It has long been known that organized material is easier to learn and remember than is unorganized material (Baddeley, 1990, p. 182), even when the organizational principle is not made clear to the participants, but is left for them to discover. For example, many years ago, Deese (1959) showed his subjects a list of 15 words that were either high associates of an initial starting word, or words that were all unassociated with each other. For a list beginning with the word 'butterfly', for example, high associates might include the words 'moth', 'insect', and 'cocoon'. Words on an unassociated list might include 'university', 'zebra', 'native', and so on. Subjects typically recalled 33 percent more from the high associates list. The improved retrieval of apparently unrelated words that is observed when subjects use mnemonic techniques supports this fundamental theoretical principle because, no matter what else mnemonic techniques accomplish, and by whatever mechanism they achieve it, nevertheless their use forces their users to organize incoming material. Moreover, the organization that the subjects subjectively apply to the material seems to be superior as a memory aid than any organization imposed by the researcher, and this condition is also met when using mnemonics.

The retrieval phenomena that are seen in the mnemonics literature are also very consistent with what is known about semantic activation and cuing (Reisberg, 1997, p. 262). For example, in a semantic network, a word that is semantically associated, even weakly, with a number of different words has a greater chance of being retrieved than does a word with only one association, even if that association is semantically very powerful. The reason is that a word that is semantically associated with a number of words – that is, a word enmeshed in a well-developed and rich semantic network – is more likely to be successfully cued because it is likely that any one of its many associates is activated by a memory search. On the other hand, a word associated with only one or a few other words has rather few 'routes' of activation that may succeed in cuing it. This explanation accounts for some of the inflexibility in mnemonic processes discussed earlier in the section on the method of loci. Because there are no semantic links from one item to the next on the list, a person using the method of loci cannot readily cue a list item from another list item.

Memory Models

Intermediate article

Bennet B Murdock, University of Toronto, Toronto, Canada

CONTENTS

Memory models are formal (analytic or simulation) models of human episodic memory. Their goal is to help in the understanding of human episodic memory, and the test of their adequacy is their ability to fit or predict experimental findings.

INTRODUCTION

Memory models are information-processing models which assume that the storage and retrieval of information in human memory is a dynamic, not a static process. New information is constantly entering the system and old information is becoming weaker or less available. These models attempt to specify the processes formally, so that quantitative predictions are possible and the models can be tested by comparing their predictions with the extensive experimental data on human memory. The models tend to focus on short-term episodic memory rather than long-term semantic memory because there is more data available and testing the models is easier.

MATRIX MODELS

The prototypical matrix model is the linear-associator model (LAM) of Anderson. It deals with associations, the building blocks of human memory. More particularly, it deals with an association between input and output. For instance, I hear the word 'echo' and I can then say the word 'echo'. Even though on paper the two 'echos' are the same, in actuality one is a stimulus (input) and the other is a response (output).

The model assumes that an item such as the word 'echo' can be represented by a vector of features where the features are normally distributed with mean zero and variance 1/N. (N is the dimensionality of the vectors: i.e. the number of features.) The model does not specify what these features are, but it does specify their underlying distribution (i.e. normal or bell-shaped).

The basic mechanism for LAM is auto-association where the association is represented by the outer-product matrix of the item vector with itself. The i,jth element is simply the product of the ith element of the item with the jth element of the same item, and it is stored in the outer-product matrix. For recall, if the item is later applied to one of the inputs then the echo will appear on the other input, which now functions as the output. Technically this involves pre- or post-multiplication of the item vector with the memory matrix depending on the input channel.

The matrix can store many auto-associations; one by one their auto-association is formed and added to the memory matrix (superposition). The items must be independent (uncorrelated) and the capacity depends on N, the dimensionality of the item vectors. The system can even do redintegration; a partial cue (a subset of the item features) can reinstate a reasonable approximation of the original item.

Even though the model can be (and has been) extended to hetero-associations (associating pairs of items), it is quite limited in scope. However, it is simple and elegant, requires no search process, and has served as the basis for much later development in the field.

ARTIFICIAL NEURAL NETWORKS

Artificial neural networks (ANNs) started in the late 1950s but these simple two-layer networks fell into disfavor when some of their limitations (basically linear independence problems) became known. However, there was a resurgence of interest when it was realized that multiple-layer networks could overcome these limitations. Most ANNs start with biologically realistic principles of neural function and they then develop an architecture to implement these functions, generally by means of computer software.

Many of the developments focus on getting computers to do interesting or useful things, but here I will discuss TECO (Sikstrom, 2000), a particular ANN which attempts to explain much psychological data on human memory. Although a very recent development, TECO (target, event, cue, and object) probably applies to a wider range of memory data than any other ANN. In many ways it is a modified version of a Hopfield net, a classic ANN which by a nonlinear iterative procedure can clear up a 'noisy' output and turn it into an exact copy of the original input.

In TECO, items and context are represented by independent nodes, which take on the binary values of 0 (inactive) or 1 (active) where the probability of being active is much smaller than the probability of being inactive. Each node is connected to every other node and these connections form the weight matrix that constitutes the memory of an ANN. The binding of item and context is achieved by auto-association as in LAM. Each time an item is presented in a context the weight matrix is updated by a Hebbian learning rule so again like other ANNs, this model uses superposition.

To explain habituation TECO assumes that there are inhibitory signals in the nodes and that the nodes are connected in a chain, where early parts correspond to perceptual areas in the brain and later parts to more semantic areas. Habituation increases with stimulus repetition, decays over time, and varies with the input frequency. The amount of encoding, the degree of forgetting, and the ease of retrieval is diminished by habituation. Including habituation in ANNs accounts for several empirical phenomena; for example, the primacy effect, the rate sensitivity of the primacy effect, long-term recency, and the shift from primacy to recency with delay.

The mirror effect is a current puzzle in the memory area; in item recognition there are fewer false alarms (saying 'old' to a new item) with rare words than common words, but more hits (saying 'old' to a studied word) with rare words. This is a puzzle if you believe recognition judgments are based on memory-trace strength; how can rare words (initially weaker) leapfrog over common words and become stronger following a single presentation?

TECO assumes that strength is based on the summed output of many neural units. If the strengths of the individual units are normally distributed, and units for common words have larger variance because they are embedded in many contexts, then the mirror effect and other related phenomena regarding the distributions of familiarity should always hold if the network is tuned to optimal performance. Optimal performance would result if the criterion were placed between the means of the old and the new items. This optimal tuning also yields a smaller variance of familiarity for new items and rare words that is consistent with experimental results.

TECO can also explain power-function forgetting curves, recognition failure of recallable words, serial-position effects in free recall, and many other memory phenomena. It is not yet clear whether TECO is subject to catastrophic interference. In a retroactive inhibition study, if subjects learn a list of A–B paired associates and then learn a second list with the same A items but new B items, they gradually forget the original B items as they learn the new B items. However, in many ANNs the networks show 'catastrophic' (i.e. very rapid) unlearning of the original B items, so these models are not consistent with experimental data.

MINERVA2

MINERVA2 (Hintzman, 1988), presumably named after a major Roman goddess, is a computer-simulation model which differs from LAM and TECO in that its memory is serially organized like a computer. Each item (example or exemplar) is stored in its own location (like books on a library shelf) and as each new item arrives it is placed at the bottom of the stack. Thus, there is no superposition; each item occupies its own discrete location.

As in TECO, items consist of binary features (+1 and −1, though unknown or forgotten features are set to 0) and, again like TECO, context and content features are concatenated (placed side by side in the same item vector). However, there is no auto-association. For paired associates, the context vector and the two single-item vectors are concatenated in a single memory trace.

When a probe is presented it is simultaneously compared to all items in memory (or in the search set which is determined by context) and an activation value is computed from the probe–item similarity values. The similarity value is the normalized dot-product of the probe with each item (the dot-product is the sum of the product of all feature values) and it is normalized by the number of active (i.e. non-zero) features in that item. The activation value is the cube of the similarity value, and the echo intensity (or resonance) is the sum of all the activation values. This echo intensity forms the basis for decision in a recognition-memory test.

MINERVA2 attempts to show how generic knowledge can develop out of episodic memory when there is only a single memory system with individual storage of exemplars (items). The model first focused on a schema-abstraction task in which subjects learn to classify selected exemplars of a small number of prototypes without seeing (or being told about) the prototypes themselves. A standard result is that old exemplars are classified more accurately than the prototypes on an immediate test, but this reverses over time.

Simulations of MINERVA2 show that it is able to reproduce not only the standard result but other results from the schema-abstraction paradigm (e.g. old exemplars are consistently classified better than new exemplars, and for new exemplars low-level distortions are consistently classified better than high-level distortions). Thus, the model shows one way that semantic memory could arise out of episodic memory, and it does not postulate a separate semantic memory.

Another accomplishment of MINERVA2 is to successfully model both judgments of frequency and recognition memory within the same basic theoretical framework. Since MINERVA2 is a multiplex model (each presentation of an item lays down a separate trace), the more often an item had been presented the greater the echo-intensity mean and variance. Item recognition (present or absent) is the special case (1–0) of frequency judgements. The model can also account for many basic findings (list-length effects, orienting tasks, and similarity effects). Even though the number of items stored in memory could be very large, in principle the judicious use of context could allow the model to focus on recent events such as the particular items presented in the most recent list.

SAM

The SAM model (search of associative memory) (Gillund and Shiffrin, 1984) is an elaboration of the earlier buffer model of Atkinson and Shiffrin, one of the early (and very influential) formal models of memory. The model has been applied primarily to item recognition and free recall, although it does make predictions about cued recall (paired associates) as well.

In SAM items are represented as images (nature not specified) and retrieval cues are used to activate (retrieve) these images. The efficacy of these cues depends on their strength, of which there are four kinds: context, item, associative, and background. These strengths depend on how long items or pairs of items have resided in the memory buffer. The memory (or rehearsal) buffer has a limited capacity (generally four single items or two pairs), and the image-strengths increase with the duration of buffer occupancy.

For recognition, the item(s) and the context cue are compared with all the items in the list, and a yes or no response is given according to whether or not the summed strength is above or below a predetermined criterion. The summed strength is the sum of the products of the item(s) and context cues with all the relevant images, so the model can apply to both item (old/new) or pair (intact/rearranged) probes. To introduce variability into the model a three-point variability scale is assumed so with this, the strength parameters, and the criterion value the model can be used to make quantitative predictions for experimental results obtained under specified conditions. However, unlike LAM, TECO, and MINERVA2 it is not a process model; rather it is a way of computing the predicted values by varying the parameter values to see if the model can produce results which match the experimental data.

For free recall, a task where the subject is asked to recall as many items as possible from the most recently presented list, there is a sampling and a recovery process. First all the items in the buffer are recalled (they are usually the last few items in the list), then using context as the cue, items are sampled until a new item is found and, if recovered (never certain), the context and recovered item are used to repeat the process until an arbitrary criterion is reached. This criterion determines the number of unsuccessful sample-and-recovery cycles the subject tolerates, and once this criterion is exceeded the process stops.

The SAM model has been very successful in accounting for a wide variety of data, at least at the qualitative level. In this regard, it is probably the best model we have. However, it has a large number of parameters (in the 1984 version, 13 for recognition and 18 for recall) and, depending on the application, one or more of these parameter values may be varied to make the model fit. In such cases it is the parameter(s), not the model, that is doing the work. On the other hand, the authors have often emphasized the qualitative rather than the quantitative predictions, and perhaps the parameters simply indicate the number of processes that must be involved.

OSCAR

OSCAR (Brown *et al.*, 2000), an acronym for oscillator-based associative recall, is different from the

models discussed so far because it deals primarily with the storage and retrieval of serial-order information. Serial-order information is what allows us to retrieve a list of items in order; for example, the days of the week, our access codes, how to spell words. This is probably the most challenging problem in the episodic memory area; there are many complex and puzzling phenomena that our models must explain.

Traditionally there have been two types of models, those based on item-to-item associations and those based on item-to-position associations. Item-to-item models are generally chaining models; if the list is ABCDE then A–B are assumed to be associated (linked), and B–C, C–D, up through D–E. Then if we can recall A (which can be a mystery in a chaining model) then A will give us B, B will give us C, and so on, until we have recalled the entire string. Thus, serial-order information is assumed to be based on linked pairwise associations.

Item-to-position models assume there is some fixed internal representation of ordinal position, perhaps like adjacent storage registers in a computer. Call these bins; then the first item goes in the first bin, the second item goes in the second bin, and so on. To retrieve the string we examine the bins in order and read out their contents. Quite apart from what the nature of these bins is, how can we remember at the same time short lists of items, such as 'IBM' or 'PC', and at the same time much longer strings, such as the letters of the alphabet or how to spell 'encyclopedia'?

OSCAR is basically an item-to-position model, and provides a simple and elegant answer to both these questions. It assumes there are a number of endogenous asynchronous oscillators in the brain that provide timing signals which provide the functional 'bins' required by any item-to-position model. That is, each item is yoked to a particular set of values of these timing signals, so to retrieve, say, a telephone number you have just seen or heard you reset the oscillators to their original initial value; then by recycling the oscillators you regenerate the telephone number.

Technically, items are represented as vectors of features (like LAM and TECO) and they are associated in an outer-product matrix with the context vector. The context vector is the output of the oscillators which is constantly changing. Recall can go in either direction, from item to context or from context to item. The model does not say much about recognition, but probably that would be easy to implement.

There are several sources of forgetting. Perhaps the learning context can be only partially reinstated at the time of recall. If only a subset of these oscillators are correctly reset then the others continue to evolve during recall and this degrades performance. Another possible source would be an inability to reinstate the oscillators to their correct initial value. This would presumably be more likely the longer the delay between study and test, and might account for the precipitous forgetting of short lists of items following a brief period of interpolated activity. Yet a third source of forgetting would be the interference among the multiple lists of items resulting from superposition in the common memory matrix.

According to the authors, one of the main reasons for preferring a model based on positional associations rather than sequential item-to-item associations is the effect of inter-item similarity on recall. If two list items, call them A and A′, are similar, and if A is followed by B but A′ is followed by D, then a chaining model would have to predict confusion in recall because, given A, there would be competing B and D associations. However, this does not seem to be the case; many studies have shown little or no difference between experimental and control lists where the control lists did not have the A–A′ similarity. OSCAR does not make this prediction because items are associated to context, not to their predecessors, so the similarity between A and A′ should not matter.

To give some idea of the explanatory power of this model, here are some of the various phenomena that OSCAR can model: separate item and order memory, serial learning, effects of item similarity on order memory, judgments of relative recency, judgments of absolute recency, probed serial recall, serial-position effects in recognition, grouping effects, grouping errors, group size effects, item and list memory, list-length effects, vocabulary size effects, and presentation rate effects. Computer simulations are run to see if the model generates results that mimic experimental data.

To give at least a very brief account of the necessary technical machinery, the processes in OSCAR (or any quantitative memory model) vary with the numerical values of the parameters just as the speed of a falling object depends upon the numerical value of the constant (parameter) for gravitational attraction. In OSCAR (again as in any other model) there are a number of parameters: the amount of change between successive learning contexts, the number of repeating learning-context vectors, the dimensionality of the vectors and their similarity, the learning rate, the learning-rate decay, the weight decay (cf. TECO), the proportion of learning context reinstatable at retrieval, the

vocabulary size, the amount of output interference, the inhibition of recalled items (present or absent), and the level of the output threshold. As many as possible of these parameter values are held constant across different applications but, as noted above, *ad hoc* changes in parameter values for specific applications weaken the explanatory value of the model.

Although OSCAR is a very impressive model of serial-order effects, questions can be raised about the context reinstatement mechanism. As the Greek philosopher Heraclitus noted (about 400 BC) you cannot step in the same river twice. Oscillators are often used in neural models of timing and counting, but there the operation is relatively automatic and they are not under voluntary control. Also, the model has not yet been applied to many of the phenomena dealing with the storage and retrieval of item and associative information, and these are important areas too.

TODAM2

TODAM2 (Murdock, 1997), the second version of a theory of distributed associative memory, is most like LAM in that it uses the same assumptions for item representation and the comparison process for recognition, but it uses a different formalism for storage and retrieval. TODAM2, like the original version, convolves item vectors so the association is still a vector, whereas LAM uses an outer product so the result is a matrix. While the vector formalism is noisier than the matrix formalism, it is more economical in terms of storage space and, more important, generalizes to multiple convolutions to explain serial-order effects. So TODAM2 can apply to item, associative, and serial-order information, and this is one of its main strengths.

Convolution and correlation are approximately inverse operations. If you convolve two items (two item vectors) and then correlate the result with one of them you recover an approximation to the other. It works either way, so 'forward' and 'backward' recall should be (as they are) equally good if the items forming the pairs are drawn from the sample pool of items.

Since the retrieved information is only an approximation to the target item in TODAM2, there are two processes involved in cued recall: correlation and deblurring (clean-up). This is like MINERVA2 except that the details of the deblurring process are not specified in TODAM2 as they are in MINERVA2. There are also two processes in recognition: a comparison process (the dot-product as in MINERVA2) and a decision process (as in SAM). The two-process recognition theories make it possible to use the classic signal detection theory to separate strength effects from interior effects, an essential requirement for any realistic theory of recognition memory.

To remember a list of items, TODAM2 assumes (like MINERVA2) that items and context are concatenated and then (unlike MINERVA2) auto-associated (auto-convolution) to bind items and context. Every auto-convolution is stored (superposition) in a common memory vector (like LAM), but context drifts slowly over the course of list presentation. It is this steady context drift that produces the extensive recency effect typically found in latency and accuracy measures in item recognition.

When a list of paired associates is presented, it is assumed that subjects store both the item and the associative information, again by superposition in a common memory vector. Each of the two items in the pair is concatenated with context and auto-convolved, and the two items in the pair are summed, concatenated, auto-convolved, and also added to the memory vector. This may sound unnecessarily complex, but it is necessary to explain some puzzling interactions (differential forgetting of item and associative information, and asymmetric effects of differential attention to items and pairs) that have recently been reported.

For serial order, TODAM2 assumes that subjects form chunks when they study a short list of items. A chunk is a sum of n-grams where an n-gram is the n-way auto-convolution of the sum of n items. While this results in a rather noisy memory trace, memory span is typically only four to five words with college students so the chunks do not have to be very big. If subjects also store item information in the common memory vector, then TODAM2 can also explain the characteristic primacy effects in ordered recall and recency effects in item recognition that are puzzling for many other models of serial-order effects.

DISCUSSION

The reader may have noticed many common mechanisms and processes in the memory models discussed here. In fact, the similarity is more real than apparent; very different terminology may obscure underlying similarities. While one can bemoan the lack of a standard unified model, perhaps the consensus is greater than it might seem. Perhaps we are starting to converge on a common model, and this will happen when the right person takes the right set of assumptions and puts them together in the right way.

CONTENTS

Throughout infancy and early childhood there are remarkable changes in the ability to remember everyday and emotional events. More frequent and effective use of memory strategies, increases in speed of processing, and developments in metamemory all contribute to the changes.

INTRODUCTION

The development of the many facets of human memory has received much attention in recent decades, and deservedly so. In addition to being a cornerstone in the broader study of cognitive development, the study of memory has implications for our understanding of children's behavior and development in a number of other domains. Consider, for example, something as basic as how a 1-year-old child's ability to recognize familiar adults influences the manner in which the child interacts with them. The development of memory has implications for adult memory and cognition as well. Few would disagree that the mnemonic ability of an adult is significantly advanced compared with that of an infant, and furthermore that there appear to be differences in mnemonic competence between individuals. The study of memory during the intervening years can shed light on the mechanisms of developmental change and also on the nature and significance of individual differences.

For brevity, this discussion is confined to children's capacity for declarative memory, which captures most of what we think of when we refer to 'remembering'. Declarative memory includes explicit recognition and recall of names, objects and events, but not those abilities that are inaccessible to conscious awareness such as skill learning and priming.

CHILDREN'S MEMORY FOR EVERYDAY AND EMOTIONAL EVENTS

As adults, we seldom contemplate the pervasive role that memory plays in everyday life. Certainly it is essential to remember where one lives and adaptive to remember the names of one's in-laws; equally important, however, is one's memory for the wide range of past events that have been experienced. This is true for both personally meaningful events such as one's wedding day, and for events as mundane as a trip to the grocery store. Whereas it is primarily memories of the former type that accumulate to shape one's 'life history', memories of both types of events serve to influence future behaviors, in part by allowing for generalized scripts about the course of actions in a given event.

Perhaps because memory seems effortless, it is easy to underestimate the range of skills involved in remembering. Sharing a past event involves projecting back in time to 'locate' the event in question, organizing the thoughts and images associated with the event, and generating a coherent narrative about it. Somewhat miraculously, children are able to do this all by 3 years of age. This has led researchers to investigate the emergence of this ability in infancy, and how it develops in the years that follow.

Memory for Events in Infancy and Early Childhood

The paradigm of choice for research on declarative memory in older children and adults is simple – verbal report. This is not an option with very young children, however, and it was not until the establishment of a suitable nonverbal analogue to this method that the early foundations of declarative memory could reliably be assessed. In the

mid-1980s researchers began using deferred imitation as a test of declarative recall during the first 3 years of life (see Bauer *et al*., 2000, for a review). Originally suggested by Jean Piaget as a hallmark of the development of symbolic representation, deferred imitation as used in laboratories today involves using an object to produce a single action (or sequence of actions) and then inviting the infant or young child to imitate it immediately, after a delay, or both. Researchers examine recall by assessing whether children reproduce the modeled actions and whether they perform a sequence of actions in the correct temporal order. The use of this technique with children ranging in age from 6 months to 36 months affords a comprehensive picture of developments in mnemonic ability in children who are preverbal or newly verbal.

By the end of the first year of life infants shown two-step sequences demonstrate retention of event-related information over delays as long as 5 weeks, and many of them evidence recall that is temporally ordered (Carver and Bauer, 1999). Over the next 2 years of life a consolidation of declarative mnemonic processes appears to occur, as indicated by age-related changes in the reliability and robustness of long-term ordered recall. For example, more than half of a sample of children who experienced four-step sequences at 20 months of age evidenced ordered recall after delays of up to 12 months (Bauer *et al*., 2000). It is important to note, however, that the developments occurring over the second and third years of life do not reflect a simple 'growth chart' function for the length of time over which memory will persist. Research consistently shows that memory for past experiences is determined in part by many additional factors such as the nature of the temporal relations inherent in an event, the number and timing of exposures to the event, active participation in the event, and the availability of cues or reminders of the to-be-remembered event. For example, whereas older children on average remember events for longer periods than younger children, age differences are reduced when children are given cues or reminders of to-be-remembered events. These factors continue to affect the formation of long-term memories later in childhood and beyond, even as the mode of expression of changes from exclusively nonverbal to primarily verbal.

Development of Verbal Expression of Event Memory

By their third birthday children are relatively adept at talking about the 'here and now' and are increasingly able to participate in discussions about past events. Considering that in most memory conversations children are not only temporally but also spatially removed from the event being discussed, it is not surprising that talking about the past lags behind talking about the present and requires more 'scaffolding'. Initially children's talk about the past is confined to simple responses to specific prompts ('What did you do at the museum?') and is reflective of the more typical aspects of events experienced ('I ate a cookie'). With continued guidance from caregivers in how and why to talk about the past, children's memory responses gradually become longer and more informative. As children learn about what is important within the context of an event and about the structure in which to frame and share their experiences, the focus of their memory talk turns increasingly to the more unique and meaningful components of the occurrence and the overall account becomes more exhaustive. Notably, recall at all ages is largely accurate, and temporal order of the events tends to be preserved just as it was in earlier nonverbal 'reports'.

The growing body of research on children's autobiographical memory, or memory for personally meaningful events, consistently reveals remarkable mnemonic competence. An influential study by Hamond and Fivush (1991), in which children aged 3½–6 years were interviewed about a trip to a theme park that occurred up to 18 months earlier, revealed that regardless of age, children were able to provide thorough accounts of their experiences and that the overall amount of information recalled did not differ as a function of age. Older children did, however, offer a greater quantity of information spontaneously and included more detail than did younger children. This suggests that as children gain more control over retrieval processes they are less dependent on cues and are increasingly able to recall and verbalize details. After more significant delays of several years, a strong reliance on cues is apparent in children of all ages. For example, when Hudson and Fivush (1991) interviewed 11-year-old children about a trip to an interactive archeology exhibit when they were 5 years old, only one child commented on the experience in response to a general open-ended prompt; nearly all of them, however, provided accurate reports of the event in response to specific questions.

Children's Memory for Emotional Events

Whereas the content of events targeted for recall in studies of autobiographical memory typically has

been positive or at least neutral, not all events that children experience, unfortunately, are positive in nature. Because it is not clear whether conclusions drawn from this body of data can be applied to memory for all types of experiences, research targeting emotionally negative, stressful, and traumatic events is necessary. Thorough awareness of memory processes under such conditions has important implications for the understanding of children's adjustment following trauma and for the evaluation of children's credibility as eyewitnesses.

For practical and ethical reasons researchers cannot intentionally subject children to controlled laboratory-based emotional events. Emergency medical treatments and prescribed medical procedures, however, afford researchers opportunities to explore children's memory for stressful real-life experiences. Though socially sanctioned and performed for the child's own good, such measures nonetheless are perceived by children as unpleasant, painful, frightening, and executed against their will. In their examination of reports by children aged 3–10 years of a painful and embarrassing catheterization procedure, Goodman *et al*. (1994) found that older children recalled more information, answered more questions correctly and made fewer errors than the youngest children. When age was controlled, it was clear that children's emotional reactions and understanding of the event (as rated by the parent), as well as maternal communication and compassion, affected children's memories.

How can children's memories of stressful, traumatic events be expected to differ from those of benign events? In a review of the relevant research, Fivush (1998) noted that the little evidence available suggests that 'memories of trauma are at least as detailed if not more so than memories of more mundane experiences' (p. 709). She emphasized, however, that direct examination of memories for different types of events is uncommon and that comparisons across studies must be interpreted with caution. In a study that included the within-participant comparison necessary to evaluate differential reporting, we asked mother–child dyads to discuss the touchdown of a devastating tornado as well as an event that preceded and an event that followed the tornado. Mothers and children produced more complete verbal reports of their recollections of the tornado than of the other events; their reports about the tornado also were more narratively coherent. These findings indicate that although children's memories of events of a highly emotional nature probably follow a developmental course similar to that for more benign events, they are likely to differ in important ways as well. More research in which memories for benign and emotional events are directly compared is needed in order to identify characteristics that are unique to memories of emotional experiences and those that are common to all event memories.

EMERGENCE AND REFINEMENT OF CHILDREN'S DELIBERATE MEMORY STRATEGIES

Forming a memory of any type of event in which one is participating takes little conscious effort. If one is present, wakeful and attentive, at least some aspects of the experience are likely to linger in memory. In other situations we use memory in a more intentional way, as in repeatedly rehearsing an important telephone number when pen and paper are nowhere to be found. Research on children's use of deliberately implemented encoding strategies such as rehearsal, organization, and elaboration suggests that younger children generally have fewer memory strategies available to them and use them less efficiently than do older children; see Bjorklund and Douglas (1997) for a review. The developmental picture is not a simple one, however; although one might expect that children would use one strategy reliably on a given task and then replace it when they learn or discover a more effective one, in practice this rarely happens.

Early Strategies: Selective Attending and Rehearsal

For some time it was thought that preschool children were astrategic. When tasks are simplified and situated in a familiar context, however, it appears that such young children do indeed do things to help them remember, such as frequently looking towards the item or place that they have been instructed to remember. Though preschoolers may be more competent mnemonists than once believed, the bulk of development in strategy use nonetheless occurs in middle and later childhood, probably as a combined result of cognitive maturation and the expectations and training that accompany formal schooling. One simple yet effective strategy that appears in the early school years is that of rehearsal, or repetition of to-be-remembered information. With age, the use of rehearsal becomes more common, and also more efficient. For example, if instructed to remember the words in a list, it is not until about 12 years of age that children will consistently rehearse in a cumulative fashion, reciting previous words along with each new word

that is stated. Even in its simpler form, however, rehearsal appears to aid recall.

Later Strategies: Organization and Elaboration

One potentially more useful memory strategy is that of *organization*. Imagine that you are given the following list to remember: carrot, pencil, monkey, celery, fish, tomato, cat, chalk, crayon. If you merely rehearsed the words with little attention to their meaning, you might have difficulty remembering all nine of them. The task becomes more manageable, however, if you realize that the words fall into three categories – vegetables, animals, and writing implements – that can be used to aid storage and retrieval. In adults, conceptually clustered recall of words that were originally presented in random order is taken as evidence of organized encoding and is associated with higher levels of recall. At younger ages, organization is assessed through physical sort–recall tasks in which children are given a study period during which they could potentially sort the randomly presented items or pictures of items. Young children rarely demonstrate spontaneous sorting behavior and typically perform no better on groups with obvious categories than on groups without them. By about 10 years of age, however, children begin to exhibit spontaneous, effective organization and to experience a resultant improvement in memory performance.

The final memory strategy to be covered, known as *elaboration*, has typically been examined in the context of a paired associate task in which participants learn pairs of unrelated items (e.g., 'buffalo' and 'tuba') and are subsequently asked to recall one member of the pair when given the other. Because participants must impose some sort of elaborate association where none exists (in our example, a buffalo playing a tuba!) this is perhaps the most complex, and certainly the most creative, of the memory strategies. Not surprisingly, it is a latecomer to the strategic repertoire, rarely appearing before adolescence or even adulthood.

PRODUCTION VERSUS MEDIATION DEFICIENCIES

To form a complete picture of the development of strategy use, we must understand why children fail to use strategies. When young children do not spontaneously use more advanced memory strategies, is it because they lack the cognitive capacity necessary to do so? A wealth of research revealing children's abilities to use and benefit from new strategies when given appropriate instruction suggests the contrary. Failure on the part of children to spontaneously produce strategies that they are capable of using is known as a *production deficiency*. Evidence for production deficiencies has been found consistently in both cumulative rehearsal and organization strategies among young children and in elaboration among school-age children. By manipulating factors such as familiarity of context and metacognitive awareness (see below) that are thought to influence children's subsequent use of trained strategies, it is possible to gain insight into why children do not use manageable strategies when it is in their best interest to do so.

Even when children are taught a strategy it does not necessarily improve their performance. So-called mediation deficiencies are most frequently observed with regard to the more sophisticated strategies of organization and elaboration. The more recently identified *utilization deficiency* also is characterized by a lack of expected improvement in memory performance, but refers specifically to children's spontaneous rather than trained production of a new strategy, and typically occurs during the early phases of individual strategy acquisition. Put differently, children exhibiting a utilization deficiency can produce the given strategy on their own, but they experience little, if any, enhancement in task performance. One commonly offered explanation for this deficiency that has received considerable empirical support suggests that the mental effort needed to execute the new strategy is so immense that the resources remaining are insufficient for encoding *per se*. As is the case with mediation deficiencies, utilization deficiencies are most frequently apparent when children employ the strategies of organization and elaboration.

Clearly, the development of children's strategy use does not proceed in a tidy, step-like fashion from employment of the least to the most effective strategies. Considerable variability is to be expected across children, across tasks, across trials, and even within the course of a single trial. Robert Siegler's strategy choice model, developed primarily in the domain of arithmetic strategies, has much to offer the understanding of children's memory strategy use as well. According to Siegler (1996), children have a variety of available strategies in their repertoire that compete with one another for use, with the winner on any given trial being multiply determined by the learning context, task variables, and the child's general cognitive ability. With maturation and practice, more sophisticated and efficient strategies win increasingly often while more

primitive strategies win less and less – but nevertheless continue to stay in the game for some time.

AGE-RELATED CHANGES IN THE SPEED OF PROCESSING

One particular aspect of children's general cognitive ability that has been consistently nominated as a contributor to observed age-related differences in strategy use is the speed with which children are able to process information. Not surprisingly, the amount of time needed to execute cognitive operations, including the memory strategies just described, decreases reliably with age (Kail, 1993). Age-related developments in speed of processing appear to be influenced by at least two factors. First, with maturation children experience an increase in the myelinization of neurons in the associative areas of the brain. Myelin is a fatty substance that surrounds nerve cells and acts as a sort of insulation, facilitating the efficient transmission of impulses. Though myelinization of the sensory and motor areas of the brain is completed within the first years of life, that of the associative areas is not completed until adolescence.

Processing speed is not determined solely by maturation, however; a second factor that has been implicated in increased speed of processing is children's growing knowledge base. Unlike myelinization, which exerts its impact on processing speed across domains, the influence of the knowledge base is domain-specific. That is, improvements in processing can be expected only in those areas that have experienced a growth in knowledge. Whereas some domains of knowledge are developed on an individual basis (e.g. children who are experts in chess or dinosaur knowledge), others are likely to manifest rather predictably among children, as in the case of overall growth in knowledge and vocabulary across the school years. In addition to the speed with which information can be processed, individual and age-related differences in knowledge within a domain have an effect on other aspects of memory, such as the frequency and efficiency with which strategies are used. Generally speaking, the more one knows about a given topic or area, the easier it is to remember new information about it.

There are several ways in which changes in speed of processing could be expected to influence children's strategy use. Most simply, if the task at hand is one that involves continuing interference, as in the oral presentation of a list of words, the ability to quickly encode, recognize, and act upon each new word is essential for successful performance. The faster processing that is seen with age increases the likelihood of completing the necessary cognitive operations before the next item is presented, thus contributing to observed improvements. The role of the knowledge base in speed of processing comes into play when you consider that children's abilities to use the more sophisticated strategies of organization and elaboration depend on their understanding of the to-be-remembered items and familiarity with the relations between them. For example, it would be impossible to impose any sort of organization on the terms tibia, hippocampus, femur, amygdala, and patella if you had not yet acquired knowledge of the human brain and skeleton. With limited familiarity with the domain at hand, the increased effort needed to deploy a strategy could easily result in a utilization deficiency.

METAMEMORY

Another aspect of children's developing cognitive ability that merits coverage is metamemory, or knowledge of the contents, processes, and limitations of memory. Specifically, it includes awareness of one's memory strengths and weaknesses, appreciation of variation in task difficulty, understanding of potential memory strategies and of situations that warrant their use, and ongoing assessment of performance during a memory task.

One simple yet informative way to assess children's metamemory knowledge at different ages is to ask them. In an oft-cited comprehensive interview study by Kreutzer and colleagues, children in kindergarten and in the first, third and fifth grades of school were asked a series of questions such as whether they remember better than other people they know, if learning pairs of related words would be easier than learning pairs of unrelated words, whether a delay would affect their ability to remember, and how they would go about looking for a jacket that was lost at school (Kreutzer *et al*., 1975). Results suggest that although young children are competent in some respects, they have an overly optimistic view of their memory abilities and have difficulty evaluating the impact of assorted variables (e.g. delay) on memory performance. For example, kindergarten children know that it is easier to remember a few items than it is to remember many, but do not understand that memory abilities vary across individuals and across situations. Results of this and more recent work suggest that young children's rudimentary awareness of memory processes gives way to quite sophisticated understanding by

about 12 years of age and refinement in the years that follow.

An important question for researchers in this area is whether improved metamemory actually translates into more advanced memory behaviors and enhanced memory performance. Although the strength of such relations was once questioned, more recent research suggests a moderate yet reliable contribution, varying in part based on the child's age, the type and difficulty of task, and the nature of the metamemory assessment. The relation appears to be strongest for older children, but is evident at earlier ages when the task is simple and familiar and the metamemory processes questioned are closely tied to success on the task. Some researchers have proposed that the component of metamemory that is most closely related to behavior is not simply the knowledge that a particular memory strategy works, but rather why it works. Importantly, research evidence suggests that the relation between metamemory and memory behaviors is bidirectional; that is, improved metamemory leads to more effective strategy use, which in turn contributes to continued improvements in metamemory.

As you might imagine, metamemory plays an important role in reversing the deficiencies observed in strategy use. As children become increasingly aware of what strategies are available, and when strategies are required, production deficiencies are less likely to result. Furthermore, children who are able to engage in insightful reflection upon memory processes might continue using a difficult, sophisticated strategy despite little gain if they believed that it would be effective with additional practice, resulting in the eventual elimination of a utilization deficiency.

As this brief review suggests, the study of memory development is multifaceted. Whereas human infants remember specific past events by late in their first year, there are substantial and significant changes in memory capacity over the course of the second year of life and well beyond. Understanding the myriad developmental changes that occur is an important piece of the ontogenetic puzzle.

Memory, Long-term

Introductory article

Alan Richardson-Klavehn, Goldsmiths College, University of London, London, UK
Robert A Bjork, University of California, Los Angeles, USA

CONTENTS

Long-term memory is central to cognitive functioning. Taking a wide variety of forms, from skills to general knowledge to memory for personal experiences, it is characterized by dynamic interactions between encoding and retrieval processes and by constructive processes, and thus differs fundamentally from current human-made information storage systems.

DEFINITION AND CLASSIFICATION OF LONG-TERM MEMORY

The ability to retain information over long periods is fundamental to intelligent thought and behavior. Memory is the 'glue', in effect, that holds our intellectual processes together, from perception, attention, and language, to reasoning, decision-making, and problem-solving. Memory also plays a critical role in social and emotional functioning, because our sense of who we and other people are is distilled from factual and autobiographical information in our memories. The study of memory, therefore, occupies a central position in the cognitive sciences.

Broadly, memory can be broken into three stages of information processing: (1) encoding, the transformation of information into a form retainable in memory; (2) storage, the holding of information in memory across a time interval; and (3) retrieval, the accessing of information from storage after a time interval and the use of that information to guide thought and behavior. This distinction between stages is important but – as clarified later – encoding and retrieval processes are intimately interconnected and cannot be understood in isolation from each other. (*See* **Information Processing**)

Distinguishing between Short-term and Long-term Memory

In everyday discourse, long-term memory is usually distinguished from short-term memory in terms of the time that has elapsed since information was encoded. Moreover, it is not unusual to find memory that persists over days or weeks being described as short-term memory. In psychology, however, the terms long-term and short-term memory have come to have specialized meanings that stem from a distinction made by William James in 1890. James observed that our consciousness is not just of the immediate present: the information that we currently attend to lingers in consciousness for some period of time. He called this lingering consciousness primary memory, and distinguished it from secondary memory, which occurs when information has left consciousness but returns to it again later. Thus, secondary memory involves retrieval in a way that primary memory does not.

James's distinction is not simply one of retention interval. It would, theoretically, be possible to retain information in primary memory indefinitely as long as one's attention remained focused on that information (i.e., as long as the information was rehearsed). Conversely, information that leaves consciousness and then returns to it is retrieved from secondary memory, even if retrieval occurs only seconds later. Thus the distinction between short-term (primary) and long-term (secondary) memory as used by psychologists is a qualitative one, not a simple quantitative one based on retention interval. In recent years, Alan Baddeley has introduced the term working memory to refer to short-term memory, which emphasizes its role in manipulating – as well as maintaining in consciousness – a variety of kinds of information. (*See* **James, William**; **Working Memory**)

Varied Forms of Long-term Memory

As with the short- versus long-term memory distinction, the main distinctions between forms of long-term memory involve reference to consciousness. The distinction between declarative and

procedural memory originated in computer science, where stored data structures were distinguished from stored programs specifying how the data were manipulated. Psychologists borrowed these terms to capture a distinction made by the philosopher Gilbert Ryle in 1949, between *knowing that* and *knowing how*. Declarative memory involves knowing consciously *that* particular events happened in one's past, or *that* particular facts are true (e.g., Paris is the capital of France). Procedural memory, on the other hand, involves knowing *how* to manipulate mental or physical objects. Such knowledge is not necessarily consciously accessible and very difficult to communicate verbally. Explaining to someone how to ride a bicycle, for example, offers them scant assistance in learning that skill. Practicing such a skill is essential to its learning. The declarative/procedural distinction is closely associated with John R. Anderson and Larry Squire. (*See* **ACT**; **Skill Acquisition: Models**; **Automaticity**; **Implicit Learning**; **Skill Learning**; **Knowledge Representation, Psychology of**)

Within declarative memory, episodic memory is distinguished from semantic memory. Episodic memory involves awareness of particular events in one's personal autobiography, whereas semantic memory involves knowledge of language, categories and concepts, and facts. This distinction is closely associated with Endel Tulving. Within episodic memory, in turn, recollection is distinguished from familiarity. Recollection involves re-experiencing the particular contextual details of a past event, such as the tone of voice in which a statement was uttered in the kitchen at nine o'clock yesterday morning. Familiarity involves the knowledge that a current situation bears some relationship to a past event, without awareness of the particular contextual details of that event. For example, we sometimes experience the strong sense that we have met someone before, without being able to recollect where and when we met them, or anything else about them. The recollection/familiarity distinction is closely associated with George Mandler and Larry Jacoby. A related distinction, between remembering and knowing, has been made by Tulving and by John Gardiner. (*See* **Semantic Memory: Computational Models**; **Episodic Memory, Computational Models of**; **Autobiographical Memory**; **Knowledge Representation, Psychology of**)

A final important distinction is between explicit and implicit memory. Explicit memory refers to conscious awareness of events in one's personal past that accompanies deliberate attempts to think back to those events. Implicit memory refers to influences of past events on one's current behavior that occur involuntarily or unintentionally, often without any current awareness of the relevant prior events. This distinction, closely associated with Daniel Schacter and Peter Graf, can be traced back to similar distinctions by Hermann Ebbinghaus, who published the first experimental studies of memory in 1885, and by a number of other influential thinkers going back to René Descartes in 1649. (*See* **Descartes, René**; **Ebbinghaus, Hermann**)

It must be noted that none of the foregoing distinctions is universally accepted. First, none is entirely clear-cut. For example, Paul Kolers and Henry Roediger have questioned the procedural/declarative distinction, arguing that all forms of memory involve the modification of procedures for manipulating information. And Schacter, Alan Richardson-Klavehn and others have pointed out that the explicit/implicit memory distinction is blurred by cases when conscious awareness of events in one's personal past comes about without any deliberate attempt to retrieve those events, a phenomenon termed involuntary explicit memory or involuntary conscious memory.

Second, a controversial question is whether these distinctions imply different information-processing mechanisms, with different bases in the structure and function of the brain. Support for the latter view comes from research by Brenda Milner, Elizabeth Warrington, Lawrence Weiskrantz and others on the amnesia (memory loss) that results from damage to limbic system structures in the brain (the hippocampus, portions of the thalamus, and connected structures). This memory loss is selective, resulting in dissociations between different measures of memory. For example, short-term memory is largely spared, whereas the acquisition of new long-term memories is severely impaired, and the declarative and explicit forms of long-term memory are impaired much more than the procedural and implicit forms. Dissociations that are similar in some respects are observed in dementias such as Alzheimer and Huntington diseases, as well as in the memory loss that accompanies normal aging. Such dissociations have led some, including Schacter, Squire, and Tulving, to argue that the brain has distinct memory systems, which may have had different evolutionary histories. Others, such as Kolers, Roediger, Mary Sue Weldon, and Bruce Whittlesea, argue that a unitary memory system – in which similar information-processing mechanisms handle a wide variety of kinds of information – can account for such dissociations.

