself; it presents, causes, and is contemporaneous with, bodily movements. The intention-in-action together with the bodily movements it causes constitute the action. According to Searle, all intentional actions have intentions-in-action but not all have prior intentions. And even when both a prior intention and an intention-in-action are present, the intention-in-action will typically be much more determinate than the prior intention.

The claim that some intentional actions need not involve prior intentions can be challenged in two different ways. Some philosophers agree that in the case of sudden or impulsive actions, intentions are absent, but, because of this absence, deny that such actions really qualify as intentional. Bratman (1987) suggests that they are purposeful and voluntary but still not intentional (nor unintentional). Conversely, one might agree that such actions are intentional, but claim that they involve an intention. Thus, Mele (1992) distinguishes between forming an intention and (passively) acquiring one, and suggests that although in the case of sudden and impulsive actions an agent may lack sufficient time to form an intention, he or she may still have time to acquire one. Similarly, in the case of actions

involving many subsidiary actions, one may contend that a prior intention normally includes a detailed plan for acting and thus that intentions-in-action are superfluous.

As Mele and Moser (1994) suggest, highly relevant to this debate is the difficult question of how much of what is going on representationally in the preparation and execution of an action should be included in the content of intentions. Work in the neuroscience of action suggests that there are multiple levels of representation and control of action, from high-level specifications of goals down to low-level specifications of neuromuscular activity. It remains an open question, partly empirical and partly conceptual, which of these representations should be considered part of the content of intentions or, if one countenances them, intentions-in-action, and what role criteria such as accessibility to consciousness or representational format (conceptual or not) should play.

CONCLUSION

Philosophical analyses of the notion of intention reveal a number of aspects – practical reasoning, planning, goal-directedness, control of action – which it may either essentially include or be closely associated with. Presumably, what we take as prototypical cases of intentions and intentional actions are cases where all dimensions are present. In less clear cases, philosophical intuitions differ. The debates over the nature of the connection between intentions and intentional actions bespeak the lack of general agreement on the respective roles and relative importance of these aspects. Different approaches privilege different aspects or weigh them differently when characterizing intentions as states of mind and when characterizing intentional actions. These disagreements may in turn be explained in part by interest in the different issues – rationality, ethics, freedom, mental kinds, motor organization – with which the notion of intention is connected. A number of studies have explored intentions from an intersubjective point of view. Some theorists are interested in collective actions and the types of shared or cooperative intentions that make them possible. Others try to characterize the abilities that underlie our capacity to interpret observed actions as intentional and to attribute intentions to the agents performing them, thus connecting work on intention with the topic of mindreading. These new perspectives may well pay special attention to features of intentions less salient in other approaches.

Intentional Stance

Intermediate article

Don Ross, University of Cape Town, Cape Town, South Africa

CONTENTS

The intentional stance is an attitude to the place of mind and psychology in the world that allows a real scientific role for such concepts as beliefs and desires without forcing us to suppose that they have literal physical (or nonphysical) correlates in people's heads.

WHAT IS THE INTENTIONAL STANCE?

One takes the 'intentional stance' (IS) towards a system – whether person, animal, machine, or group – whenever one explains and predicts its behavior using so-called 'intentional' concepts such as 'belief' and 'desire'. For example, one might explain or predict a delivery-person's leaving a package outside the front gate, instead of on the doorstop, by saying 'she believes that the dog is vicious, and she doesn't wish to get bitten'. Or, to use the original example due to Daniel Dennett (who introduced the IS as a technical idea), one might explain a chess-playing computer's move by saying 'it wants to get its queen out early'. To predict the behavior of the machine, one must ascribe to it the desire to play winning chess, in addition to some beliefs about chess rules, good strategies, and the probable reactions of opponents. In general, to take the IS towards a system is to assume that that system is related to states of the world by a network of intentions, and that these intentions relate to each other in standard ways familiar in our 'folk psychology': for example, if a person desires outcome x, and believes that doing y is a good way to bring about x, and fears other consequences of doing y less than she desires x, and believes that she can do y, then she will do y. (*See* **Folk Psychology**)

It may seem that in the case of the chess-playing computer, the assumption that the machine has beliefs and desires is just a pretense, like assuming that the actor in a film really does fear being eaten by the surrounding aliens. The pretenses may be necessary in both cases – you cannot enjoy the film if you keep reminding yourself that the actor's beliefs are feigned, and you cannot predict what the computer will do if you do not treat it like a real chess player – but, one might think, to take either pretense literally would be to lose touch with reality. Dennett would agree that the case of the actor involves pretense, but he argues that, if the chess-playing computer is complicated enough, we should take the IS towards it just as we take the IS towards people – including ourselves.