As argued by Morris Moscovitch and others, resolving these issues will involve clarifying the

extent to which the varied forms of memory involve different versus common information-processing components and on understanding the relationship between these components and brain structure and function. Recent advances in imaging the activity of the living brain (neuroimaging) are making an important contribution in these respects. Whatever their interpretation, however, the selective memory impairments that have fueled the current controversies offer a striking illustration of the complexity and variety of memory, and of the centrality of memory to intellectual and social functioning. Such memory impairments often have a catastrophic effect on an individual's ability to hold down a job, remain informed about ongoing affairs in the world, and maintain normal social relationships. (*See* **Human Cognition**; **Aging and Cognition**; **Memory: Implicit versus Explicit**; **Memory, Development of**; **Neural Basis of Memory: Systems Level**; **Amnesia**; **Alzheimer Disease**; **Huntington Disease**; **Neuroimaging**)

THE DYNAMIC CHARACTER OF LONG-TERM MEMORY

The remainder of this article focuses on the cognitive processes involved when new information is added to long-term memory and later retrieved. At first thought, libraries and computers might seem useful metaphors for understanding these processes. In computers, for example, files are created (encoding), held on disk (storage), and subsequently made active again (retrieval). Such metaphors, however, can be highly misleading. They suggest that encoding and retrieval are strictly sequential, and that encoding new information does not involve retrieving information that is already stored. With human memory, by contrast, encoding new information *depends* on retrieval of information already in memory. The computer metaphor also suggests that the act of retrieving an item makes that item no more and no less accessible in the future, and does not affect the accessibility of other items. With human memory, by contrast, retrieval renders the retrieved information more accessible in future, and can have either positive or negative effects on the retrievability of other information, depending on circumstances. Furthermore, such metaphors suggest that memories are stored in specific spatial locations, whereas human memories appear not to be stored in specific locations in the brain, but in distributed networks of brain cells (neurons), each of which participates in the storage of many memories.

The key to understanding the unique properties of human long-term memory is to appreciate that it has a dynamic character not shared by current human-made information storage systems. That is, the state of memory is constantly changing as a result of encoding and retrieval processes that are intimately interdependent. This unique character is a product of the properties of the brain as an information-processing device and may reflect the evolution of memory from the perceptual mechanisms of the brain.

The Interdependence of Encoding and Retrieval

Levels of processing, encoding specificity, and resonance

Research from the 1970s onwards has greatly enhanced our understanding of encoding and retrieval processes in long-term memory. One important principle to emerge is that the primary determinant of long-term retention is the level of cognitive processing when new material is encoded – irrespective of intention to learn, or amount of repetition or rehearsal, both of which have little impact on long-term retention. Shallow levels of processing involve attending to the physical characteristics (typically, appearance or sound) of material, whereas deep levels of processing involve attending to the meaning of material, with deep processing usually resulting in superior retention. Both shallow and deep processing involve retrieving pre-existing knowledge about appearance, sound, or meaning; the resulting memory trace is a by-product of the processing involved in retrieving that knowledge. This levels-of-processing principle originated with Fergus Craik and Robert Lockhart.

A second principle to emerge is that when encoded material is later retrieved, the stimuli present in the retrieval environment (retrieval cues) also play an important role in whether that material is retrievable. For successful retrieval, it is critical that the information provided by the retrieval cues matches the information in the memory trace, which will in turn reflect the type of processing engaged at encoding. This encoding specificity principle originated with Endel Tulving and Donald Thomson.

The interaction between level of processing at encoding and the cues present at retrieval is illustrated by the results of an experiment reported by Ronald Fisher and Fergus Craik. They asked people to study pairs of words, with the words in the pairs related either by meaning (e.g., *sleet–hail*) or by

sound (e.g., *pail–hail*). The meaning relationship led to a deep level of processing, whereas the sound relationship led to a shallow level of processing. Later, people's ability to recall the second word from each pair was tested via a cued recall test, in which cues were provided to assist with retrieval. The cues either involved the first word in the pair presented at encoding (e.g., *associated with sleet* and *rhymes with pail*, respectively), a similar word (e.g., *associated with snow* and *rhymes with bail*, respectively), or a different word (e.g., *rhymes with bail* and *associated with snow*, respectively).

When the original first word in the pair was presented as a retrieval cue, there was a substantial recall advantage for deep (meaning) over shallow (sound) processing at encoding (54 percent versus 24 percent), but when the cue was a similar word the advantage for deep processing was reduced (36 percent versus 18 percent), and when the cue was a different word the advantage was almost eliminated (22 percent versus 16 percent). This result demonstrates that both the level of processing at encoding and the cues present at retrieval are critical. If it were simply the case that deep processing produces stronger or longer lasting memory traces than shallow processing, then the advantage for deep processing would be observed regardless of retrieval conditions. And if, on the other hand, the only important factor is the match between retrieval cues and memory traces, then increasing the degree of match should benefit performance regardless of the level of processing at encoding. Instead this result suggests that deep processing produces memory traces containing information that is distinctive in comparison with the information contained in other memory traces. As a consequence, when a retrieval cue matches a trace that resulted from deep processing, only that trace is likely to be activated. By contrast, when a retrieval cue matches a trace that resulted from shallow processing, many other traces become active, because they also contain information matching the retrieval cue. In consequence, there is interference that impairs retrieval.

Combining the principles of levels of processing and encoding specificity leads to a more general principle that can be called the principle of selective resonance. The resonance idea is drawn from physics. A 440 Hz tone emitted near the undamped strings of a piano, for example, will lead to sympathetic resonance in the strings tuned to 440 Hz and, to a lesser extent, in the strings tuned to frequencies that have harmonic relationships to 440 Hz (e.g., 880 Hz, 220 Hz). Retrieval can be thought of as resembling resonance. Memory traces are 'tuned' to specific frequencies, based on the information encoded into them. At retrieval, they 'resonate' to the extent that they share information with retrieval cues. Retrieval succeeds when the resonance is unique to relevant traces, and not shared with irrelevant traces.

The selective resonance idea can be traced to the little-known memory theorist Richard Semon, who coined the term ecphory in 1921 to describe the process whereby memory traces (or engrams) resonate in response to retrieval cues, and to Hedwig Von Restorff, who demonstrated the importance of distinctiveness for memory in 1933. More recently, Roger Ratcliff has demonstrated that the resonance concept forms a realistic basis for formal mathematical models of retrieval. In addition, the principle of selective resonance is a natural property of recent models of memory that postulate networks of interconnected units analogous to networks of neurons in the brain (connectionist models). These models, developed by James A. Anderson, James McClelland and others, solve the conundrum of where memories are stored by postulating that they are stored in a distributed form, as changes in the connections between many units, with each unit participating in the storage of many memories. Finally, processes akin to selective resonance appear to be a fundamental property of neural information processing, starting with perception, where groups of neurons are 'tuned' to respond selectively to particular features of stimuli impinging on the senses. The resonance principle thus suggests that our memory capabilities may have evolved as an extension of our perceptual capabilities, with some of the underlying neural information-processing principles being carried through. (*See* **Human Cognition**; **Connectionism**; **Distributed Representations**; **Encoding and Retrieval, Neural Basis of**; **Learning and Memory, Models of**; **Pattern Vision, Neural Basis of**; **Perceptual Systems: The Visual Model**; **Memory Models**; **Perception: Overview**)

Perceptual memory tests and transfer appropriate processing

Deep processing at encoding is typically superior to shallow processing in supporting long-term retention but – as discussed earlier – such superiority can disappear when the cues at test mismatch those present at encoding. Might there then actually be circumstances in which shallow processing is superior to deep processing? The answer is yes. Tests such as cued recall, recognition memory, in which people are asked to discriminate previously presented material from material not previously

presented, and free recall, in which retrieval is not aided by external cues, show advantages for deep processing because succeeding on such tests requires semantic, meaning-related, processing. These tests are classified as conceptual tests. In special circumstances, however, when a memory test demands retrieval of information concerning the perceptual characteristics of previously encountered information (perceptual tests), the advantage of deep over shallow processing can be reversed. For example, Barry Stein showed that shallow processing at encoding was superior when people later had to recognize whether or not words had been shown to them in a particular configuration of upper and lower case letters. Such reversals can occur because shallow processing results in memory traces that contain more distinctive information about the perceptual – as opposed to semantic – characteristics of studied items than does deep processing.

In the light of such findings, John Bransford, Jeffrey Franks and others have argued that the levels-of-processing principle – which can be taken to imply universally superior retention for deep levels of processing – should be reformulated as the transfer appropriate processing principle. This principle retains Craik and Lockhart's fundamental insight that the content of the memory trace is a by-product of cognitive processing at encoding, but it asserts that the value of a particular level of processing at encoding is relative to the kind of processing that is later required at retrieval. (*See* **Memory: Implicit versus Explicit**)

Retrieval as an encoding event

The fundamental interplay of encoding and retrieval processes is further illustrated by experiments on the impact of retrieval on later memory performance. The generation effect, first systematically explored by Norman Slamecka and Peter Graf, is a particularly good example. Inducing people to actively generate items from semantically related cues (e.g., *horse-c_ _t*, the generated item being *cart*) produces better later memory for those items than does simply reading them (e.g., *horse-cart*). Generating, like deep processing, creates more semantically distinctive memory traces than does reading. Another illustration is the impact of retrieving newly acquired material on the later retrieval of that material. Thomas Landauer, Robert Bjork and others have demonstrated that testing people on newly acquired material – versus providing an additional exposure to the material – can result in superior later recall. Moreover, provided that recall succeeds, the more difficult or involved the recall is, the greater its positive effects on later recall. Thus retrieval modifies the state of memory, acting as an additional encoding event, such that retrieved material is rendered more accessible later. These positive effects of retrieval are known as test effects. (*See* **Memory**; **Learning Aids and Strategies**; **Education, Learning in**)

Environmental, mental state, and temporal context effects

The principle that reinstating the kind of cognitive processing engaged at encoding is critical for later retrieval extends to the influence on cognitive processing of environmental context (e.g., location and other ambient environmental stimuli) and of mental state context (e.g., mood states and drug states). Alan Baddeley, Eric Eich, Steven Smith and others have shown that retrieval is often less successful if these forms of context are changed between encoding and retrieval. However, such context effects are not always observed. They appear to be more likely when retrieval occurs in the absence of explicit cues, as in free recall tests; when people are unable to mentally reinstate the context present at encoding; and when the context either becomes explicitly associated with the to-be-remembered material at encoding or exerts an explicit or an implicit influence on the semantic interpretation of the material.

Changes in context can have positive as well as negative effects, as revealed in research by Smith, Arthur Glenberg, Robert Bjork and others. Material encountered on multiple occasions in different contexts is more retrievable later than is material always encountered in the same context. In addition, material encountered on multiple occasions is much more retrievable later when those occasions are spaced apart in time rather than massed together, a temporal context effect termed the spacing effect. These benefits appear to arise, in part, from a common mechanism: encoding variability. That is, changes in context across encounters vary the kind of cognitive processing involved when the material is encoded. In the case of spaced repetition, such variation occurs as a result of a drift in environmental and mental state context over time – an idea first formalized by William Estes in his 1955 stimulus fluctuation theory. Variable encoding benefits memory because it increases the likelihood that some aspect of the cognitive processing engaged at retrieval will match information in the memory trace.

Another factor in the enhanced retention that results from encoding variability is that retrieval is also an encoding event. On the second and

subsequent encounters with the material, it is necessary – if the repetition of the material is to count as such psychologically – that the material is recognized as having been encountered earlier. Such recognition is more difficult, and thus the retrieval involved more powerful as an encoding event, when context changes across the successive encounters with the material. This retrieval-based explanation of the benefit of encoding variability again illustrates the intimate relationship between encoding and retrieval processes. (*See* **Memory**; **Learning Aids and Strategies**; **Learning, Psychology of**; **Education, Learning in**; **Mathematical Psychology**)

Forgetting, Interference, and Inhibition

Any theory of memory must explain why information is often forgotten over time. The most obvious hypothesis relies on a further metaphor for memory, and the one that is perhaps most intuitive: memory traces are like characters engraved on a stone or wax tablet, or like footprints in the sand, and these imprints weather away over time. Stated more scientifically, the hypothesis is that memory traces have strengths that decay with time. As with the strength interpretation of level-of-processing effects, however, this hypothesis cannot explain forgetting. One illustration of the inadequacy of this strength–decay idea is the recognition failure of recallable words, a phenomenon discovered by Endel Tulving and Donald Thomson. They showed that words (e.g., *queen*) studied in the context of weakly related words (e.g., *woman–queen*) were often forgotten on a recognition test when presented in the context of strongly related words (e.g., *king–queen*). However, these forgotten items were often successfully retrieved on a subsequent cued recall test when the weakly related word presented at encoding (e.g., *woman*) was provided as the cue.

The importance of this finding is that the original recognition failure cannot be attributed to decay of trace strength, because it would then have been impossible for the items to be retrieved on the later – and nominally more difficult – cued recall test. Instead, the recognition failure occurred because the target word was presented in a changed associative context in the recognition test – a powerful demonstration of the encoding specificity principle. John McGeoch was the first to argue, in 1932, that forgetting from long-term memory, rather than being a consequence of the decay of memory traces, reflects an inability to retrieve those traces. He argued that such retrieval failures are caused by (1) changes in associative, environmental, and mental-state context over time that he termed altered stimulating conditions, and (2) interference between competing traces in memory. McGeoch's two-factor theory of forgetting has stood the test of time, and fits well with the resonance conception of retrieval described earlier.

Such interference effects were a major focus of research on human learning carried out in the behaviorist tradition (ca. 1900–1970). Conclusions from this research are (1) that interference is the greater the more the similarity in content between the interfering materials; (2) that new learning interferes with old learning (retroactive interference), but, that as time passes, old learning recovers to interfere with the new learning (proactive interference); and (3) that interference can take the form of competition between the sets of materials, evidenced as a confusion at retrieval about which set of materials is which, or as unlearning of the materials, evidenced as the inability to bring a particular set of materials to mind.

Recent research suggests, in addition, that the process of retrieving information from memory can itself cause forgetting. Successful retrieval, as discussed earlier, makes the retrieved material more accessible later, but at an apparent cost: other material associated to the cues guiding retrieval can become less accessible later. Michael Anderson, Robert Bjork, Elizabeth Bjork, and Barbara Spellman have demonstrated such retrieval-induced forgetting by showing that the repeated retrieval of particular members of a category of previously studied words can inhibit subsequent access to the other nonretrieved members of that category. Such inhibited access is apparently a consequence of the need to suppress – that is, not overtly respond with – those items during the earlier retrievals of the target items.

Retrieval-induced forgetting and related effects point to another dynamic property of memory. In order to avoid catastrophic interference as a result of the large amount of information stored, only a limited portion of the information can be accessible for retrieval at any given time. From an adaptive point of view, the portion of information that is most accessible at any given time should be the portion retrieved in the recent past, because that information is most likely to be relevant in the near future. When forgetting is viewed in this way, it can be seen to be essential to the efficient functioning of memory, and thus far from a negative phenomenon. This adaptive theory of interference, inhibition, and forgetting has been formulated as a new theory of disuse by Robert and Elizabeth

Bjork, integrating and extending ideas put forward by Edward Thorndike in 1914 and William Estes in 1955. (*See* **Learning, Psychology of**; **Rational Models of Cognition**)

THE CONSTRUCTIVE CHARACTER OF LONG-TERM MEMORY

The library and computer storage metaphors for human memory, which are misleading for the reasons suggested earlier, are misleading in another respect. They suggest that the storage capacity of human memory is gradually used up as more material is stored. By contrast, there is no known limit to the human capacity to acquire new information. Indeed, acquiring new information in the form of organized knowledge *creates* further capacity. This ever-expanding capacity reflects constructive processes that are unique to human memory. While these processes have the positive effect of enabling the retention of astounding quantities of information, they can also have serious negative effects, by leading to memory distortions and illusions. Such negative effects show that human memory – in contrast to a videotape recorder (another misleading metaphor) – is not a literal record of previously encountered information. Even vivid memories of personally experienced events can be attributions of currently experienced mental events to the past.

Organization, Chunking, and Expertise

Encoding, as discussed earlier, involves bringing pre-existing knowledge in memory to bear on the interpretation of new information. To understand our unlimited capacity to acquire new information, Fergus Craik has suggested that memory, rather than being thought of as a library, computer, or videotape, should be thought of as a scaffolding. The scaffolding is the organized information in memory, which forms a framework for the interpretation of new information, and which permits new information to be attached. It follows that the more scaffolding there is, the greater the capacity to attach (encode) new information. Such organized information plays an important role in retrieval as well: it permits reconstruction of the likely properties of the material.

There are many experimental demonstrations of the powerful positive effects of organizing new material in terms of existing semantic knowledge. For example, Gordon Bower and his colleagues gave people four opportunities to study and freely recall 112 words drawn from various semantic categories. When the words were presented separated into the semantic categories (e.g., *minerals–metals–alloys: bronze, steel, brass; minerals–stones–precious: sapphire, emerald, diamond*), recall of this very large number of words was almost perfect by the second study and recall attempt, and perfect by the third. By contrast, when the identical 112 words were presented in a randomly intermixed fashion for the same amount of study time, recall reached only around 60 percent by the fourth study and recall attempt.

When confronted with new material to learn, as a student for example, a common difficulty is that the material appears to lack organization, and is therefore meaningless. Effective learning requires abstracting the structure of to-be-learned material. One important component of such abstraction is 'chunking', a term coined by George Miller in 1956. A famous example of the importance of chunking, originating with Karl Lashley in 1951, is the following French sentence: *Pas de lieux Rhône que nous*. Even to a French speaker, this sentence is not memorable, because it is nonsensical. However, sounding the sentence out a few times (with the correct French pronunciation) soon leads to a reorganization of its constituent units that renders it instantly memorable – but as an English sentence. Most apparent examples of learning by rote repetition – for example, learning of scripts by actors, and even of sequences of steps by dancers – actually involve some form of chunking.

Chunking also plays a central role in creating differences in memory ability between experts and novices in a particular field. Adriaan De Groot, for example, showed that expert chess players remembered chess positions much more accurately than novice chess players, but that this advantage was not attributable to the experts having better overall memory capabilities: when the chess pieces were randomly arranged, the memory difference between experts and novices disappeared. Instead, the experts' superior memory depended on their ability to chunk groups of pieces according to their knowledge of positions that might be expected to occur in a game.

Exceptional and apparently astounding memory abilities can also be acquired by developing sophisticated chunking strategies. For example, William Chase and Anders Ericsson trained an individual to recall over 80 sequentially presented random digits, even though he could initially recall only an average seven. His ability reflected strategies for grouping the numbers into meaningful chunks, not a general increase in 'memory power' with training: When the task was switched to remembering random letter sequences, he could once

again recall only around seven. Naturalistic studies of memory experts who perform in public also usually confirm that they have learned sophisticated chunking strategies to perform their apparently photographic feats. Thus, memory is not like a muscle that can be 'strengthened' purely by repetitive exercise. (*See* **Lashley, Karl S.**; **Memory**; **Learning Aids and Strategies**; **Expertise**; **Memory Mnemonics**; **Education, Learning in**; **Learning and Memory, the Ecology of**)

Memory Distortions, Illusions, and Attributions

The inevitable role of existing world knowledge in the encoding and retrieval of new information has negative as well as positive consequences, as first reported by Frederick Bartlett in 1932. The then-prevailing experimental practice, originating with Ebbinghaus, was to attempt to examine memory for new information in isolation from pre-experimental knowledge by asking people to learn simple and often meaningless materials. Bartlett, by contrast, asked people to learn stories, which gave maximum scope for the influence of pre-experimental knowledge to be revealed. In recall of the stories, details were omitted, leaving memory for the gist, or main structural elements. Bartlett also found that new elements were introduced and existing elements distorted in accordance with knowledge – including cultural and social preconceptions – about the kind of events likely to have occurred in the story.

The kinds of general world knowledge that influenced and distorted the recollections of the participants in Bartlett's experiments are termed schemas. More recent experimental research with textual materials, as well as naturalistic research on memory for real-world events, conducted by Gordon Bower, John Bransford, Jeffery Franks, Ulric Neisser and others, has clarified the processes by which schemas produce these distortions and additions. At encoding, the specific information provided is elaborated in terms of schemas (e.g., assumptions and inferences are made), and these elaborations become part of the memory trace for the material. At retrieval, information provided by retrieval cues, by the schemas, and by specific information retrieved, which includes the elaborations made at encoding, combines to produce a reconstruction of the previously encountered information – one that can contain significant distortions. Once again, encoding and retrieval processes are intimately interwoven. (*See* **Bartlett, Frederic Charles**; **Schemas in Psychology**; **Memory Distortions and Forgetting**; **Learning and Memory, the Ecology of**)

Such distortions are also evident when people 'remember' recent well-circumscribed events that in fact never occurred. A striking recent example was reported by Henry Roediger and Kathleen McDermott, who updated an experimental procedure introduced by James Deese in 1959. People studied a number of lists of words, with the words within each list consisting of semantic associates (e.g., *mad*, *fear*, *hate*, *rage*, *temper*, *fury*) of a particular prototype word (e.g., *anger*), which was not itself studied. On a later recognition test, previously studied semantic associates were mixed with the nonstudied prototype words, and with other nonstudied words that were unrelated to the previously studied words (e.g., *bread*). People were well able to reject the unrelated words as not having been studied. But they were just as likely to endorse the nonpresented prototype words as having been studied as they were the actually presented words. Critically, they did not just guess that the nonstudied prototypes could plausibly have been studied. They not only 'recognized' them with high confidence, but also claimed to re-experience vividly the details of their prior occurrence (e.g., what they were thinking at the time). This false memory phenomenon, therefore, is not just a memory distortion, but a memory illusion.

This and other memory illusions illustrate that our understanding – or misunderstanding – of our own memory processes, which is termed metamemory, plays a critical role in long-term memory. There is considerable evidence, for example, that we monitor the fluency with which information is currently processed. When that fluency exceeds the fluency we would expect – based on our knowledge of how fluently that kind of information is normally processed – we face a problem of attribution. Where does that unexpected fluency come from? We could attribute it to current external conditions that make the information especially easy to process, the information being well established in memory, a recent encounter with the information, or some other factor.

These attributions about the source of current processing fluency are adaptive in the sense that they are usually valid. But they can sometimes be mistaken, causing striking memory illusions of various kinds. For example, Larry Jacoby and his colleagues found that increasing the identifiability of sentences spoken against a noise background, by presenting those sentences earlier in a supposedly unrelated task, causes a misattribution of that increased identifiability to a lowered level of the

background noise. And Lynne Reder and her colleagues found that prefamiliarizing key words in general knowledge questions, such as the words *golf* and *par* in the question *What is the term in golf for scoring one under par?*, increases the likelihood that people judge that they know the answer to the questions – but without improving their actual ability to answer them. Similar illusions of knowledge, based on general familiarity with a subject domain, can be evident in students' judgments of their comprehension and future memory of textual material, as shown by Arthur Glenberg, William Epstein and their colleagues.

Finally, with regard to the illusory recognition phenomenon described earlier, Bruce Whittlesea has recently theorized that there is unexpected fluency in the semantic processing of the nonpresented prototypes when they appear on the recognition test, caused by the prior presentation of their associates. This unexpected fluency results in the automatic construction of vivid 'recollections' of earlier encounters with the prototypes. Whether or not this particular theory stands the test of time, such attributional theories of memory are important more generally because they raise the possibility that all memories – whether veridical or illusory – are constructions based on current cognitive processing. (*See* **Memory**; **Learning Aids and Strategies**; **Metacognition**; **False Memory**; **Education, Learning in**)

CONCLUSION

The overall picture that emerges from just over a century of scientific research is that human long-term memory is exceptionally complex and sophisticated: it is varied, dynamic, and constructive, and quite unlike current human-made memory devices in virtually every important respect. The resulting capacities of human long-term memory are stunning, which can make its limitations – in terms of forgetting, distortions, and illusions – seem equally stunning. These limitations, however, are part and parcel of a neural information-processing system that is remarkably well adapted to cope with the demands of living in a constantly changing and ever more complex world.

CONTENTS

Mental disorders frequently disrupt cognition. Computational models are mathematical representations of cognitive or neural processes. These models have been applied to simulate cognitive deficits, to relate cognitive deficits to disturbances of neuroanatomy and neurophysiology, and to make predictions of the effects of brain disturbance on cognitive function.

INTRODUCTION

Psychiatric and neurological disorders are frequently accompanied by specific disturbances of perception, cognition, affect or motor control. In addition, these disorders have been associated with abnormalities of neuromodulation or neural connectivity, or loss of neurons. Computational models have been applied to simulate and predict human cognitive performance. More recently, computational models of neural circuit architecture and function have been used to relate cognitive deficits to neural abnormalities in specific disorders. (*See* **Amnesia**; **Aphasia**; **Dyslexia**; **Memory Consolidation**; **Neurons, Representation in**; **Neurons, Computation in**; **Neural Development**; **Synapse**; **Hebb Synapse: Modeling of Neuronal Selectivity**; **Hebbian Cell Assemblies**; **Levels of Analysis in Neural Modeling**; **Learning and Memory, Models of**; **Attention, Models of**; **Neurotransmitters**; **Neural Degeneration**; **Synaptic Plasticity, Mechanisms of**; **Language Comprehension**; **Memory Models**; **Working Memory**; **Model Fitting**)

Computational models have been instantiated at three general levels in mental disorders. Some models have focused solely on the cognitive level, and do not attempt to relate the architecture of the model to the neural substrates of a disorder (e.g. Carter and Neufeld, 1999). A second type of model has been motivated by the role of specific regions of the brain in cognitive disorders, or the role of a neurotransmitter in specific functions (Cohen and Servan-Schreiber, 1992; Haarmann *et al*., 1997). A third approach uses experimental studies of the properties of neurons and neural circuits in animals to design neural circuit simulations, and then lesion components of this neural model to determine how the lesion affects information processing within the circuit (Grunze *et al*., 1996; Hasselmo and Wyble, 1996). Most models have used neural network models to simulate mental disorders. Because neural network models employ an architecture of parallel, interconnected processing units which resemble the architecture of the nervous system, they may be better suited to modeling brain disorder than serial, symbolic programs with a single central processing unit. The distributed processing units in neural networks allow great flexibility in the level of implementation of the model. For example, processing units can represent the properties of individual neurons within a circuit, or abstract representations such as visual features or words. In this article, neural network models which attempt to capture the cognitive or biological features of several major mental disorders will be reviewed. SCHIZOPHRENIA

Schizophrenia is a mental disorder characterized by cognitive deficits, hallucinations, delusions,

and disturbances of social and emotional behavior. Neuropathology suggests a reduction in neural connectivity, possibly secondary to abnormal synaptic pruning during development. In terms of neurotransmission, there is evidence of abnormal dopaminergic transmission, and of *N*-methyl-D-aspartate (NMDA) receptor function in schizophrenia. Notably, normal adults may develop transient psychotic symptoms similar to schizophrenia as a result of the use of amphetamines (which increase dopaminergic activity) or ketamine (a drug that blocks NMDA receptors). The application of neural network models has provided the first formal insights into the way in which these neural and cognitive features might be related (Grunze *et al*., 1996; Hoffman and McGlashan, 1997). Two models will be discussed here.

NMDA receptor function may be disrupted by schizophrenia. What would be the consequences of such a disturbance within local cortical circuits? At the circuit level, Grunze *et al*. (1996) studied the role of NMDA in modulating local circuit inhibition within the rate hippocampus. These neurophysiological findings were then used to develop a biophysical model to test the functional consequences of NMDA blockade. Grunze *et al*. found that inhibitory neurons in hippocampal circuits were highly sensitive to NMDA antagonists. Inhibitory neurons provide recurrent or feedback inhibition of the activity of excitatory, glutamatergic neurons. If NMDA receptors are dysfunctional in schizophrenia, recurrent inhibition would also be diminished, resulting in hyperexcitability within the circuit. A learning simulation using an auto-associative network showed that such a failure of recurrent inhibition would result in the spread of activation to irrelevant patterns during recall. This inappropriate spread of activation within a set of representations may contribute to such symptoms as 'loose associations' in speech, and disturbance of physiological measures of inhibition, such as P50 sensory gating and prepulse inhibition (Nestor and O'Donnell, 1998).

Dopaminergic neurotransmission is probably affected by schizophrenia as well. Dopaminergic modulation may play a role in prefrontal cortex maintenance of contextual information, and may affect gain in neural circuits. Cohen and Servan-Schreiber (1992) developed a back-propagation model of schizophrenic cognitive dysfunction which attempted to capture these features of schizophrenia, and they used the model to simulate deficits in task performance. The model had input, associative and output modules for learning. A context module affected the flow of information through the associative module. The context module provided functions similar to working memory (maintenance and manipulation of task-relevant information) and selective attention. Cohen and Servan-Schreiber found that reduction of gain in units in the context module resulted in degradation of internal representations in the context module. This may be analogous to the effects of dopamine dysregulation on prefrontal cortex function. The degradation of contextual modulation, in turn, resulted in deficits in network simulations of the Stroop task, the continuous performance test and a lexical disambiguation task. These simulated deficits were similar to those observed experimentally in schizophrenia. For example, individuals with schizophrenia show a bias towards the dominant meaning of a word, regardless of the prior context. Thus when provided with the prior statement 'You can't keep chickens', followed by 'without a *pen*', patients with schizophrenia were more likely to say that *pen* referred to a writing implement rather than to a fenced enclosure. When the function of the context module was degraded by reducing gain of units in the context module, the model showed the same pattern of dominant response errors as subjects with schizophrenia. Figure 1 illustrates the network model for this experiment.

Although the Cohen and Servan-Schreiber model did not attempt to model at the level of neural circuits, it did demonstrate how a model may incorporate pathophysiological data into simulations of cognitive deficits, and it identifies mechanisms which may be responsible

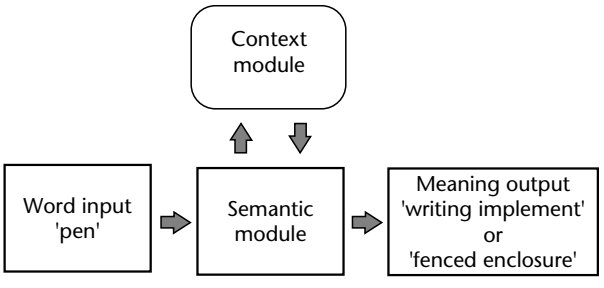

Figure 1. Diagram of connectionist model used in a lexical decision task implemented by Cohen and Servan-Schreiber (2001). The context module allows the system to disambiguate an input which could have either a dominant or a subordinate meaning. Decreasing the gain of the units in the context module produced a bias towards dominant meanings of an input, which was similar to the behavioral performance of patients with schizophrenia in lexical decision tasks.

for behavioral deficits in superficially dissimilar tasks.

HALLUCINATIONS

Auditory hallucinations are associated with a variety of mental disorders, such as affective psychosis and schizophrenia. Hallucinations are often characterized by hearing voices which an individual does not experience as his or her own, and which do not originate from auditory stimulation. In schizophrenia, such psychotic symptoms usually appear in adolescence or young adulthood, coinciding with the developmental interval in which large-scale synaptic pruning occurs in cortical areas. To investigate whether hallucinated speech could arise from pathological over-pruning, Hoffman and McGlashan (1997) developed a back-propagation network model of speech perception. The model had four layers, namely an *input layer* which represented phonetic features of words, a *hidden layer* that integrated feedforward projections from the inputs and recurrent projections from a temporary storage layer, a *storage layer* that represented working memory processes by storing a copy of previous hidden layer activation, and an *output layer* that represented semantic and syntactic features of words. To determine which word (if any) the model detected, output layer activation was passed through a decision algorithm. Before and after pruning, the authors counted the number of correct identifications, misidentifications and hallucinations for full, degraded and null (zero-valued) phonetic inputs. Hallucinations were defined as the presence of a detected word given a null input. Competitive pruning was modeled by modifying weights between the temporary storage and hidden layers.

Hoffman and McGlashan (1997) found that partial pruning of the network, which simulated normal developmental processes, enhanced the ability of the network to detect words. However, over-pruning impaired the network's ability to detect words, and it produced stereotyped hallucinations. Although this simulation did not attempt to model speech perception at the level of neural circuits, it does support the neurodevelopmental usefulness of selective synaptic elimination. Furthermore, the model proposes a plausible developmental mechanism for schizophrenia that is consistent with morphological findings of decreased synaptic density and that predicts perceptual and working memory disturbances which are also found in the disorder.

LANGUAGE DISORDERS

Computational approaches have also been used to model disturbances of language processing caused by stroke. Classic theories of aphasia are framed in terms of the differential role of cortical regions. For example, left temporoparietal lesions often produce Wernicke's aphasia, which is associated with severe language comprehension deficits. Computational models allow a formal representation of semantic and syntactic mechanisms that are affected by aphasia. Haarmann *et al*. (1997) postulated that left temporoparietal lesions cause sentence comprehension problems because they reduce the capacity of working memory for language. The authors tested this hypothesis in a hybrid computational model that combined the spreading activation of connectionist approaches with production rules (if…, then… statements). Their model contained three subsystems of production rules, namely a lexical access system, a parse tree system and a thematic role mapping system (Figure 2). The lexical access subsystem took the perceptual representation of single words as input, and activated word meanings, word syntax and verb structures as outputs. The parse tree subsystem applied grammar-based production rules to the syntactic output of the lexical access system to generate parse tree representations. Finally, the thematic role mapping subsystem combined word meanings and verb structures from the lexical system with parse tree representations to produce thematic role bindings (indicating who did what to whom). The performance of the model was determined by the activations of the thematic role binding units, which represented correct comprehension of parts of sentences. In the model, working memory capacity was defined as the total number of activation units that were available per unit of processing time. Activation spread at each processing step when conditions in the antecedent (if…) of production rules matched active elements in working memory.

In this model, aphasic performance was simulated by decreasing working memory capacity, or the amount of activation available per processing step. In situations where working memory demand (total activation summed across active antecedent conditions and production rule targets) exceeded capacity, target activations were reduced in order to maintain activations within the model's capacity. This modulation of working memory capacity resulted in a pattern of performance that mirrors aphasic deficits. The model demonstrated forgetting (which was instantiated by below-threshold

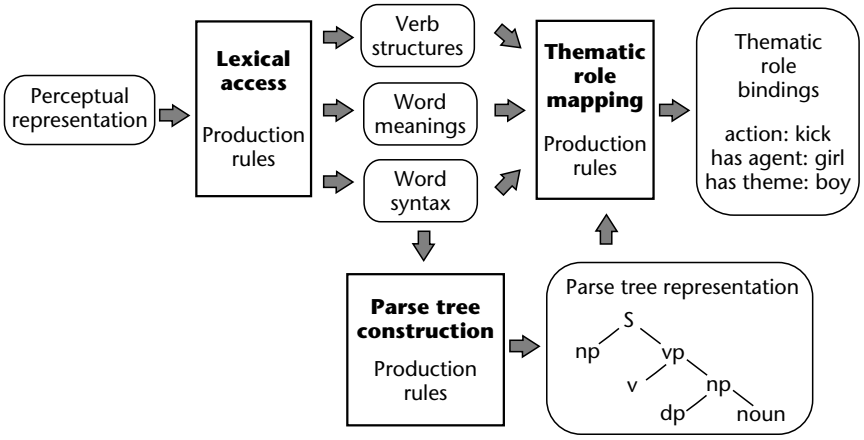

Figure 2. Computational model of semantic and syntactic mechanisms affected by aphasia (adapted from Haarmann *et al*., 1997). In this figure, production rule systems are represented by square boxes and active elements of working memory are denoted by rounded boxes. Different thematic roles include action, agent and theme. The input string 'The girl kicked the boy' activates the thematic role bindings as follows: action, kick; agent, girl; theme, boy. The working memory capacity reductions that are postulated to occur in aphasia are represented in the model by a reduction in the total number of elements that can be active at once.

activations), slower processing (which emerged because more processing steps were required to produce threshold activations) and partial comprehension (which corresponds to occasions when some processing steps never occurred because subthreshold activations did not engage production rules). These deficits closely resemble the patterns of forgetting, slower processing, and partial comprehension that are found in experimental studies of aphasia. The model also captures the interaction between sentence complexity and illness severity which is found in patients. Models with severely decreased working memory capacity performed like patients with severe aphasia – both showed progressively worse sentence comprehension performance with increasing sentence complexity.

ALZHEIMER DISEASE

Alzheimer disease is an adult-onset disorder associated with a progressive dementia. Initially, anterograde amnesia is the most severe deficit, but remote memories are also lost as the disease progresses. Neuropathological changes include loss of neurons and a reduction in cholinergic innervation of the cortex.

Hasselmo and Wyble (1996) used a neurophysiological model of pattern learning to show how cholinergic activity may play a central role in both the memory deficits and neural damage in Alzheimer disease. Within neural circuits, neurophysiological evidence and biophysical models suggest that acetylcholine suppresses association-fiber synaptic transmission, while direct afferent input remains effective. This allows learning of new patterns using the Hebb rule, while suppressing interference and runaway synaptic modification. If cholinergic activity was reduced, as occurs in Alzheimer-type dementia, the metabolic demands of the resulting runaway modification could result in the spread of neuronal damage and degeneration. Moreover, the functional consequences of excessive synaptic modification would include the disruption of learning and retrieval which has been observed in Alzheimer disease.

CONCLUSION

Computational models show promise for simulating experimental data and developing behavioral predictions with regard to cognitive processes in mental disorders. However, current models are limited due to their simplified representation of inputs, outputs and cortical circuits. The human cortex is estimated to contain billions of neurons, and each neuron may have thousands of connections. Current neural models typically use a small number of processing units and connection weights which cannot approach this level of biological complexity. In addition, because models have many parameters which can change as a function of initial weights, connections and learning, it is not clear how the fit of the model to experimental data or neural mechanisms can be rigorously tested. Nevertheless, the computational models

reviewed here often represent the first attempt to develop mathematical simulations of neural and cognitive deficits associated with mental disorders. The full potential of computational modeling of neural and cognitive systems may depend on the development of hardware and software which better represents the architecture of the brain.

Mental Models

Intermediate article

William F Brewer, University of Illinois at Urbana-Champaign, Urbana, Illinois, USA

CONTENTS

A mental model is a form of mental representation for mechanical–causal domains that affords explanations in these domains. The term 'mental model' is also used to refer to specific mental representations of static spatial domains, and for model-based reasoning about logic problems.

INTRODUCTION

Mental models are a form of knowledge representation. They have been hypothesized to play an important role in our interactions with the physical world. The term 'mental model' and its underlying psychological constructs have wide usage in the disciplines of cognitive psychology, cognitive development, science education, and human factors. There has been some confusion about the nature of mental models and the terms used to describe them. In particular, the term 'mental model' was used differently in two very influential books, both entitled *Mental Models* and both published in the same year (Johnson-Laird, 1983; Gentner and Stevens, 1983). This article will attempt to resolve some of the confusions in this area and to describe the aspects of the mental model construct that have made it valuable to researchers across a wide variety of disciplines.

MODELS IN SCIENCE

The introduction of mental models into psychology was inspired by their use in the physical sciences. The model-based approach to science reached its fullest development in British physics in the late nineteenth century (Klein, 1972). Scientists such as Kelvin, Thomson and Maxwell argued that for a scientific theory to be successful it had to provide a mechanical–causal model. Boltzmann (1902, p. 790) described the model-based approach to science as the belief that 'physical theory is merely a mental construction of mechanical models, the working of which we make plain to ourselves by the analogy of mechanisms we hold in our hands, and which have so much in common with natural phenomena as to help our comprehension of the latter'.

There are several important points to be noted in this description. Models are mental constructs in the minds of scientists. Models make use of mechanical–causal entities. The models in the mind have an analogical relation with the events that are to be explained in the world, and it is this relation that gives them their power. The models provide an understanding and explanation of events in the world. It should be noted that this usage of the term 'model' is quite different from its usage in the term 'mathematical model' in psychology, which involves the use of formal mathematical tools to describe some behavior.

With the advent of relativity theory and quantum mechanics, the model-based approach in physics was replaced with a formalist approach. The ability of physics to develop these very successful abstract approaches may give the impression that model-based approaches are not important in science. However, almost all the major developments in science before the twentieth century were model-based; and, apart from work in theoretical physics, many of the major advances in science in the twentieth century were model-based (e.g. plate tectonics, molecular biology). Indeed, most scientific theories of the natural world except for modern theoretical physics are (mechanical–causal) models.

JOHNSON-LAIRD MODELS

The work of Kenneth Craik formed a crucial link between the construct of models in the physical

sciences and the construct of models in psychology. In a far-sighted book, Craik (1943) used ideas from the physical sciences to develop a model-based approach to the mind. He suggested that human beings construct internal models of reality, and that these models have a 'relation structure' to the world, which allows individuals to make successful predictions about the future occurrence of events in the world by manipulation of the internal model.

Johnson-Laird's work on mental models represents one model-based approach in modern cognitive science. Johnson-Laird developed the construct of mental models as a new form of knowledge representation needed to understand language comprehension and logical reasoning. He stated that 'a model *represents* a state of affairs and accordingly its structure is not arbitrary like that of a propositional representation, but plays a direct representational or analogical role. Its structure mirrors the relevant aspects of the corresponding state of affairs in the world' (Johnson-Laird, 1980, p. 98). This model-based approach was quite different from most other proposals for the representation of knowledge (e.g. semantic features, semantic networks, propositions), in that the analogical assumption imposed constraints on what could be represented and how; so this form of representation was not as arbitrary and unconstrained as some other proposals. (*See* **Knowledge Representation, Psychology of**)

Johnson-Laird's model-based proposals have had a major influence on two areas of research: reasoning and text representation. Johnson-Laird used the idea of models to attack the view that people reason with some form of abstract mental logic. He and others have argued convincingly that people convert abstract logical problems into specific models and then manipulate the information in the models to generate conclusions. (*See* **Reasoning**; **Deductive Reasoning**)

Johnson-Laird's proposals have a number of powerful consequences in the area of mental representation of text information. He argued that many forms of text can be represented in terms of a mental model; and he often used the example of a text describing a spatial array. When Johnson-Laird was developing these ideas, most theories of text representation assumed that the structure of a text could be analyzed in terms of the concatenation of the sentences that made up the text. The mental model approach to texts describing spatial arrays made it obvious that one needed representations both for the linguistic form of the text itself and for the information conveyed by the text. This was a major advance in the study of linguistic discourse and has led to a wide range of experimental studies (e.g. Bower and Morrow, 1990). (*See* **Discourse Processing**)

Another important approach to the representation of text information at the time of the development of the mental model construct was the analysis of information in terms of schemata or generic knowledge structures. The use of schema representations remains a viable approach to the analysis of very stylized genres (e.g. soap operas, fairy tales). However, the mental model approach made clear the need for forms of knowledge representation that could account for the construction of a coherent mental representation from a text describing information that was new to the reader or hearer. Much of the early work on mental models of text focused on the processes involved in the construction of a specific mental model from a text describing an unfamiliar spatial array, with little discussion of the background knowledge that was used in the construction process (Brewer, 1987). (*See* **Schemas in Psychology**)

MENTAL MODELS IN HUMAN FACTORS

In the area of human factors there was a somewhat independent development of a construct of mental models (Wilson and Rutherford, 1989). In the early development of this area of research, theory tended to derive from stimulus–response psychology and the focus was on simple manual tasks. However, as researchers looked more deeply at what was going on in apparently simple tasks, and as they looked at complex process control tasks (e.g. someone controlling the operations of a chemical plant), they began to feel the need for new forms of mental representation. They needed a kind of knowledge structure that would allow them to account for the fact that operators were making (often correct) predictions about the future states of the various physical systems they were controlling. In fact, driven by the nature of the real-world tasks they were trying to understand, researchers in human factors began using the mental model construct 10 or 15 years before researchers in most other areas of cognitive science.

In the early period of the use of the mental model construct in human factors research it was often called an 'internal model', but later the term 'mental model' became standard. Rasmussen (1986, p. 141) provides an interesting definition of mental model as used in human factors research: 'A mental model of a physical environment is a

causal model structured in terms of objects with familiar functional properties. The objects interact in events, i.e., by state changes that propagate through the system.'

Most of the theorizing in this area has focused on mental models in long-term memory (roughly, the operators' theories of the tasks they are performing). However, much of the practical research has involved investigations of particular instantiations of mental models. For example, a researcher in human factors might study someone operating a plastics plant and find that the individual explains his or her actions at a specific moment by stating that he or she has just increased the temperature in one of the reactors because some of the feed material was not of good quality. Thus, human factors data typically relate to the dynamic moment-to-moment instantiation of the underlying mental model from long-term memory.