We will first briefly explain the reasons for this view, which might initially seem absurd, and then describe the role it has played in cognitive science.

ARGUMENTS FOR THE INTENTIONAL STANCE

Understanding the logical path that leads to the IS requires some reference to the history of attempts to locate the place of mind in nature. Most philosophers before the twentieth century believed that minds were nonphysical entities of some sort. On this view, beliefs and desires could be thought of as real states of 'mental spirit'. However, if mind–body dualism is rejected, then it is necessary to replace the dualist's spiritual states by physical ones. An obvious idea here is that every intentional state – every state, that is, that is 'about' some other state or object p, and so could be described in terms of a belief that p, desire that p, fear that p, or other 'propositional attitude' – must be identical with a brain state, directly identifiable and describable in the language of neuroscience. This idea faces immediate philosophical questions, however. How could a brain state be 'about' an indefinite class of objects (e.g. 'purple things'), or, perhaps worse, an indefinite class of abstract objects (e.g. 'democratic countries')? After all, nothing in a brain is purple or democratic. Moreover, people, who have explained and understood each other in intentional terms for millennia, do not directly observe brain states, even their own. What we observe, at least in the case of others, is just behavior. (*See* **Propositional Attitudes**)

In 1949, the philosopher Gilbert Ryle sought to resolve this problem by arguing that the concept of mind, and its subsidiary concepts, including the intentional concepts, are constructed from observable patterns in behavior. The mental states that we think we directly perceive as 'inner states' in our own cases are in fact, according to Ryle, judgments about our motivations and general dispositions, which, because they happen automatically, 'feel like' inner perceptions.

One of Ryle's foremost students was Daniel Dennett. Around the time (1969) that Dennett published his first book, the view that mental states are identical to brain states was collapsing under the assault of functionalism. If the mind–brain identity theory were true, the functionalists argued, then, by definition, no two creatures with significantly different brains could ever share a common belief. What content a belief has, the functionalists argued, must be a function of that belief's role in a general network of intentional states. What grounds the whole network, Dennett added, are observable patterns in behavior and expectations about behavior (e.g. the belief that *p* is the state that interacts with other beliefs and desires to produce a disposition to say 'yes' when asked whether '*p*'). When one system interprets another, or a system interprets itself, in terms of such patterns of expectation, then the intentional stance is taken. (*See* **Functionalism**)

The integration of work in artificial intelligence (AI) with cognitive science more generally during the 1970s contextualized the idea of the IS. If you are trying to construct a mind, do you need to deliberately build in, one by one, the millions of beliefs and desires you think it will need if it is to be genuinely intelligent? Or, even if you think the system can build these for itself using some learning procedure, must it ultimately come to possess millions of physically distinct symbolic tokens, one for every distinct intentional concept, that it can then internally manipulate? Dennett argued that not only does neuroscience provide no evidence for such a picture, but that it seems too inefficient a kind of design to have been produced by evolution. In real, changing, environments, such serial symbol-processing incurs enormous computational search and retrieval costs. It also fails to exploit the fact that the external world itself stores plenty of information. A system that can just be disposed to react appropriately given various input patterns can achieve complex behavioral capacities using a much less complicated content-storage system. And if a system's reaction patterns can be shaped by its environment over time, so that it acquires new dispositions as it learns, then, if it has a symbolic bookkeeping system like a language, it might try to keep track of these shifting systems of dispositions by labeling them. The labels can be stored in the world – in texts, and in networks of other systems' dispositions. And then the labels themselves can be triggers of dispositions. Thus I can cause you to judge that you believe that Winston Churchill liked brandy.