Because of the nature of human factors research, most of the data and theory in this area relate to the process of human beings interacting with human cultural artifacts. In many cases (e.g. flying airplanes, operating a nuclear power plant) one can think of the domain as having two aspects: the underlying mechanical–causal processes and the intentionally designed artifacts (e.g. control panels). This means that researchers must often consider the operator's mental model, the artifact designer's mental model, and the interaction of the two.

There has been considerable research on mental models for various types of computer-related tasks. It is not clear that mechanical–causal models are a reasonable representation for computers. This suggests either an inappropriate use of the model construct or the need to expand the mental model construct beyond mechanical–causal domains to deal with abstract–causal domains.

Researchers in human factors have carried out studies using techniques such as structured interviews and think-aloud protocols to attempt to describe the mental models used in various types of tasks. There have been two main lines of theoretical and empirical work. First, there is a strong belief that equipment should be designed so that it is consistent with or supports appropriate operator mental models. Second, there have been a number of studies of the role of mental models in instruction. There is considerable evidence that when the operator's task can be carried out in a script-like or procedural way (e.g. 'when the red alarm flashes turn the big switch off'), helping the operator develop an appropriate mental model for the task does not improve performance. However, most researchers believe that mental models improve performance when the operator has to solve a new problem (e.g. troubleshooting), and there is some limited empirical support for this.

MENTAL MODELS IN SCIENCE EDUCATION

The mental model construct was also developed somewhat independently in the area of science education. In the 1960s and 1970s a number of studies suggested that children showed 'misconceptions' in their understanding of certain natural phenomena. School children think that heat and cold move though objects like fluids, that plants obtain their food from the ground, and that boats made of iron should sink. Driver and Easley (1978) synthesized some of these studies and made the point that young children appear to develop 'alternative frameworks' for explaining many phenomena in the course of their interactions with the world and the adult culture. Driver and Easley's theory was loosely based on Thomas Kuhn's approach to the philosophy of science. They suggested that children's alternative frameworks showed how the same phenomenon could be explained by very different conceptual systems. They suggested that the children had simply developed an alternative theory of the phenomenon to that currently held in science.

Researchers in science education have not developed a common term for these types of beliefs held by children. They have been called misconceptions, alternative frameworks, children's science, students' conceptions, naive knowledge, etc. Many of these beliefs involve mechanical–causal explanations of phenomena. Indeed, some researchers have argued (e.g. Andersson, 1986) that many of the children's misconceptions are based on an overapplication of mechanical–causal theories. Thus, it would appear that many of these misconceptions should be considered as children's alternative mental models of the natural world.

Empirical studies in this area have focused on the domains of the natural world that are typically studied in school. The emphasis has mostly been on the mental models that the children have in long-term memory. Many researchers believe that instruction should consist of techniques that will facilitate the replacement of children's alternative mental models with the accepted scientific mental models. In other words, the goal is to have the children understand the world in ways closer to those of current scientific theories. Most investigators feel that knowing the child's current mental model should help in the design of instructional

techniques. However, children's self-generated mental models tend to be very resistant to change with most of the forms of instructional intervention that have been tried.

MENTAL MODELS IN DEVELOPMENTAL PSYCHOLOGY

Within the field of developmental psychology there is a research tradition that focuses on children's understanding of the natural world (Wellman and Gelman, 1992). Much recent work in this area has adopted the view that children are like little scientists and that from their observations of the natural world they develop conceptual understandings of natural phenomena. These mental representations of the natural world are often called 'naive theories'. Some of the research in this area has focused on topics such as children's theories about the minds of other people, and this work does not seem to fit well within the mechanical–causal framework of mental models. Some of the most explicit discussions of mental representation in children occur in this work on theory of mind; but these types of theories do not have an analogical relation to the physical world and do not make use of mechanical–causal mechanisms. Instead, they emphasize the role of abstract theoretical entities. Thus, these naive theories do not seem to be model-based. (*See* **Naive Theories, Development of**)

However, within the area of child development research there are a number of studies of mechanical–causal domains. For example, Vosniadou and Brewer (1994) have investigated young children's understanding of the day–night cycle. They found that children develop a variety of explanations based on mechanical–causal mechanisms, and they use the term 'mental model' to describe these mental representations.

GENTNER–STEVENS MODELS

It is difficult to characterize the similarities in the set of papers that were published in the important volume edited by Gentner and Stevens in 1983. These papers come from quite different research traditions: human factors, science education, and child development. However, they focus on mechanical–causal domains (including both human artifacts and the natural world); and most of them focus on mental representations that are in long-term memory, though often in a problem-solving context that includes a dynamic, constructed representation. This collection of papers is distinguished from most other discussions of mental models in that a number of them attempt to represent the mental models using representation schemes taken from the field of artificial intelligence.

IMAGES AND MENTAL MODELS

Many discussions of mental models describe them as having image properties. Participants in model-based experimental investigations often describe their phenomenal experience while carrying out the task as having an image of the situation. In the human factors literature a number of investigators have stated that individuals are able to solve model-based problems by envisioning a causal sequence 'in their mind's eye'. (*See* **Imagery**)

However, a number of theorists have argued that static images are not rich enough to account for performance on model-based tasks, and that some more dynamic knowledge-based form of representation is needed. For example, Johnson-Laird (1983, p. 157) suggests that images may be views of a richer underlying knowledge structure.

BARSALOU'S PERCEPTUAL SYMBOLS

Barsalou (1999) proposes a new form of knowledge representation which he calls 'perceptual symbols'. These representations have both spatial properties, derived from perception, and symbolic–generative properties, derived from frame representations. Barsalou argues that perceptual symbols are the underlying form of representation for a wide range of forms of knowledge, including very abstract knowledge. Barsalou does not focus on knowledge related to mechanical–causal domains, but his perceptual symbols have properties that make them a very plausible way to think about mental models in such domains.

ANALYSIS OF THE MENTAL MODEL CONSTRUCT

The different approaches to the mental model construct can be clarified by an analysis of mental models in terms of the domain of application and the type of knowledge that is assumed to reside in long-term memory. The classification of mental models by domain of knowledge is necessary because different forms of knowledge have different characteristics (for example in the static spatial domain, causality is not a relevant consideration). Their classification by information in long-term memory is justified by Brewer's (1987) argument that mental models as used by Johnson-Laird are best distinguished from schemata by the fact that

they are assumed to be constructed at the time of input, whereas schema representations are assumed to already be in long-term memory. This distinction will be applied across the different accounts of mental models discussed earlier.

Preformed Spatial Knowledge

Preformed spatial knowledge in long-term memory has sometimes been called a mental map or a spatial schema. When someone is exposed to an appropriate instance (e.g. a particular map of the USA) they use their generic mental map of the USA to form an instantiated location representation (e.g. a specific mental map in which Florida is green).

Constructed Spatial Knowledge

Constructed spatial knowledge in long-term memory consists of general principles of organization in Euclidean space, not generic preformed spatial information. When someone is exposed to an appropriate instance (e.g. a text description of an unfamiliar town) they can use the information in it, along with these general principles, to construct a new specific spatial representation. Johnson-Laird focuses on this process, and he refers to the new spatial representation as a mental model.

Preformed Mechanical–Causal Knowledge

Preformed mechanical–causal knowledge in long-term memory is an understanding of mechanisms (e.g. how filter coffee machines work or how the day–night cycle works). This type of knowledge has been given various names. Within human factors research it is often called a 'mental model'; within science education it has been called by various names including 'misconception' or 'alternative conception'; within developmental psychology it is usually called a 'naive theory'.

When someone is successful in dealing with a specific instance of the general information in long-term memory, then one typically says that the instance has been explained by the mechanical–causal model or theory. This class of phenomena covers much of problem solving in science education and troubleshooting in human factors.

Constructed Mechanical–Causal Knowledge

Constructed mechanical–causal knowledge in long-term memory consists of general principles, not a previously understood model or theory. This type of knowledge has been less well studied, and does not have a generally accepted name. In a wide variety of situations one deals with instances by constructing a new model. For example, this is what happens when one understands a Rube Goldberg cartoon (an unfamiliar and implausible causal chain). The same process may be operative when someone is taught a new theory to explain a particular instance of a phenomenon. In the most creative cases, this is what occurs when a child develops a naive theory or a scientist constructs a new theory to explain a particular mechanical–causal phenomenon.

PSYCHOLOGISTS' REPRESENTATIONS OF MENTAL MODELS

There is a difficult ontological problem in the psychological study of knowledge representation, which is particularly evident in the study of mental models. Are mental models something inside the heads of individuals, or are they a form of representation that psychologists as scientists are using to study individuals? This is a difficult question, and many researchers avoid it. For theorists with a realist view in the philosophy of science there are special difficulties. The problem is particularly acute for those who argue for some form of analogical relation. Is the analogical relation between the representation in the mind of the individual and the world, between the theorists' representation and the mind of the individual, or between all three? In practice, the term 'mental model' is typically used with a systematic ambiguity. For those researchers who are instrumentalists in the philosophy of science there is no problem: for them, mental models are just a construct used to account for the data and there is no issue of what is really in the head.

DEFINITION OF MENTAL MODELS

Analysis of the mental model construct as it is used across a wide range of fields shows that it is a complex construct, but suggests enough agreement to provide a general definition: a mental model is a form of mental representation for mechanical–causal domains that affords explanations for these domains. This type of mental model can be thought of as a subtype of naive theories of the physical world. Mental models contain mental representations of objects in space and the causal relations among the objects. The information in the mental

model has an analogical relation with the external world: the structure of the mental representation corresponds to the structure of the world. This analogical relation allows the mental model to make successful predictions about events in the world. Mental models give rise to the phenomenological experience of mental images, and the process of working out the causal relations of a mental model is often described as 'running the model in the mind's eye'. The term 'mental model' is used to refer both to general model-based knowledge in long-term memory and to temporary specific mental representations constructed in the course of understanding particular events in the world.

The term 'mental model' is also used to refer to mental representations of static spatial domains. In this usage, the term is typically restricted to the specific mental representations that are used to represent unfamiliar spatial arrays. These spatial mental models have an analogical relation with the spatial information in the external world and are typically experienced in terms of visual mental images. This usage of the term is also applied to the case where abstract logical problems are solved by converting them to spatial model-based formats.

Mental Rotation

Intermediate article

Yohtaro Takano, University of Tokyo, Hongo, Bunkyo-ku, Tokyo, Japan
Matia Okubo, University of Tokyo, Hongo, Bunkyo-ku, Tokyo, Japan

CONTENTS

Mental rotation refers to rotational transformation of an object's visual mental image. Mental rotation may indicate that, unlike the object's verbal description, the image shares some spatial and visual properties with the object itself.

INTRODUCTION

When psychological studies of mental imagery revived in the late 1960s, arguments centered upon the question of whether mental imagery should be distinguished from language as a separate system of mental representation. Although mental imagery was repeatedly shown to facilitate word retrieval, this did not convince many psychologists that mental imagery and language are different kinds of representation. Mental rotation attracted great attention because it appeared to attest that mental imagery has some spatial and visual properties that are lacking in language. (*See* **Mental Imagery, Philosophical Issues about**)

RELATION BETWEEN ANGULAR DISPARITY AND RESPONSE TIME

Mental rotation was first reported by Shepard and Metzler (1971). Participants in their experiment were shown a pair of objects like those in Figure 1(a), and asked to judge as quickly and accurately as possible whether they were the same or different. When the two objects were different, they were mirror images of each other as in Figure 1(a). Angular disparity between them was varied from 0 to 180 degrees. Response time was measured between presentation of the objects and a participant's response.

Mean response time for the 'same' pairs was found to be proportional to angular disparity (see 0–180 part of Figure 1(b)). Shepard and Metzler (1971) interpreted this finding as follows: to make mirror image discrimination, participants mentally rotated the image of one object at a constant speed until it is aligned with the other.

This interpretation triggered a lively debate as to whether an image was actually rotated or not. The most convincing evidence of rotation was provided by Cooper (1976), who estimated the speed of mental rotation (i.e. the slope of the linear function) for each participant in an experiment similar to Shepard and Metzler's (1971). In a subsequent experiment, the participant was asked to rotate the image of a presented standard object clockwise. A test object was later presented in the orientation that the standard object's image was expected to take at that very moment. The participant could not predict where the test object would be presented. Nevertheless, the results showed that the participant was able to make mirror image discrimination

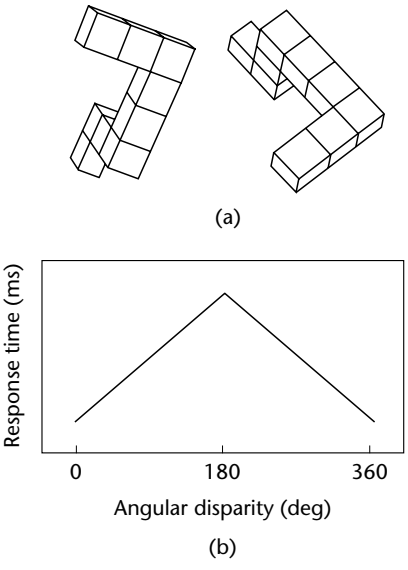

Figure 1. Materials and results in a typical mental rotation experiment: (a) an example of a 'different' pair of objects used by Shepard and Metzler (1971); (b) a schematic illustration of a typical mental rotation function.

at any angular disparity as fast as when the test and standard objects were presented in the same orientation. This strongly suggested that the image was actually present at the expected orientation. It follows that the image was actually rotated at least in that it passed through the intermediate rotational path.

Whether rotation is real or not, the systematic relation between angular disparity and response time provided strong evidence that mental imagery is different from language. In the case of language, the time to transform a sentence, for example 'The object is upright', into the sentence 'The object is tilted by X degrees' does not systematically relate to the value of X.

NON-MONOTONICITIES AT 180 DEGREES

When angular disparity exceeded 180 degrees, it was found that response time did not continue to increase monotonically but turned to decrease up to 360 degrees. In other words, it showed non-monotonicity at 180 degrees. As a result, a typical mental rotation function became an inverted V, as in Figure 1(b). This implies that it was possible to choose the shorter rotational path before starting the rotation.

The basis for identifying the shorter rotational path consists of those structural properties that are not affected by orientational change (Takano, 1989). In the case of the two objects in Figure 1(a), the human visual system detects the following structural properties irrespective of the objects' orientations: each object is composed of cubes, one end is composed of two cubes while the other end has only one, the two ends are orthogonal to each other, and so on. These orientation-free properties can be used to identify the corresponding parts between the two objects. Once the corresponding parts are identified, it is not difficult to determine the shorter rotational path.

INFLUENCES OF COMPLEXITY AND FAMILIARITY

Familiarity

It was found that more familiar objects could be rotated faster. To rotate unfamiliar objects like those in Figure 1(a) by 180 degrees, participants in Shepard and Metzler's (1971) experiment had to spend about 3000 ms. When objects were familiar alphanumeric characters, the time was reduced to 230–1200 ms.

The most dramatic demonstration was provided by Sayeki (1981) who told his participants to regard one of Shepard and Metzler's (1971) objects as a human body. In the case of Figure 1(a), the left object is a sitting person who is extending the left arm, whereas the right object is a person extending the right arm. Once an originally unfamiliar object was likened to a human body, it suddenly became a very familiar one. To rotate it by 180 degrees, Sayeki's (1981) participants needed only 180 ms.

Complexity

Early experiments found no effect of complexity on the speed of mental rotation. It turned out, however, that the reason for this absence was that participants reduced complex objects to simpler properties that were indispensable for making a same/different discrimination. When the task was changed so that the reduction was impossible, the speed of mental rotation was found to be slower for more complex objects.

It was also found that the speed of mentally rotating complex objects became faster as a result of practice (Heil *et al.*, 1998). Given that intensively practised objects become familiar, this effect of practice may be essentially identical to that of familiarity.

Mental rotation seems to have some limitation in its ability to deal with complex structures. Thompson's (1980) 'Thatcher illusion' is its most impressive demonstration: a face with some modifications looks almost normal when it is inverted, whereas it looks monstrous when it is upright. It is impossible to see the monstrous face by mentally rotating the inverted one. This suggests that mental rotation does not have sufficient capacity to transform such a complex structure as a human face while holding its structural details intact.

SITUATIONS THAT REQUIRE MENTAL ROTATION

A Basic Principle

In general, mental rotation occurs when a 'different' object is a mirror image of an original, whereas it does not when a 'different' object is of other types. Takano (1989) explained this by making a distinction between orientation-bound and orientation-free structural properties.

When two figures are mirror images of each other, they differ only in orientational relation between their constituent parts. In Figure 1(a), for

example, the left object's 'arm' extends to the *left* of its 'body', whereas the right object's 'arm' extends to the *right* of its 'body', if both objects are upright. This type of structural property is orientation-bound in that it is altered by a whole figure's orientational change. In Figure 1(a), in fact, the 'arm' of the right object which is not upright extends to the *left*, not *right*, of its 'body'. Therefore, it is impossible to compare orientational relations directly between two objects while they are in different orientations. To compare the orientational relations between the two objects, their orientations have to be aligned first. A common way of alignment is mental rotation.

When two objects are not mirror images of each other, there always exist structural differences that are orientation-free. Imagine, for example, that a non-mirror-image 'different' object is made by adding one more cube to the end of the left object's 'arm' in Figure 1(a). Then, it will be easy to tell whether a test object is the same or different, irrespective of its orientation. Mental rotation is not needed in this case.

Flexible Strategies

The human brain is an extremely complex and thus flexible system. Therefore, whether mental rotation is actually conducted or not sometimes differs from the above basic principle's prediction.

On the one hand, mental rotation could be conducted when it is unnecessary in principle. Suppose that you are looking for a toy. You have to discriminate it from other similar-looking objects, which could appear in any orientation for you. Although they may differ from the toy in some orientation-free properties, you cannot tell beforehand exactly what will be the differences. In such a situation, it may be wise to mentally rotate a similar-looking object to see whether it is the wanted toy. Thus, mental rotation may be conducted in natural settings as a convenient tool even if it is not indispensable. This sort of mental rotation was confirmed in an experiment, where participants failed to detect differences in orientation-free structural properties between compared objects because of their complexity. They did conduct mental rotation, though it was unnecessary in principle (Takano, 1989).

On the other hand, mental rotation may not be conducted when mirror images have to be discriminated. Mental rotation can be skipped because it is not the only way to discriminate between mirror images. If an object's form is remembered in various orientations, mirror image discrimination can be made without mental rotation (Tarr and Pinker, 1989) because the orientational relation in a presented object can be directly compared to that in the original object remembered in the same or neighboring orientation.

Another way of skipping mental rotation is to remember regularities in changing orientational relation. Suppose, for example, that part *A* is to the right of part *B* in an object. When the object is rotated by 90 degrees clockwise, *A* is below *B*; when the object is rotated by 180 degrees, *A* is to the left of *B*. If these regularities are utilized, mirror image discrimination can be made without mental rotation because the orientational relation in a presented object can be compared directly to that in the original object if the latter orientational relation is transformed adequately on the basis of these regularities (Takano, 1989).

THEORIES OF MENTAL ROTATION

Theoretical arguments about mental rotation centered upon the nature of mental representation of visual imagery. In the imagery (or analogue–propositional) debate, which continued for more than ten years, the analogue camp (e.g. Kosslyn, 1973) argued that the mental representation of a visual image is analogous to the corresponding physical object or its physical representation (e.g. a picture) with regard to some spatial and visual properties. The propositional camp (e.g. Pylyshyn, 1973) argued that the mental representation of an image is composed of propositions, a system of symbols that resembles language but is distinguished from it by different vocabulary and grammatical rules.

Mental rotation attracted a great deal of attention as the most convincing evidence for the analogue camp because mental rotation of a visual image closely resembled physical rotation of a physical object. The propositional camp showed that such properties as complexity and familiarity affected the 'speed' of mental rotation, and argued that a visual image differs from its corresponding physical object because a physical object's rotation speed is not affected by its complexity or familiarity. However, this type of criticism failed to show that the mental representation of an image must be propositions, because a representation could still be an analogue while it is different from its corresponding physical object in some respects (e.g., a picture of a person may be different from the real person in its size, material, temperature, and so on).

In the course of the imagery debate, the analogue camp was able to provide rational accounts for

experimental findings presented by the propositional camp; conversely, the propositional camp was also able to provide rational accounts for experimental findings presented by the analogue camp. Anderson (1978) claimed that the debate would not be resolved by any experimental data because any behavior of an analogue system would be mimicked by a propositional system equipped with appropriate processes that deal with propositional representation, and vice versa. This claim can be considered a special case of the Duhem–Quine thesis that any core assumption (e.g. propositional mental representation of imagery) can be made consistent with any empirical data by appropriately modifying peripheral assumptions.

Although the imagery debate thus has not reached any clear-cut resolution, a variety of experimental findings presented during the debate as to mental rotation provide an invaluable empirical basis to infer exactly what spatial and visual properties are manifested by visual mental imagery, whether they are implemented by analogue or by propositional representation.

Metacognition

Intermediate article

Petra Scheck, University of Maryland, College Park, Maryland, USA

CONTENTS

Metacognition is 'cognition about one's own cognition'. Judgments about past or future memory performance can be examined with respect to their basis, their similarities to other judgments, and their accuracy at predicting memory performance.

INTRODUCTION

Introspective observations have been criticized as being unverifiable, and for a period in the middle of the twentieth century were largely eschewed by the field of psychology. Since the 1970s, experimental paradigms have been developed to examine the accuracy of introspections. Unlike previous introspective methods, these new methods of examining metacognitive accuracy called for specific judgments about performance that could later be compared with criterion measures.

Metacognitive judgments can be tested with regard to their accuracy at predicting memory performance. Research on metacognitive judgments is of interest because it informs us of when the monitoring of memory is accurate and of when the output from monitoring serves as input to control processes (e.g. rehearsal) that affect subsequent memory.

INTROSPECTION

Introspective judgments were investigated in the early years of psychology by researchers such as Wundt and Titchner. Their style of investigation involved observations and reports about tiny 'slices' of consciousness, with extended reports about a single introspective slice.

In the early twentieth century, introspection was attacked on two fronts. Firstly, Freud's theory of the unconscious postulated that not all mental activity was available to introspection, and that unconscious activity affected behavior. Secondly, radical behaviorists such as Watson and Skinner considered introspection to be irrelevant to the understanding of behavior, arguing that there were no reliably valid introspections. Because of these (and other) problems, the study of introspection fell out of favor, and (except in the field of perception) had little influence in psychology until the 1960s.

With the advent of cognitive psychology in the 1960s, introspection was revived. However, instead of assuming that introspections were accurate, cognitive psychologists compared them to relevant behavior. Such comparisons revealed situations in which metacognitive judgments have above-chance accuracy. For instance, investigators became interested in situations in which metacognitive judgments were very accurate (e.g. Nelson and Dunlosky, 1991), as compared to other situations in which they were mostly inaccurate, and an attempt was made to treat those findings as clues about the underlying mechanisms of metacognition.

FEELINGS OF KNOWING

Hart (1965) was one of the first researchers to investigate the accuracy of introspections about human memory. The 'feeling of knowing' (FOK) is an experience in which one has a feeling that a currently unretrieved item is nevertheless in memory. Hart investigated whether FOKs are accurate at predicting subsequent memory performance. He used the recall–judgment–recognition paradigm in which subjects receive a recall test, often consisting of general knowledge questions such as 'What is the capital of Australia?' or 'What star is called the North Star?' For answers recalled incorrectly, or when no answer is

produced, subjects are asked to report their FOK by indicating the likelihood that they would recognize the unrecalled answer.

Hart's experiments showed that a positive FOK was associated with higher probability of recognizing the correct answer than was a negative FOK, indicating that FOK judgments are at least somewhat accurate. Hart showed that subjects should be encouraged to guess on the recall test, even when they do not think they know the answer. This is important because when subjects are unsure of an answer, they may be reluctant to guess. Imagine a subject who retrieves an answer for a particular question, but fails to give the answer because he or she fears that it is incorrect (i.e. has low confidence in it). That item is scored as an omission, and thus will be given an FOK rating and included on the recognition test. The subject will probably give the item a high FOK rating, because although no answer was reported, one did come to mind, indicating that the subject has at least some (perhaps correct) knowledge about the question. Subsequently, if the unreported answer was correct, it will appear on the recognition test, and the subject will almost certainly recognize it as the correct answer. This will exaggerate FOK accuracy, because accuracy depends on the ability of subjects to use FOK judgments to discriminate between items that will be correctly recognized and those that will not. The item in question will probably be recognized, adding to the number of items given high FOKs that were subsequently correctly recognized.

Procedures for Investigating FOK Judgments

General knowledge questions are not the only kind of questions that have been used to study FOKs. Noun–noun paired associates (e.g. 'OCEAN – TREE') have also been used to investigate FOK judgments. In this procedure, subjects study a list of items, and during the recall test are asked to recall the second word when prompted with the first. As with general knowledge questions, subjects are asked to make FOK judgments for items that are not correctly recalled, and then a recognition test occurs for those items.

The difference between general knowledge questions and paired-associate learning is relevant. People are able not only to accurately monitor items that have been stored in memory for a relatively long time, but under some circumstances (Nelson and Narens, 1990) can also monitor items that are recently acquired.

Basis of FOK Judgments

Some researchers have investigated the factors on which FOK judgments are based. For example, Nelson *et al*. (1982) investigated whether the degree of learning affects the magnitude of FOK. Subjects learned paired associates to a criterion of one, two, or four correct recalls, and received a recall test four weeks later. Items not recalled during the test were ranked by the subject according to the likelihood that they would be correctly recognized. The results showed that subjects' FOK ranks increased with degree of learning, indicating that this is one factor on which FOK judgments may be based.

Reder and Ritter (1992) investigated the basis of very rapid FOK judgments that occurred prior to extended attempts at recall. Subjects were asked to solve mathematics problems. Some of the previously solved problems were presented again, while other problems consisted of the components of previously solved problems but with at least one critical change. For example, the subject may have previously solved the problem '6×19'. Subsequently, the 6 and 19 might be presented again, but with a different operand (e.g. '$6 + 19$'). Upon seeing the problem, subjects were asked to make an FOK judgment, estimating whether they could recall the answer or whether they would have to compute it anew. The results showed that higher FOKs were associated with familiar components of a problem even when the operand was changed, indicating that FOK judgments may be based partially on familiarity with the cue rather than on the subject's retrieval of the answer.

It is important to discover the factors that affect FOK accuracy in order to determine whether FOK judgments are monitoring unrecalled answers directly or whether they are monitoring information available from external cues and recalled portions of answers that are diagnostic of subsequent memory performance.

JUDGMENTS OF LEARNING AND ALLOCATION OF STUDY

Students studying for an examination make judgments about whether various facts have been learned sufficiently to be recalled in the exam or whether further study is required. This phenomenon is known as 'judgment of learning' (JOL). Judgment of learning is a kind of metacognitive monitoring process. The students also make decisions about which items to continue studying. This is known as 'allocation of study' and is a kind of metacognitive control process.

Paired Associates and JOL

Participants in a typical JOL experiment learn a list of items. The experimenter is able to control the duration of study, number of repetitions, order of presentation, and other factors that may affect performance. Paired associates are particularly well suited to the study of JOLs because they provide stimuli for a cued-recall test, which is useful for controlling effects caused by the order of recall.

Only the stimulus item of the pair should be present at the time of the judgment. Presence of the partial or entire response word at the time of the judgment has been shown to reduce the accuracy of the JOL in predicting recall (Dunlosky and Nelson, 1992).

Procedures for Investigating JOLs

After studying a given item, subjects may be prompted to make a JOL by giving a percentage confidence judgment that in about ten minutes they will be able to recall the second word of the pair when prompted with the first. Subjects make this judgment, known as an 'individual-item' JOL, for each pair.

An 'aggregate' JOL may also be made for the entire list. Here, subjects are asked to estimate how many of the items they will be able to recall in the test.

Kinds of Accuracy

Item-by-item JOLs can be used to investigate 'relative accuracy', which is the ability of people to distinguish items that will be correctly recalled at test from those that will not. For example, imagine that a person has studied two pairs, 'OCEAN – TREE' and 'DAFFODIL – BLOOD', and then made JOLs for both pairs, assigning the first pair a JOL of 80% and the second pair a JOL of 20%. If at test the person recalls 'TREE' when prompted with 'OCEAN' and fails to recall 'BLOOD' when prompted with 'DAFFODIL', the person can be said to have been accurate insofar as the item that received the greater JOL was also the item that had the better outcome during recall.

Another type of accuracy is 'absolute accuracy', which can be measured both for individual item JOLs and for aggregate JOLs. Absolute accuracy refers to the extent to which the cardinal value of the JOL corresponds to the percentage of correct recall. For example, if the person has studied and made item-by-item JOLs, and then, at test, recalls none of the items that had received a JOL of 0%, 20% of the items that had received a JOL of 20%, and 40% of the items that had received a JOL of 40%, then this person can be said to have perfect absolute accuracy. Likewise, for aggregate JOLs, absolute accuracy is the degree to which the aggregate JOL matches the percentage of recall.

Production of Accurate JOLs

The student studying for an examination will be interested in any strategy that will make JOLs more accurate, in order to know which items need further study and which are already learned well enough to be recalled later. Although individual-item JOLs made immediately after study are generally above-chance at predicting subsequent retention, they are far from perfectly accurate. JOLs have been shown to be very accurate when they are made at least 30 seconds after study (Nelson and Dunlosky, 1991). This is known as the 'delayed-JOL effect'. Although 30 seconds of filled activity is sufficient to produce a substantial increase in JOL accuracy, judgments made after a longer delay (e.g. five minutes) may be even more accurate (Kelemen and Weaver, 1997).

Monitoring and Control Processes

It is important to understand the way in which information acquired during metacognitive monitoring processes is used for metacognitive control. For instance, some researchers have investigated the interplay between JOLs and the allocation of subsequent study. In an experiment by Nelson *et al*. (1994), subjects studied, and made JOLs for, Swahili–English equivalents (e.g. 'ARDHI – SOIL'). Each subject then studied again either the items receiving the highest JOLs (from that subject) or those receiving the lowest JOLs (from that subject). Further study improved multi-trial learning more when it was devoted to the items that had received the lowest JOLs (but for boundary conditions, see Metcalfe and Son, 2000).

RETROSPECTIVE CONFIDENCE JUDGMENTS

Students leaving an examination may think about the questions, judging which of them were answered correctly. Such judgments are called 'retrospective confidence judgments' (RCJs). They may relate to individual items or to the aggregate (for example, an estimate of the percentage of answers that were correct).

Procedures for Investigating RCJs

In the laboratory, the procedures for investigating RCJs are similar to those for investigating other metacognitive judgments. Subjects are shown the cue for the judgment, which consists of a question (in the case of general knowledge questions) or the first word of a pair (in the case of paired associates). Sometimes the subject's answer is displayed along with the cue. Treadwell and Nelson (1996) showed that the accuracy of aggregate RCJs is not affected by the amount of information provided in the prompt for the judgment (cue alone, cue with subject's answer, or cue with answer and the list of choices). This is an important difference from JOLs, whose accuracy is affected by the content of the cue (as discussed above). Individual-item or aggregate judgments are elicited as described previously.

Accuracy of RCJs

Koriat *et al*. (1980) asked subjects to make RCJs for general knowledge questions. They found that when subjects were asked to give reasons for why their answer may be incorrect, the subjects gave more accurate RCJs than when they were asked to give reasons for why their answer was correct or when they were not asked to give any reasons. This finding suggests that subjects may search automatically for reasons for why their answers are correct – a phenomenon known as 'confirmation bias' – whereas searching for reasons why the answer may be wrong is not automatic, and must be done deliberately in order to increase the accuracy of RCJs.

FEELING OF WARMTH IN PROBLEM SOLVING

In an investigation of the feeling-of-warmth phenomenon, Metcalfe and Wiebe (1987) proposed two broad categories of problems, namely incremental problems and insight problems. Incremental problems are solved by degrees, with each step taking the person a little closer to the solution. Metcalfe and Wiebe predicted that people will make incremental feeling-of-warmth judgments for these types of problems, with ratings increasing as steps in the problem are completed. By contrast, insight problems are typically solved suddenly. Feeling-of-warmth judgments for insight problems were predicted to be fairly low and constant until the problem was solved, at which point they would increase suddenly. Metcalfe and Wiebe had subjects solve either incremental or insight problems, making feeling-of-warmth judgments every 15 seconds. The results confirmed the predicted patterns. These results suggest that the feeling of warmth is accurate only for incremental problems, and not for insight problems. With insight problems, a low feeling of warmth does not necessarily indicate that the problem is difficult or even that the person is far from the solution.

SUMMARY

Metacognitive judgments reflect the monitoring of one's own memory when they occur as predictions about subsequent performance on studied items (as in JOLs), as predictions about subsequent retrieval of currently unretrieved items (as in FOKs), as predictions of the accuracy of answers given on a test (as in RCJs), and as predictions of the imminence of solving problems (as in feeling-of-warmth judgments). In some circumstances, as in the case of delayed JOLs, metacognitive judgments are highly accurate; in other circumstances, as in the cases of immediate JOLs and feelings of warmth about insight problems, they are less accurate. It is important to know when metacognitive judgments are accurate, so that we may use them to control our cognitive processing effectively, and to know when they are inaccurate, so that we may discover ways to improve them.

Metaphor Processing, Psychology of

Introductory article

Dedre Gentner, Northwestern University, Evanston, Illinois, USA
Brian Bowdle, Northwestern University, Evanston, Illinois, USA

CONTENTS

A metaphor is a statement that characterizes one thing in terms of another thing, juxtaposing concepts from separate domains of experience. Metaphor can be used to describe abstract or unfamiliar topics, and to express ideas difficult to convey with literal language.

INTRODUCTION

A metaphor is a statement characterizing one thing in terms of another, where the two are normally considered to be unlike: for example, 'Time is a river'. Metaphors involve the juxtaposition of concepts from separate domains of experience; they ask us to think of something in terms of something else that is radically different. Aristotle regarded metaphor as the *master trope* – the figure of speech most associated with poetic genius. Such figurative juxtapositions of concepts can be expressed in a variety of ways.

Metaphors are closely related to similes, which have an explicit comparison term: for example, 'Time is like a river'. In a standard metaphor or simile, the first term ('time') is called the *topic* and the second term ('river') is called the *vehicle*. The interpretation of the metaphor is called the *ground*. In a good metaphor, the interpretation reveals something interesting about the topic, and sometimes about the vehicle as well.

Metaphors serve a number of cognitive and communicative functions. For instance, they can provide a compact and memorable way of expressing ideas that would be difficult to convey with literal language. Metaphors are often used to describe abstract or unfamiliar topics. For example, time (a relatively abstract dimension) is often described using metaphors drawn from space, as in 'The holidays lie before us' or 'Summer is coming fast'. Metaphors are common in literary and poetic contexts. They are also associated with new discoveries in scientific domains, as in the water wave metaphor for light. Metaphors are also common in everyday discourse. Systems of metaphors pervade our language and are often used to discuss abstract ideas. For example, people speak of 'life as a journey' with its 'pitfalls' and 'rough places' and occasional moments of 'coasting'. Cognitive linguists like Lakoff, Turner, and Fauconnier have analyzed systems of metaphors such as 'marriage as a journey' and 'politics as war'. There is evidence that some conceptual metaphoric systems, such as the space–time metaphors noted above, are not just ways of talking, but are also used in thinking.

METAPHOR AND LITERAL SIMILARITY

Literal similarity comparisons differ from metaphors in that, in literal similarity, many or most properties match, whereas in metaphor only a few properties match. As Ortony noted, the matching properties in a metaphor are often far more salient in the vehicle than in the topic. The metaphor acts to highlight otherwise unnoticed properties of the topic. Gentner and her colleagues found that many of these highlighted properties are relational: for example, 'Sermons are sleeping pills' conveys that they both put people to sleep. Because properties of the vehicle are used to illuminate the topic, metaphors are strongly directional. This directionality is a key diagnostic of literal versus metaphorical comparison. Whereas literal comparisons can typically be reversed – for example, 'A sweater is like a jacket/A jacket is like a sweater', a metaphorical comparison cannot – for example, 'Some jobs are jails/Some jails are jobs'.

THEORIES OF METAPHOR COMPREHENSION

A central question in research on metaphor is how metaphors are understood. In the past, metaphor was viewed as a peripheral aspect of communication, secondary in status to literal language. Early models of metaphor comprehension treated metaphors as deviations from proper literal language – as literally false expressions that violate the usual norms of communication. Current models view metaphor more positively, as a normal part of language. However, theories differ in exactly how metaphor is processed.

One long-standing approach is to view metaphor comprehension as property-matching. In this view, metaphors are understood by means of finding common properties, and the interpretation of a metaphor is the set of properties shared by the two terms. For example, 'The road was a silver ribbon' conveys the common property of a long thin silver line. This idea that metaphor comprehension involves a search for commonalities is intuitively appealing and widely accepted. However, it is not the whole story. In general, metaphors also convey new information that can be imported from the vehicle to the topic. For example, the metaphor 'That senator is a puppet' can be used to convey that the senator is being manipulated by someone else. Thus, metaphors do more than highlight existing commonalities – they create new insights about the topic.

Metaphors thus involve both highlighting common information and projecting new information from vehicle to topic. There are two current theories that attempt to explain both these aspects of metaphor: one likens metaphor to analogy, and the other likens metaphor to category inclusion. Taking the analogy view, Gentner and colleagues propose that metaphors are processed by means of the same structure-mapping processes that are used to understand analogies. Analogies are often used to explain or predict the behavior of an unfamiliar complex or abstract system by comparing it to another, better understood system: for example, 'Electricity is like water flow' or 'Poverty is a disease'. Further, the information conveyed by an analogy is typically relational information, rather than simple object properties. For example, the electricity/water flow comparison does not mean that electricity is wet or blue like water, but rather that it obeys the same relational principles: it flows from a high place (high voltage) to a low place (low voltage), it is impeded by obstacles (resistors), and so on.

On this view, metaphors are like analogies. They are comparisons between two situations that highlight common information and invite inferences from the base (the vehicle) to the target (the topic). For example, to understand a metaphor like 'A suburb is a parasite' the hearer first compares the topic and vehicle (base) representations, arriving at a common relational system: for example, 'A suburb uses the resources of a city just as a parasite uses the resources of an organism'. Once this structural match is established, any additional properties connected to the common relational system are projected as possible influences – for instance, the knowledge that parasites can sap the strength of an organism might be transferred to the topic concept, resulting in the inference 'Suburbs can sap the strength of a city'. By mapping the set of relations in the vehicle to the topic, one gains new insight into the topic.

Another prominent approach views metaphors as category statements. In the Attributive Category theory of Glucksberg and his colleagues, metaphors are understood as class inclusion statements. The idea is that in a metaphor one asserts that the topic is a member of the category of which the vehicle is a prototypical member: for example, the metaphor 'A suburb is a parasite' asserts that suburbs can be classified as parasites. Of course, suburbs do not fit the literal meaning of parasite – 'an organism that lives off another organism'. A metaphorical meaning such as 'something that lives off the resources of another entity without recompense' must be invoked or created from the vehicle. By assigning the topic 'suburb' to this metaphorical category, the properties of the metaphorical category derived from the vehicle can be attributed to the topic. On this account, metaphors are processed differently from literal statements. An open question for category theories is what signals the listener to create a metaphorical category instead of using the literal meaning of the vehicle.

PSYCHOLOGICAL EXPERIMENTS ON METAPHOR

Much early metaphor research was devoted to testing the claim that metaphors are deviant forms of language that require extra processing to be understood. According to the deviance view, hearers first try to derive a literal interpretation of

the expression. They then assess whether that interpretation is plausible, given the context. Only if the literal interpretation is anomalous or false does the listener start over again and derive a metaphoric interpretation. One implication of this approach to metaphor comprehension is that, because literal interpretation precedes metaphoric interpretation, metaphors should take longer to process than literal statements. A second implication of deviance models is that, because literal interpretations are taken to be obligatory, metaphoric interpretations should be sought only when literal interpretations are defective. Neither of these predictions has been reliably borne out in empirical studies. Most researchers now believe that the processes involved in comprehending metaphoric language are much the same as those used for literal language.

An influential piece of early research by Glucksberg and his colleagues dealt a conclusive blow to the two-stage deviance view. Their studies provided strong evidence against the view that people first attempt a literal interpretation and resort to metaphorical interpretation only if the literal interpretation is anomalous. Participants were simply asked to make *true or false* judgments. The materials included true category statements (e.g. 'Some birds are robins'), false category statements (e.g. 'Some birds are apples'), and metaphorical statements (e.g. 'Some jobs are jails'). Note that the answer is 'true' only for the first class; the other two are 'false'. The key question concerned how people would process the metaphors. According to deviance theory, people should have been fast to reject metaphors; they simply had to press 'false' as soon as they realized that the literal meaning was false. However, the results showed the reverse. Participants took much longer to reject metaphors than ordinary false statements, suggesting that the metaphorical meaning was noticed early and interfered with participants' ability to classify it as false. This finding dealt a serious blow to the dual-stage theory, for it showed that processing of metaphorical meanings begins *before* the literal judgment has occurred.

More recently, the metaphor interference effect has been used to trace the mechanisms by which metaphor is comprehended. Wolff and Gentner showed that the metaphor interference effect is equally strong for reversed metaphors (e.g. 'Some jails are jobs') as for forward metaphors (e.g. 'Some jobs are jails'). This suggests that metaphor processing begins with a symmetric alignment, as in the structure-mapping model, rather than by a directional projection from the vehicle to the topic.

'DEAD' AND LIVING METAPHORS

Recent evidence suggests an evolution in metaphor processing. Metaphors with novel vehicles are processed as comparisons, whereas conventional metaphors are processed as categorizations. This occurs because initially novel vehicles become conventionalized over time. If a given metaphoric base is used repeatedly in the same way, the abstraction it conveys becomes more and more accessible. Eventually the metaphoric meaning can be stored as a secondary word meaning. For example, 'goldmine' once referred solely to a shaft in the ground from which gold is excavated. But it has taken on a secondary metaphoric meaning – now listed in most dictionaries – as 'anything that is a source of something valuable' (as in 'A garage sale is a goldmine'). At this point the metaphor has a dual representation.

If this process of conventionalization continues, the metaphoric meaning can become quite stable and fixed. For example, the assertion 'My computer is a dog' conveys that the computer is no good, even if both speaker and hearer believe that dogs are loyal, intelligent, and reliable, because 'dog' has a stock metaphoric meaning. At this point the metaphor has become a stock metaphor and lost its early creative potential. Such metaphors are sometimes referred to as 'dead' metaphors.

If the conventionalization process continues still further, the metaphor may even lose its connection to the original literal meaning. For example, the term 'deadline' in the American Civil War meant a line around a prison camp; any prisoner crossing the line was shot. It was then metaphorically extended to a game of marbles, and then further extended from space to time: in newspaper parlance, it meant a time limit after which an article was unacceptable. Eventually, the literal meaning disappeared. The word 'deadline' now retains only its originally metaphorical sense of a time limit. In this way, metaphors can create new meanings.

Model Fitting

Introductory article

In J Myung, Ohio State University, Columbus, Ohio, USA
Mark A Pitt, Ohio State University, Columbus, Ohio, USA

CONTENTS

In model fitting, the computational model under investigation is evaluated for its adequacy in describing the underlying regularities of observed data.

INTRODUCTION

A measure of advancement in cognitive science, or in any other scientific discipline, is the discovery of general laws and principles that govern the cognitive phenomenon of interest, whether it be language comprehension or problem-solving. As these underlying principles are not directly observable, they are formulated in terms of hypotheses. Computational models in cognitive science are formal expressions of such hypotheses. At its most basic level, a computational model consists of a set of assumptions about the structure and functioning of the cognitive processes under investigation. The goal of modeling is to infer the form of this underlying process by assessing how well the model mimics human behavior. This article provides an overview of some of the key challenges in this endeavor.

PARAMETER ESTIMATION

Once a model is specified with its parameters and data have been collected, one can assess the model's goodness of fit (GOF) to the data. Goodness of fit refers to how well the model fits a particular set of observed data, which is often interpreted as a measure of the model's suitability: the better the fit, the more closely the underlying cognitive process is assumed to be approximated. GOF is measured by finding parameter values that provide the 'best' fit to the data in some defined sense. This process is called 'parameter estimation'.

There are two generally accepted methods of parameter estimation: least squares estimation (LSE) and maximum likelihood estimation (MLE). To describe these methods, let $X = \{X_1, X_2,\ldots,X_n\}$ denote a data sample of n observations and $Y_i(w)$ denote a model prediction for each X_i $(i = 1,\ldots,n)$ where $w = (w_1,\ldots,w_k)$ is a parameter vector. In LSE, we seek the parameter values that provide the most accurate prediction of the data, measured in terms of how closely the model fits the data. Formally, the sum of squared errors (SSE) between observations and predictions is minimized:

$$SSE(w) = \sum_{i=1}^{n} (X_i - Y_i(w))^2 \quad (1)$$

In MLE, on the other hand, we seek the parameter values that are most likely to have produced the data. This is obtained by maximizing the likelihood of the observed data sample. For computational ease, the log-likelihood is instead maximized in practice and is given as follows, assuming independent observations:

$$\ln L(w) = \sum_{i=1}^{n} \ln f(X_i|w) \quad (2)$$

In the equation, $L(w)$ is the likelihood function; $f(X_i \mid w)$ is the probability density function for observation X_i; ln denotes the natural logarithm of base e. If X is normally distributed, minimization of LSE is equivalent to maximization of MLE and, therefore, the same parameter values are obtained under either method. Otherwise, the two solutions tend to differ.

Finding the parameters that maximize the log-likelihood or minimize the sum of squared errors often requires use of a nonlinear optimization routine that attempts to find optimal parameters by trial and error. Optimization proceeds over repeated fittings that converge on the best set of parameter values. First, an initial set of parameters

is chosen either at random or by guessing, and the log-likelihood or the sum of squared errors for the chosen parameters is evaluated. On the next iteration, by taking into account the results from the previous iteration, a new set of parameters is obtained by introducing small changes to the initial parameters so that the new parameters are likely to lead to improved performance. Details of how this updating scheme is done define different optimization algorithms, such as the Gauss–Newton method, the Levenberg–Marquardt method, and the simplex method. The refitting process continues until improvements are judged to be negligible on an appropriately predefined criterion.

MODEL EVALUATION

On the face of it, GOF might seem like a good measure of a model's ability to capture the underlying cognitive process. This would be the case if the data reflected only the underlying process. Unfortunately, behavioral data contain random errors ('noise') because mental processes are stochastic in nature. An implication of noise-corrupted data is that a model's best fit to a data sample (the goodness of fit) can be decomposed into two portions, one that represents the model's ability to capture the underlying regularity, and one that arises from the model fitting random noise:

$$\begin{aligned} \textit{Goodness of Fit} = &\textit{Fit (underlying regularity)} \\ &+ \textit{Fit (random noise)} \end{aligned} \quad (3)$$

We are interested in only the first term on the right-hand side of the equation, but the second term is impossible to remove when fitting a single data set. This is because properties of a model can enable it to provide a good fit to the data for reasons that have nothing to do with the model's ability to approximate the underlying regularity but everything to do with fitting random noise. Such properties together refer to a model's 'complexity', and consist of the number of parameters and its functional form. A complex model is one with many parameters that are combined in a highly nonlinear fashion in the model equation. These properties enable it to absorb random error very easily. Consequently, a complex model often fits data better than a model with fewer parameters and a simpler functional form.

The solution to this problem of over-fitting a single data set is to change the model selection measure so that fit to random error is penalized rather than rewarded. The influence of random error can be minimized by measuring a model's fit to multiple data sets generated by the same cognitive process. To fit all data sets well (i.e. generalize), the model must be able to capture only the underlying regularity in the data and not the random noise. Generalizability, then, should be the measure of a model's suitability.

To illustrate, suppose that model M_1 provides 99% of the variance accounted for. In this case, for example, only 50% of the variance represents the model's true ability to capture the underlying process and the rest (49%) may be due to fitting random noise. In model M_2, which accounts for 80% of the variance overall, 70% is traced to the regularity whereas only 10% is traced to random error. M_2 should be selected over M_1 as the former generalizes better than the latter (70% versus 50%). On the other hand, if we were to choose between the two models based on overall goodness of fit, M_1 would be chosen instead, which is undesirable. This is because the improved fit of M_1 over M_2 can be traced to the former accounting for more of the nonsystematic variation in the data than the latter (49% versus 10%), suggesting that M_1 is more complex than M_2. This point is illustrated in Figure 1. Dots represent data points and curves

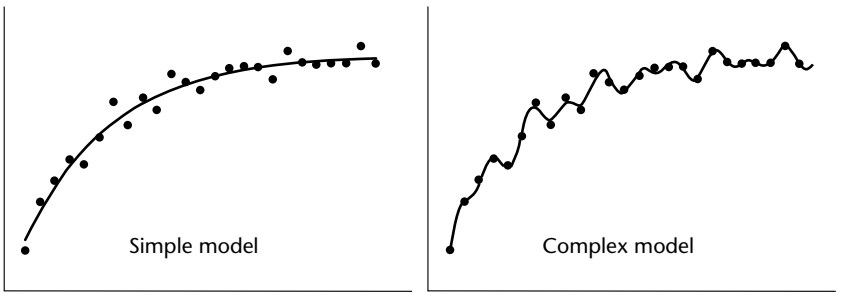

Figure 1. The effect of model complexity on goodness of fit. Two models (lines) were fitted to the same data set (dots). A simple model (left panel) provided a good fit to noisy data, capturing the general trend of the data pattern, whereas a complex model (right panel) over-fitted the same data.

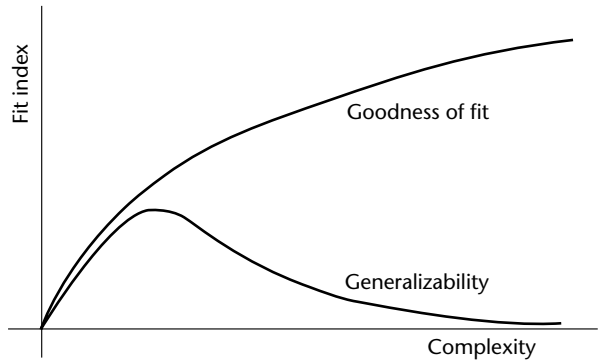

Figure 2. Illustration of the relationship between goodness of fit and generalizability as a function of model complexity.

represent best fits by two hypothetical models. The simple model captures the general trend in the data whereas the complex model enhances goodness of fit by fitting not only the general trend but also noisy patterns in the data.

To summarize, we should assess the adequacy of a model by its generalizability, not goodness of fit, by taking into account the complexity of the model. The intricate relationship among goodness of fit, generalizability, and model complexity is illustrated in Figure 2. Goodness of fit increases positively with complexity. Generalizability also increases with complexity but only up to the point where the model is complex enough to capture the regularities in the data. Beyond this point, generalizability of the model begins to drop as the additional complexity will only enable it to capture random error, but no longer the underlying regularity. An implication is that selecting among models based solely on goodness of fit will result in an overly complex model that generalizes poorly.

MODEL SELECTION METHODS: AIC AND BIC

The central tenet of model selection is achieving good generalizability by finding the best compromise between goodness of fit and complexity by trading off one for the other, thereby formalizing the principle of Occam's razor. As generalizability is not directly observable, it must be inferred from data. The overarching goal of many model selection methods has been the estimation of a model's generalizability. Here we introduce the two most commonly used selection criteria: the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC). In both, goodness of fit is measured by the log-likelihood, $\ln L(w_0)$, where w_0 represents the parameter vector that maximizes $L(w)$. However, they differ in how model complexity is measured: in AIC it is the number of parameters (k), whereas in BIC the sample size (n) is also taken into account. In short, the two criteria are defined as follows:

$$AIC = -2 \ln L(w_0) + 2k \tag{4}$$

$$BIC = -2 \ln L(w_0) + k \ln n \tag{5}$$

For normally distributed data, the first term can be rewritten in terms of the sum of squared errors as $\{n \cdot \ln (SSE\ (w_0)) + \text{constant}\}$. In each criterion, the first (lack of fit) term and the second (complexity) term together represent a measure of lack of generalizability in the sense that the lower the criterion value, the higher the generalizability. Accordingly, the model that minimizes a given criterion should be chosen.

AIC and BIC represent important progress in tackling the model selection problem. In these criteria, however, complexity is defined primarily as the number of parameters in a model. Another dimension of complexity that can also significantly affect model fit is its functional form, which refers to the way in which the parameters are combined in the model equation. For instance, two models, $y = ax + b$ and $y = ax^b$, may not be equally complex though both have the same number of parameters. The minimum description length method described below, which represents an improvement over AIC and BIC, considers functional form as well as the number of parameters.

MINIMUM DESCRIPTION LENGTH

Minimum description length (MDL) originated from coding theory in computer science and regards both model and data as codes. The idea is that any data set can be appropriately encoded with the help of a model, and further, that regularities or patterns in the data imply redundancy. The more we compress the data by extracting this redundancy, the more we uncover the regularities underlying the data. Thus, code length is directly related to the model's generalizability. From this standpoint, the best model is the one that provides the shortest description of the data by maximally compressing it. Formally, the description length of the data is given by the sum of the description length in bits of the data when encoded with the help of the model, $L(D \mid M)$, and the description length in bits of the model itself, $L(M)$: thus $MDL = L(D \mid M) + L(M)$. This definition is broad enough

to be applied for any well-defined models, even qualitative models. For a quantitative model, MDL takes the following form:

$$MDL = -\ln L(w_0) + \frac{k}{2}\ln\left(\frac{n}{2\pi}\right) + \ln\int dw\sqrt{\det(I(w))} \quad (6)$$

where $I(w)$ is the Fisher information matrix of sample size 1 in statistics and $\det(I)$ is the determinant of the matrix. The first term of the MDL can be interpreted as a measure of lack of fit, and the second and third terms together are a measure of model complexity. Model evaluation in MDL is therefore carried out by trading off lack of fit for complexity.

The second term, $(k/2)\ln(n/2\pi)$, represents the effects of complexity due to the number of parameters k. The third, integral, term captures the effects of complexity due to functional form. To see this, note that the Fisher information matrix $I(w)$ is determined by the log-likelihood function $\{\ln L(w)\}$ which depends upon the form of the model equation; for example, whether $y = ax + b$ or $y = ax^b$. It is also worth noting that the second term increases logarithmically with sample size n whereas the third term is independent of sample size. This means that as sample size increases, the contribution of the effects due to functional form relative to those due to the number of parameters will gradually diminish. Thus, functional form effects will become negligible when sample size is sufficiently large, in which case the MDL is approximately equal to one-half of the BIC.

CONCLUSION

Parameter estimation is a fairly straightforward undertaking, making model fitting easy and accessible to members of the scientific community. The meaning of a good fit is far less straightforward, and can be misleading. A model can fit a data sample well for reasons other than providing a good description of the underlying process, which is why generalizability must instead be used when comparing competing computational models of cognition. MDL is one of the most promising tools to date that measures generalizability.

Motion Perception, Psychology of

Introductory article

George W Mather, University of Sussex, Brighton, UK

CONTENTS

Motion perception is important for figure–ground segregation, three-dimensional vision, and visual guidance of action. Specialized brain cells detect image motion. Adaptation in these cells leads to illusory motion, such as the motion after-effect.

INTRODUCTION

An essential attribute that distinguishes all animals from plants is their capacity for voluntary movement. Animals move to find mates, shelter, and food, and to avoid being eaten. But the ability to move brings with it the need to sense movement, whether to navigate through the world, or to detect the movement of other mobile animals such as approaching predators. For sighted animals, this means sensing movement in the visual image that is projected into the eye. The image is formed on a sheet of light-sensitive cells that line the inside of the eye – the retina. Specialized neural processes are required to detect the presence of movement in the retinal image.

USES OF MOTION INFORMATION

Surfaces, shapes, and objects in the scene under view create spatial patterns of light and dark in the retinal image. The image is very rarely still, as in a photograph. Instead, it is in a state of continuous change, due to the movement of objects in the scene (e.g. an approaching predator) or to shifts in the position of the observer's eyes, head, or body (e.g. while running away from the predator). Perception of movement in the image is crucial, because it can be used in a number of ways.

Figure–Ground Segregation

Shapes and objects that are invisible while static (e.g. camouflaged animals) are revealed as soon as they move relative to the background. Many animals have evolved special ways of moving, in an attempt to defeat figure–ground segregation. For example, prey animals such as lizards and rodents move in short, rapid bursts in between periods of complete stillness, in order to minimize the chances of detection by predators. Predators such as cats tend to move slowly and smoothly to avoid being seen by their prey.

Extraction of Three-dimensional Structure

When any solid object moves, the images of its various parts that are cast on the retina move relative to each other. Relative motion of this kind can be used to extract the three-dimensional structure of the object. For example, in a sideways view of a rotating globe, surface markings near the equator move across the field of view more rapidly than markings near the poles. In addition, markings near the equator follow almost a linear path, whereas those near the poles follow more elliptical paths. This highly structured variation in speed and direction is sufficient for the perception of the shape's three-dimensional structure.

Visual Guidance of Action

As an observer moves about, image detail 'flows' across the image on his or her retinas, to create a characteristic motion pattern known as 'optic flow'. A great deal of information can be extracted from optic flow, including the speed and direction of self-motion. For example, as you run through a wood, looking ahead, image details arising from rocks on the ground, and from trees ahead, appear near the center of your vision and then flow through your field of view as they disappear behind you, creating an expanding flow field. This pattern of motion flow allows you to navigate

a path through the wood without colliding with trees or misplacing your feet. The powerful movement effects experienced in 'Imax' movie theaters are due to optic flow.

MOTION CUES

The movement of objects under view, or of the observer through the world, cause the spatial pattern of light and dark in the image to fluctuate over time. For example, if you are looking across a relatively dark room, and a friend wearing light clothing moves across your line of sight, then the amount of light falling in the small region of the image at the center of your vision will suddenly increase just as the friend intersects your line of sight, and then decrease again once he has passed through. If the room is empty, and you switch on a light, then again the amount of light falling on the image at the center of your vision will increase. How can the brain distinguish between changes in image intensity due to movement and changes due to other causes, such as changing illumination? In order to solve this problem, the brain must combine information from several places in the image, rather than gathering information from just one place at a time. A change in illumination causes a change in intensity *everywhere* in the image simultaneously, whereas movement causes changes in only a very small part of the image at a time, as Figure 1 demonstrates.

The left-hand and middle panels of Figure 1 show two views of a scene containing a light human figure moving across a dark background. It is difficult to tell what movement has occurred between the two views by inspecting them individually. The right-hand panel shows the changes in light intensity that took place between the two views. Bright areas correspond to places where intensity increased over time from the first view to the second view, and dark areas correspond to places where intensity decreased from the first view to the second view. Gray areas were unchanged between the two views. Notice that the 'difference image' on the right effectively isolates the parts of the scene that contained movement. Stationary features disappear. This would allow the observer to detect the presence of movement, perhaps for figure–ground segregation.

Is it possible to infer the *direction* in which the figure was moving? Some parts of the scene increased in intensity over time (light in the right-hand panel), and other parts of the scene decreased in intensity over time (dark in the right-hand panel). Increases in intensity occurred where a bright edge belonging to the figure moved rightward into a region of the image that was previously dark (e.g. the shin of the leading leg). Decreases occurred where the edge of the figure moved out of a region of the image, returning that region to darkness (e.g. the calf of the leading leg). The brain can therefore infer the direction of a shape's movement by finding its edges, and then detecting whether the intensity of the image increases or decreases over time in the region of these edges.

Since the 1960s it has been known that the brain possesses specialized 'motion-detecting' neurons that respond specifically to movement. Each neuron responds only to movement in a specific direction over a small part of the image. Groups of these first-stage neurons are connected to second-stage neurons that integrate information over relatively large areas of the scene, in order to signal the movement of whole shapes and objects.

Figure 1. Cues for motion detection. The left and middle panels show two views of a human figure moving across the field of view, taken at slightly different times. The right panel shows the changes in light intensity that took place between the two views, created simply by subtracting the light intensities in the first image from the intensities in the second image. The 'difference image' effectively selects only the parts of the scene that moved in between the first view and the second view.

THE MOTION AFTER-EFFECT

The early Greeks were the first to discover a striking visual illusion now known as the motion after-effect (or MAE). The philosopher Aristotle noticed that if he stood in the middle of a river, and directed his gaze down at the fast-flowing water for a short time, when he shifted his gaze towards the riverbank the stationary scene appeared to flow backwards in the opposite direction to the river. This illusion has been rediscovered a number of times, most famously by Thomas Addams, a Scottish scientist. He visited the Falls of Foyers on the banks of Loch Ness, and noticed that if he fixed his gaze on the falling waters for a short time, and then looked at the rock face beside the falls, the rocks appeared to move upwards for a short time. For this reason the effect is also known as the waterfall illusion. It is powerful, robust, and easily demonstrated. A convenient way to experience the illusion today is to view the title credits of a TV program or movie. It is important to fix one's gaze steadily at the center of the screen rather than track the credits as they roll by. After about 30 seconds of adaptation, subsequently viewed scenes should appear to move in the opposite direction to the credits.

The MAE is thought to arise from adaptation in motion-detecting neurons in the brain, of the kind described in the previous section. While viewing an image containing contours moving in a particular direction, cells 'tuned' to respond to that direction will initially respond quite strongly. However, after prolonged exposure their ability to respond is reduced, and takes some time to recover back to normal levels.

Our perception of movement depends on a competition between cells tuned to different directions, rather like a tug-of-war, as shown in Figure 2. Normally, in the presence of a stationary image and without prior exposure to motion, the two opposing teams ('left' and 'right' in the top row of Figure 2) are well matched at a low level of activity, so we see no motion. While viewing a rightward-moving pattern the 'right' team is very active, and easily overcomes the 'left' team to win the competition, leading us to see rightward motion (middle panel). Afterwards, the 'right' team takes some time to recover, allowing the 'left' team to win even while not very active in the presence of a stationary pattern (bottom panel). As a result, illusory motion to the left is seen – the MAE. Once the adapted neurons recover, any bias in favor of one team disappears, so the illusion is no longer seen.

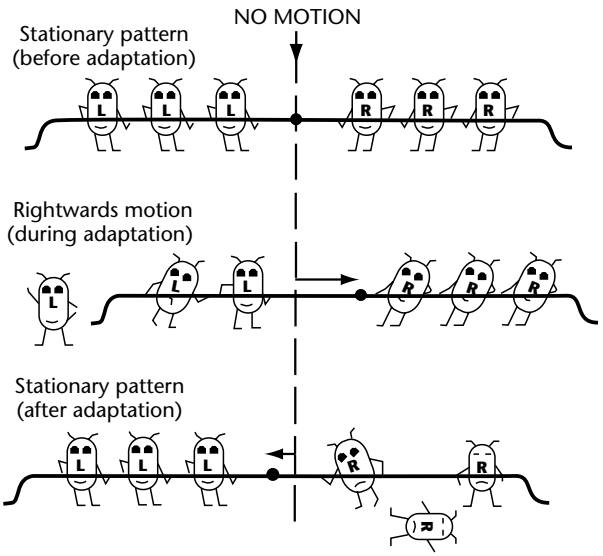

Figure 2. Explanation of the motion after-effect. Two teams of cells signal the direction of movement in the image. One team is active in the presence of leftward motion (L), and the other is active in the presence of rightward motion (R). The direction of perceived movement depends on the result of a tug-of-war competition between the teams. Previous adaptation suppresses the activity of one team, biasing the result of the competition.

Perceptual research on the properties of the MAE indicate that the illusion represents the combined effect of adaptation in at least two populations of cells in the brain, probably corresponding to the first-stage and second-stage motion-detecting neurons described above.

APPARENT MOTION

In natural images of real scenes, moving objects change position in the image in a smooth, continuous manner. If one could inspect the image over shorter and shorter time periods, the shift in position would become smaller and smaller, until at infinitesimal time intervals, the position shift would also be infinitesimal. For example, the left-hand panel of Figure 3 shows a disk drifting to the right over time. Space is plotted horizontally, and time is plotted vertically. The solid outlines represent the positions of the disk at times 1 and 16. The dashed outlines represent the positions of the disk at intermediate times. For obvious reasons, this kind of movement is called 'real movement'.

It is also possible to create the perception of movement in an image by changing the position

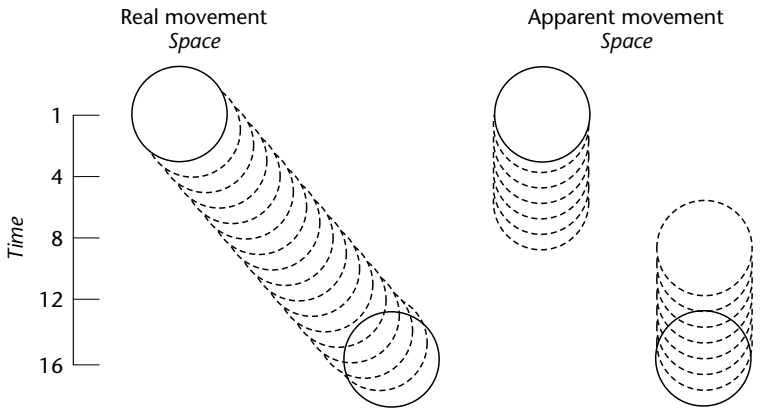

Figure 3. Real movement versus apparent movement. See the text for an explanation.

of an object suddenly over a relatively large distance. If one could inspect the image over sufficiently short time periods, there would be no shift in position. For example, the right-hand panel of Figure 3 shows a disk occupying just two discrete positions. As before, the solid outlines represent the positions of the disk at times 1 and 16. The disk shifts position only once, at time 8. So at all other times the disk remains stationary either at the first position or at the second (dashed outlines).

Observers do perceive movement in stimuli of this kind – it is the basis for the movement seen in TV and movies. TV images are displayed as a series of static images or frames presented very rapidly (50 frames per second in Europe, 60 frames per second in the USA). Any impression of movement seen in TV images is an illusion created by discrete changes in object position from one frame to the next in the display sequence. This kind of illusory perceived movement is called 'apparent movement' or 'phi movement', to distinguish it from the real movement seen in natural images.

Why is the apparent motion so effective and compelling? A common fallacy is that it results from the 'persistence of vision'. According to this explanation, each static image persists in our vision for a short time, so that successively presented static images blend together into one apparently continuous scene. However, it is known that visible persistence lasts only about one-tenth of a second, yet apparent motion can be seen between two stationary shapes even when the second shape appears half a second after the first shape has disappeared. Visible persistence may *contribute* to the perceived smoothness of apparent motion, but it cannot account for the perception of motion itself.

The effectiveness of apparent motion stimuli is almost certainly due to their ability to activate motion-detecting neurons in the brain. As described earlier, motion-detecting neurons rely on the systematic changes in image intensity created by a moving object. Apparent motion stimuli also create systematic changes in image intensity. Provided that the parameters of the apparent motion sequence are chosen carefully, it should excite motion-detecting neurons as effectively as real movement. As one would predict from this explanation, good apparent motion is indistinguishable from real movement. Movie and TV animations do seem very smooth and realistic, unless one sits in the very first row in front of a large movie screen. From this position the discontinuity of the movement, particularly in fast action sequences, can be seen easily.

However, responses in motion-detecting neurons are not the only explanation for apparent movement. It has also been argued that we can perceive motion independently of activity in neural detectors, as a result of perceptual inferences or of shifts in attention. According to the perceptual inference theory, apparent motion is the outcome of a perceptual inference to explain the otherwise mysteriously sudden appearance and disappearance of shapes in apparent motion displays. According to the attention-shift theory, apparent motion can also be perceived when mobile shapes or objects in the image capture and hold the attention of the viewer. As the objects change position in the image, one's focus of attention shifts to keep track of them. This shift in attention itself gives rise to the perception of apparent motion. Advocates of such high-level processes do not see them as inconsistent with the notion of lower-level neural motion detection, but rather as separate processes that co-exist with low-level detection. It therefore seems likely that the perception

of apparent movement is mediated both by low-level processes (motion-detecting neurons) and by high-level processes (inference and attention).

INDUCED MOTION

On a cloudy, moonlit night, as relatively large clouds move quickly across the face of the moon, it often seems as if the clouds are stationary but the moon is moving. This illusion is an example of 'induced motion': the appearance of motion in a stationary stimulus induced by the physical movement of another stimulus. Generally, induced motion is most effective when a large, slowly moving shape surrounds a smaller, stationary shape, such as the moon surrounded by clouds.

The simplest demonstration of induced motion consists of a small spot surrounded by a large frame, as shown in Figure 4. If the frame moves slowly sideways while the spot remains stationary (left-hand panel), observers tend to perceive the frame as stationary and the spot as moving (right-hand panel).

Induced motion highlights the problem of motion attribution. As mentioned earlier, movement in the visual image is detected by specialized motion-detecting neurons. Image motion can arise from two general sources, either movement of objects in the scene under view, or movement of the observer's body. It is obviously crucial to attribute motion to the correct source, but responses in motion-detecting neurons cannot distinguish between them.

The brain appears to use several strategies to solve the problem of motion attribution. These strategies are usually sufficient to arrive at the correct interpretation, but in certain situations the interpretation may be erroneous, leading to illusions such as induced motion.

One strategy is to make use of nonvisual information in order to determine whether the observer is moving through the scene. Movement of the eye, head, and body can be established using information from the muscles (or from commands to move the muscles), and from the balance (vestibular) sense. When movement in the image can be accounted for entirely by bodily movement, then no motion is perceived. For example, eye movements

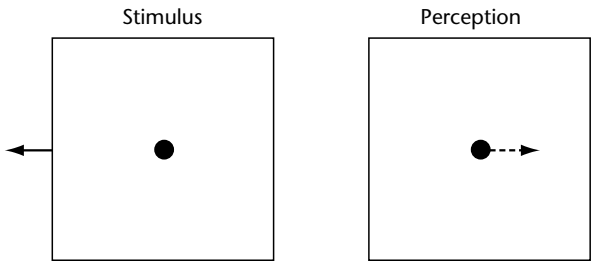

Figure 4. Induced motion. The physical stimulus consists of a small stationary spot surrounded by a slowly moving frame (left). Perceptually (right), the frame appears to be stationary while the spot appears to move.

create movement in the image. When the eyes turn to the left, the whole image translates to the right on the retina. This translation excites motion-detecting neurons in the brain, yet we do not perceive the world to move. The image motion that results from eye movement is correctly attributed to the eye movement, so no motion is perceived.

A second strategy, or heuristic, used in motion attribution relies on assumptions about the nature of the real world. In general, relatively large shapes and objects in a viewed scene tend to remain fixed in position, while small shapes and objects are likely to move. Large areas in a viewed scene may be filled by, for example, the wall of a building or the side of a hill. These shapes are extremely unlikely to move. Small areas, perhaps representing human or animal figures, or vehicles, are very likely to move. Consequently if there is relative movement between a small object and a large object, then the brain has a tendency to attribute the motion to the small object.

Motivation

Introductory article

Nira Liberman, Tel Aviv University, Tel Aviv, Israel

CONTENTS

The study of human motivation focuses on the objects of human pursuit, and how pursuit of these objects is structured and organized.

INTRODUCTION

The root of the word motivation is 'to move', and the study of human motivation is about what moves people. Two main questions have been addressed: what are the things that people typically consider worthy of pursuit; and what are the laws that describe the strength of motivation and the organization of goal pursuit? Motivation is a central research area both in basic psychological science and in applied disciplines that face a need to motivate people towards specific behaviors, such as the psychology of education, which is concerned with motivation towards acquiring knowledge and norms of behavior; the psychology of sales and marketing, which is concerned with motivation to purchase different products; and the psychology of human resources in organizations, which is concerned with work motivation.

DRIVES AND NEEDS

People are motivated to seek pleasure and to avoid pain. But what are the things that people find pleasurable and painful? The great variety of pleasurable and painful objects has been classified into a number of content categories, which correspond to different views of human nature.

Types of Need

Drives

Obviously, people, like other animals, seek to satisfy physical needs, s uch as the needs for food, water, sleep and sex. These motives, often called 'drives', are instigated periodically as a result of deprivation, and may be fulfilled by concrete entities (e.g. food, drinks). The need to relieve physical pain, although not instigated by deprivation, is also considered a drive. The study of drives, which has been conducted primarily with animals, dominated the early stages of motivational science.

It has been found, for example, that the intensity of a drive depends on the extent of deprivation, and that the intensity of the motivation to seek a drive-reducing stimulus (e.g. food) depends on the intensity of the drive (e.g. hunger), on the strength of prior learning (e.g. how strongly a given situation is associated with the possibility of obtaining food), and on the expected value of the outcome (e.g. how much food one expects to get). Drives have often been regarded as a general state of agitation, which motivates the organism to 'do something'. The drive-oriented study of motivation emphasizes the animal nature of humans.

The need for stimulation was added to the category of drives after studies on sensory deprivation dramatically demonstrated that both humans and animals seek sensual stimulation (e.g. sounds, sights, touch) even if it is not associated with any tangible reward (e.g. food). In these studies, participants are deprived of sensory input by being placed in an isolated quiet room wearing goggles that permit only homogeneous light. Very few people are able to stay in this state for longer than eight hours, even for a high payment. In one study, an audio recording of a stock market record was made available to participants. The intensity of the need for stimulation was revealed by the fact that participants requested to hear this quite uninteresting recording again and again.

Social needs

The need to be accepted within a social group, to form warm, continuous and rewarding relationships with friends and family, to love and to be loved are social needs. Subsumed within this general category are the motivations to make a favorable impression on others, to attract intimate

partners, to gain high social status, to avoid conflict with others, to distinguish one's own group from other groups, and sometimes to disparage other groups and their members. The study of social motivation suggests a view of people as social beings.

Mastery needs

The desire to control and predict oneself and one's environment, both social and physical, has been termed a need for 'mastery'. The motivations to uncover the truth, to enhance one's abilities and to manipulate the environment are subsumed under this general category. Mastery needs underlie scientific activity and activity that is directed towards technological advancement. Therefore, the study of mastery needs suggests an image of people as lay scientists.

Self-enhancement needs

People are motivated to see themselves and anything connected to them (e.g. the social groups they belong to, their possessions) in a favorable way. For example, people prefer positive feedback to negative feedback of equal informative value. The need to maintain a positive view is often at odds with the motive to have accurate knowledge, inasmuch as people often face unpleasant self-relevant information. When the self-enhancement motive prevails over the mastery motive, then people deny, avoid or seek to disqualify negative self-relevant information. For example, people tend to be more critical of the validity of ability tests on which they scored low than of tests on which they received a high score. The study of self-enhancement needs suggests an image of people as interested lawyers.

Approach and Avoidance Motivation

Within each of the needs specified above, approach motivations may be distinguished from avoidance motivations. Approach motivations are directed towards desirable outcomes (e.g. food, success), while avoidance motivations are directed away from undesirable outcomes (e.g. danger, pain). For example, a person may strive to succeed in an examination, or, alternatively, strive to avoid failure in an examination. Situations that involve advancement and improvement needs and maximal goals (i.e. a goal to achieve the best possible outcome) usually activate the approach system (e.g. looking for a luxurious car). On the other hand, safety and security needs and minimal goals (i.e. a goal to satisfy a minimal acceptable level) usually activate the avoidance system (e.g. seeking to move out of a dangerous neighborhood). Approach and avoidance create different types of positive and negative effect. Specifically, successful approach of a desirable outcome (e.g. finding a luxurious car) produces joy whereas successful avoidance of an undesirable outcome (e.g. moving out of danger) produces relaxation. A failure to approach produces disappointment, whereas a failure to avoid produces anxiety.

Individuals differ in their generalized tendency to approach or avoidance. Thus, the same situation may be conceived in terms of approach by some individuals (e.g. trying to get grade B or higher on an exam) and in terms of avoidance by others (e.g. trying to avoid getting grade C or lower). Because of the different types of emotions characteristic of approach and avoidance, these two personality types are associated with different types of pathologies. Depression, being the result of continuous failure of the approach system, would be characteristic of approach-oriented individuals. Anxiety, being the result of continuous failure in the avoidance system, would be characteristic of avoidance-oriented individuals.

Conscious and Unconscious Motivation

People are not always aware of, and are sometimes wrong about, the motivations that guide their behavior. The notion of unconscious motivation is of central importance in the psychoanalytic tradition, according to which people are guided by repressed sexual and aggressive motives. More modern notions of unconscious motivations are not restricted to these two motives: people's ability to introspect on their own psychological processes, including motivation, is limited and fallible, and any motivation can operate outside conscious awareness.

For example, studies on social influence often find effects of which the participants are unaware. In such studies, effects would be observed (e.g. participants would comply with a request to sign a petition more if it is presented by an attractive person than if it is presented by an unattractive person), which participants would not admit to nor be aware of (e.g. when asked to explain, either in private or in public, how they decided whether to sign the petition, participants would not mention the attractiveness of the person making the request). In this example, participants are unaware of the fact that some of their motivation in complying with the request is interpersonal (e.g. to win the

approval of, or make a favorable impression on, an attractive individual). Similarly, people tend to be unaware of (and ready to deny) the effects of self-enhancement needs on their behavior.

The existence of unconscious motivations implies that researchers of motivation cannot always rely on introspective self-reports, however confidential, but rather have to apply more indirect methods of study.

The Origin of Needs

There is little doubt that physiological, social, mastery and self-enhancement needs exist in humans. People spend a lot of money, time and energy to satisfy these needs. The origin of these needs is, however, controversial. A number of theoretical approaches have attempted to reduce the various needs to one or two basic motives.

Evolutionary theory postulates a single basic motive – spreading one's genes – and derives from it all other motives. According to evolutionary theory, people seek to attract opposite-sex partners in order to reproduce and thereby spread their genes. People seek to succeed (e.g. accumulate wealth) and to gain social approval in order to enhance their offspring's chances of survival. Even personal survival, in this view, is sought for the purpose of promoting reproduction and enhancing the chances that one's offspring would survive and further reproduce.

Freud's psychoanalytic approach reduced all human motives to sexual and aggressive drives. A somewhat related but more modern theoretical approach maintains that at the root of all human motives is the need to overcome the fear of death. This theory suggests that people strive to forget the fact of their inevitable physical demise and to extend their symbolic presence beyond it. In this view, scientific, artistic and religious activities are best understood as attempts to symbolically extend one's existence beyond physical death. It has been proposed also that one's culture or social group serve a similar function (i.e. provide symbolic existence beyond physical death), and therefore the motivation to be a valuable member of a valuable community are also explained as ways to overcome the terror of physical death.

The Relative Importance of Needs

The relative importance of the various needs has also been a subject of theoretical controversy. For example, some theorists contend that self-enhancement needs are subordinated to social needs, so that people strive to form positive views of themselves in order to be able to form more rewarding social relations. Other theorists hold the reverse view, namely, that social needs are subordinated to self-enhancement needs, so that people's ultimate goal in forming social relations is to feel good about themselves.

The relative strengths of different needs varies between individuals. For example, some individuals tend to assign more importance to social needs while other individuals tend to assign more importance to mastery needs. It was once assumed that women tend to have weaker mastery needs than men, but this assumption has been criticized on methodological grounds and is no longer believed to be true in general.

The relative strengths of the motives also varies between cultures. For example, it has been suggested that in collectivist cultures, such as exist in many communities in east Asia and South America, social needs are stronger and mastery needs are weaker than in Western, individualistic cultures. For example, a conflict between personal benefit and the benefit of one's group is more likely to be resolved in favor of the former motive in individualistic cultures than in collectivist cultures.

THE EXPECTANCY–VALUE MODEL

Motivation may be conceptualized as a force having direction and strength. Motivation is directed towards those things that people find worthy of pursuit (e.g. food, social approval, knowledge) or away from those things that they find aversive (e.g. pain, failure). But what determines the strength of motivation? In other words, what determines the amount of effort that people would be willing to invest in pursuing an outcome? For example, what would determine the intensity of a student's efforts in preparing for an examination? Several influential theoretical frameworks represent motivational strength as the product of the value of the goal towards which motivation is directed and the expectancy of achieving it:

$$\text{motivation} = \text{expectancy} \times \text{value} \quad (1)$$

In this equation, 'value' is the desirability of the goal (e.g. how important it is for the student to do well on the examination) and 'expectancy' is the goal's attainability. The multiplicative relation between value and expectancy means that to maintain motivation, both expectancy and value have to be nonzero. If expectancy approaches zero (e.g. if the goal is judged to be unattainable), the goal will

not be pursued, no matter how attractive it is. If value approaches zero (i.e. the goal holds very little attraction), it will not be pursued, no matter how easy it is to achieve.

Expectancy

Various constructs have been proposed for expectancy, most notably probability and controllability or efficacy (the extent to which increasing one's efforts increases the likelihood of attaining the goal or the magnitude of the attained outcome).

Probability is the expectancy of outcomes that are determined by chance (e.g. lottery draws) and of outcomes over which one has little or no control (e.g. getting flu). For example, one's motivation to buy a lottery ticket would increase as the value of the prize increases and as one's estimated chances of winning increase; and one's motivation to get a flu vaccination would increase the more one dislikes having flu and the higher one estimates one's chances of getting flu.

Controllability and efficacy refer to the belief that increasing one's motivation would result in a corresponding increase in either the likelihood of attaining the goal or in its magnitude: in other words, to the belief in the usefulness of one's efforts. For example, the motivation to study for an examination would increase the more important the examination is and the more one believes that studying increases one's chances of success. The motivation to adhere to a diet would increase the more important it is for one to lose weight and the more weight one expects to lose for each 'unit of dieting effort' (i.e. the more effective one believes the diet to be).

The expectancy–value model is widely used in various kinds of decision-making, and has the status of a normative theory, that is, a theory of how decisions should be made in order to achieve optimal outcomes. For example, in comparing alternative financial investments, a decision maker is advised to multiply the expected revenue of each alternative (e.g. in decisions on investing in developing new products, an estimation of how profitable would be each product) by the estimated likelihood of that revenue (how likely is successful development of each product), compare the product across alternatives, and pursue the alternative with the highest product. In comparing alternative treatments for a disease, the decision maker (in this case the physician) is advised to multiply the desirability of the outcome of each alternative treatment by the likelihood of the outcome, and pursue the alternative that yields the highest product. In many real-life situations, the alternatives have multiple possible outcomes (and corresponding probabilities), so the computations may be fairly complex. Computer programs may be used to support experts making decisions.

Value

Value is comprised of costs and benefits. For example, the value of installing an air conditioner in one's car may be thought of as the difference between the benefits and the costs associated with buying and maintaining it (e.g. more pleasant driving versus increased monetary costs and fuel consumption). Costs may refer to depletion of resources that could be used towards other ends (e.g. money, time, energy), or to negative aspects of outcomes (e.g. the noise of the air conditioner). Benefits (positive) and costs (negative) are multiplied by their respective expectancies (e.g. probabilities), and these products are added together to determine the overall motivation. If the sum of the products is positive, the person would be motivated to approach the outcome. If the sum of the products is negative, the person would be motivated to avoid the outcome.

The expectancy–value model of motivation has a number of interesting implications for both motivation and personality psychology. We will briefly examine three such implications below: probability-dependent value; distance-dependent expectancy and value; and personal beliefs in expectancy.

Probability-dependent Value

Sometimes the value of an outcome depends on the probability of achieving it. For example, doing well on a difficult examination is both more advantageous and less likely than doing well on an easy examination. We can model such situations by postulating that value $= k\,(1-p)$, where the expectancy p is between 0 and 1 and k is a constant. In this case, motivation may be expressed as $kp(1-p)$. Since this is maximized at $p=1/2$ motivation will be strongest at tasks with intermediate difficulty and would decrease when the task is made either too difficult or too easy. Indeed, many studies have documented a preference for achievement tasks of intermediate difficulty, and more intense efforts on such tasks, compared with tasks that are either too easy (and therefore are not valuable enough) or too difficult (and therefore too unlikely to yield success).

Distance-dependent Expectancy and Value

In many situations efficiency of effort (and thus also expectancy) increases as one approaches the goal. For example, people may notice that their studying efforts are more efficient closer to the examination because less of what they learn will be forgotten, and because failing to learn gets harder to compensate for. Hungry rats that are running towards a food incentive close the gap towards the goal by 50% with each step when they are two steps away from the goal, but only by 1% when they are 100 steps away from it. Thus, a unit of effort (i.e. a step) is more efficient closer to the goal.

Distance also influences the psychological intensity of value, so that people typically value imminent outcomes more highly than delayed ones. The tendency of people to be impatient about positive outcomes has been termed 'myopia' by economists. For example, people require a relatively large monetary compensation in order to agree to delay in receiving a payment or a product. Another example of myopia is when people choose to purchase cheaper products with relatively high maintenance costs (e.g. a cheaper air conditioner with higher electricity consumption). Presumably, they do so because saving on maintenance is removed in time, so that its psychological importance is discounted relative to saving on the buying price, which is immediate.

Research on discounting of value suggested that costs undergo steeper temporal discounting than benefits. For example, parachute jumping may be perceived as both fun (positive value) and scary (negative value). Both fun and fear would be less intense from a distant than from a close perspective, but the decrease in the intensity of fear would be steeper than the decrease in the intensity of fun. An approach-avoidance conflict results: a parachute jumping in the distant future may seem more fun than scary (and thus would be approached), but in a closer perspective it may seem more scary than fun (and thus would be avoided).

It follows from the expectancy–value model of motivation and from the increase in both value and expectancy closer to the outcome that motivation should increase the closer one gets to the goal. For example, students would be more motivated to study closer to the exam, and hungry rats would pull harder closer to a food incentive, both because their efforts get more efficient and because the incentive seems more intense. This phenomenon, known as the 'gradient of motivation', has been documented in many studies with both humans and animals.

Personal Beliefs in Expectancy

Expectancies may vary not only between situations (e.g. different tasks, different distances from the goal) but also between individuals. Research in personality has documented stable interpersonal differences between generalized beliefs about the controllability of significant life events, as well as between generalized beliefs about the efficacy of efforts towards achieving important outcomes. Thus, some people tend to believe that whether they succeed or fail depends on their efforts, whereas other people tend to believe that success and failure are determined by external events beyond their control. Similarly, some people believe that their efforts are efficient towards achieving desirable outcomes, whereas other people believe that investing effort may yield little outcome. Some people believe that important personal qualities, such as intelligence or social skills, are unchangeable entities, whereas other people believe that these qualities are malleable and may be acquired by learning.

The expectancy–value theory predicts that higher expectancy should result in higher motivation. Higher motivation, in turn, should yield, overall, better outcomes than lower motivation. Indeed, it has been found that beliefs in high expectancy are associated with high levels of motivation and achievement. For example, people who hold a generalized belief that they control events in their lives tend to perform better academically and to engage in more preventive health behaviors than those who do not hold such a belief. People who believe that academic ability may be acquired through learning, rather than being a fixed entity, show greater persistence in the face of difficult tasks and greater motivation to undertake academic tasks after failure. Finally, a large body of research has shown that attributing negative events to external, global and unchangeable causes (i.e. a belief that the expectancy of changing the cause of negative events is low) is associated with depression and with a tendency not to initiate attempts to change an undesirable situation.