Many AI programs, especially those running on 'connectionist' architectures, do not store the beliefs by which we can reliably explain and predict their dispositions separately, at distinct physical addresses in their internal circuits. Instead, these dispositions are consequences of the interactions of patterns of informational activity distributed across the system. Some evidence from neuroscience suggests that, at least in their general cognitive operations, brains work in this way too. If this is so, then there is no particular neural state of your brain that codes your belief about Churchill and brandy. Your belief just consists in the fact that your whole system of dispositions is such that your behavior is consistent with that belief, and inconsistent with its denial. When you wonder whether you have that belief, you take the intentional stance towards yourself, and, on the basis of a very simple piece of behavior – asking yourself a question in English – you rightly judge that you do. This is the same sort of procedure by which we judge that the computer believes appropriate things about chess: we put it into a game situation and look for certain sorts of patterns in its behavior. (*See* **Connectionism**)

PROBLEMS WITH THE INTENTIONAL STANCE

There are two different ways in which the intentional stance can be invoked in cognitive science. If one does not wish to be committed to a metaphysical position on the mind, one can merely agree that we can and do assume the IS towards systems for various practical (including scientific) purposes, while remaining agnostic on the question of whether there is more to having a mind than being the sort of system to which the IS is usefully taken. This philosophically cautious use of the IS is generally uncontroversial. Taken this way, the IS is just a rough measuring device for studying interactions between systems with goal-directed behavior patterns and their environments.

Dennett and his followers, however, understand the significance of the IS in a stronger sense. Following Ryle's lead, they argue that no discrete

inner physical state of a system can be identified with a particular intentional state, in the sense of having, by itself, all and only the content picked out by the IS-level description (e.g. the content 'that Churchill liked brandy'). Therefore, they argue, to be an intentional system – that is, a system with a mind – is just to be a system that exhibits behavioral patterns that cannot be adequately explained and predicted without use of the IS (Dennett, 1991b).

Critics of this view argue that it does not explain minds, but rather explains them away. They claim that it amounts to supposing that minds and intentions are merely useful fictions, and that in that case they are not proper scientific objects; and the ultimate goal of cognitive science should be to eliminate them. This view is known as eliminative materialism. (*See* **Eliminativism**)

Dennett and his followers respond to this criticism, first, by noting that the IS may ultimately be indispensable. We may never be able to explain and predict the behavior of a complex system, even a system we have designed and built ourselves, such as a sophisticated chess-playing computer, merely by reference to its internal causal network. We might have to make reference to its web of inferential and causal relations with the world of chess and chess-related patterns and objects: after all, that is what the system is tracking in both its behavior and its learning. If this point is granted, the Dennettian can then argue that patterns of this sort are fully 'real' in the only sense of 'reality' that matters: they encode information in such a way that, if you miss the encoding, there is something about the world you will not be able to know (Ross, 2000).

THE INTENTIONAL STANCE AND COGNITIVE SCIENCE

Even cognitive scientists who do not wish, like Dennett, to explain the very idea of mind by reference to the IS, have found the IS perspective useful in practice.

Firstly, the IS has been helpful to scientists building and theorizing about models of distributed cognition, in which the world-oriented behaviors of the models can only be described at the whole-system level. If described strictly at the level of their internal operations, these systems – even brains themselves – do not seem to exhibit any intentional behavior at all. Their designers must, however, have target 'intentional' behaviors to guide their work. This requires the assumption of the IS towards them (Clark, 1989). (*See* **Distributed Representations**)

Secondly, those who study the minds of non-human animals and prelinguistic human infants must form and test hypotheses about relationships between the creatures' behaviors and their goals and functions, but face the problem that they cannot determine these, as with adult humans, by asking the subjects themselves to describe them. These researchers into what Dennett has called 'cognitive ethology' begin precisely with the rudimentary IS framework – the idea of a psychology based on beliefs and desires – and try to determine its details for other species and for young humans. Work of this sort with children strongly suggests that the capacity for using the IS is a genetically natural part of human development, which arises in systematic and predictable intervals as people mature. (Autism appears to be a syndrome arising from a variety of developmental and genetic mishaps that interfere with the capacity for assuming the IS (Griffin and Baron-Cohen, 2002).) This perspective adds weight to the scientific and empirical 'reality' of the IS, regardless of the philosophical debate. (*See* **Autism**)

Finally, Dennett has himself built an extensive theory of consciousness using the scaffolding of the IS (Dennett, 1991a), and this has played a significant role (along with rival views) in providing a conceptual framework for empirical research.