SELF-REGULATION

While the objects of pursuit are usually easy to discern (e.g. one knows that eating a meal would satisfy one's hunger), the way to achieve these desirable outcomes may be less obvious. Often,

satisfying even relatively simple drives requires elaborate and extended action plans. For example, getting to a restaurant to satisfy one's hunger may involve choosing a place, getting into the car, driving, waiting, and so on.

The system of self-regulation is responsible for ensuring successful goal pursuit. The tasks of self-regulation include setting a goal, designing means towards achieving it, specifying the conditions under which pursuit has to begin, monitoring for these conditions and setting the system in motion when they materialize, monitoring progress, comparing progress to a standard, finding alternative means in case of insufficient progress, and, finally, disengaging from goal pursuit upon goal achievement or in case of a repeated failure to achieve sufficient progress. In addition, the self-regulation system resolves conflicts among coexisting goals when only one of them can be pursued.

Goal Hierarchies

It is convenient to conceptualize goals as organized in hierarchies of varying levels of abstraction (e.g. doing well academically, passing an examination, reading a book, following lines of print). Goal hierarchies are organized so that each goal (e.g. reading a book) is subordinated to a higher-level goal – which answers the question of why that goal is being pursued (e.g. to pass an exam) – and superordinate to lower-level goals, which constitute the means towards achieving the goal and answer the question of how the goal is to be pursued (e.g. following lines of print). At very high levels of the goal hierarchy are abstract goals, which typically specify general guidelines concerning the type of person one should or should not be (e.g. famous, kind, wealthy). Such abstract goals are often referred to as life tasks, values or self-guides. At very low levels of the goal hierarchy are simple and concrete actions (e.g. picking up the phone).

Cybernetic models of action control specify the process of translating goals into actions. They suggest that goals are translated into subordinated goals (i.e. the 'how' level) repeatedly until a level is reached at which the required action is obvious or automatic. For example, if the goal is studying for an examination, then one might think of reading a textbook as a means towards achieving it. If how to read is obvious, it will not be further translated into means (e.g. a person will not tell him- or herself 'I need to open a book', but rather will perform this action automatically). If, however, how to read is not obvious (e.g. if the book cannot be found), then reading would be further translated into subgoals. Difficulties during goal enactment also foster translation of the action into subgoals. For example, if reading proves difficult because of an ink blot on a page, the person will become conscious of the otherwise automatic action of following lines of print.

Monitoring Progress

Monitoring of progress towards the goal is performed throughout the process. If progress is found to be unsatisfactory, then alternative means for pursuing the same goal are sought. For example, while reading a textbook in order to prepare for an examination, a student would assess periodically whether her rate of reading suffices to ensure that she will cover the desired material. If the rate is too slow, she might try to study in a different way (e.g. ask a friend for her notes). If progress is too slow but no alternative means are available, then one may try to lower the level of the aspired goal (e.g. the student might decide to study only part of the material) or abandon it (give up the goal of doing well in the examination). Monitoring of sufficient or good progress elicits positive emotion, whereas monitoring of insufficient progress elicits negative emotion. It follows that goal attainment, which is naturally accompanied by slowing down of progress, may sometimes be accompanied by a decrease in positive emotion.

Many studies have documented the beneficial effects of easy monitoring of progress on motivation and performance. For example, it has been found in many workplace situations that concrete goals, set by either others or oneself (e.g. 'your goal is to sell five insurance plans tonight') increase performance, both relative to a situation in which no goals are set and relative to less specific goals (e.g. 'do your best'). It is believed that the beneficial effect of concrete goals is due to their facilitative effect on monitoring. Thus, a concrete goal makes it easy to estimate, at each point, how far one is from the goal and whether progress is sufficient to ensure goal attainment. If progress is judged to be insufficient, efforts may be increased until the appropriate level is found. Such feedback on the rate of one's progress is impossible with more general goals such as 'do your best'.

Disengagement

Disengagement occurs when goals are achieved or abandoned. (As noted above, goals are abandoned when judged unattainable.) In cybernetic systems,

disengagement is followed either by returning to the higher-level goal, to which the attained goal was subordinate, in order to receive further subgoals, or by setting a different, unrelated goal. For example, after finishing reading the book, the person will return to the superordinate goal of studying for the examination, and see if there is anything else that has to be done for studying (e.g. read one's notes). If no further action is required to meet the superordinate goal, then the superordinate goal will be disengaged. Alternative goals may then be pursued (e.g. the student may go out with friends to pursue the goal of socializing).

Unfulfilled goals are difficult to disengage, and thus can create a state of rumination – intrusions of goal-related thoughts, increased memory of and overall sensitivity to constructs that are related to the goal, and even the appearance of dreams related to the unfulfilled goal. Usually, after repeated feedback indicating lack of progress, people would disengage unfulfilled goals, or try to substitute other goals for them. For example, a person who failed to get a desired job would first ruminate about it, but gradually would cease to think of that job and set out to find another one. However, when the unfulfilled goal is important (e.g. because it is judged indispensable for satisfying a basic need), it is not likely to be abandoned or replaced with a substitute, and a state of rumination may persist for extended periods of time (e.g. months or even years). A familiar example of a state of rumination is that arising from an unrequited (and unsubstituted) love.

Goal Conflict

Because people strive to satisfy multiple needs, they often experience goal conflict: a motivation to pursue more than one goal at a time. Often, one needs to decide which goal is to be pursued and which has to be abandoned or 'put on hold' (i.e. await execution at a later time). It is theorized that people pursue the strongest of a set of simultaneously experienced motivations.

Of particular interest are conflicts between long-term and short-term goals, often referred to as a 'temptations'. For example, one may strive to lose weight but be tempted by a rich dessert. One may strive to obtain good grades in an examination, but be tempted to party on the evening before. Typically, a long time in advance people resolve the conflict in favor of the long-term goal (i.e. when offered a rich cake in a distant future situation, people readily reject it, indicating that they would rather keep their diet), but as the time of the short-term goal approaches, they become more likely to pursue it (i.e. people would be quite likely to take a rich cake that is offered immediately and break the diet). It is thus often suggested that the motivation to pursue short-term goals undergoes steeper decay over temporal distance than the motivation to pursue long-term goals. For example, the motivation to eat a fatty cake or to go out with friends is strong close to engaging in these activities and sharply decays as they are removed in time. By contrast, the motivations to diet or to study remain relatively constant over temporal distance.

People often attempt to overcome temptations by removing them either physically (e.g. avoiding buying rich cakes, disconnecting the phone on the night before the exam), or mentally (e.g. trying not to think about the cake). To minimize temptations, people may also assign in advance penalties for succumbing to temptations or rewards for successfully overcoming them (e.g. a person promising herself a vacation if she loses weight), mentally exaggerate the importance of the long-term goals (e.g. convincing herself that getting slimmer is the key to social success), or mentally exaggerate the negative consequences of succumbing to the temptation (e.g. convincing herself that eating a cake is more detrimental to the diet than it really is).

Research has shown that by five years of age some children develop effective strategies to delay gratification. They learn to wait for a larger reward (e.g. two marshmallows) later rather than succumb to an immediate smaller reward (e.g. one marshmallow). For example, five-year-olds typically know that in order to facilitate waiting they should cover the tempting reward or at least avoid looking at it. It has been found that effective strategies to delay gratification in young children are associated with higher achievement in adulthood. The ability to delay gratification is believed to be an important component of emotional intelligence.

INTRINSIC AND EXTRINSIC MOTIVATION

It is useful to distinguish between intrinsic and extrinsic motivations for performing an activity. When extrinsically motivated, people perform an activity in expectation of a reward (e.g. people work in order to get money) or a desirable outcome (e.g. students study in order to get a good grade in an examination). Extrinsically motivated behavior may be controlled by external rewards, because reducing (or increasing) the extrinsic reward results in a corresponding decrease (or increase) in the motivation to perform the activity. Such

behavior would not be performed in the absence of rewards.

When intrinsically motivated, people perform an activity for its own sake, usually because they derive pleasure from being engaged in it (for example, a person may enjoy playing music or a child may enjoy solving a puzzle) and perform these activities with no expectation of a tangible external reward. People typically report greater enjoyment and satisfaction when performing an activity for which they are intrinsically, rather than extrinsically, motivated. Intrinsic motivation is typically associated with greater commitment to the activity (e.g. greater chances of spontaneous resumption after an interruption). In addition, it has been suggested that intrinsic motivation enhances creativity.

Increasing Intrinsic Motivation

What are the antecedents of intrinsic motivation? In other words, what determines whether a person would be intrinsically or extrinsically motivated to perform an activity? It is believed that intrinsic motivation may develop via a process of internalization, whereby an activity that is originally performed because of an explicit request by another person (e.g. a parent or a teacher), who often offers rewards for performing it (or punishment for not performing it), becomes internalized, and is later performed in the absence of an external request. For example, children typically require an explicit request (and sometimes even the threat of tangible sanctions) in order to clean up their room, and they would not clean in the absence of an authority figure delivering the request. Gradually, however, (at least some) children would come to appreciate the value of a clean room, and eventually clean up in the absence of an explicit request, being motivated solely by the intrinsic value of the process or the outcome (i.e. because they enjoy cleaning or because they enjoy having a clean room).

Internalization is a gradual process, which follows a number of stages. An activity that was previously regulated externally may be 'introjected': it may be performed because the authority figure is imagined or expected, rather than being physically present, as in the fully externalized case. For example, a child imagines how angry the mother would be when she comes and sees the messy room, and starts to clean it up. The next stage, 'identification', comes with the recognition of the underlying value of a behavior or its outcome (e.g. a child recognizes that a clean room is valuable towards some end, such as making it easier to find things). Finally, at the stage of full internalization, the person comes to derive pleasure from the outcome or the process itself, rather than merely perceiving it to be useful to some end as in the case of identification. For example, when cleaning is fully internalized, a child enjoys cleaning or having a tidy room.

This analysis suggests that helping a person recognize the underlying value of actions should be conducive to internalization. For example, explaining the merits of studying when trying to motivate a person to study would increase the likelihood of a fast internalization of that behavior. It is also evident from this analysis that a subjective perception of free choice would be associated with increased intrinsic motivation. Indeed, research has demonstrated higher intrinsic motivation with tasks involving choice (e.g. when students could choose one of a number topics of study), compared with a no-choice situation (e.g. when the topics were assigned).

Undermining Intrinsic Motivation

Interestingly, giving an extrinsic reward for an intrinsically motivated activity decreases intrinsic motivation. For example, children typically enjoy solving puzzles or drawing, and would engage in such activities spontaneously. However, after they are offered a prize (i.e. an external reward) for doing those activities, their tendency to engage in them spontaneously, in the absence of an external reward, decreases. Monkeys exhibited a similar pattern of behavior: they would press a button to obtain a puzzle to manipulate, but after being offered a reward of food for solving the puzzle, they stopped using the puzzles on their own (i.e. in the absence of the food incentive). Setting contingencies such as 'you have to do your homework if you want to play outside' or 'you have to eat soup in order to get cake' has a similar effect of undermining intrinsic interest in the activity that is designated as a means towards another activity.

It is for this reason that increasing external rewards as a means to motivate people is not always a good strategy to achieve internalization and an enduring behavioral change. Increasing extrinsic rewards may be an effective method of behavioral control only if one plans to administer rewards each time the behavior in question is to be performed and does not expect it to be performed otherwise. For example, increasing payment for extra hours of work should be effective in increasing the worker's motivation to work extra

hours, and does not appear to be problematic inasmuch as workers are not expected to work extra hours with no compensation. However, rewarding homework externally could be problematic inasmuch as one does not intend to continue to reward this behavior in the future, but rather hopes that it will be internalized.

CONTENTS

Motor control is concerned with the processes that allow the central nervous system to interact with the world. How we learn to control movement is central to our understanding of all human behavior.

FITTS' LAW

Pressing a switch, posting a letter through a slot, hitting a nail with a hammer, and many similar tasks all involve moving something from one place to another over a certain distance. A task can vary in the distance to be covered and in the accuracy of placement required. For example, if you hit a nail with a hammer, the size of the nail head determines the accuracy with which you need to position the hammer in order to hit it. It is a matter of common observation that in tasks like these people move more slowly when they need to be more accurate. There is a basic principle at work here: people are limited in how fast they can perform a task while maintaining the requisite level of accuracy. People can be fast or they can be accurate, but they are limited in their ability to be simultaneously fast and accurate. Clearly, it is of practical importance to know what these limits are.

Paul Fitts was one of the first to systematically study this relationship in the laboratory. Using a simple task that involved repeatedly moving a hand-held stylus between two targets, Fitts discovered a mathematical form for the rule that relates speed of performance to the accuracy demands of the task. In later experiments, the same rule was found to apply to a range of other tasks such as single reaching movements to visible targets, placing pegs in holes, and picking up an object. In all these experiments the participants were instructed to perform as fast as possible while maintaining accuracy. These instructions were intended to ensure that the participants performed close to the limits of their ability. The results of performance under different requirements for placement accuracy were interpreted to reveal the way people trade off performance speed for accuracy in tasks requiring placement or positioning (the speed–accuracy trade-off). The measure of the speed of performance used in this kind of experiment is the time taken to complete a movement (movement time, abbreviated MT). The size of the target (denoted as either S or W) is used as the measure of required placement accuracy. The rule Fitts discovered relates MT to the the size of the target (S) and the distance to be moved (A for amplitude) and is written as follows:

$$\mathrm{MT} = a + b \log_2(2A/S) \qquad (1)$$

where a and b are constant parameters. This equation has come to be called Fitts' law: it captures quantitatively the everyday observation that greater accuracy (small S) results in movements of a slower speed, and that moving over greater distances takes longer than moving over smaller distances. Note that movements over different distances to the same-sized target are not performed at a slower speed when the movement distance is greater, despite taking longer; quite the opposite, in fact – people move at higher speeds when they move further.

The values of the parameters a and b in Fitts' law are constant for particular people performing a particular task. If you use Fitts' law to describe the experimental data from a group of people performing one task, say putting pegs in different-sized holes, you will require particular values for a and b. If the same people perform another task, say pressing switches of different sizes, different values for a and b will be required. Different values of a and b will also be required to describe the data

from different groups of people performing the same pegs-into-holes task.

Although Fitts' law has been found to describe the data from a large number of experiments it is necessary to be aware of the limits of its applicability. Since the law is an empirically derived relationship, it may apply only to data of the type collected in the experiments that support it. As mentioned above, there are many such experiments; these have investigated a variety of different tasks, task conditions, and groups of people. Three things about these experiments and the data collected are always very similar, however. First, the data are obtained from people who are required to perform close to the limits of their ability to be both fast and accurate. Second, the targets at which movements are directed are always stationary relative to the person performing the task. Third, the data are the average data from a group of several people. It has been found that Fitts' law often fails to adequately describe data obtained from a single person. It also fails to describe performance when the target is in motion and may also fail to describe data obtained in situations where people were not required to perform as fast and accurately as possible: you can, after all, move as slowly as you like to touch a large target.

Even for the types of data and experimental context from which the law was originally derived, there is some debate about whether the form of the relationship proposed by Fitts [eqn 1] provides the best description of the data. Fitts' law provides a good description of most data sets, typically accounting for over 90% of the variance. Other formulations of the speed–accuracy tradeoff – such as the power law formulation

$$\mathrm{MT} = \alpha(A/S)^{\beta} \qquad (2)$$

where α and β are constant parameters – have been found to provide slightly better descriptions of the data.

Whichever formulation provides the 'best' description of the data, we are still faced with an unanswered question: why is there a lawful relationship between movement duration, accuracy, and amplitude, and why does it take the quantitative form that it does – Fitts' law, [eqn 1]? More generally, we can ask why people move slowly when they need to be accurate. It is generally agreed that the basic reason for this behavior lies in the fact that human movement always has some intrinsic inaccuracy in it, partly because the processes in the nervous system and the muscles that generate movement are contaminated by noise. As a result, any movement you make will deviate slightly from the ideal movement. If you move to a target, these deviations may be large enough to cause you to miss the target. Clearly, this is more likely to happen if the target is small. Starting from this basic principle, two reasons for slowing down when greater accuracy is required have been proposed. First, if you move slowly you will have more time to detect that you are going to miss the target and to make some sort of correction to compensate for your inaccuracy before the movement is completed. Second, the faster a movement is performed the larger the deviations from the required movement tend to be, and so even without making any corrections, a slower movement might be more accurate. These two proposed reasons are not mutually exclusive – slower movements may be intrinsically more accurate and provide the time necessary to correct errors before the movement is over.

CONTROLLED AND BALLISTIC MOVEMENT

As mentioned above, one explanation for why people move more slowly when they need to be accurate is that slow movements allow people to correct for errors while the movement is being executed. When such corrections are made, the movement is said to be 'controlled'. While it is possible for a person to become aware of an error in a movement and respond with a consciously intended correction, skilled performance is characterized by correction processes that operate without conscious awareness.

In general terms, controlled movements are those in which sensory information obtained after the movement was initiated contributes to movement production. The term 'online' is often used to refer to this kind of sensory control of movement. There are a number of different ways in which sensory information can make an online contribution. In aiming and placement tasks sensory information has been shown to be used to make discrete corrections to the ongoing movement: a deviation from the required movement is detected and then a corrective response is produced that is incorporated into the ongoing movement. In other types of movement, sensory information is used to drive performance more continuously and directly. It is known, for example, that some types of eye movement can be driven in this way. These include tracking eye movements, made when you follow a moving object with your eyes, and the vestibular–ocular reflex that allows you to keep your gaze fixed on an object when you move your head

around. The idea that sensory information drives movement production in a continuous fashion has been suggested for other types of motor task such as catching a ball, but the empirical evidence is equivocal.

So far we have implicitly assumed the existence of processes that produce movement without online control by sensory information. Movements that are not influenced online by sensory information are often called 'ballistic' movements, by analogy with firing a projectile – once a projectile such as a bullet leaves the gun its trajectory is no longer influenced by the person who fired it. This analogy should not be taken too literally. A movement that is executed without an online contribution from sensory information is not necessarily executed without any control. Empirical work has shown that motor commands from higher centers in the nervous system can drive movements throughout the period of their execution even in the absence of any online sensory contribution. The production of such movements is not ballistic in the sense of a projectile – the brain does not cause a movement to be 'fired off' like a bullet. The nearest thing in the repertoire of human performance to a movement that is 'fired off' in this fashion is a saccadic eye movement (saccades are the rapid movements that you make when you shift gaze from one object to another). Because of these misleading implications of the term 'ballistic', it is more usual nowadays to refer to movements that are not controlled by sensory information as 'open-loop' movements. It should be clear that care is needed in using the terms 'controlled' and 'ballistic' to describe human movement: the distinction being drawn is between movements where sensory information contributes to performance in an online fashion, and movements where there is no online sensory contribution.

It is important to recognize that most motor tasks performed in everyday life are neither purely controlled by sensory information nor open-loop (ballistic), but rather combine both types of control. For example, in the many aiming and placement tasks that conform to Fitts' law, people initially make an open loop movement towards the target position. As the hand or object being aimed nears the target, the person can detect deviations and errors using vision and, based on this visual information, make online corrective adjustments to the initial open-loop movement. This idea was first proposed by Woodworth at the end of the nineteenth century, and it has since become an established principle of human motor control.

INVERSE KINEMATICS

Most of the tasks that have been discussed so far involve moving something from one place to another. Such tasks are fundamental to most of the things we do in everyday life, from making a cup of tea to playing a game of tennis. When we consider the performance of such tasks we often restrict our attention to the thing being moved – the hand when reaching for something, the finger when pointing at something, the hammer head when hammering in a nail, the racket head when hitting a tennis ball. The thing being moved is sometimes referred to as the 'end-effector', a term originally introduced in robotics.

Since it is the end-effector that executes the task – grasps the object, presses the switch, hits the ball – it is natural to suppose that the nervous system controls the movement of the end-effector, both the path it follows and the speed with which it moves. Thus, the idea arose that the nervous system preplans the trajectory of the end-effector: this plan is the basis for the open-loop component of aimed movements discussed earlier. The nervous system cannot directly control the movement of the end-effector; it can control it only indirectly by contracting muscles and moving body segments around joints. Thus, in order to make the end-effector move along a planned trajectory the nervous system must determine the rotational motions of the contributing body segments necessary for producing the planned motion of the end-effector and also the muscle forces necessary to cause the body segments to move that way.

The problem of determining the segment motions (often called joint motions) that will produce a required motion of the end-effector is called the 'inverse kinematics problem'. The term 'kinematic' means that the motions are considered without reference to the forces that cause them, and it is 'inverse' because you are going from the motion of the end-effector back to the motions around the joints that resulted in that end-effector motion. In order to solve this problem it is necessary to have information about the lengths of the body segments involved and their ranges of motion. When the nervous system possesses such knowledge, in either explicit or implicit form, it is said to possess a kinematic internal model of the body. Note that the accuracy of the model affects the accuracy of movement – if the model is not accurate, then any movement planned using the model will be inaccurate. This is another source of the inaccuracy of human movement

zmentioned at the end of the earlier discussion of Fitts' law.

In human movement a desired motion of the end-effector and a kinematic model of the body is generally insufficient to solve the inverse kinematics problem. That is, these factors alone are not sufficient to find a unique set of joint motions that produces the planned end-effector motion. This is due to the fact that many, possibly infinitely many, different motions of the same body segments can often produce the same end-effector motion. When a system can produce the same result in many different ways it is said to possess 'redundancy'. A redundant system is flexible and adaptable – if one way is blocked you can choose another. When you are free to choose, however, you do not want to be like Buridan's ass, trapped motionless between two or more apparently equal choices. What you need is something that helps you make a choice. Several proposals have been made concerning what this might be.

One popular idea, supported by empirical data, is that the nervous system establishes linkages between joints such that if one joint moves in a particular way, a linked joint is constrained to move in a related way. The existence of such linking constraints between joint motions means that some types of motion are not possible. Linkages of this kind have been called 'joint synergies'. An everyday analogy is the linkage that exists between the steered wheels of a motor vehicle. The two front wheels are linked together so that when the steering wheel is turned the two wheels move together. The linkage prevents the wheels moving independently. The existence of joint synergies reduces the number of possible solutions to the inverse kinematics problem – some logically possible solutions are excluded because of the existence of the synergies.

MOTOR FEEDBACK

Feedback is the name given to the situation in which the output of a system (what the system is achieving) provides an input to the same system. If the output is fed back as input, what the system is doing affects what the system does next. When we talk of feedback in the control of movement we are usually referring to the situation in which performance of movements at one moment affects the nervous system via the sensory systems and by this route can influence later performance. Sensory information about what you are currently doing or what you have done is referred to as 'sensory feedback'.

Sensory feedback about movement can be provided by different sensory systems. For example, feedback about the movements actually being made can be provided by the visual system – you need only look at what you are doing to obtain information about your performance. Such information can also be provided by the sensory organs embedded within the tissue of your muscles, joints, ligaments, and skin – often called 'kinesthetic feedback'. Both visual and kinesthetic feedback provide information about how your body is currently moving or about its current posture. Kinesthetic feedback can also convey information about the amount of force being developed by a muscle or being exerted on an object – information that the visual system cannot provide.

Sensory feedback about how a limb is moving or positioned and about the amount of force being developed can be used online to adjust performance through controlled movements. Feedback can also be about the outcome of a movement or action. This is the most familiar kind of feedback: it is obtained after you have completed your performance and informs you about what was achieved. For example, after you have played a shot in tennis you acquire visual feedback about the outcome – where did the ball land? Outcome feedback is clearly not the kind of feedback that can be used in the online control of movement: it cannot be used to make the kind of adjustments discussed above. Outcome feedback is nevertheless important for motor performance as it can be used to guide the process of motor learning. Many experimental studies of the use of outcome feedback in motor learning have attempted to control exactly what feedback was available to participants by preventing them directly observing performance outcomes; instead, the feedback is provided verbally by the experimenter or by a display device such as a meter or computer screen. In these cases the outcome feedback is referred to as 'knowledge of results'. Research using this technique for providing feedback has demonstrated its importance in the learning process.

SKILL AND LEARNING

Skill can be defined as a special ability acquired through training. Implicit within such a definition is the idea that skill is based upon learning. If one considers that most purposeful voluntary controlled movement is acquired after birth, it might be argued that all those who research motor control are concerned with the issue of learning at some level. In line with this, one of the major stimuli to

research in the area of motor control has been the desire to understand how humans reach certain levels of proficiency in tasks involving movement. The motivation behind this desire is straightforward – if we understand how skilled actions are learned, then it should be possible to design training programs that optimize the level of performance achieved by an individual in a particular task. Moreover, discovering how skills are learned would potentially allow individuals to achieve a set level of proficiency in the shortest possible time. The practical implications of optimized training are clear: athletes reaching the highest sporting achievements, increased work productivity in jobs involving manual control, and therapeutic strategies for conditions characterized by deficits in motor ability. Thus, it is not surprising that many studies in motor control have been concerned specifically with how people perform a given task under different learning conditions.

Initial attempts to understand the development of skilled behavior explored specific questions related to practical issues of whether it is better to practice the whole skill (e.g. typing bimanually) or components of the skill (e.g. typing unimanually), the influence of knowledge of results (see above), and the optimum intervals between training and rest, etc. There is no doubt that these approaches have yielded important practical information that can be used, for example, by sports coaches when devising specific training programs. The limitation of such approaches is that they tend to be task-specific and often fail to shed light on the underlying mechanisms that support skilled behavior. It is therefore worth considering the progress made in elucidating the mechanisms that underpin the learning of motor skills.

Modern attempts to understand motor learning have adopted computational approaches in order to clarify the problems faced by the nervous system and to explore possible solutions employed by the system. These approaches all advocate ways in which the system can acquire knowledge about the environment and suggest how the system can modify (adapt) its behavior in response to changes in the body or the environment. There are three major computational approaches to learning: supervised, unsupervised, and reinforced learning schemes. There are a number of different methods of implementing learning models (e.g. artificial neural networks). One of the ultimate goals of motor research is to use such models together with empirical investigation in order to identify the manner in which the human nervous system learns to make skilled movement.

SEQUENTIAL RESPONSE LEARNING

The control of human movement rests upon the nervous system maintaining and updating information about the relationship between the environment and the neuromuscular apparatus. Furthermore, the production of a number of complex behaviors rests upon the nervous system storing information about the relative sequence of a number of different actions. The acquisition of information about the correct sequence of events within a complex task is referred to as 'sequential response learning'.

The necessity of sequential response learning is well known to experienced pianists. A number of musical compositions require the pianist to play a lengthy sequence of notes that run up (or down) the piano keyboard. The difficulty is that the pianist quickly runs out of fingers and thumbs, requiring the seamless transition of the hand to the right (or left). One possible solution to this problem is known as 'fingering' and involves the pianist learning to move the thumb underneath the fingers at the appropriate point to play the subsequent note while simultaneously pivoting the hand in the desired direction. In order to become accomplished at this task the pianist must learn the correct sequence of digit movements (responses) for all of the different scales in all of the various keys. It will be noted that a countless number of everyday tasks also require sequential response learning.

A number of investigators have established that normal participants can learn complex patterns of sequences without being able to explicitly report the pattern of the sequence. These experiments show that participants' reaction time is decreased when asked to make repetitive responses to a complex series of stimuli. It has been argued from these experiments that sequential response learning involves implicit memory (where previous experience facilitates performance without the explicit recollection of that experience). It has been discovered that patients with dense anterograde amnesia are capable of showing sequential response learning. These findings have been used to argue that sequential learning does not require the brain systems that are responsible for explicit memory.

Motor Development

Introductory article

Karen E Adolph, New York University, New York, USA
Idell Weise, New York University, New York, USA
Ludovic Marin, New York University, New York, USA

CONTENTS

Motor development refers to changes in children's ability to control their body's movements, from infants' first spontaneous waving and kicking movements to the adaptive control of reaching, locomotion, and complex sport skills.

CLASSICAL AND CONTEMPORARY THEORIES OF MOTOR DEVELOPMENT

Early Pioneers

Researchers in the 1930s and 1940s provided the first detailed descriptions of change in infants' motor skills. Arnold Gesell, for example, identified 22 stages in the development of crawling, beginning when infants lifted their heads from a prone position and ending when they could crawl smoothly on their hands and feet. Myrtle McGraw described seven primary stages in the development of walking, progressing from newborns' reflexive stepping movements to independent walking at the end of infants' first year.

These early pioneers believed that motor development resulted from neuromuscular maturation – largely autonomous changes in infants' brains, muscles, and growing bodies. From this perspective, rich catalogs of motor milestones would yield insights into the maturation process. Normative descriptions of motor milestones were widely published in books, journals, and newspaper columns and are still the accepted guidelines for informing clinicians, doctors, and parents about the path of normal motor development.

However, the early pioneers may have done their job too well. Once neuromuscular maturation became the broadly accepted explanation for motor development and the major skills were amply cataloged, the urge for further research dwindled. From the 1950s to the 1980s, motor development was virtually ignored by developmental psychologists.

Contemporary Approaches

In the 1980s, interest in motor development was rekindled as new research methods and sophisticated recording technologies provided improved ways of measuring and analyzing infants' motor skills. More important, recent conceptual advances opened a new perspective for understanding developmental change. Neuromuscular maturation has lost its privileged status as the central impetus for motor development. Emphasis on the contributions of peripheral factors, perceptual information, and learning for adaptive control of movements have reinvigorated the field of motor development research.

A prominent influence on contemporary research is the dynamic systems approach inspired by the Russian physiologist Nicholai Bernstein, and popularized and expanded by developmental psychologist Esther Thelen. On the dynamic systems account, new motor skills may emerge from the confluence of many interacting factors, each with its own developmental trajectory. Each factor must be in place, sufficiently ripe and ready to go, but no factor enjoys privileged status compared with any other. Independent walking, for example, may emerge when infants have sufficient muscle strength, slimmed down body proportions, motivation to go some place, balance control, the appropriate environmental properties to support the action, as well as brain maturation.

A second prominent influence is the perception–action approach inspired by James and Eleanor Gibson. They argue that perception and movement are linked together. To be planned and executed adaptively, actions require perceptual information

about the relevant properties of the environment and the body, and the relationship between them. On the other hand, perceptual information typically requires movement to create the relevant structures in light, sound, and other ambient arrays of energy. For example, exploratory movements of the eyes, head, body, and extremities generate perceptual information in light, sound, muscles, and skin. Actions likewise generate more information for perceptual systems. Perceptual-motor learning is critical for discovering and honing exploratory movements and for discriminating and using the relevant information obtained from exploration.

Importance of Posture

On both classical and contemporary accounts, posture plays a central role in motor development. On the classical neuromuscular maturation account, infants' slow triumph over gravity as they acquire increasingly erect postures is evidence of greater cortical control of actions. On the contemporary dynamic systems and perception–action accounts, posture is the biomechanical foundation for action. Manual skills, locomotor skills, and even lifting or turning the head require a stable postural base. Each postural milestone in development (sitting, crawling, walking, etc.) requires learning about a new perception–action system.

The first step of learning to control a new postural system is to co-contract large muscle groups. This co-contraction frees up resources and allows attention to be focused on the goal-directed part of the movement. However, co-contraction results in jerky, energetically inefficient movements. After extended practice, muscles are activated in sequence and muscle forces are used sparingly so as to exploit gravitational and inertial forces which impel movements for 'free'.

MANUAL SKILLS: EXPLORING OBJECTS

Reaching and Grasping

Arm movements begin before birth. Fetuses wave their arms, produce isolated finger movements, and display coordinated arm–hand movements such as bringing their thumb to their mouth. After birth, infants must cope with gravity outside the buoyant, fluid-filled womb. Newborns' arm-flaps and jerky arm extensions become successful reaching to objects at four to five months. Careful motion analysis shows that infants initially solve the problem of getting their hand to a target in their own way. More sluggish infants must overcome gravity to move their arms from their sides, and more active infants must dampen inertial forces to control ongoing, spontaneous arm-flaps.

Like reaching, infants' first grasps are inefficient. They open their hand to the proper shape only after contacting the object. By about eight months, babies can use visual information about object size, shape, and orientation to adjust the shape of their hand before contacting the object. Infants need not look at their hand to guide its shaky path to the target because successful reaching and grasping in the dark occurs at the same time as in the light. However, visual information about the object's location and other properties is extremely important for planning arm and hand movements adaptively. A dramatic illustration is that young infants can intercept moving targets. They do so by moving the hand on the opposite side of their body to the appropriate location before the object arrives.

Apparently, coordination between manual skills and perceptual exploration is fundamental. In addition to hand–mouth behaviors, newborns turn their heads to keep an outstretched arm in view. Older infants use their reaching and grasping skills to bring objects (and fingers) to their mouths, and coordinate visual, tactile, and oral exploration by alternating between looking at the object, turning and fingering it, and sucking on it.

Even a simple reaching task requires balance control. When an arm is extended over the base of support, the center of gravity is displaced. Before babies' back and abdominal muscles are strong enough to support them in a sitting position, they must use their hands to maintain balance in a 'tripod' configuration. After onset of independent sitting at five to six months, their hands are free to reach, grasp, and manipulate small objects. Over the next several months, infants become skilled at coordinating reaching and leaning so as to prevent falling over.

Using Hand-held Implements as Tools

Once infants master the motor components of reaching and grasping, they can use these skills to extend their own abilities and to bring about rewarding outcomes. Babies bang rigid objects against rigid surfaces to make a noise, but cease banging squishy objects on squishy surfaces. When given a choice between different objects and surfaces, they test various combinations to find the object/surface combination that makes the most noise. Although nine-month-olds can hold a

spoon and use it to bang on their high-chair tray, it isn't until several months later that they can manage fine motor control and incorporate the spoon into a complex plan for transporting food to their mouth.

Swiss psychologist Jean Piaget was first to describe how older infants separate reaching and grasping into means for achieving ends. For example, after eight months or so infants reach and pull a cloth to bring a toy on the cloth into closer proximity. Similarly, older infants extend their reaching space by leaning forward with a stick in their hand to contact an object. Toddlers use canes as tools to rake in objects out of reach. They show understanding of the relationship between tool and target by turning the cane to the appropriate orientation.

BALANCE AND LOCOMOTION: EXPLORING THE LAYOUT

Interlimb Coordination in Crawling and Walking

Precursors of locomotion begin long before infants take their first steps. Fetal and newborn spontaneous arm and leg movements contribute to building and strengthening muscles necessary for later locomotion. Coordination between limbs may already be in place in newborns. When the constraints of muscle strength and balance control are removed, newborn infants produce the 'crawling', 'swimming', and 'stepping' reflexes. They display crawling movements when placed on a gentle downhill slope, swimming movements when put into a pool of water, and stepping movements when held upright on a table. Each of these movements resembles the coordination patterns of later appearing skills. And each shows a U-shaped developmental trajectory: the reflexive patterns displayed by newborns disappear and then reappear months later in altered form.

The classical explanation for this trajectory was neuromuscular maturation: as cortex becomes more refined and myelinated, the reflexive movements are inhibited and then reappear under cortical control. Recent research supports the contemporary dynamic systems account – that the central nervous system is not a privileged factor and that peripheral factors may play the pivotal role in development. When stepping infants' legs are weighted to simulate fat gain, they stop stepping. When non-stepping infants' legs are held in a tank of water, they step. When non-steppers are held in an upright position over a motorized treadmill, they step. Apparently, the peripheral factors of leg muscles and leg fat were the key factors in the U-shaped trajectory. Infants stop stepping when their legs are too fat and weak. Similarly, the treadmill compensates for leg strength by stretching the leg backward and allowing it to pop forward like a spring.

Crawling is usually infants' first success at independent locomotion. Many infants invent idiosyncratic styles of crawling at first, such as scraping along on their bellies. However, maintaining balance on hands and knees is highly constrained biomechanically and nearly all infants crawl the same way from their first week on hands and knees – a modified diagonal trot. Practice using idiosyncratic belly crawls is not wasted, however, because ex-belly crawlers are twice as fast and efficient as infants who skipped this phase, once both groups of babies begin crawling on hands and knees.

Independent walking typically appears after several upright transitional stages (pulling to a stand, balancing, and cruising sideways using furniture for support). There is a dramatic change in walking gait from infants' first steps to the toddler years and beyond. New walking is characterized by small steps with a wide space between the feet. Toes point outward and the legs are almost straight. Elbows are bent upward and the palms face the ceiling. Rather than a heel-to-toe progression like adults, infants walk on their toes or plant their whole foot down at one time. This strange gait pattern progressively improves so that by seven years of age children walk like adults.

Balance Control

Locomotion requires continual adjustment to disequilibrium by using compensatory sway to keep the center of mass over the base of support. Sometimes compensatory movements are obvious, as when trying to recover from a fall. Other times, as when just standing or walking on flat ground, it is not as apparent. However, detailed recording shows that the body is constantly swaying, even if movements are invisible to the naked eye. Keeping balance is especially difficult for infants because their body proportions are top-heavy and they fall faster given their short stature.

Children rely on several sources of information for balance control: somatosensory information from their muscles, joints, and skin, vestibular information from accelerations of the head, and visual flow information created by the body's movement. When visual flow is simulated by surreptitiously moving the surrounds (as in a flight

simulator), standing adults generate compensatory sways in accordance with the simulated visual flow. Walking infants also respond with compensatory movements, but they overcompensate and often stagger and fall. Even babies who cannot locomote independently show signs of sensitivity to visual information relevant for balance control by moving their heads in accordance with simulated flow.

Navigation over Variable Terrain

Adaptive locomotion requires learning. When newly locomotor infants are challenged with variable terrain, they show little ability to distinguish safe from risky ground. For example, at the edge of a cliff or steep slope, they plunge over heedlessly. (Infants are always protected in such experiments by covering the drop-off in safety glass or having a trained experimenter nearby to provide rescue.) After several weeks of locomotor experience, they avoid risky ground. Surprisingly, learning appears to be specific to each postural milestone in development. For example, experienced crawlers avoid risky slopes, but the same infants attempt the same risky ground a few weeks later after they begin walking.

CONCLUSION

Motor development does not stop after infancy. After mastering basic postural, manipulative, and locomotor skills, children acquire a host of more complex activities – writing, playing the piano, jumping, skipping, etc. As in infant development, later skill learning begins with stiff, wasteful, and uncoordinated movements and becomes progressively more rhythmical, smooth, and efficient.

Motor development is not an isolated domain. The newest research in motor development focuses on interactions between acquisition of new motor skills and developments in perceptual, cognitive, social, and affective domains.

Motor Learning Models

Introductory article

Daniel M Wolpert, University College London, UK
Zoubin Ghahramani, University College London, UK

CONTENTS

Motor learning models are adaptable systems within the central nervous system which are responsible for skilled motor behavior.

INTRODUCTION

Humans demonstrate a remarkable ability to produce skilled behavior effortlessly. Our own perception of the effort involved in such skill is in stark contrast with the complexity of the algorithms required to control robots even with their currently meagre performance. The basic requirement for such performance is to learn the transformations between sensory and motor variables (Figure 1). Such transformations are accomplished by the environment and by the musculoskeletal system; these physical systems transform descending motor commands from the central nervous system (CNS) into a new configuration of the body (state) which in turn generates sensory feedback from touch and position sensors in the body. It is also possible, however, to consider internal transformations, implemented by neural circuitry, that mimic this external motor-to-sensory transformation (Figure 1). Such internal transformations are known as internal forward models. Forward dynamic models, for example, predict the next configuration of the body (e.g. position and velocity of the arm) given the current configuration and the motor command. This is in contrast to internal inverse models, which invert the motor-to-sensory transformation, providing the motor command that will cause the desired change in configuration. As inverse models produce the motor command required to achieve some desired result they can be used by the CNS to control the motor system.

INVERSE MODELS FOR CONTROL

Several models have been proposed for how the motor commands are generated. The equilibrium point control model suggests that the CNS specifies spatial parameters and relies on the spring-like properties of muscles and reflex loop to move the limb. For example, a set of muscle activations defines a stable equilibrium position of the hand in space. Movement is achieved by playing out in time a set of such equilibrium positions along a desired trajectory. This model uses muscle and spinal cord properties as a feedback controller to pull the hand along the desired trajectory. Because of the dynamics of the system, the actual positions may not follow exactly the desired trajectory. An alternative proposal is that an inverse model is constructed to map desired states into motor commands. These two approaches can be contrasted by considering the problem of moving a ball around a circular path by specifying the forces acting on it. For inverse model control the equations of motion are solved and the forces on the ball applied to generate the desired acceleration. For equilibrium point control, the ball is attached by a spring to a control point which is simply moved around the circular path, with the ball following along behind.

FORWARD MODELS FOR PREDICTION

To control the body the CNS needs to know its configuration, that is its state. However, the CNS faces two problems. First, considerable delays exist in the transduction and transport of sensory signals to the CNS. Second, the CNS must estimate the configuration from noisy sensory signals. For example, consider a tennis ball we have just hit. If we simply used the retinal location of the ball to estimate its position, our estimate would be delayed by around 100 ms. A better estimate can be made by predicting where the ball actually is, using a forward model. This estimate can be improved by knowing how the ball was hit (i.e. the motor command), in conjunction with an internal

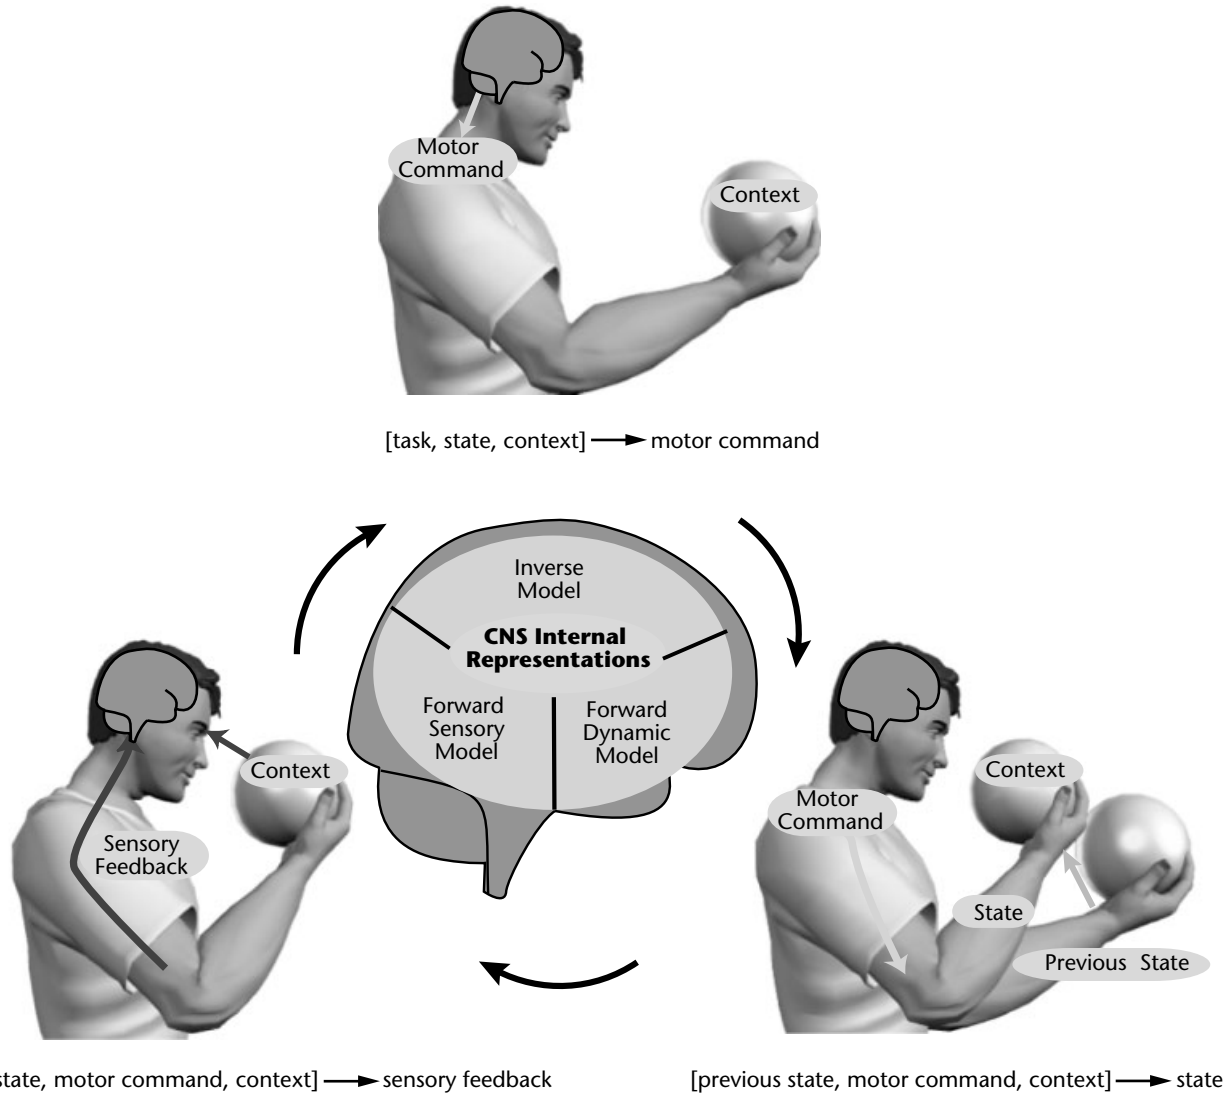

Figure 1. The sensorimotor loop and the relationship between motor commands, state, context, task and sensory feedback. The loop can be divided into three stages which govern the overall behavior of the sensorimotor system. The first stage specifies the motor command generated by the central nervous system (CNS) given the state and a particular task (top). The second stage determines how the state changes given the motor command (right). The third closes the loop by specifying the sensory feedback given this new state (left). These three stages are represented in the CNS as internal models – the inverse model, forward dynamic model and forward sensory model.

forward model of the ball's dynamics. This combination, using sensory feedback and forward models to estimate the current state, is known as an 'observer', an example of which is the Kalman filter. The major objectives of the observer are to compensate for the delays in the sensorimotor system and to reduce the uncertainty in the state estimate which arises due to noise inherent in both the sensory and motor signals. Such a model has been supported by empirical studies examining estimation of hand position, posture and head orientation. Damage to parietal cortex has been linked to inability to maintain such state estimates.

Using an observer it is also possible to predict the future. For example, by estimating the outcome of an action before sensory feedback is available, a forward model can reduce the deleterious effects of feedback delays in sensorimotor loops. Such a system is thought to underlie skilled manipulation. For example, when we move an object held in the hand, the fingers tighten their grip in anticipation to prevent the object slipping, a process shown to rely on prediction. State prediction can also be used

in mental simulation of intended movements, and damage to parietal cortex can lead to an inability to simulate mentally movements with the affected hand.

Sensory prediction can also be used to cancel out the effects of sensory changes induced by self-motion, thereby enhancing more relevant sensory information. Predictive mechanisms underlie our inability to tickle ourselves; the forward model predicts and attenuates the tickle sensation. It has been shown that the reduction of the felt intensity of self-applied tickle critically depends upon on the precise spatial and temporal alignment between the predicted and actual sensory consequences of the movement. Similarly, sensory predictions provide a mechanism to determine whether a movement is self-produced (and hence predictable), or produced externally. It has been proposed that a failure in this mechanism may underlie the delusions of control which can occur in schizophrenia, in which patients may feel that their body is being moved by forces other than their own. Interestingly, damage to the left parietal cortex can lead to a relative inability to determine whether viewed movements are one's own or not.

LEARNING INTERNAL MODELS

Internal models, both forward and inverse, capture information about the properties of the sensorimotor system. These properties are not static but change throughout life both on a short timescale, owing to interactions with the environment, and on a longer timescale, owing to growth. Internal models must therefore be adaptable to changes in the properties of the sensorimotor system. Learning can be considered as reducing an error measure associated with the internal model, for example a prediction error for a forward model. In order to learn, the system needs to measure this error signal and update parameters in the model, such as synaptic weights, to reduce future errors.

Since forward models predict the consequences of an action, the environment readily provides an appropriate training signal. The predicted outcome of an action can be compared with the actual outcome, and the discrepancy – the error signal – used to update the forward model.

Acquiring an inverse internal model through motor learning is generally a difficult task. Unlike forward models, the appropriate training signal for inverse models – the error in the motor command – is not directly available. When we fail to serve an ace no one tells us how our muscle activations should change to achieve this task. Instead, we receive error signals in sensory coordinates, and these sensory errors need to be converted into motor errors before they can be used to train an inverse model. An ingenious solution to this problem, called feedback–error–learning, proposes that a hard-wired, but not perfect, feedback controller exists which computes a motor command based on the discrepancy between desired and actual sensory feedback. The motor command is the sum of the feedback controller motor command and the output of an inverse model. If the feedback controller were to produce no motor command, then there would be no discrepancy between desired and actual sensory feedback, there would be no error in performance, and the inverse model would be performing perfectly. Based on this reasoning, the output of the feedback controller can be regarded as the error signal, and used to train the inverse model, an approach that is highly successful. Neurophysiological evidence supports this learning mechanism within the cerebellum for the simple reflex eye movement called the 'ocular following response'. This suggests that the cerebellum constructs an inverse model of the eye's dynamics.

Recent work on learning novel dynamics has focused on the representation of the inverse model. If people make point-to-point movements when the dynamics of their arms are changed, either by interaction with a robot or by Coriolis forces present in a rotating room, it has been shown that over time they adapt and are able to move naturally. Several theoretical questions have been addressed using this paradigm. The learning of dynamics generalizes in joint-based coordinates, learning depends on the states experienced but not on the order in which they are experienced, state-dependent fields are learned more efficiently than temporally changing fields, and during learning both forward and inverse models are simultaneously adapted.

MODULARITY OF INTERNAL MODELS

Human motor behavior demonstrates an enormous repertoire which enables us to interact with many different objects in a variety of different environments. No single internal model can capture the behavior of all the varieties of objects and environments that we interact with. One attractive hypothesis is that the sensorimotor system builds multiple internal models and switches between them when the context becomes appropriate. For example, the moment we grasp an object and lift it off a table, the dynamics of our arm change

abruptly and therefore a different controller is switched in. There are two challenges for the central nervous system in building a modular controller: the first is determining when to switch between different controllers; and second, the controllers must be adapted to cover the range of objects and environments the individual has to learn.

One approach to learning when to switch between different control modules is to use an architecture that has multiple paired forward and inverse models, each pair constituting a module. Each pair is tuned to a different context, for example to objects with different dynamics. Each forward model predicts the behavior of the motor system corresponding to its context. The array of forward models can then be used to determine which context we are acting in. Each forward model makes a prediction of the consequences of the descending motor command and these predictions are compared with the actual sensory feedback. The set of errors can be used to determine the likelihood of each context – the smaller the error, the more likely the context. This array of models therefore acts as a set of hypothesis testers. In addition, sensory information can be used to set the prior probability of each context; for example, sensory information can be used to select a module based on an object's visual appearance prior to physical interaction with the object. The likelihood and the prior probability can be optimally combined using Bayes' rule, which takes the product of these two probabilities and normalizes over all

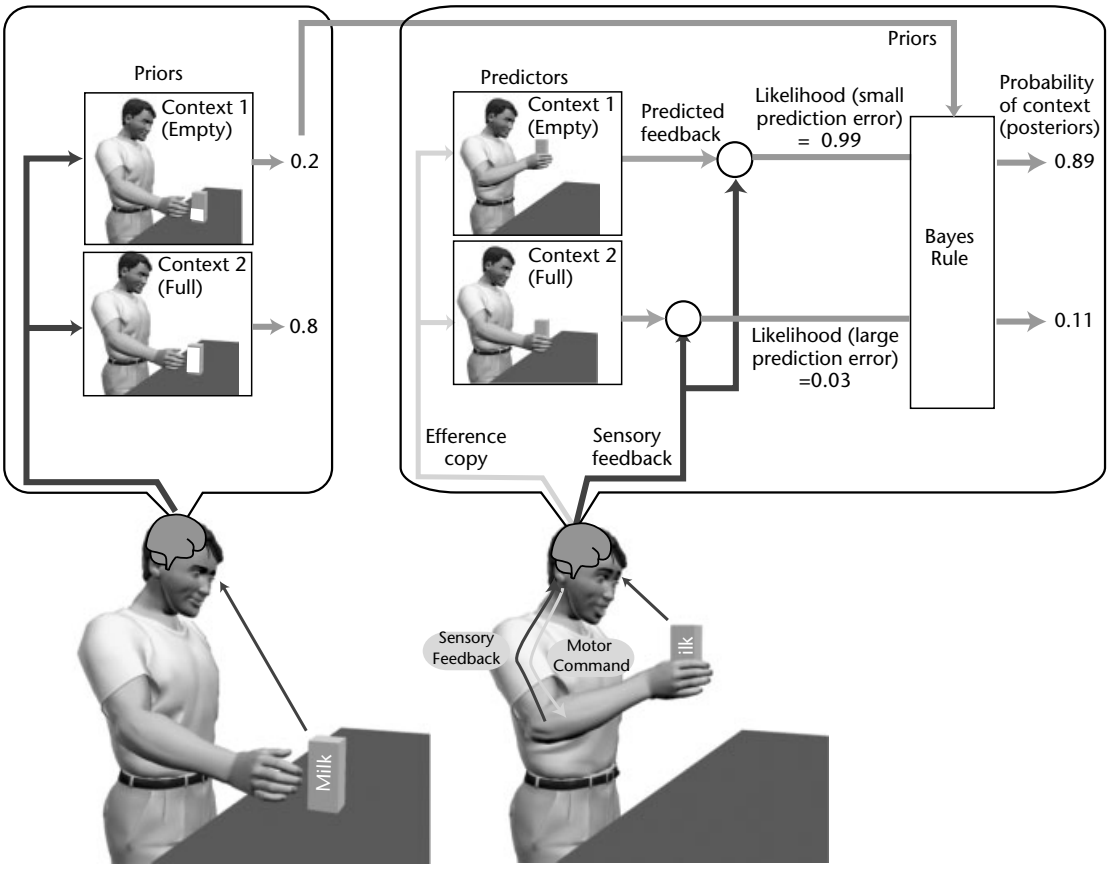

Figure 2. Context estimation with just two contexts: that a milk carton is empty or full. Initially sensory information from vision is used to set the prior probabilities of the two possible contexts; in this case, the carton appears more likely to be full. When the motor commands appropriate for a full carton are generated an efference copy of the motor command is used to simulate the sensory consequences under the two possible contexts. The predictions based on an empty carton suggest a large amount of movement compared with the full carton context. These predictions are compared with actual feedback. As the carton is in fact empty, the sensory feedback matches the predictions of the empty carton context. This leads to a high likelihood of an empty carton and a low likelihood of a full carton. The likelihoods are combined with the prior probabilities using Bayes' rule to generate the final probability of each context.

possible contexts, to generate a probability for each context. These probabilities are then used to switch between the controllers, with modules with higher probability contributing more to the final motor command. Although the set of predictors start off naive in this model, they compete to learn the experienced dynamics, differentiating over time. This competition is achieved by making the amount by which each module learns proportional to the probability of its context. This ensures that different models learn different contexts.

Figure 2 shows a person picking up what appears to be a full milk carton but is in reality empty. This shows how the predictive models correct on-line for erroneous prior probability assessment which initially weighted output of the controller for a full milk carton more than that for an empty one. Bayes' rule allows a quick correction to the appropriate control even though the initial strategy was incorrect. This example has two modules representing two contexts. However, the modular architecture can, in principle, scale to thousands of modules (that is, contexts). The interpretation of the processes necessary for context estimation is consistent with recent neurophysiological studies in primates showing that the central nervous system models the expected sensory feedback for a particular context as well as representing the likelihood of the sensory feedback given the context.

CONCLUSION

Internal models are fundamental for understanding state estimation, prediction, context estimation, control and learning in the motor system. These processes are the basis for human motor behavior.

Multidimensional Scaling

Intermediate article

Mark Steyvers, Stanford University, Stanford, California, USA

CONTENTS

Multidimensional scaling is a family of techniques for fitting spatial distance models to proximity data for the purpose of exploratory data analysis and/or analysis of the structure of mental representations.

ASSUMPTIONS OF MULTIDIMENSIONAL SCALING

Multidimensional scaling (MDS) describes a family of techniques for the analysis of proximity data on a set of stimuli to reveal the hidden structure underlying the data. The proximity data can come from similarity judgments, identification confusion matrices, grouping data, same–different errors, or any other measure of pairwise similarity. The main assumption in MDS is that stimuli can be described by values along a set of dimensions that places these stimuli as points in a multidimensional space, and that the similarity between stimuli is inversely related to the distances of the corresponding points in the multidimensional space.

The Minkowski distance metric provides a general way to specify distance in a multidimensional space:

$$d_{ij} = \left[\sum_{k=1}^{n} |x_{ik} - x_{jk}|^r\right]^{1/r} \quad (1)$$

where n is the number of dimensions, and x_{ik} is the value of dimension k for stimulus i. With $r = 2$, the metric equals the Euclidian distance metric while $r = 1$ leads to the city-block metric. A Euclidian metric is appropriate when the stimuli are composed of integral or perceptually fused dimensions such as the dimensions of brightness and saturation for colors. The city-block metric is appropriate when the stimuli are composed of separable dimensions such as size and brightness (Attneave, 1950). In practice, the Euclidian distance metric is often used because of mathematical convenience in MDS procedures.

MDS can be applied with different purposes. One is exploratory data analysis; by placing objects as points in a low dimensional space, the observed complexity in the original data matrix can often be reduced while preserving the essential information in the data. By a representation of the pattern of proximities in two or three dimensions, researchers can visually study the structure in the data.

It has been used also to discover the mental representation of stimuli that explains how similarity judgments are generated. Sometimes, MDS reveals the psychological dimensions hidden in the data that can meaningfully describe the data. The multidimensional representations resulting from MDS are also often useful as the representational basis for various mathematical models of categorization, identification, and/or recognition memory (Nosofsky, 1992) or generalization (Shepard, 1987).

Some of the issues in MDS can be illustrated with the analysis of a face similarity judgment task. In Figure 1(a), the average of a group of subjects' similarity ratings is given for 10 faces shown in Figure 1 (c). The idea is to reveal some of the perceptual dimensions that subjects might have used when generating similarity judgments for these faces.

TECHNIQUES FOR MDS

There are many different MDS techniques to analyze proximity data and many issues in the analysis and interpretation of the results. First, there is the distinction between metric and nonmetric MDS. The goal of metric MDS is to find a configuration of points in some multidimensional space such that the interpoint distances are related to the experimentally obtained similarities by some transformation function (e.g. a linear transformation function). If the proximity data are generated with Euclidian distances for some stimulus configuration, then a procedure called classical metric MDS (Torgeson, 1965) can exactly recreate the configuration of points. Because a closed-form solution exists to find such a configuration of points, classical metric MDS can be performed efficiently on

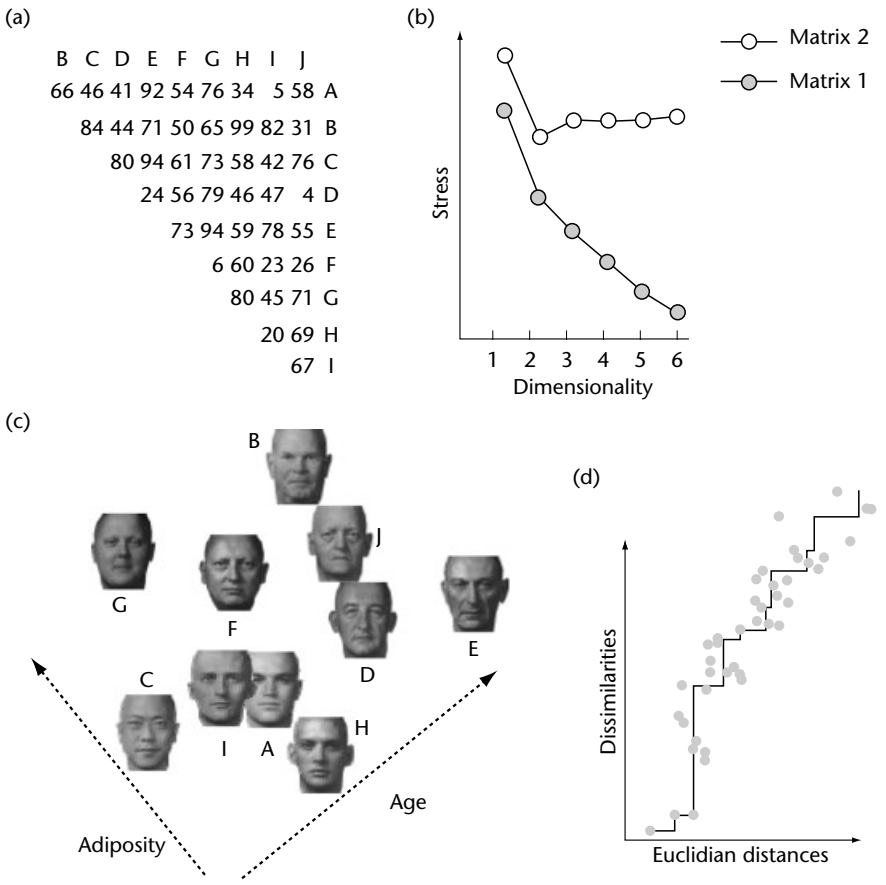

Figure 1. Analysis of a face similarity judgment task. (a) The average of a group of subjects' similarity ratings; (b) scree plot, for selecting dimensionality; (c) two-dimensional (age, adiposity) scaling solution for the 10 faces; (d) Shepard plot, showing the relationship between predicted distances and observed dissimilarities.

large matrices. In nonmetric MDS (first devised by Shepard in 1962), the goal is to establish a monotonic relationship between interpoint distances and obtained similarities. The advantage of nonmetric MDS is that no assumptions need to be made about the underlying transformation function; the only assumption is that the data are measured at the ordinal level.

Kruskal (1964) proposed a measure for the deviation from monotonicity between the distances d_{ij} and the observed dissimilarities o_{ij} called the *stress* function:

$$s = \sqrt{\frac{\sum_{ij} (d_{ij} - d_{ij}^*)^2}{\sum_{ij} {d_{ij}}^2}} \qquad (2)$$

Note that the observed dissimilarities o_{ij} do not appear in this formula. Instead, the discrepancy between the predicted distances d_{ij} and the target distances d_{ij}^* are measured. Based on the current configuration of points, the target distances d_{ij}^* are found by monotonic regression and represent the distances that are monotonically related to the observed dissimilarities o_{ij}. Several iterative minimization algorithms exist to move the object points in a multidimensional space in order to minimize stress (see Borg and Groenen, 1997).

In the face similarity example, Figure 1(d) displays what is known as the Shepard plot. It shows the relationship between predicted distances d_{ij} (for the two-dimensional scaling solution in Figure 1(c)) and observed dissimilarities as filled circles, and can serve to decide what metric transformation would be appropriate to relate one to the other. The line in the plot shows the relationship between the target distances d_{ij}^* found by monotonic regression and observed dissimilarities. Kruskal stress essentially is a measure based on the sum of the squared deviations between the filled circles and the line along the abscissa.

Another distinction in MDS is between weighted MDS, replicated MDS, and MDS on a single matrix

(Young and Hamer, 1994). In replicated MDS, several matrices of similarity data can be analyzed simultaneously. The matrices are provided by different subjects or by a single subject tested at multiple times, and a single scaling solution captures the similarity data of all matrices through separate metric or nonmetric relationships for each matrix. This approach can take individual differences in response bias into account. In weighted replicated MDS (e.g. INDSCAL: Carroll and Chang, 1970), the dimensions in the scaling solution can be weighted differently for each subject or subject replication, to model differences in attention or sensitivity for the different dimensions.

Finally, there is the distinction between deterministic and probabilistic MDS. In deterministic MDS, each object is represented as a single point in multidimensional space (e.g. Borg and Groenen, 1997) whereas in probabilistic MDS (MacKay, 1989), each object is represented as a probability distribution in multidimensional space. In understanding the mental representation of objects, this last approach is useful when representation of objects is assumed to be 'noisy' (i.e. the presentation of the same object on every trial gives rise to different internal representations).

An important issue in MDS is choosing the number of dimensions for the scaling solution. A configuration with a high number of dimensions achieves very low stress values but cannot easily be comprehended by the human eye, and is apt to be determined more by noise than by the essential structure in the data. On the other hand, a solution with too few dimensions might not reveal enough of the structure in the data.

A well-known method to select the dimensionality is the scree test (also known as the elbow test) where stress (or other lack-of-fit measure) is plotted against the dimensionality. Ideally, this choice is visually obvious from the 'elbow' in the scree plot where, after a certain number of dimensions, the stress is not reduced substantially. However, in many data sets, stress decreases smoothly with increasing dimensionality, making the choice of appropriate dimensionality very difficult with this method. In Figure 1(b), the filled circles show the scree plot for the face similarity data set. Note that a slight elbow is present at two dimensions, which suggests that a two-dimensional configuration might be appropriate.

A more salient indicator for the appropriate dimensionality can be obtained by cross-validation. The idea is to test how the configuration optimized to model the proximity data for one group of subjects can generalize to the proximity data of a different group of subjects. In Figure 1(b), the open circles show the stress value for a second group of subjects, with a clear rise in stress value after two dimensions while the stress continues to decrease for the first group of subjects. In this case, it seems reasonable to conclude that a two-dimensional configuration is appropriate because it can best generalize to other subjects. Lee (2001) has explored other techniques to determine dimensionality based on balancing the trade-off between model fit and model complexity.

Another important issue is the interpretation of the scaling solution resulting from MDS procedures. If the proximity data were generated by a function of the distances along some set of dimensions, then the resulting configuration of points in a scaling solution should reflect those dimensions. However, often Euclidian distances are used in scaling procedures so that the orientation of axes in the resulting configuration is arbitrary: any rotation of the axes would result in the same distances (and therefore stress). In such cases, the researcher can either visually scan the configuration in order to choose an orientation of axes that leads to interpretable results, or apply less arbitrary procedures by multiple regression analyses. In such analyses, the idea is to regress meaningful variables on the coordinates for the different dimensions and rotate the solution so as to maximize the interpretability. In Figure 1(c), the two-dimensional scaling solution is shown for the 10 faces. After visual inspection, the configuration can be interpreted as the perceptual dimensions of age and adiposity.

ADVANCES IN MDS

The success of the MDS approach arises in part from the simplicity of the underlying assumptions and the wide availability of computer software to create scaling solutions. Recent research has expanded the scope of the MDS approach in several directions. In Isomap (Tenenbaum *et al.*, 2000), stimuli are represented as points lying on a nonlinear manifold in some multidimensional space. Similarity is then computed as the geodesic distance on the manifold (i.e. the shortest distance along the manifold) as opposed to Euclidian distance in MDS. This technique is capable of discovering the nonlinear degrees of freedom that underlie complex data sets.

A drawback of most MDS algorithms is that a $N \times N$ matrix of similarity judgments is needed to scale N objects. Therefore, the number of similarity ratings needed depends quadratically on the number of objects, which leads to practical

limitations (e.g. subject time, number of subjects) on the number of objects that can be used in scaling studies. With modified MDS procedures, the amount of data that needs to be collected might be reduced. In the anchor point method (e.g. Buja *et al*., 1998), subjects rate all similarity pairs involving N objects and a smaller number of K anchor points that provide a representative sample of N objects. A modified MDS procedure then analyses the $N \times K$ similarity matrix in order to scale N objects. Future research will have to show how small K can become relative to N in order for this technique to make drastic savings possible in the similarity data collection.

Another recent advance in MDS models is the feature mapping approach (Rumelhart and Todd, 1992; Steyvers and Busey, 2000). In the traditional approach, the physical representation of the features comprising the stimuli is explicitly ignored. In such a purely top-down approach, the multidimensional representations are sometimes difficult to relate back to the physical stimulus by visual interpretation or regression analyses. In the feature mapping approach, in addition to the proximity data, additional physical measurement on the set of stimuli is available. The goal is to find a mapping between the set of physical measurements of a stimulus and the position of that stimulus in an abstract psychological space. With this approach, the multidimensional space is related directly to the physical dimensions of the stimuli.

CHALLENGES FOR MDS

Tversky and Hutchinson (1986) have argued that, for language-related stimuli that have conceptual as opposed to perceptual relations, geometric models based on MDS may fail to capture some aspects of the data and might therefore be inappropriate as a representational basis. For such stimuli, tree or graph-theoretic structures might be better suited than spatial/dimensional models based on MDS. Nevertheless, the geometric model of similarity has been applied to a wide variety of stimuli rich in conceptual structure. In 'latent semantic analysis' (Landauer and Dumais, 1997), words are placed in a high dimensional semantic space by a procedure related to MDS by analyzing the co-occurrence statistics for words appearing in contexts in a large corpus. In this semantic space, words with similar meaning are placed in nearby regions of the space. While the latent semantic analysis approach has been very successful in modeling human performance in a variety of semantic tasks, it remains to be seen to what degree a geometric model is appropriate to model language-related processes.

Also, for some highly structured objects, the simple geometric model for similarity as used in MDS may not be particularly revealing for analyzing the process of generating similarity judgments. In a geometric model, it is assumed that the set of objects can be described by a fixed collection of feature values where the process of generating similarity judgments is always based on the differences for the same set of features. However, for highly structured or complex objects, the features that play a role in the similarity judgments may differ depending on what objects are compared. In alignment models (Goldstone, 1994), similarity is assessed dynamically by an alignment process that analyzes which features play corresponding roles in the objects that are compared.

CONTENTS

Music cognition addresses the mental activities involved in perceiving, learning, remembering, and producing music.

INTRODUCTION

Music cognition addresses the mental activities involved in perceiving, learning, remembering, and producing music. Most of these mental activities are implicit and unconscious; even listeners without musical training can make sophisticated judgments about music. Psychological studies of music include perception of sound properties, understanding of pitch and rhythm, development of musical abilities, musical skill and performance, and parallels with language.

PERCEPTION OF SOUND PROPERTIES IN MUSIC

Four qualities of sound are especially important in music perception: pitch, duration, loudness, and timbre. Pitch arises from the perception of a sound wave's frequency (number of vibrations per second); loudness arises from the perception of amplitude or intensity (sound pressure change); duration is the perception of the time over which a sound is heard. Most musical instruments produce complex sound waves, which contain several frequencies (called harmonics) and amplitudes that change over time; timbre arises from the perception of these harmonics and their onsets (called attack transients). The lowest frequency in a complex tone, called the fundamental frequency, determines the perception of pitch.

UNDERSTANDING OF PITCH AND RHYTHM

Pitch and rhythm may be the most psychologically important dimensions of music. Most music in Western cultures, including classical, rock, and jazz styles, is based on 12 pitch classes, referred to as tones C, D, etc. (Music in most cultures uses pitch classes, but they are often tuned to different frequencies.) Tones whose frequencies differ by a factor of two, called an octave, are perceived as having the same pitch quality or 'chroma' and belong to the same pitch class. Each musical piece is composed primarily of tones from seven of the pitch classes, called a diatonic scale. Major and minor scales are defined for each pitch class by the intervals (number of pitch steps) between the tones. The key often refers to the pitch class from which the scale is built. There is a hierarchy of relative importance among tones in a key; tonality is the perception of pitches in relation to the tonic, the central prominent tone. Interestingly, each tone is perceived differently, depending on its key context. For example, the tone C is perceived as most important (the tonic) in the key of C and less important in the key of F.

Despite this complexity, listeners' understanding of pitch structure does not require explicit training. The statistical regularity with which tones, chords, and keys occur provide enough information for listeners to identify the tonic, or judge two tones as related. Tones that occur more often are perceived as more stable or less likely to change. Listeners can recognize a familiar melody based on the up-and-down pattern of pitch changes, called the melodic contour, even when the pitch classes have changed. With training, most listeners acquire the ability to name the pitch of a tone in relation to other pitches, called relative pitch. A few listeners have absolute pitch, or the ability to name pitches heard in isolation (without a reference pitch). Acquisition of absolute pitch may be related to the age at which musicians first learn to name pitches.

When listeners tap along with music, they are often responding to the rhythm: a temporal pattern that arises from many variables, including duration (from a tone's onset to its offset) and inter-onset interval (from one tone's onset to the next tone's onset). Meter and tempo also influence the perception of rhythm. Meter is a regular alternation of strong and weak beats in twos (such as marches) or threes (such as waltzes) at many hierarchical temporal levels. Tempo is the pace or rate of music; listeners show preferences for tempi around 300–900 ms per beat. People tend to tap and reproduce rhythms accurately at this tempo, suggesting that an internal pulse operating around this tempo guides perception and performance.

Music perception reflects a combination of pitch and rhythm at several hierarchical levels. Listeners tend to segment music into short groups: a group is a set of successive tones that are related. The perception of group boundaries is influenced by accents, or tones that stand out from others, caused by changes in pitch, duration, intensity, or timbre. Listeners also segment simultaneous or overlapping tones into perceptual parts or voices, called streams. Stream segregation is thought to reflect innate, 'bottom-up' perceptual processes, unaffected by general knowledge. Music perception is also influenced by 'top-down' knowledge: well-learned schemas, or acquired knowledge of tonal or metrical relationships. Schemas influence listeners' expectations and aid their memory for music. Schemas may also contribute to listeners' emotional response to music: schemas generate unconscious expectations for upcoming events, and musical events often occur that conflict with schematic expectations. Listeners experience arousal and an emotional response to the musically unexpected events.

DEVELOPMENT OF MUSICAL ABILITIES

Studies of musical development often focus on infants' responses, measured by attentiveness or listening preferences, because infants allow a test of which musical abilities are established prior to much musical exposure. Infants are typically exposed to certain types of music, including lullabies and play-songs sung by parents and other caregivers. Songs that adults sing to infants are higher in pitch, slower in tempo, and more expressive overall than the same songs sung to adults. By seven months old, infants are more attentive to these infant-directed songs than to other forms of singing.

Many basic perceptual abilities of infants resemble those of adults. For example, infants and adults are sensitive to the same pitch and rhythmic dimensions of music. Infants recognize the equivalence of pitches that are an octave apart. Around six months old, infants' babbling in response to music often preserves the melodic contour, and they respond the same way to melodies whose specific pitches are altered, as long as they retain the same melodic contour. By six months old, infants can produce body movements in response to the musical rhythm and they are sensitive to changes in tempo and rhythm. Finally, six-month-old infants prefer music that is segmented into natural phrase units more than music that is segmented in the middle of phrases (see example shown in Figure 1). Thus, infants attend to and group musical sequences according to the same perceptual principles as adults.

Other musical abilities develop with further musical exposure. By two to three years old, children spontaneously produce novel musical phrases in song, and can repeat short phrases accurately; by four or five years old, they can accurately imitate musical rhythms. By seven years old, children are sensitive to at least two metrical levels in musical rhythm; with musical training, adults show sensitivity to more metrical levels. Implicit knowledge of chord and key relationships also increases with musical exposure; the perception of hierarchical tonal relationships begins around the age of seven, but continues to develop into adulthood.

Figure 1. Example of natural (top) and unnatural (bottom) musical phrase segments in 'Twinkle, twinkle, little star'.

Interestingly, adults become less sensitive than infants to musical changes that preserve typical, schematic relationships of well-learned musical styles.

MUSICAL SKILL AND PERFORMANCE

Music performance is a rapid, fluent motor skill. Most people hum, clap, or perform in other ways that reflect sophisticated musical skills. Scientific studies of music performance, aided by computer-monitored musical instruments, focus on several cognitive and motor factors: segmenting and retrieving structural units from memory, coordinating motor movements, communicating structure and emotion with expressive features, and acquiring these skills.

Performers do not mentally prepare entire musical pieces at once, but instead segment them into smaller units such as phrases. In eye–hand span tasks, pianists are shown music notation briefly and then perform from memory; they recall musical segments that fit within short-term memory constraints. Errors in memorized performance indicate memory constraints on how far ahead performers can plan. Performance errors often result in tones that are similar to the intended tones in harmony, key, or meter. Thus, performers' musical knowledge reflects the same harmonic, diatonic, and rhythmic structures as listeners' knowledge.

After musical events are retrieved from memory, they must be transformed into appropriate movements. Internal clocks or timekeepers regulate and coordinate the production of different parts of a performance, such as hands in instrumental playing or performers in ensembles. Performers are more accurate at reproducing musical rhythms whose durations form simple ratios (1:1 or 2:1) that coincide with a simple internal timekeeper, than those whose durations form complex ratios (3:2 or 4:3). Musical motion is often compared to physical motion; for example, performers reduce the tempo near phrase boundaries at a rate similar to slowing down from a run to a walk.

Performers communicate musical structure and emotion to listeners through acoustic variations in frequency, amplitude, duration, and timbre, often termed 'expression'. Expression differentiates one performance from another, similar to how prosody (the rhythm and intonation of speech) differentiates one speaker from another. Expressive features of performance often coincide with structurally important events, such as metrical accents or phrase boundaries. Expressive features also signal emotional content; 'happy' tunes tend to be performed louder and faster than 'sad' tunes. Emotional content is linked to musical structure in performance: the expressive performance features that convey emotion tend to coincide with unexpected (less likely) structural features. (*See* **Prosody**)

How are performance abilities acquired? With short-term practice (hours), performers segment music into larger units, anticipate future events more, and increase expressive features. With long-term experience (years), performers monitor and adjust their performances better, refine expressive features, and extend their knowledge of how to perform one melody to unfamiliar melodies. Individual differences in performance skills are tied in part to accumulated practice over a lifetime. General memory and motor factors in performance increase most during the first few years of skill acquisition, whereas sensitivity to specific musical features such as phrase structure and meter increases across all skill levels.

PARALLELS BETWEEN MUSIC AND LANGUAGE

Music and language show interesting parallels in their structure and in how people perceive and produce them. They are found in all human cultures, and children spontaneously acquire both. Potentially universal mental activities in language and music include: auditory grouping/segmentation strategies; rhythmic structure in perception and production; and grammatical rules that influence understanding of music and language.

Listeners segment a continuous stream of sound into discrete units in speech and music. Two basic perceptual principles influence segmentation in both domains: first is sensitivity to acoustic changes or contrasts that define the boundaries of a unit, such as attack transients that occur at musical tone onsets or noise bursts at phoneme boundaries. Contrasts also mark larger units, such as changes in tempo (slowing down) that mark phrase boundaries in both music and speech. Second is sensitivity to periodic or repeating patterns, such as meter in music and in language. Memory limitations also influence segmentation: for example, the size of musical and verbal phrases is usually within short-term memory limits.

Rhythmic structure influences the relative importance that listeners attribute to individual elements in both music and speech, especially poetry. Tones (music) and syllables (speech) are accented in production with higher pitch, longer duration, and greater amplitude, which lead to the perception of rhythm. Music and speech commonly build

on a foundation of alternating strong and weak beats or pulses. Although human speech is not as rhythmically regular as most music, listeners tend to perceive alternating strong and weak stresses as rhythmically regular in both domains, and rhythmically regular music and language are better remembered.

Finally, humans have the capacity to understand an unlimited number of melodies or sentences: a grammar is a model of this capacity. Grammars, or a limited set of rules that generates an unlimited number of sequences, have been proposed for music as well as language. A compositional grammar can generate music in a particular style, such as counterpoint or jazz. A listening grammar applies a set of rules or implicit knowledge of the acceptable combinations of tones, chords, and rhythms in a musical style. The result is the perception of musical units such as phrases, hierarchical relationships among units, and harmonic or tonal tension and relaxation. A challenge for listening grammars is to accommodate different but equally correct segmentations of the same music. Thus, one difference between musical and linguistic grammars is that music is more flexible and less constrained in its grammar than language.

CONCLUSIONS

Scientific study of musical abilities has grown tremendously since the early 1990s, due to technological advances and theoretical overlap with related fields in cognitive science such as artificial intelligence, linguistics, neuroscience, and philosophy. Related topics include neural bases and computational models of musical behavior. Although music may be a specialized human ability, it is not special in its underlying perceptual, memory, and motor components.

Naive Theories, Development of

Intermediate article

Susan A Gelman, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

A naive theory (also referred to as commonsense theory or folk theory) is a coherent set of knowledge and beliefs about a specific content domain (such as physics or psychology), which entails ontological commitments, attention to domain-specific causal principles, and appeal to unobservable entities.

INTRODUCTION

Children construct naive theories of physics, psychology, and biology by preschool age, with precursors in infancy. These theories provide a framework for children's developing knowledge, but also embody misconceptions that persist into adulthood.

ORIGINS OF NAIVE THEORIES AND DOMAIN KNOWLEDGE

Early in childhood, children begin to form bodies of knowledge, beliefs, and reasoning in several core domains, including language, physical objects, biological processes, psychological states, numerical reasoning, and spatial reasoning. What type of account best explains the development of such knowledge? The most prominent accounts are those referring to modules, to expertise, and to theories.

Modular approaches typically assume that domain-specific knowledge is innately constrained, biologically determined, and invariant in developmental outcome, and prime examples include the visual system or human language (syntax). Expertise approaches focus on the role of experience, attention, and practice in the gradual accrual of expertise in these domains, with attendant high variability in developmental outcomes. Example domains of expertise include reading, knowledge about dinosaurs, and chess; see, for example, Chi (1978). In contrast to both these positions, naive theories are characterized as undergoing important restructuring over time, and as informed (within broad constraints) by input and cultural beliefs. Candidate domains for theories that emerge early in childhood include psychology (Wellman, 1990), physics (McCloskey, 1983) and biology (Keil, 1994).

Evidence for naive theories (also known as commonsense or folk theories) includes ontological commitments, attention to domain-specific causal principles, appeal to unobservable entities, resistance to counterevidence, and coherence of beliefs (Carey, 1985). Ontological kinds reflect the basic categories of what sorts of entities there are in the world, and differ by domain (e.g. a folk theory of psychology concerns mental entities such as beliefs and desires, whereas a folk theory of physics concerns physical entities such as objects and substances). Naive theories also entail domain-specific causal explanations (e.g. the law of gravity cannot apply to mental states). Unobservable entities (e.g. gravity, beliefs, germs) are invoked to provide explanatory constructs that make sense of overt evidence (e.g. objects falling, people's actions, illness).

Naive theories are distinct from scientific theories in several major respects. Naive theories provide abstract frameworks for interpreting information, and thus are neither as precise nor as explicit as scientific theories. Thus, a child maintaining a naive theory of object motion and mechanical causation would be unable to state the assumptions or principles of the theory, although the child's expectations and predictions would be consistent with a set of implicit assumptions and principles. Indeed, the processes of reflection, awareness, and articulation appear to increase with development and themselves bring about theory change (Karmiloff-Smith, 1992). Naive theories are also not as accurate as scientific theories, though they may share striking similarities with them (e.g. Atran, 1990). Moreover, the process of naive theory construction

differs from the scientific process. Indeed, children have notorious difficulty with crucial scientific reasoning tasks, and for example fail to test systematically all possibilities to determine a causally relevant variable (Inhelder and Piaget, 1958). Changes in such capacities continue throughout childhood and into adulthood.

NAIVE PHYSICS

A naive theory of physics is concerned with the existence, movements, and interactions of physical objects, and the physical effects of such movements and interactions. Important components appear to be in place in early infancy. Four-month-old infants expect physical objects to move on paths that are connected (continuity constraint) and not to move through physical obstructions (solidity constraint). By 6 months of age, infants appreciate that the motion of inanimate objects requires direct physical contact. Other components develop later, with time and experience; for example, an expectation that objects will obey the law of gravity and a capacity to gauge the degree of contact needed for an object to be supported by a surface (e.g. Baillargeon *et al*., 1995).

Some of the experimental evidence that is interpreted as support for an early-developing naive physics stands in sharp contrast with traditional accounts of cognitive development, according to which infants are incapable of grasping even the most rudimentary physical principles. For example, Piaget's classic work on the object concept (Piaget, 1955) seemed to demonstrate that until about 12 months of age, children tend to assume that objects that disappear from sight no longer exist (a lack of 'object constancy'). In contrast, experiments indicate that infants as young as 3–5 months of age can track the existence of objects hidden behind a barrier and even reason about their size and numerosity (e.g. Baillargeon *et al*., 1995). These striking differences in research findings can be attributed to fundamental methodological differences: Piaget's work examined infants' overt search behaviors, include reaching and grasping; tasks finding early competence typically examine infants' gaze and dishabituation of gaze.

Naive physics continues to influence human reasoning throughout childhood and into adulthood. Adults appear to be remarkably resistant to input that would refute errors in their naive physical theories. For example, even those who have had college-level instruction in physics continue to err on some simple physical reasoning tasks, such as predicting the trajectories of balls rolling out of curved tubes (McCloskey, 1983).

NAIVE PSYCHOLOGY

A naive theory of psychology is often referred to as a 'theory of mind'. Interpreting behavior in a coherent, mentalistic framework is crucial for many tasks, including predicting and explaining the actions of others, engaging in deception, understanding and engaging in pretense, forming attachments to imaginary companions, and learning word meanings; see Wellman (1990) for a review. For example, if I know that you left your keys in the kitchen but I see you looking for them in the bedroom, then I can infer that you mistakenly believe that you left your keys in the bedroom.

Early accomplishments are found in children as young as 3 years of age, who accurately reason about mental states such as emotions and desires, understand links between perception and knowledge, and correctly distinguish mental from physical entities (Wellman, 1990). Between 3 years and 5 years of age, there is an important shift in children's reasoning about false beliefs. For example, consider a scenario in which the child is shown that a crayon box has unexpected contents (a toy truck instead of crayons), but another person is not shown the contents of the box. In other words, the child has access to information that the other person does not. When presented with a scenario of this sort, 3-year-old children typically make the error of attributing knowledge to the ignorant person (stating that the other person will say that the crayon box contains a toy truck), erroneously assuming that the person's beliefs will match objective reality. In contrast, 5-year-old children recognize that the other person does not have the same knowledge state, thus appropriately recognizing that subjective beliefs may conflict with objective reality. By 5 years of age, children are skilled in reasoning about a wide array of psychological tasks, and recognize that even potent mental states (e.g. visual imagery, dreams) are distinct from physical reality, that thoughts are subjective, and that psychological entities (in the form of beliefs and desires) explain and predict people's actions (Wellman, 1990). An exception to these general findings is that autistic children are considerably impaired in their naive psychological reasoning (Baron-Cohen *et al*., 1993).

Even infants appreciate some components of a naive psychology. By 18 months of age, infants distinguish intentional from accidental action when imitating an adult model (Meltzoff, 1995)

and learning a new word (Tomasello and Barton, 1994), and appreciate the subjectivity of desires and their link to emotions (Repacholi and Gopnik, 1997). Together, these findings contradict traditional claims by Piaget (1929) that young children are realists and are confused by the distinction between mental and physical phenomena.

NAIVE BIOLOGY

A naive theory of biology is concerned with classification of the world of living things (animals and plants), reasoning about biological processes such as growth, illness and reproduction, and distinguishing living from nonliving entities. There is controversy about when a naive theory of biology develops. Some have proposed that biology emerges as a new domain, out of psychology, in middle childhood (Carey, 1985). According to this view, young children account for biological processes by appealing to psychological explanations (explaining that people eat because they are hungry, rather than because their body needs nutrients). In contrast, others argue that biology is an independent theory domain from preschool age or earlier (Keil, 1994).

This debate seems to reflect the incomplete state of children's biological knowledge and thus leads to arguments over what constitutes a theory. At the very least, by preschool age children have certain clear understandings of how biological entities are distinct from both psychological entities and inanimate objects. For example, 4-year-old children recognize that biological processes (e.g. growth, heartbeat) are not under direct conscious control (Inagaki and Hatano, 1993) and that physical illnesses are contagious in a way that psychological disorders are not (Keil, 1994). Furthermore, preschoolers appreciate that there are numerous processes that apply only to living things, including growth, self-generated motion, illness, healing, and teleological action (Gelman and Opfer, 2002). Further evidence that naive biology is operating as a domain for young children is that preschoolers appeal to nonobvious constructs (namely, germs and invisible particles) to explain the biological processes of contamination and illness (e.g. Kalish, 1996). Furthermore, by 3 years of age children treat living kind categories as if they have a category essence (Gelman *et al*., 1994). Much less is known about biological reasoning in children below preschool age, including infants and toddlers.

As with naive theories of physics, naive theories of biology give rise to predictable errors and biases, including a tendency toward vitalism (Inagaki and Hatano, 1993) and creationism (Evans, 2000), and the persistence of certain folk-biological categories that have no scientific counterpart (Atran, 1990).

Natural Kinds and Artifacts

Intermediate article

Susan A Gelman, University of Michigan, Ann Arbor, Michigan, USA

CONTENTS

Natural kinds are categories of things found in nature (e.g. living things, natural substances); artifacts are categories of things created by humans (e.g. furniture, clothing). These two distinct sorts of concepts differ in their implications for human reasoning.

INTRODUCTION

Natural kind concepts and artifact concepts differ from one another in several important respects, with consequences for human reasoning. These differences are found in young children as well as adults.

PHILOSOPHICAL AND PSYCHOLOGICAL DISTINCTION

Human concepts are not all alike, and the ways in which they differ have important implications for human reasoning. One fundamental distinction is based on content domain, specifically, natural kinds versus artifacts. Natural kinds are categories of naturally occurring things (including animals, plants, naturally occurring substances such as gold, and natural formations such as stars); artifacts are categories of entities created by humans (e.g. tools, vehicles, clothing, toys, etc.). The distinction between natural kinds and artifacts rests in the *category* under consideration, and does not apply to objects *per se*. For example, a yellow, metal circle can be construed as either a substance (gold) or an object (ring). It is only when one considers the category to which the object is assigned that one can determine whether it is a natural kind (gold) or artifact (ring).

The distinction between natural kinds and artifacts has implications beyond content alone, although these differences are of degree and not absolute. Natural kind categories are hypothesized to differ from artifact categories in at least four major respects (see Schwartz, 1977). First, natural kinds have *rich inductive potential*, so that we can infer indefinitely many novel properties about members of a natural kind, based on information about just one or a few instances (Gelman, 1988). Thus, for example, upon learning a set of facts about one tapir (what it eats, where it sleeps, the number of bones in its skeleton, its resting body temperature, its method of hunting prey, the organization of the structures in its brain, the location of its spleen, etc.), we readily infer that other tapirs are likely to have the same properties. Although artifacts also have inductive potential, it tends to be more limited (consider, for example, the inductive potential of the categories CUP or HAT). Second, natural kinds are treated as having a hidden, nonobvious *essence* that is responsible for the other properties that category members share (e.g. DNA for animals; H_2O for water; Medin, 1989), and that enables constancy over transformations (e.g. from infant to adult; from caterpillar to butterfly). Artifacts do not possess an intrinsic physical essence in the same respect, although the intentions of the person who designed the object can be considered crucial to artifact identity (Bloom, 2000). Third, natural kinds are named in accord with a *division of linguistic labor*, such that meanings are not fully contained within a speaker but are determined in part by a community of experts. Thus, most individual speakers cannot distinguish diamonds from zircons, but instead rely on gem specialists (Putnam, 1975). Some artifacts also have such a division of labor (e.g. carburetor), although others do not (e.g. ball). Fourth, natural kind categories are universally organized into *taxonomic hierarchies* (e.g. beagles are a kind of dog; dogs are a kind of mammal; mammals are a kind of animal). Artifacts appear to fit less neatly into taxonomic hierarchies (e.g. Atran, 1990; but see Rosch *et al*., 1976).

Altogether, these domain distinctions reflect ordinary speakers' implicit assumptions that natural kind categories are 'real' (e.g. one discovers a natural kind category, such as tiger) whereas

categories of artifacts are artificial (e.g. one invents an artifact category, such as shoe). However, both natural kind and artifact categories are human constructions, and the properties listed above are *psychological* claims concerning these human constructions – not metaphysical claims concerning the structure of the world.

DIFFERING INDUCTIVE POTENTIAL

Induction is one of the central functions of categories. All categories permit inductive inferences concerning novel properties, which in turn allow us to expand our knowledge about the world. Even preverbal infants appreciate the inductive potential of categories (Baldwin *et al*., 1993). None the less, one of the most striking differences between natural kinds and artifacts is that the former allow a greater extent of inductive inferences, including inferences concerning non-obvious properties and inferences to atypical category members.

When research participants are given a choice between extending a novel fact on the basis of membership in a natural kind category versus outward appearances, they tend to favor category membership (Gelman and Markman, 1986). For example, adults learned that a particular flamingo has a right aortic arch and that a particular bat has a left aortic arch (novel and unfamiliar properties). When asked about the cardiac structure of a blackbird (physically more similar to the bat than to the flamingo), they inferred that it has a right aortic arch, like the flamingo, as both are members of the category 'bird'. Similarly, when 4-year-olds received the same task, but with simpler properties (e.g. the flamingo 'feeds its baby mashed-up food'; the bat 'feeds its baby milk'), they too tend to favor category membership. Further studies indicate that children as young as 2 and 3 years of age expect category members to share important, non-obvious similarities, even in the face of salient perceptual dissimilarities. For example, upon learning that an atypical exemplar is a member of a category (e.g. that a flying fish is a fish), children and adults draw novel inferences from typical instances to the atypical member (Gelman and Markman, 1986). By 7 to 8 years of age, children draw more inductive inferences within natural kind than artifact categories (Gelman, 1988).

ESSENTIALISM AND PSYCHOLOGICAL ESSENTIALISM

Philosophers have long suggested that members of a category share a non-obvious, immutable core (or essence) that confers identity and predicts a vast array of other properties. On this view all humans, for example, have something deep and hidden in common that makes them human. Specific essentialist construals can be found in concepts as divergent as *soul* and *DNA*, though essentialism may also be an unarticulated, placeholder notion – a belief *that* a category has a core, without knowing *what* that core is (Medin, 1989). For example, a child might believe that girls have some inner, non-obvious quality that distinguishes them from boys and that is responsible for the many observable differences in appearance and behavior between boys and girls, before ever learning about chromosomes or human physiology. Thus, psychological essentialism requires no specialized knowledge.

It is important to distinguish between essentialism as a philosophical position and psychological essentialism as a folk belief. The former addresses the nature of reality (a metaphysical question); the latter addresses the nature of people's ordinary belief systems (a psychological question). Psychological essentialism is a human reasoning bias that may not accurately characterize biological species (e.g. Sober, 1994). There is widespread agreement that essentialist construals of race, though ubiquitous, are deeply flawed (see Hirschfeld, 1996; Templeton, 1998).

Experimental studies of essentialism have documented that natural kind categories have the following properties: a non-obvious basis (natural kind categories are based on 'hidden' features that can yield classifications that contradict surface appearances, e.g. leading us to classify whales as mammals, to classify legless lizards as lizards instead of snakes, and to consider caterpillars and butterflies to be different stages of the same kind of animal), anomalous instances (e.g. an albino, dwarf tiger is still a tiger, even though it more closely resembles a domesticated cat), and constancy of identity over transformations.

One of the strongest pieces of evidence for the latter comes from Keil (1989), who asked research participants to consider hypothetical scenarios such as the following: an entity can be altered through surgical means so that in appearance and behavior it in no way resembles its original incarnation. For example, a raccoon is (hypothetically) operated upon so that it resembles a skunk in every outward respect (size, coloration, shape, odor, behavior). By 7 to 8 years of age, children who hear such stories report that the animal is still a raccoon, despite its appearance and behavior. Importantly, such transformation stories yield very different

results for artifacts. Thus, a coffee pot transformed into a bird feeder is reported to change in fact into a bird feeder. Adults likewise treat the animal transformations as immaterial, but the artifact transformations as affecting identity.

Further evidence for an essentialist bias can be found in studies indicating that young children (in some studies, as young as 4 years of age) judge nonvisible internal parts to be especially crucial to the identity and functioning of an item. These expectations are evident in children's concept learning, judgments of identity, and word learning (see Bloom, 2000, for review).

The finding that young children hold essentialist beliefs thus suggests that human concepts are not constructed atomistically from perceptual features. More generally, these findings illustrate the independence of similarity and category membership in human reasoning (Smith *et al*., 1998).

DEVELOPMENT OF SENSITIVITY

The possible roots of reasoning about natural kinds, particularly essentialism, have been much disputed. Some investigators have suggested that essentialism is a by-product of Western philosophy (dating back to Plato in the fourth century BC) or Western cultural traditions (Rorty, 1979), or a reflection of access to scientific processes and knowledge available to the lay audience (e.g. given the discovery of microscopic organisms, DNA, and other nonobvious entities). In contrast to these positions, the evidence briefly summarized above suggests that children are essentialists long before formal schooling. It is therefore unlikely that either Western philosophy or scientific theories are prerequisites to essentialism. The developmental findings provide particularly strong evidence, given children's well-documented focus on object appearances on many cognitive tasks (Inhelder and Piaget, 1964).

Recent research has begun to examine the roots of the natural kind–artefact distinction by examining a related distinction in infancy, the animate–inanimate distinction (see Rakison and Poulin-Dubois, 2001, for review). The animate–inanimate distinction appears fundamental in brain organization (Caramazza and Shelton, 1998), and may be the basis of an eventual distinction between natural kinds and artifacts. Preverbal infants distinguish animals from inanimate objects, making use of both featural information (e.g. faces, contour) and dynamic information (e.g. autonomous motion, contingent motion). The distinction is then recruited in infants' conceptual understanding of the world, with respect to socio-emotional understandings, theory of mind, and predictions of actions (see Gelman and Opfer, 2002, for review). In older children, the animate–inanimate distinction guides children's reasoning about a vast range of concepts, including contagion, teleology, language, and theory of mind (Gelman and Opfer, 2002). Thus, the animate–inanimate distinction, like the natural kind–artifact distinction, organizes much of human knowledge.

Neuropsychological Development

Introductory article

Michelle de Haan, University College London, London, UK
Mark H Johnson, Birkbeck College, London, UK

CONTENTS

Neuropsychological development concerns the growth in the structure and function of the brain and nervous system in relation to mind and behavior, and has been shown to involve an interaction of genetic inheritance and environmental experience.

INTRODUCTION

Humans' complex intellectual abilities are thought to be mediated by the extraordinary functional capacity of the cerebral cortex. It is often assumed that maturation of the cerebral cortex causes or allows specific advances in cognitive, perceptual, or motor abilities in infants and children. However, brain development is not merely the unfolding of a genetic plan that imposes itself on behavior in such a direct way. A striking characteristic of the development of the human brain is that it continues for a long period after birth. As a consequence, development is a period of plasticity during which the environment and the child's interactions in it can influence later phases of brain development. Thus, normal development of the brain depends on the interaction of genetic inheritance and environmental experience. (*See* **Early Experience and Cognitive Organization**)

THE ADULT CEREBRAL CORTEX

The cerebral cortex is a thin, flat sheet of cells (about 3–4 mm thick) which becomes increasingly convoluted, or folded, with both phylogenetic and ontogenetic development. Fitting the increasingly large brain into the skull causes the greater surface area to be compressed, like a crumpled sheet of paper, into that space. In humans, the cortex consists of six layers, each of which contains particular types of cells and has particular patterns of inputs and outputs. For example, much of the information perceived by our senses enters the cortex in layer IV. The mature cortex can also be divided into distinct functional areas based on variations in the cytoarchitectonics, or cell type and structure. The six layers are not equally thick in each of these areas, but rather each can vary in thickness according to the region's function. For example, layer IV, which receives sensory inputs, is thicker in primary visual cortex than in motor cortex.

The development of the cerebral cortex can be divided into four processes: (a) proliferation, or the dividing of cells to make new cells; (b) migration, or the movement of cells to their appropriate positions; (c) differentiation, or the acquisition by each cell of its unique characteristics such as shape and neurotransmitter type; and (d) myelination, or the covering of the neuron with a fatty sheath that speeds its communication of signals. As we shall see, these processes involve not only additive events, but also regressive events. (*See* **Neural Development**)

PRENATAL DEVELOPMENT OF THE CEREBRAL CORTEX

Proliferation of Neurons

Development of the nervous system begins from just a few cells in a sheet of tissue called the neural plate. By the third or fourth week of development, the edges of the neural plate begin to fold in to form a hollow structure called the neural tube. The ventricles of the brain and the spinal canal develop

from the hollow area inside the tube, while all of the cells that make up the brain develop from the layer of cells that line the tube. These neurons begin to rapidly divide, or proliferate, at approximately the sixth fetal week and they continue to divide until approximately the eighteenth week. It is commonly believed that after this time no new cortical neurons are ever formed, although some recent studies challenge this view and indicate that a relatively small number of neurons may continue to be formed in several areas of the adult cortex. (*See* **Neurogenesis**)

Neuron Migration

Neurons are not born in the exact position they will occupy in the adult cortex. Instead they must travel or migrate from the proliferative zone where they are formed to the position they will occupy in the mature cortex. This occurs through an active form of migration in which young cortical cells migrate past previously created cells towards the surface of the brain. Thus, neurons born earliest remain in the deepest layers of the cortex while neurons born later take positions closer to the surface, creating an 'inside-to-outside' pattern. Neurons find their way to the correct position with the help of support cells called radial glia, whose long fibres act like a climbing rope. Disruption of neuron migration can lead to disorders of brain structure and function. For example, in the migration disorder called lissencephaly, the cortex is abnormally thick, has only four layers, and shows an absence or decrease of surface folding. This condition is associated with profound mental retardation, seizures, and a short lifespan.

Over-production of Neurons and Programmed Cell Death

It is estimated that the average number of neurons in the adult human cortex is 21 billion. Yet during the course of development the number of neurons reaches an even higher level than that seen in adulthood. The normal development of the nervous system involves the programmed cell death of neurons to remove the excess cells. Certain neuron populations die through a process called apoptosis. In apoptosis, cells die as part of a gene expression-related program of cell differentiation. The balance within the cell of expression of 'pro-death' and 'anti-death' genes determines whether or not it will survive. Apoptosis is characterized by cell shrinkage, and thus is different from the process of necrotic cell death that occurs following brain damage, which is characterized by cell swelling.

There are several reasons why the seemingly wasteful process of programmed cell death may occur. One is that certain neurons may serve only a temporary purpose and die when they are no longer needed. For example, in the mammalian cerebral cortex, neurons located below the area where cortical neurons are forming provide a temporary target for subcortical neurons carrying sensory information. When the cortical neurons have formed and migrated to their proper positions, the subcortical projections retract their temporary connections to form new ones with these cortical neurons. The temporary target neurons are no longer needed and so are eliminated by programmed cell death. Another purpose for cell death is to allow the number of neurons innervating (providing input to) a target to match the size of the target. How many neurons survive is thought to be controlled by competition for a limited supply of growth factors supplied by their target tissues. A small target will produce a smaller amount of chemicals to promote the survival of neurons and thus would support relatively few neurons; in contrast, a larger target would produce more and thus would support more neurons. In this way, the number of neurons innervating a target can be precisely matched without this information having to be explicitly preprogrammed. For example, developing sympathetic neurons require a chemical called nerve growth factor for survival and die in its absence. Thus, targets could control their amount of innervation by sympathetic neurons through the amount of nerve growth factor they produce.

Programmed cell death is a normal part of prenatal brain development. There is some evidence that the elimination of surplus neurons may continue even into the first years of postnatal life; however, this is a continuing area of investigation. Inappropriate activation of the pathway for cell death in adults and children has been implicated in some neurological diseases, such as Parkinson's Disease and spinal muscular atrophy (an inherited childhood motoneuron disease).

POSTNATAL DEVELOPMENT OF THE CEREBRAL CORTEX

Once neurons have migrated to their final positions, they further differentiate to take on their mature characteristics. The differentiation of cortex into distinct areas or regions is not simply due to the reading off of a genetic 'map' in the cortical cells themselves, but rather is heavily influenced by factors outside the cortex.

Dendritic Arborization

The dendrites of a neuron are like antennae, picking up signals from many neurons and passing the signal down the axon and on to other neurons. The pattern of branching of dendrites is important, because it will affect the quantity and quality of signals the neuron receives. During cortical development one change that occurs is an increase in size and complexity of neurons' dendritic trees. Dendrites typically begin this process of differentiation once they have completed migration and are in their final position within a cortical layer. For example, by adulthood the length of the dendrites of neurons in the frontal cortex can increase to over 30 times their length at birth. Dendritic branching occurs at different times in different areas and layers of the cortex. For example, dendritic trees of cells in layer V of primary visual cortex are already at about 60 per cent of their maximum extent at birth; in contrast, the mean total length for dendrites in layer III is only at about 30 per cent of maximum at birth. Dendrite branching is one of the properties of neurons that can be influenced by the environment during development. For example, laboratory animals that receive environmental stimulation show more dendritic branching than those that do not.

Myelination

Myelin is a fatty sheath that surrounds neuronal pathways and increases the efficiency of neural transmission. The process by which this fatty sheath is formed around neurons, called myelination, begins before birth and continues for many years after birth. Studies of post-mortem brains and more recent studies using magnetic resonance imaging to visualize myelination indicate that not all regions of the brain are myelinated at the same time and the same rate. For example, myelination in cortical areas that process sensory information tends to occur earlier than myelination in areas that process motor information. The very last areas to complete myelination are the tracts of the cortical association areas, where this process is not complete until 20–30 years of age. Several investigators have noted that the areas that tend to myelinate first are those whose functions emerge earliest in life. For example, the visual cortical pathways myelinate relatively early, and visual function develops rapidly in the first year of life; in contrast, frontal cortical pathways myelinate later and over a more protracted period, and frontal cognitive functions develop over a more protracted period into adolescence. While myelination does facilitate synaptic transmission, under-myelinated connections in the young human brain are still able to transmit signals. Thus, even before myelination is completed, cortical areas are likely to be at least partially functional. Delays in myelination can occur during development, and can be associated with delayed maturation of function: for example, delayed myelination of motor cortex is associated with a delayed acquisition of motor milestones.

Synapse Overproduction

Synapses are the regions of communication between neurons. Studies of post-mortem tissue indicate that there is a steady developmental increase in the density of synapses in several regions of the human cerebral cortex to levels even higher than those observed in adults. This period of synapse overproduction is believed to play an important role in the enhanced plasticity, or sensitivity to experience, of the cortex during development. (*See* **Synapse**)

An increase in synaptogenesis begins around the time of birth for all cortical areas studied to date, but, at least in humans, the timing of the most rapid burst of synapse formation and the final peak density occur at different ages in different cortical areas. In the visual cortex there is a rapid burst of synapse formation at 3 to 4 months, and the maximum density of around 150 per cent of adult level is reached between 4 and 12 months. A similar time course is observed in the primary auditory cortex (Heschl's gyrus). Synaptogenesis also starts at the same time in a region of the prefrontal cortex; however, the density increases much more slowly and does not reach its peak until after the first year. Because the period of synapse overproduction is thought to be related to periods of developmental plasticity to experience, this pattern suggests that different cortical regions and the behavioral functions they mediate are most sensitive to environmental inputs at different times.

The differential time course of development of different cortical regions is also observable in the living human brain using a measure of the metabolic activity of the brain called positron emission tomography (PET). In infants under 5 weeks of age glucose uptake is highest in sensorimotor cortex, thalamus, brain stem, and the cerebellar vermis, while by 3 months of age there are considerable rises in the parietal, temporal, and occipital cortices, basal ganglia, and cerebellar cortex. Maturational rises are not found in the frontal and dorsolateral occipital cortex until approximately 6–8 months. These measures, like the measures of

synapse density, also show an increase above adult levels. There is a sharp rise in overall resting brain metabolism (glucose uptake) after the first year of life, with a peak of approximately 150 per cent of adult levels achieved somewhere around 4 to 5 years of age for some cortical areas. While the overall level remains above the adult level until 4 to 5 years, an adult-like *distribution* of resting activity within and across brain regions is observed by the end of the first year. (*See* **Neuroimaging**)

Synaptic Pruning

Following the overproduction of synapses, there is a period of synaptic loss. The elimination of synapses is a selective, and not a random, process. As with the timing of the bursts of synaptogenesis, the timing of the reduction in synaptic density is different in different cortical areas. For example, synaptic density in the visual cortex returns to adult levels between 2 and 4 years, while the same point is not reached until between 10 and 20 years of age for regions of the prefrontal cortex. One hypothesis is that the decrease in levels of brain metabolism to adult-like levels seen in the PET scan may reflect the decrease in synaptic contacts. In support of this idea, the peak of glucose uptake in the visual cortex of cats coincides with the peak in overproduction of synapses in this region. However, when the time course of synaptogenesis and glucose metabolism are compared in humans, it is apparent that the peak of glucose uptake occurs *after* the peak of synaptic density. Thus, the decrease in brain metabolism may reflect other factors (e.g. that less brain activity is required for certain skills once they are well learned).

EXPERIENCE-EXPECTANT AND EXPERIENCE-DEPENDENT GROWTH OF NEURAL CONNECTIONS

How is the brain able to achieve the very specific and adapted pattern of connections required for it to function normally? One possibility is that all of this information is prespecified in the genetic plan. However, given the sheer number of connections, many scientists have questioned whether the genome is even large enough to encode all of this information. Another possibility is that at least some aspects of this pattern are shaped by experience. In this view, the formation of the specific pattern of connections occurs by the overproduction and subsequent pruning of synapses, which allows information to be stored by selecting useful connections and eliminating surplus ones. This process is called 'experience-expectant' plasticity and is a mechanism that allows some aspects of experience to 'fine-tune' brain anatomy through selective synaptic loss. The synapses that are retained are those that respond to aspects of the environment that are common to all members of a species. For example, if the visual cortex is deprived of the input of patterned light due to a cataract, or clouding of the lens, connections in the visual cortex and visual function will not develop normally. This shows that the input of patterned light is necessary for normal structural and functional development of the visual cortex. Thus, aspects of brain organization can emerge commonly in most members of the species not because the organization is genetically encoded but because the brain is shaped by aspects of environment common to all species. (*See* **Innateness, Philosophical Issues about**; **Synaptic Plasticity, Mechanisms of**)

This time of plasticity does not last indefinitely but follows a developmental timetable. If certain synaptic connections are not laid down early in life, they are less likely to become established later in life. For example, in one study young and old owls were fitted with prisms that distorted their visual input. They were then tested to see whether they would be able to recalibrate the brain areas involved in relating visual and auditory information based on this altered visual input. Young owls were able to recalibrate in 3 weeks, but old owls never could. Moreover, if the prisms were replaced on the young owls once they were adults, they retained their ability to adjust to the altered experience. This study shows both that the effects of experience may be time-limited, and that the effects may persist into adulthood even if the experience itself was only temporary. Thus, once the number of neurons stabilizes at the mature level, changes in function may also stabilize or 'freeze' at a particular level.

While some experiences are typically common to all members of the species (e.g. hearing spoken language), other types of information may be useful only to individuals (e.g. whether that language is Spanish or English). A mechanism is also needed to store information that is unique to individuals. This second mechanism by which experience influences synapse development is called 'experience-dependent'. This refers to changes in the brain that can be specific to the individual and act to optimize adaptation to the particular characteristics of their environments. For example, rats show substantial changes in their brains if they are living in an 'enriched' social and physical environment compared to if they live in relative

isolation. These changes include production of new synapses and increases in complexity of the dendritic branching. Learning in humans may also involve creation of new synapses, although some scientists believe that in human adults the number of synapses remains stable and learning only modifies existing synapses by strengthening or remodeling them.

SUBCORTICAL VERSUS CORTICAL CONTROL OF BEHAVIOR

As the cortex develops and becomes increasingly mature, it can play an increasingly important role in regulating behavior. It allows more intentional, purposeful, behavior, in part by inhibiting the more automatic subcortical pathways. For example, newborns will automatically grasp an object placed in their hand, but this reflex disappears at 2 months of age when more controlled hand manipulations begin to emerge. The disappearance of this reflex and the emergence of the more purposeful hand movements are thought to be due to cortical development and the inhibition of brainstem neurons. The importance of the cortex for inhibiting this reflex can be demonstrated in adult humans or monkeys following lesions of particular regions of the frontal cortex: they show a reappearance of the newborn's palmar grasp reflex or 'forced grasping'. (*See* **Motor Development**)

The increasing influence of cortical control over behavior with development can also be observed in other domains, such as face recognition. Newborn infants will move their eyes further to follow a moving face than many other patterns. This preferential orienting response is thought to be primarily mediated by subcortical neural circuitry because of its developmental time course: it is present at birth and then declines sharply between 4 and 6 weeks after birth. The time course of disappearance of this response is similar to that of other newborn responses thought to be mediated by subcortical circuits, such as the grasp reflex described above. At the same time that this early tendency to visually follow faces decreases, a new response to faces emerges. At 6 to 8 weeks of age infants begin to show an increased visual attention to faces seen in the centre of vision. Both these changes are thought to be due to cortical development, which both inhibits subcortical reflexes and allows emergence of new functions. (*See* **Face Perception, Neural Basis of**; **Face Perception, Psychology of**)

The early subcortical reflexes of the infant may themselves play a role in cortical development. These reflexes may help ensure that infants receive certain inputs from the environment that are needed for the experience-expectant learning of the cortex. Thus, they serve to organize and stabilize information for cortical regions to incorporate.

EEG AND ERP TECHNIQUES

One very useful tool for studying cortical development in human infants is recording the electrical activity of the brain (a response caused by banks of neurons firing simultaneously). This activity can be recorded by means of electrodes that rest on the scalp surface. The electrical signals recorded at the surface are thought to reflect primarily cortical, rather than subcortical, activity. These recordings can be of either the spontaneous natural rhythms of the brain (electroencephalography – EEG), or the electrical activity induced by the presentation of a stimulus (event-related potential – ERP). EEG is ideally suited to study behaviors that occur over prolonged time periods (e.g. experience of emotion), while ERPs are more suitable for studying cognitive processing, because they retain precise information about the timing of cortical activation. (*See* **Event-related Potentials and Mental Chronometry**)

ERPs can be used to study several types of questions about cortical development: for example, ERPs can be used to investigate the timing of the emergence of cortical function. In studies of the brain activity related to making eye movements (saccades) in adults, a particular response called the spike potential occurs in the ERP just prior to the onset of the eye movement. This spike potential is not observed in young infants but is detectable by 12 months of age, suggesting that mature cortical control of saccadic eye movements does not emerge until at least that time. (*See* **Eye Movements**)

ERPs can also be used to investigate how experience shapes cortical development. For example, they have been used to study the influence of experience on the development of speech processing. Newborn infants discern differences between all the phonetic units used in the world's languages. This is an instance where infants' abilities are superior to those of adults: adults find it difficult to discriminate contrasts not found in their native language while infants do not (e.g. adult native speakers of Japanese find it difficult to discriminate the English /r/ and /l/, while both American and Japanese infants are quite able to make this discrimination). Infants' abilities change dramatically, however, between 6 and 12 months of age. This can be shown in the ERP in a deflection known as the mismatch negativity (MMN). The MMN reflects auditory processing by thalamocortical pathways. At 6 months

infants' MMN to contrasting phonemes reflects mainly the physical difference between the phonemes. However, by 12 months this is no longer the case: the MMN is enhanced if the contrast normally occurs in the native language but reduced if it does not. Thus, the experience of hearing the native language alters the cortical response to the auditory input. The functional significance of the MMN for later language processing is illustrated by the fact that children showing language-learning impairments show smaller amplitudes of MMN and show difficulty in discriminating speech contrasts. (*See* **Speech Perception, Development of**; **Auditory Event-related Potentials**)

IMMATURE BRAIN'S RESPONSE TO INJURY

The young brain's remarkable plasticity can also be observed in its response to injury. Damage to particular brain areas can have less serious consequences when the damage occurs during infancy than when it occurs during adulthood. One example is the effect on language of damage to the left hemisphere of the cerebral cortex. In the majority of normal adults, the left side of the brain plays a dominant role in language, and damage to the left perisylvian areas results in severe difficulties in speaking known as dysphasia or aphasia. In contrast, similar damage occurring in the first 5 years of life has much less devastating consequences. For example, in one study of 16 children who sustained similar injuries in the first 5 years of life, none had any detectable dysphasic symptoms. Thus it seems that before the age of five or six, brain areas other than those typically used are able to take on the functions of speech and language. However, by 6 years of age, as in adulthood, the left hemisphere of the normal child begins to dominate, so that left hemisphere injury that occurs at this age or later does produce a form of aphasia. The process of development can be thought of as an 'increasing restriction of fate'. What this means is that as the biological development of an individual proceeds, the range of options for further specification or specialization available to the organism decreases. The young organism shows plasticity in that there are still options available for alternative developmental pathways. As the brain develops and different regions become specialized for different functions, such as language, there are increasingly few or no options left for reorganization. (*See* **Aphasia**; **Brain Asymmetry**; **Language Development, Critical Periods in**; **Modularity in Neural Systems and Localization of Function**)

SUMMARY AND CONCLUSIONS

The normal development of the brain depends on the interaction of genetic inheritance and environmental experience. The genes provide the general structure of the nervous system, and the activity of this system as it interacts with the environment provides fine-tuning. Initially the young brain contains more components and connections than it will in adulthood, and the inputs it receives shape the elimination of this surplus. This provides a mechanism by which individuals can develop in similar ways even if the plan of development is not encoded specifically in the human genome. The brain continues to learn throughout the lifetime and to adapt to the unique characteristics of environments, but this process involves the addition to or strengthening of existing connections of the brain rather than their elimination.

CONTENTS

How do infants conceive of objects? In particular, do infants realize that objects continue to exist when hidden? Recent research indicates that although infants represent hidden objects from a very early age, their ability to reason about these objects improves dramatically during the first year of life.

PIAGET AND OBJECT PERMANENCE

As adults, we often observe events in which objects become hidden. For example, we might see a cup being pushed behind a teapot, an apple being lowered inside a bowl, or a fork being covered with a towel. Our representations of these events include both the objects that are directly visible – the teapot, the bowl, and the towel – and the objects that are not – the cup, the apple, and the fork. Piaget (1954) was the first researcher to ask whether infants, like adults, represent hidden objects. He concluded that it is not until infants are about 8 months of age that they realize that objects continue to exist when hidden. This conclusion was based primarily on analyses of infants' responses in manual search tasks. Piaget found that young infants typically do not search for objects they have observed being hidden: if a toy is covered with a cloth, for example, infants aged 5 to 7 months make no attempt to lift the cloth and grasp the toy, even though they are capable of performing these actions. Piaget speculated that for the young infant objects are not permanent entities that continue to exist when hidden; rather, they are transient entities that cease to exist when they cease to be visible.

PIAGET QUESTIONED

For several decades, researchers generally accepted Piaget's (1954) conclusion that young infants lack a notion of object permanence. This state of affairs began to change during the 1980s, however, when experiments conducted with novel, more sensitive methods yielded results that contradicted Piaget's conclusion. One such method was the violation-of-expectation method. In a typical experiment conducted with this method, infants see two test events, one consistent (expected event) and one inconsistent (unexpected event) with the expectation examined in the experiment. With appropriate controls, evidence that infants look reliably longer at the unexpected than at the expected event indicates that they (1) possess the expectation under examination; (2) detect the violation in the unexpected event; and (3) are interested or surprised by this violation.

The Rotating Screen Task

One often-cited example of a violation-of-expectation task used to examine whether young infants represent hidden objects is the rotating screen task (e.g. Baillargeon, 1987). In a series of experiments, 4.5- and 5.5-month-old infants were first habituated to a screen that rotated through a 180° arc in the manner of a drawbridge; the screen rotated continuously, first away from and then back toward the infants. Next, a box was placed behind the screen, and the infants saw an expected and an unexpected test event (see Figure 1). In both events, the screen began its rotation as before, progressively hiding the box. In the expected event, the screen rotated until it reached the hidden box, and then returned to its original position on the apparatus floor. In the unexpected event, the screen rotated through a full 180° arc as though the box was no longer present; the screen then returned to its original position, revealing the box standing intact behind it. The infants looked reliably longer at the unexpected than at the expected event, suggesting that they (1) believed that the box continued to exist after it disappeared from view; (2) expected the screen to stop against the hidden box; and (3) were surprised when this expectation was violated.

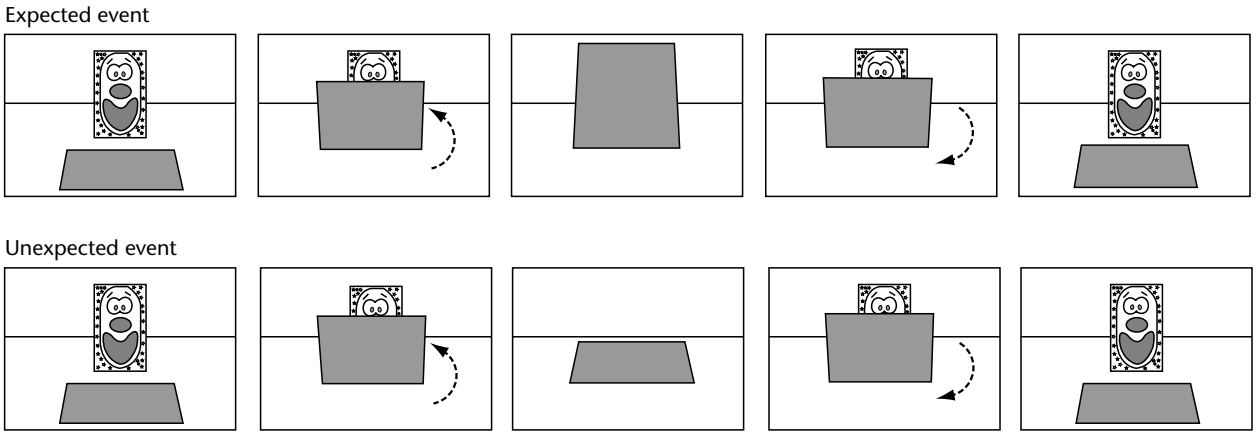

Figure 1. Schematic drawing of the test events used in Baillargeon (1987).

This interpretation was supported by control experiments in which the box was either absent or placed out of the screen's path; the infants in these experiments looked about equally at the two screen rotations.

These results were among the first to cast doubt on Piaget's (1954) conclusion that young infants lack a notion of object permanence. Since then, about three dozen reports have provided converging evidence that infants aged 2.5 to 7.5 months can represent hidden objects (for a partial listing, see Baillargeon, 2000). These reports were produced by different laboratories, using a wide variety of violation-of-expectation and other tasks. This substantial body of evidence has led many researchers to conclude that young infants, like adults, appreciate that objects continue to exist when hidden.

Perceptual Biases

A few researchers have recently questioned some of the initial results taken to reveal a notion of object permanence in young infants (e.g. Bogartz *et al.*, 2000). The concern is that these results could be explained by low-level perceptual biases in infants' processing of events. For example, it has been suggested that the infants in the rotating screen task could have looked reliably longer at the unexpected than at the expected event simply because they were habituated to the screen rotating through a 180° arc and preferred this familiar rotation in the test events. This and other similar alternative interpretations have been useful in reminding researchers to examine closely their data for possible confounds. Nevertheless, these interpretations have themselves become the subject of criticism, on several grounds (e.g. Aslin, 2000; Baillargeon, 2000). First, control experiments are generally ignored. For example, the alternative explanation just presented does not address the finding that control infants tested without a box behind the screen did not show a preference for the familiar 180° rotation. Second, a different perceptual bias is typically invoked for each separate result, giving rise to concerns about theoretical coherence and parsimony. Finally, the alternative interpretations proposed to date do not consider the many reports that have provided further evidence of object permanence in young infants.

DEVELOPMENTS IN INFANTS' RESPONSES TO HIDDEN OBJECTS

The evidence that infants aged 2.5 months and older are able to represent and to reason about hidden objects does not mean that these abilities undergo little or no development. Research over the past 10 years has uncovered many separate developments during the first year in infants' ability to reason about hidden objects. Four such developments are discussed below.

Predicting When Objects Should be Occluded

Recent evidence suggests that, although young infants recognize that an object continues to exist *after* it becomes hidden by a nearer object or occluder, they are rather poor at predicting *when* it should be occluded. In a series of experiments (e.g. Aguiar and Baillargeon, 1999, in press), infants aged 2.5 to 3.5 months saw an object move back and forth behind a screen; a portion of the screen was removed and the infants judged whether the object should remain hidden or become (at least partly)

visible when passing behind the screen. The results indicated that, by 2.5 months of age, infants have formed an initial concept of occlusion centered on a simple *behind/not behind* distinction. When the entire midsection of the screen is removed to form two separate screens, infants expect the object to become visible in the gap between them. However, if the screens remain connected either at the top or at the bottom by a short strip, infants no longer expect the object to become visible: they view the connected screens as a single occluder and expect the object to be hidden when behind it. Over the course of the next month, infants rapidly progress beyond their initial concept. At about 3 months of age, infants begin to consider the presence of a *discontinuity in the lower edge* of the screen. Although infants still expect the object to remain hidden when passing behind two screens that are connected at the bottom by a short strip, they now expect the object to become visible when passing behind two screens that are connected at the top by a short strip. Finally, at about 3.5 months of age, infants begin to consider the relative *heights* of the object and screen. When the object passes behind two screens that are connected at the bottom by a strip, infants expect the object to become partly visible if it is taller but not shorter than the strip.

Inferring the Presence of Occluded Objects

A number of experiments have examined young infants' ability to posit – rather than to merely represent – the presence of objects behind occluders. For example, Aguiar and Baillargeon (in press) showed 3- and 3.5-month-old infants a toy mouse that moved back and forth behind two screens connected at the top by a strip; the mouse did not appear in the gap between the screens. The 3-month-olds showed surprise at the event, but the 3.5-month-olds did not: these older infants apparently guessed that *two* identical mice were involved in the event, one traveling to the left and one to the right of the screens. Additional results supported this interpretation: for example, 3.5-month-olds again failed to show surprise at the event (1) when the screens were briefly lowered prior to the event to reveal a mouse and a small screen that was sufficiently large to hide a second mouse, but *not* (2) when the screens were lowered to reveal only one mouse. The infants thus produced a two-mouse explanation unless given information directly contradicting such an explanation. Together, these results indicate that, by 3.5 months of age, infants can posit hidden objects to make sense of (at least some) events that would otherwise violate their occlusion knowledge.

Reasoning About Occlusion and Other Events

New findings indicate that infants form distinct event categories and learn separately how each category operates (for a review, see Baillargeon and Wang, 2002). Because infants learn at different rates about events involving occluders, containers, and covers, striking décalages can be observed in their reasoning about these different event categories. For example, recent experiments compared infants' ability to reason about height information in occlusion and containment events (Hespos and Baillargeon, 2001). Infants aged 4.5 to 7.5 months saw a tall object being lowered either behind an occluder or inside a container; the height of the occluder or container was varied, and the infants judged whether the object could be fully or only partly hidden. The occlusion and containment events were perceptually very similar (e.g. in some experiments, the occluders were identical to the containers with their backs and bottoms removed). The results indicated that, at 4.5 months of age, infants are surprised to see a tall object become fully hidden behind a short occluder; however, it is not until infants are about 7.5 months of age that they are surprised to see a tall object become fully hidden inside a short container. Infants thus learn to consider the relative heights of objects and occluders several months before they do the same for objects and containers.

Mapping Objects From Occlusion to Other Events

Xu and Carey (1996) examined 10- and 12-month-old infants' ability to individuate the objects in an occlusion event – that is, to determine how many distinct objects were involved in the event. The infants first watched the following event sequence: an object (e.g. a ball) emerged from behind one edge of a screen and then returned behind it; next, a different object (e.g. a bottle) emerged from behind the other edge of the screen and again returned behind it. This sequence was repeated several times, and then the screen was lowered to reveal one or both of the objects. Only the 12-month-olds showed surprise at the one-object outcome. Xu and Carey concluded that the younger infants did not realize that two distinct objects were

involved in the occlusion event. They speculated that 10-month-old infants still lack specific object concepts such as ball and bottle, and that these concepts do not become available until the end of the first year, when word learning begins.

The finding that 10-month-old infants fail at the individuation task devised by Xu and Carey (1996) has been confirmed by many researchers. However, the interpretation of this finding has been questioned. First, rhesus macaques succeed at similar tasks, despite their lack of language (e.g. Uller *et al*., 1997). Second, prelinguistic infants also succeed at similar tasks when processing demands are reduced (e.g. Wilcox and Schweinle, 2002). For example, 5.5-month-old infants show surprise at a one-object outcome if the initial event sequence is considerably shortened (e.g. the first object disappears behind one edge of the screen, the second object emerges from behind the other edge, and the screen is immediately lowered).

Wilcox and Baillargeon (1998) proposed an alternative interpretation of the negative results obtained by Xu and Carey (1996). This interpretation rests on the distinction between event-mapping and event-monitoring tasks. In an event-mapping task, infants see events from *two* different event categories and judge whether the two events are consistent. In an event-monitoring task, infants see an event from *one* event category and judge whether successive portions of the event are consistent. Tasks such as that of Xu and Carey are event-mapping tasks: each test trial involves first an *occlusion* event (when the objects emerge successively from behind the screen) and then a *display* event (when one or both objects rest on the apparatus floor). To succeed, infants must (1) retrieve their representation of the occlusion event and (2) map the objects in this representation onto those in the display event. According to Wilcox and Baillargeon, young infants have difficulty completing this retrieval and mapping process.

Wilcox and her colleagues have tested several predictions derived from the preceding analysis (e.g. Wilcox and Chapa, in press; Wilcox *et al*., in press). One finding was particularly striking: 9.5-month-olds showed surprise at a one-object outcome when they viewed it through (1) a thin frame filled with a clear plastic, but not (2) an empty frame (the filled or empty frame was revealed when the screen was lowered). According to Wilcox, the infants tested with the empty frame faced an event-mapping task: they saw first an occlusion and then a display event, and they experienced the usual difficulty in mapping one event onto the other. In contrast, the infants tested with the filled frame faced an event-monitoring task: they saw a single, ongoing occlusion event involving first an opaque and then a clear occluder, and they easily kept track of the objects as the event unfolded. These results support the notion that event mapping poses special difficulties for young infants.

SUMMARY

Piaget (1954) was the first researcher to examine whether infants, like adults, represent hidden objects. Data from manual search tasks led him to conclude that infants younger than 8 months do not realize that objects are permanent entities that continue to exist when hidden. However, subsequent data obtained with violation-of-expectation and other tasks showed that even very young infants represent the continued existence of hidden objects.

In recent years, researchers have explored infants' ability to reason about hidden objects in various events. These experiments have brought to light significant developments in infants' ability (1) to posit the presence of occluded objects; (2) to predict when objects should be hidden in occlusion and other events; and (3) to map or keep track of objects across occlusion and other events.

CONTENTS

Infants are born with the ability to detect visible surfaces as separate from one another, but not to perceive them as linked behind an occluder. This latter ability develops rapidly across the first several months after birth.

INTRODUCTION

When we look around us, we see a world that is occupied by objects at various distances, an experience that is made possible by light that is reflected from the object surfaces to the eye. What we *see directly* and what we *know* about objects, however, are quite different. The pattern of light reaching the eye from object surfaces is actually *fragmented* across space and time. That is, few objects are visible in their entirety from a single vantage point, because objects typically occlude one another, and any momentary view of the visual array is apt to change when either the observer or objects begin to move. Despite these potential challenges to the visual system, we do not experience a mercurial patchwork of disconnected image fragments, but instead perceive a stable layout of coherent objects that maintain their boundaries over time.

Objects are seen as separate from one another by virtue of the fact that reflectance characteristics of surfaces vary as a function of their composition, spatial arrangement, and movement. To perceive objects, we must attend to and utilize the visual information that specifies *surface segregation*: color, luminance, texture, orientation, contour, motion, and depth. But there is more to the problem of object perception. An object may be partially occluded, such that one part of its surface is visible in one part of the optic array, and another part visible somewhere else. To perceive this object accurately, the observer must unify these visible surfaces across the spatial gap, a process known as *unit formation*. The visual information that supports unit formation includes the common motion and similarity of disparate surfaces, as well as the alignment of their edges as they intersect the occluder and the shape formed by the joined regions. Surface segregation and unit formation, therefore, rely on the observer's ability to detect and accurately use numerous visual cues available in the optic environment.

Now consider the state of affairs for a neonate (a newborn infant). She has spent her entire life to that point in darkness (in the womb), and is suddenly confronted with the visual array, a kaleidoscope of colors, shapes, and motion. To perceive objects accurately, she must solve the problems outlined previously (detection and utilization of pertinent visual information, leading to surface segregation and unit formation), but she has had little or no exposure to patterned light until now. How do these problems come to be solved, with the onset of visual experience?

The question of the origins of object perception is an ideal candidate for framing in the terms of the classic nature–nurture debate: do infants perceive objects accurately from the start of postnatal life, suggesting that object perception is an innate capacity? Or is there some developmental timetable for this capacity, involving, for example, neural maturation or a period of experience watching and acting on objects? As we will see, this question has guided much of the research in the area, and still informs the debate. It is becoming increasingly clear, nevertheless, that a nativist, or nature-oriented, point of view cannot explain the bulk of the evidence that neonates do not perceive objects accurately. Instead, it appears far more likely that accurate object perception is a set of skills that emerges over the first several months after birth. These empirical facts, discussed in more detail below, shift the question to *mechanisms of development*: how, exactly, the infant's visual system changes to support accurate perception of objects. (*See* **Object Concept, Development of**)

PERCEPTION OF OBJECT UNITY

Young infants' perception of partly occluded objects has been investigated with displays that depict two rod parts, moving back and forth above and below an occluding box, against a textured or patterned background (Figure 1(a)), using a method developed by Kellman and Spelke (1983). Infants watch this display, and their looking towards the display is recorded. When looking times decline according to a preset criterion (e.g. half their original level), the infants are then shown two new test displays, each of which matches the first display in different ways. The display depicted in Figure 1(b), for example, matches a percept of the rod parts' unity (i.e. a 'complete' rod), and the display depicted in Figure 1(c) matches a percept of disjoint surfaces (i.e. a 'broken' rod). (Note that either 'interpretation' of the rod-and-box display is plausible, although adults are likely to perceive object unity in this display.) After infants repeatedly view any single stimulus until looking times wane, a process known as *habituation*, they typically will show a preference for a novel stimulus, relative to a familiar stimulus. Researchers have capitalized on this tendency towards posthabituation novelty preferences to probe the conditions under which infants will perceive object unity, in two kinds of investigation: the visual cues used by infants to perceive partly occluded objects, and the developmental origins of object perception. (*See* **Vision: Occlusion, Illusory Contours and 'Filling-in'**)

Exploring Infants' Use of Visual Information: Gestalt Principles?

Kellman and Spelke (1983) found that four-month-old infants looked longer at a broken rod, relative to a complete rod, after habituation to a three-dimensional rod-and-box display in which the rod parts were aligned across the occluder and underwent common motion. Results from a control condition revealed that there was no inherent preference for either test display, suggesting that longer looking at the broken rod was indeed a novelty preference, arising from the infants' habituation experience (i.e. watching the rod-and-box display and perceiving object unity). This effect generalized to a display in which a rod part above the box was paired with an irregular polygon shape below the box. The rod part and polygon underwent common motion but were mismatched in shape and surface texture, and the infants appeared to perceive them as unified. In contrast,

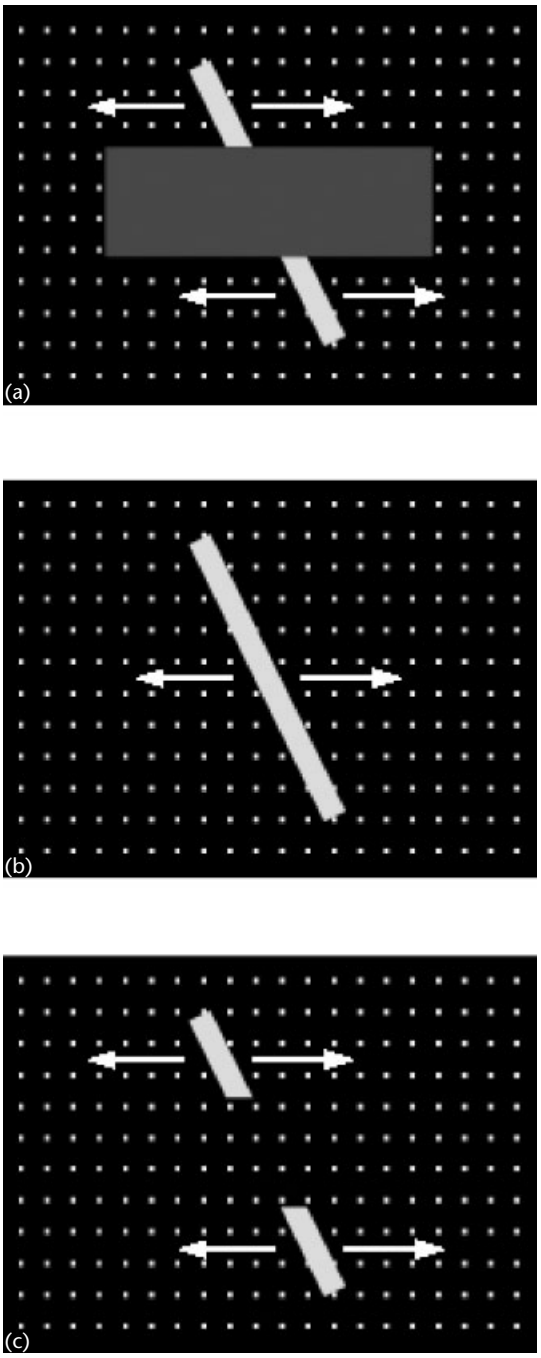

Figure 1. Displays used in investigations of infants' perception of object unity: (a) rod-and-box display, in which two rod parts are aligned and undergo common motion above and below an occluder; (b) complete rod test display; (c) broken rod test display. After habituation (repeated exposure) to (a), infants will typically look longer at (c) if they perceived the unity of the rod parts, and will look longer at (b) if they perceived the rod parts to be disjoint objects. Adapted from Johnson and Aslin (1996).

infants provided no evidence of unit formation in any stationary displays: no posthabituation preference was found under these conditions. Adults, in contrast, reported perception of object unity readily in these stimuli, presumably on the basis of 'static' information: the alignment of the rod parts, the fact that the conjoined rod segments comprise a simple, regular form, and so on.

These results raise intriguing questions about the nature of infants' perceptual development. It seems that some kinds of visual cue for occlusion are informative (e.g. motion) whereas others are not (e.g. alignment). For adults, the case is quite different: we exploit a range of cues in object perception tasks, including static information. This latter observation led the Gestalt psychologists during the last century (e.g. Koffka, 1935) to propose that the visual system is predisposed to organize the optic array into the simplest possible configuration. In general, this tendency accords with perception of objects as simple, regular forms with smooth contours rather than the fragmentary images that reach the eye. This idea was expressed more formally in terms of Gestalt 'principles', those visual cues that aided perceptual organization of our complex visual environment. These principles included *common fate* (or common motion), *good continuation* (or alignment), *good form*, *symmetry*, and *simplicity*, all of which are available in the rod-and-box display depicted in Figure 1(a), and thus may guide adults' percepts of unity. Because the visual system is inherently predisposed towards this kind of organization, according to the Gestalt view, it follows that infants should experience objects in like manner to adults, but we have seen that this is not the case: only a subset of the visual cues seem effective for infants' unit formation. (*See* **Perception, Gestalt Principles of**)

Edge-sensitive versus Edge-insensitive Processes

Kellman (1996) has suggested that young infants are 'edge insensitive', meaning that they fail to use alignment cues in unit formation tasks. Instead, infants younger than about six months are presumed to rely exclusively on motion information. After six months, an 'edge-sensitive' process is hypothesized to emerge, which takes advantage of static information, in addition to motion. This two-process theory is consistent with the findings presented thus far, in that four-month-olds perceive unity when two surfaces move together, even if dissimilar in shape and texture. When stationary, however, surfaces are not perceived as unified, even with other Gestalt information.

Recently, evidence has emerged for a kind of edge sensitivity in young infants that was not tested directly by Kellman and Spelke (1983). Johnson and Aslin (1996) presented four-month-olds with computer-generated (two-dimensional) rod-and-box displays in which the rod parts above and below the occluder were either misaligned (Figure 2(a)) or nonaligned (Figure 2(b)), and underwent common motion, until habituation of looking occurred. Following habituation, the infants viewed broken and complete rod test displays (these displays matched the configuration of the misaligned and nonaligned rod parts, not the aligned rod parts seen in Figure 1(a)). According to the Kellman (1996) two-process account of unit formation, four-month-olds are edge-insensitive, and would be predicted, therefore, to perceive the rod surfaces in both these displays as unified, and subsequently should look longer at the broken rod test displays relative to the complete rod. A different pattern of results was obtained, however. Infants who were habituated to the misaligned rod parts (Figure 2(a)) exhibited no posthabituation preference, and the infants who saw the nonaligned rod parts looked longer at the *complete* rod, the opposite result than the prediction. These results appear to reflect edge sensitivity in these infants: when the edges were misaligned, unity was indeterminate, and when edges were not aligned, the rod parts were perceived as disjoint surfaces.

In another experiment, Johnson and Aslin (1996) asked whether the presence of a textured background is necessary for young infants' unit formation, perhaps as a depth cue (i.e. the covering and uncovering of background texture provides information for the closer distance to the observer of the moving surface). Again, this manipulation should have no effect on infants' perception of object unity, under the two-process theory, but infants tested in a textureless rod-and-box condition (Figure 2(c)) showed no posthabituation preference. As in the case of the misaligned rod display, this outcome is most likely a result of an indeterminate percept: neither unified nor disjoint surfaces.

The Johnson and Aslin (1996) findings, then, begin to provide evidence for edge sensitivity in four-month-olds, and other cues are implicated in the process as well. Young infants attend to edge alignment in perception of object unity, just as they do common motion. What is the role of texture? Depth information is impoverished in these

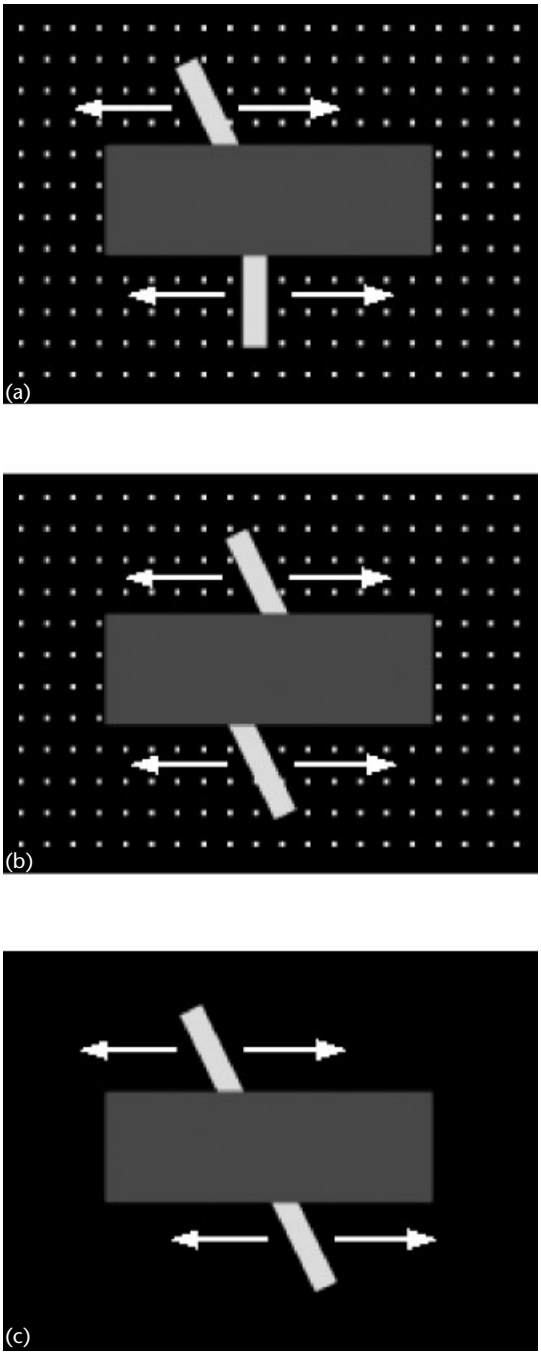

Figure 2. Displays used in investigations of the visual information used by four-month-old infants to perceive object unity: (a) misaligned rod display; (b) nonaligned rod display; (c) no texture display. In none of these displays did the infants appear to perceive object unity, suggesting that the common motion available in the displays was insufficient to specify connectedness. In addition to motion, infants also rely on edge alignment and depth cues to perceive unity. Adapted from Johnson and Aslin (1996).

two-dimensional displays, and we speculated that without the additional information for surface segregation that is provided in three-dimensional stimuli (i.e. placement of individual surfaces into their constituent depth planes relative to the observer), unit formation by the immature visual system may be precluded. The role of texture, therefore, is to provide an additional depth cue. Interestingly, this additional depth information is not needed by adults to perceive unity in the textureless display; apparently those cues that remain are sufficient to specify unity.

The Threshold Model

We have seen that the two-process theory of unit formation, while accurate in many respects, falls short of accounting for the range of evidence described this far concerning four-month-olds' perception of object unity. A *threshold model* may provide a preferable account of these data (Johnson, 1997). The threshold model posits that surface segregation and unit formation build on several subprocesses, and if any of these subprocesses are disrupted, accurate object perception can be precluded. Nakayama and Shimojo (1990) noted that in order to perceive unity in an occlusion display, the observer must determine in which depth plane each surface resides (*depth placement*), and determine which contours in the scene belong with which objects (*contour ownership*). Depth placement relies on depth cues, of course, and texture, for example, aids perceptual segregation of the rod and box surfaces into their constituent depth planes. Contour ownership may rely on edge alignment, and when rod edges are nonaligned, infants may perceive them as belonging to separate objects, as if the contours of the rod ended at the box. These results suggest that unit formation and surface segregation are multiply determined by independent sources of information, and, ultimately, object perception depends upon both the *sufficiency* of visual information and the *efficiency* of the observer's perceptual and/or cognitive skills. Unit formation and surface segregation, on this account, proceeds from an initial analysis of individual feature elements: edge orientations, surface intersections (at points of occlusion), and surface motions (Marr, 1982). From here, a description of the relative distances of surfaces is constructed, incorporating depth information from three-dimensional layout and other cues such as motion and texture. Young infants' skills at these subprocesses are somewhat compromised relative to adults, which explains improvements in performance with development.

Exploring Development of Perception of Object Unity: Core Principles?

Kellman and Spelke (1983) proposed that the roots of unit formation lie in an unlearned conception of what objects are like: 'Humans may begin life with the notion that the environment is composed of things that are coherent, that move as units independently of each other, and that tend to persist, maintaining their coherence and boundaries as they move' (p. 521). Infants' object perception has been posited to embrace certain 'core principles' that guide reasoning about objects from the start of postnatal life (Spelke and Van de Walle, 1993). These principles include cohesion (objects cannot move through the space occupied by another object) and contact (two surfaces that undergo a common, rigid motion tend to be connected). The contact principle is similar to the edge-insensitive process suggested by Kellman (1996), and as we have seen, does not provide an adequate account of recent evidence concerning four-month-olds' responses to object unity. Nevertheless, it might be that younger infants' object perception is guided by core principles.

Recall that the infants observed by Kellman and Spelke were four months of age, and that there was no direct evidence concerning origins of object perception. When neonates were tested using similar rod-and-box displays, the infants responded with the *opposite* looking-time pattern during test: a preference for the complete rod (Slater *et al*., 1990). Neonates, therefore, appeared to perceive disjoint rod surfaces in the rod-and-box display, disaffirming the nativist perspective suggested by Kellman and Spelke (1983) and Spelke and Van de Walle (1993). Core principles, therefore, do not seem to offer a plausible account of early object perception. On the contrary, neonates' responses to object occlusion seem to be quite inaccurate.

Exploring Development of Perception of Object Unity: Timing

The time between birth and four months, then, seems to be the period during which accurate responses to occlusion emerge. At what age can infants first perceive object unity? In the first study to explore this question, Johnson and Náñez (1995) reported that two-month-olds exhibited no preference for either a broken or a complete rod test display after habituation to a rod-and-box display. This suggests that two months of age represents a time of transition from perception of disjoint objects in the display (the neonates' response) to unit formation (the four-month-olds' response). Recall, however, the stipulations of the threshold model: it may be that we supplied insufficient visual information to support unit formation in a very young population that may have relatively ineffectual perceptual skills. This hypothesis was tested by presenting two-month-old infants with rod-and-box displays in which more of the rod was visible as it moved back and forth, either by reducing box height, or by incorporating gaps in the box (Johnson and Aslin, 1995). In each condition, the infants showed a consistent posthabituation preference for the broken rod relative to the complete rod, implying perception of object unity during habituation. Perception of object unity, therefore, may be a skill that is fragile in its earliest form, but nevertheless is available to even very young infants if given adequate perceptual support (see also Kawataba *et al*., 1999).

Our finding of two-month-olds' perception of object unity raises a vital question: will neonates perceive object unity as well, if given additional perceptual support? This possibility was investigated by Slater *et al*. (1996), who presented neonates with 'full-cue' three-dimensional rod-and-box displays that were rich in visual information: reduced occluder height, increased depth separation between rod, box, and background, and background texture (for additional depth information). Even with these added cues, however, the neonates provided no evidence of unit formation: they showed a clear and consistent posthabituation preference for the complete rod, relative to the broken rod.

Consider the implications raised by these experiments with neonates. No evidence emerged for perception of object unity. This result cannot be due to a general inability to distinguish between the surfaces in the display because of poor acuity, for example. Relative to adults, neonates' visual function is compromised in terms of acuity, contrast and color sensitivity, and so on. Even at birth, however, infants move their eyes volitionally, to (presumably) desired targets, most likely for closer inspection, and reflexively, in response to motion in the optic array. Neonates also exhibit visual preferences when differing stimuli are paired, looking longer, for example, at stripes versus a homogeneous gray, at curved versus rectilinear contours, at moving versus static stimuli, and others (Slater, 1995). Infants are born, therefore, with rudimentary visual skills, and do not scan the visual environment randomly. Instead, scanning patterns are structured from the start of postnatal life.

Neonates do not achieve unit formation, but decisive evidence was obtained for the other of our

object perception subskills outlined previously: surface segregation. Note that the neonates in the Slater *et al*. (1990, 1996) experiments looked longer at the complete rod during test. This implies perception of disjoint objects during habituation, when viewing the rod-and-box display. Neonates, therefore, are capable of perceiving the rod surfaces as separate from the occluder and background; in other words, they accomplished figure–ground segregation. If they had been unable to distinguish the rod surfaces from the occluder, say, there would have been no posthabituation preference, because both the broken and the complete rods would be equally novel. Responding to the partly occluded rod as consisting of disjoint objects suggests that the neonates perceived its boundaries to end at the point of intersection with the occluder.

MECHANISMS OF DEVELOPMENT

The research described in the previous sections outlines a timetable for the development of perception of object unity. At birth, infants respond to a partly occluded object as if it were composed of separate surfaces, and by two months, infants will perceive the unity of these surfaces under limited circumstances. By four months, the range of circumstances under which unity is perceived expands considerably, provided there is sufficient visual information, and there are improvements after this time as well (e.g. unit formation from static information). A bit of reflection reveals that this is one of the most profound changes that will occur in an individual's experience, which makes it one of the most intriguing questions for researchers in perceptual development. At birth, infants apparently perceive the world as a mosaic of disconnected shapes that must change continuously with every surface motion and with every movement of the self (including eye movements). There is a rapid turnabout of this state of affairs, such that within a few months the world must be experienced in a radically different way: a stable layout composed of coherent, bounded entities.

How does this expeditious and radical change occur? At present no single account encompasses the entire range of developmental evidence, but the threshold model holds promise in identifying important theoretical links that might help explain the emergence of unit formation. Recall that the model is based on the conjecture that improvements in information-processing skills underlie development of the ability to bind features into coherent surface and object percepts. Independent evidence is beginning to emerge that is consistent with this postulate, from observations of infants' eye movements, connectionist modeling, and neurophysiological development.

Eye Movements

A central tenet of the threshold model is the suggestion that with increased proficiency at information pickup, infants are more liable to detect and utilize information as appropriate in object perception tasks. Recording of eye movements can serve as an important tool to investigate this suggestion. Johnson and Johnson (2001) recorded scanning patterns in infants between 2 and 3.5 months as they viewed partly occluded rod displays, with a corneal-reflection eye tracker which provides extremely accurate data concerning the patterning and timing of eye movements. We predicted that older infants would scan more often in the rod's vicinity, scan more to both visible rod parts, and scan less in uninformative regions of the stimulus. Older infants produced a higher proportion of fixations per second than did younger infants, and scanned more extensively across the display, whereas younger infants scanned less often in the vicinity of the bottom rod part. Younger infants' fixations in the bottom region of the display were more frequent, however, when provided with longer stimulus presentations. We did not obtain direct evidence concerning perception of object unity in this study, but these results reveal important advances in scanning efficiency in the age range of interest to our question of the emergence of unit formation. (*See* **Visual Attention**)

Connectionist Modeling

Connectionist models are computer programs designed to respond to input stimuli and produce an output that reflects pattern recognition or a prediction about what might come next in a sequence. Connectionist models of developmental processes can provide important indicators concerning mechanisms of change, because the starting conditions and environmental context in which development occurs can be manipulated precisely in ways that are impossible with living systems. (*See* **Cognitive Development, Computational Models of**)

Mareschal and Johnson (2002) programmed connectionist models of the development of perception of object unity. These models were built with standard architectures and learning procedures (i.e. input, hidden, and output layers, and a back-propagation algorithm) and provided with

sensitivity to information that influences infants' perception of object unity (object orientation, motion, and background texture) and a transient memory (to retain stimulus information for brief durations). They were then trained with input representing partly occluded rod displays in which the rod moved back and forth behind an occluder, and emerged from either side, so that the object was both fully and partly visible during each translation. After varying amounts of training, the models were tested for perception of object unity with events in which the rod parts did not emerge from behind the occluder. The models perceived unity reliably in most of these test events. Learning efficiency was strongly dependent on the training environment: which cues were made available, and training duration. Surface binding, then, arose from an initial perceptual sensitivity combined with transient memory and experience in viewing objects that became occluded and again fully visible.

Developmental Neurophysiology

One way in which the visual system may bind perceptual features into coherent objects is with synchronized firing patterns across collections of neurons (Singer and Gray, 1995). If the neonatal cortex is incapable of achieving such coherent, synchronous activity (because, for example, of a general excess of 'noisy', chaotic firing), this might restrict the extent to which disparate surface fragments in the optic array could be bound into unified objects. Recent support for this possibility comes from evidence that synchronized neural activity shows marked improvements between six and eight months (Csibra *et al*., 2000). A second possible limitation may be deficiencies in long-range neural connections within and between areas of the immature visual system (Burkhalter *et al*., 1993), which, again, might impede the linking of spatially separate locations. There is evidence that these processes extend well beyond infancy, and into childhood (e.g. Kovács, 2000). (*See* **Binding Problem**; **Object Perception, Neural Basis of**; **Gamma Oscillations in Humans**)

CONCLUSION

The development of object perception has been investigated by assessing the extent to which young infants achieve perceptual completion in partly occluded object displays. These experiments lead to two conclusions. First, neonates are capable of figure–ground segregation, but do not perceive the unity of a center-occluded object; the ability to perceive object unity emerges over the first several postnatal months. Second, by four months, infants rely on a range of Gestalt visual information in perceiving unity, including common motion, alignment, and good form. This developmental pattern is hypothesized to rely on the increasing ability to detect and utilize appropriate visual information in support of the binding of features into surfaces and objects. Evidence from habituation experiments, changes in infant attention, computational modeling, and developmental neurophysiology is all consistent with this view. Specifically, the increasing ability of infants to perceive the world accurately appears to be rooted in a foundation of rudimentary visual skills that are present at birth, followed by a combination of visual experience and neural maturation.

Perception: Overview

Introductory article

James R Pomerantz, Rice University, Houston, Texas, USA

CONTENTS

Perception is the complex sequence of processes by which we take the information received from our senses and then organize and interpret it, which in turn allows us to see and hear the world around us as meaningful, recognizable objects and events with clear locations in space and time.

INTRODUCTION

Definitions and Distinctions

Perception is the process by which we organize and interpret information about the world that has been collected by our sensory receptors. The story of perception begins outside the body with external stimuli – the physical energy in dabbles of light or pitches of sound – that happen to impinge on receptors in the eyes, ears, nose, tongue, skin and elsewhere. At those receptors the physical stimuli are converted into neural signals – into the language of our nervous system – by a process called transduction. The neural signals, which convey raw sensations, are in turn transformed into perceptions – that is, the images that we consciously experience and which are most often recognizable, meaningful and clearly placed in space and time. Without perception, we would no more recognize a familiar visual stimulus, such as the exterior of our house or the appearance of our grandmother, than does a camera, which can faithfully record patterns of light but has no understanding of what it is recording. Thus although both cameras and eyes detect and record patterns of light, it is the brain that analyzes these patterns into perceptions that tell us what is out there in the world around us.

Perception serves to interpret sensations in all of their various forms or modalities. Those modalities include vision (eyes), audition (ears), olfaction (nose), the tactile senses (skin), gustation (tongue) and the vestibular senses (inner ear). Note that each of these modalities itself embraces many components. For example, our eyes register not only the presence of light but also variations in light intensity (brightness), wavelength (color), location (edges and depth) and patterning over time (flicker and movement). Similarly, our skin registers pressure, temperature changes, pain, and so on.

Perception, aesthetics and survival

Perception is important because it is the source of virtually all that we know about the world around us – from the appearance of the evening sunset to the sound of a loved one's voice, and from the width of a pit we must leap across while on the run to the smell of food that has gone bad and should therefore not be eaten. Perception allows us to appreciate the joys and beauties of our environment, and so contributes to our aesthetic sense, including the appreciation of paintings and music. It also gives us some critical tools which we need in order to survive. Without perception, we would not last long in our sometimes hostile surroundings. Although certain of our perceptual abilities, such as color vision, may seem to be dispensable luxuries, in fact they have proved to be vital to our survival. Not only can we use color to identify foods that are safe to eat, but also color helps us to locate the edges of objects, which in turn speeds up our recognition of those objects and thus our reactions to them. Figure 1 shows how much easier it is to spot food in a colored image than in one containing only shades of gray.

Measurement

In any field of study, scientific observation requires a system of objective measurement – a scheme by which numbers can be assigned in meaningful ways to the structures and processes that we are studying. If perceptions are to be analyzed properly, they too need to be measured. If we want to know whether a human's eyes are as sensitive to

Figure 1. [*Figure is also reproduced in color section.*] Color helps us to differentiate between objects and to overcome camouflage. Notice how much easier it is to spot the edible food in the colored image.

light as are the eyes of a hawk, or whether they are as sensitive during the day as at night, we would need accurate measurements to answer these questions. If we want to know whether two bells that are rung simultaneously sound twice as loud as just one bell, again we need measurements. The complicating factor is that perceptions are private, subjective experiences which are locked up inside our individual minds. How then can we study and measure perception objectively?

Psychophysics

The branch of cognitive science that attempts to perform these measurements is called psychophysics, so named because it studies the mathematical link between physical entities and psychological responses. One of the earliest measurements ever to be attempted in the area of perception is called the threshold, which refers to the intensity level of the weakest stimulus (i.e. carrying the least amount of energy) that can be perceived by a human observer. Imagine a light bulb that is controlled by a rheostat (dimmer) whose knob can be rotated to increase or decrease the physical intensity of the light. In its simplest form, the experiment would involve the observer (you, for example) rotating the rheostat alternately clockwise, then anticlockwise, and so on until you were satisfied that you had found the exact point on the knob where the light crossed the boundary – the threshold – between visibility and invisibility. One would then measure the objective intensity of that just detectable light using physical instruments, and the resulting reading would give us the threshold measurement that we seek for our one observer (you).

Although they are simple in conception, these experiments become complicated in practice. If we repeat the knob-setting procedure many times with the same observer, we obtain slightly different answers each time, partly because our ability to detect light may change over time (e.g. as we adapt to being in the dark). Thus we must look at the entire distribution of measurements that we make and calculate an average. Moreover, the threshold that we measure depends on a number of additional variables. For example, the wavelength (color) of light that is used (500-nm wavelength is about the most detectable), where in the eye the light is shone (the fovea, or center of vision, is actually quite poor at detecting dim lights), and a host of other factors make a significant difference to the result that we obtain. In a classic experiment from the 1940s, it was discovered that under ideal circumstances the human eye is able to detect a light if as few as 10 rods (the commonest type of light-sensitive cell in the eye) are stimulated, and that absorbing merely a single quantum may be sufficient to activate one rod. In recent years, the idea of a strict threshold has been superseded by a different way of thinking, called *signal detection theory*, in which faint stimuli are proposed to occur against a background of ever-present sensory noise (think of random 'snow' on a television set tuned to a weak signal, or of static on a poor telephone connection), and in which processes akin to statistical decision-making are employed to help observers to determine whether they are perceiving genuine (albeit faint) signals or just the backdrop of noise.

Another question addressed by psychophysics involves scaling. The issue here is the rate at which a percept changes as the stimulus that produces it is changed. For example, if the physical intensity of a light were to be doubled, would it look twice as bright to the human eye? Experiments conducted over many decades have established that the answer to this is a firm no. Instead, the human perceptual systems are now known to be nonlinear. More precisely, they appear to follow a 'power-law' function, where the perceived brightness of

a light, for example, varies according to its physical intensity raised to the power 0.3. Although this may sound complicated, in fact it simply means that as the intensity of a stimulus is changed by some percentage, its percept changes by some other percentage. Thus as a light's physical intensity increases by a factor of 10, its perceived brightness increases by only a factor of 2 (10 raised to the power 0.3 is approximately 2). The exponents for different sensations vary widely. For example, for the perceived intensity of an electric shock the exponent is about 3.5, so that as the intensity of the stimulus is increased 10-fold, the perception of that shock increases by a factor of over 3000 (10 raised to the power 3.5 is 3162).

Eight Basic Facts About Perception

Although there is a virtually unlimited number of facts known about perception, they can be grouped into a smaller number of critical principles. The following eight facts cover the basics of what is known and widely accepted about perception today.

Perception is limited

Although it may seem that our senses allow us to perceive the complete world around us, in truth we perceive only the smallest fraction. For example, only the narrowest sliver of the electromagnetic spectrum (the band with wavelengths ranging from 400 to 700 nm), which we call light, is perceived by humans (Figure 2). The rest, including ultraviolet, infrared and radio waves, passes by us or through us undetected. The same is true for sound pitches with frequencies above 20 kHz or below 20 Hz, and with odors such as natural gas that our noses fail to detect. We are unable to detect events that occur either too slowly (e.g. the movement of the hour hand on a clock) or too quickly (e.g. a speeding bullet) to be noticed. The same is true of entities that are too small or too large to be seen with the naked eye (e.g. microorganisms that are only visible under a microscope).

Perception is selective

Despite these limitations with regard to what we can detect, our perception of the world is narrowed even further by the selectivity of our attention. At any one time we may be attending almost exclusively to one object in our environment (e.g. a person with whom we are speaking), while we ignore everything else (e.g. other conversations, the passing of nearby cars, the chirping of birds, the tightness of our socks on our feet). It often takes stimuli with special properties, such as the loud sirens and flashing lights on ambulances, to capture our attention. In some cases the selectivity of our perception is achieved by specialized systems or tools in our sensory systems. For example, eye movements help to direct our gaze, and eyelids help us to block out vision altogether. However, in other cases our selectivity is achieved largely in our brains, as for example in audition (where we have no ear movements or 'earlids' to help to direct our attention).

Perception refers to the distal stimulus, not the proximal stimulus

The distal stimulus is the physical object or event that is typically separated from you by some distance. The proximal stimulus is the image of that object or event (e.g. in light or sound patterns) that arrives at your sensory receptors and whose characteristics are partly determined by chance (e.g. viewing angle and illumination conditions). When you look at your grandmother wearing a red sweater, she is the distal stimulus. By contrast, the image of her that strikes your eye and is projected on to your retina is the proximal stimulus. As she

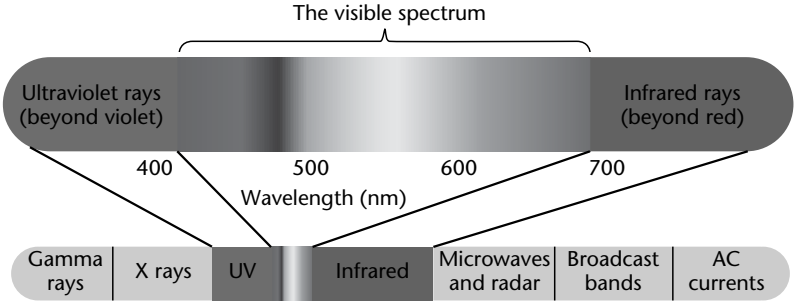

Figure 2. [*Figure is also reproduced in color section.*] The visible spectrum. Humans can see wavelengths in the range 400–700 nm, but they fail to detect energy outside that range. Note that only a small portion of the range of electromagnetic radiation gives rise to visible light. Also note that the hue depends on the particular wavelength.

walks towards you, her image expands on your retina, but you do not see her growing larger. As she walks out through the door into the sunlight, you do not see the door changing shape as it swings through a series of trapezoidal projections to your eyes. As the sun falls on your grandmother, you do not see her sweater changing brightness or color (although you may see the color more clearly). So important is our ability to keep our percepts constant despite changes in the proximal stimuli which we receive that we shall visit this matter again in the section on constancies.

Perception requires time

It seems as if we perceive objects and events in the world in real time (i.e. at the very moment when they happen or appear), but this is not the case. Instead, we perceive the world with a slight time lag, as it was a moment earlier. For example, the sluggishness of our visual system can be demonstrated by considering fluorescent lamps or television screens, which appear to be illuminated continuously but in fact are flickering (e.g. at 50 Hz in the UK and at 60 Hz in the USA). A flashlight whirled rapidly in the dark appears to form a complete circle of light – another side-effect of the sluggishness of vision. A particularly striking demonstration of this phenomenon, known as metacontrast, requires specialized equipment, but in summary it involves flashing a disk (a filled circle) of light, pausing briefly, and then flashing an annulus (ring- or doughnut-shaped) of light just encircling the point where the disk had appeared. When the timing is set just right, observers see only the annulus, and not the disk. Thus a later event prevents you from seeing an earlier event – something that could never happen if we saw the world in real time. Given that perception involves a sequence of processes, it should not be surprising that it takes time to operate.

Perception is not entirely veridical

The key word here is *veridical*, which means accurate, faithful or with high fidelity. Our perception of the world is so laced with inaccuracies (generally called illusions) that it may seem surprising that humans have survived as well as we have! Some of our misperceptions of the world are not the fault of our sensory or perceptual systems, but rather are caused by physical phenomena. For example, a pencil that is placed in a glass of water appears to bend (Figure 3). We should call this an optical illusion rather than a visual illusion, because it is caused by optics – light rays are being bent (refracted) when they pass from water into air. A camera would record this bending in exactly the same way as our eyes do. However, other illusions are clearly caused by properties of our perceptual system. Dozens of powerful geometric illusions have been discovered, such as that shown in Figure 4, but many illusions can be seen outside textbooks and laboratories. For example, the moon looks larger to the human eye when it is low in the sky, near the horizon, than when it is high in the sky, near the zenith.

Figure 3. A bent pencil in a glass of water: an 'optical' illusion whose cause lies in optics and not in faulty perception.

Many scientists believe that illusions should not be regarded simply as mistakes, but rather should be viewed as inevitable side-effects of shortcuts and assumptions made by our perceptual system that normally serve us well.

Perception requires memory

Although it may not be immediately obvious, we would not be able to perceive the world very well if we could not store our perceptions in memory. Consider the act of recognition (which means 'knowing again'). How could we possibly recognize our grandmother if we had no memory of what she looked, sounded and felt like? How could we see an object as moving or hear a pitch

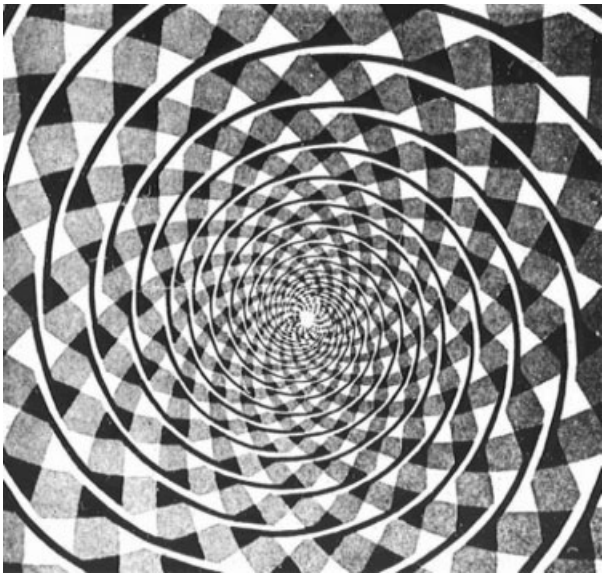

Figure 4. An example of a visual illusion that is not optical but originates in our sensory or perceptual system. The illusion here is that the apparent spirals are really concentric circles.

as rising if we had no moment-to-moment memory of where the stimulus had been a second earlier? We would be unable to compare objects for differences, to determine trajectories of moving objects, or to perceive speech or melodies if we had no perceptual memory. According to the most widely accepted theories, recognition requires the matching up of incoming sensory information with information that was stored earlier in our memory system. This could involve either an explicit memory store or alternative neural mechanisms that implicitly hold past information (as a sheet of paper 'remembers' a fold), but somehow information about the past is retained.

Perception requires internal representations

Early philosophers believed that when we look at an object, a tiny copy of that object enters our bodies through our senses. We now know better, but we also know that some process or structure in the system (probably a neural structure or circuit) is required for us to perceive the external world, and we call this an internal representation. According to this view, our sensory signals are processed to the point where the internal representation is activated. These internal representations can be regarded as the perceptual memories that were discussed in the previous paragraph.

Consider the perceptual imagery that many of us experience when we close our eyes and try to recall how many windows there were in the house where we grew up. Many scientists believe that such recollection activates the same internal representations that would be stimulated if we were to tour the house itself with our eyes open. According to prevailing theories of perception, objects and their sensory qualities are represented by the particular neurons (nerve cells) that they trigger in the brain. Although it is difficult to imagine that the conscious experience of the color green, for example, corresponds to nothing more than the activation of certain neurons in the brain, this nonetheless is the consensus view among researchers.

Perception is influenced by context

Stimuli rarely if ever appear in isolation. Instead, they appear in a context of other stimuli distributed in time and space, and those other stimuli can exert a powerful influence on our percepts. One familiar example is how short the referees in basketball games appear to be. In fact they are often taller than average, but when surrounded by the unusually tall players of this game, they certainly seem to be short. Similarly, a particular musical note may sound pleasant in the context of one chord, but grating (discordant) in another. In gustation, orange juice can taste delicious, but not immediately after brushing one's teeth with toothpaste (the added sugar of which temporarily masks the sweetness of the orange juice, thus making its sourness more prominent). These effects are so important to our understanding of perception that they will be discussed in a later section of this article (on context effects).

DIRECT PERCEPTION

Several theoretical frameworks have been proposed for understanding how perception works, but two of them dominate the field, namely *direct perception* and *unconscious inference*. Direct perception, which is most closely associated with the psychologist J. J. Gibson, may agree more closely with our intuitions or personal introspections. Briefly, it holds that our perception of the world around us is direct in the sense that there are no intermediate steps, no inferences, and no drawing on learned knowledge or thought-like processes for us to perceive the world. We simply see the world, the theory claims, rather than inferring or making guesses about it. In Gibson's framework, the observer and the environment are tightly coupled in such a way that changes in the latter are relayed faithfully and directly to the former. Gibson argued that there are structural invariants in the

environment that contain a wealth of information that an observer can use to determine the structure of the world.

One example Gibson used for a structural invariant is the texture gradient (Figure 5). When looking at such gradients, even when they are pictured on the flat pages of a book, observers tend to see the texture receding into the distance. Is this the result of an inference that the shift in grain size of the texture in the picture signals depth (perhaps an inference resulting from learning and experience)? Gibson did not think so. Instead he argued that texture gradients have consistent geometric properties which can be picked up directly by an observer and used to determine directly not only that the texture is receding in depth but also the precise angles and distances which that entails. One can judge that the two cylinders in Figure 5 are of about the same size because they cover about the same amount of brick on which they sit, proportionally speaking.

This example is rather abstract, so let us consider another that is more concrete. Suppose you are driving straight down a road and you see another automobile approaching yours from a side road running perpendicular to your stretch of road. How can you determine whether this car is on a collision course with yours as you head towards the intersection? Before you start reaching for your calculator and struggling to recall the appropriate formulae from trigonometry, be advised that there is an easier, 'direct' way to arrive at the answer. As you drive down the road, if the angle from your car to the other car does not change, this means that you are going to collide. It is a simple geometrical fact, and one that Gibson might argue typifies the way in which our perceptual system has evolved to pick up on these invariants (the above rule works regardless of the distances involved, the angle formed between the two roads, or the constant speeds of the two cars) and allow direct, immediate and accurate perceptions.

Figure 5. A texture gradient of the type described by Gibson.

UNCONSCIOUS INFERENCE

The other well-known theoretical framework for perception is unconscious inference, which is most closely associated with Herman von Helmholtz (and more recently with Irvin Rock, Richard Gregory and Julian Hochberg). In contrast to direct perception, unconscious inference holds (as its name implies) that perception takes place through various intermediate steps, and that those steps involve inference, guessing and other thought-like processes (although Helmholtz believed that we are unaware of these inferences, and he therefore described them as unconscious).

According to unconscious inference, percepts are constructed from evidence provided by our senses. This evidence is too vague and incomplete to serve as anything more than a set of clues so, like a detective, our perceptual system works from these clues to develop hunches or hypotheses about the world. These hypotheses then lead to implications that the perceptual system can further test to determine whether a hunch is right or wrong.

We are all familiar with situations in which sensory information is far from complete because viewing conditions are poor. Consider lying in bed in a darkened room and seeing a shadow on your wall, which you take to be an intruder in your room. Alarmed, you leap out of bed and switch on your light, only to discover that it was merely the faint shadow of an overcoat being cast on your wall that you were seeing. This would be a case of an incorrect hypothesis being generated from flimsy perceptual evidence (and moreover being evaluated by a drowsy detective). According to unconscious inference, this is how perception operates all of the time, even when the conditions for perception are excellent.

The evidence in support of unconscious inference comes from several sources, including experiments which show that what we perceive depends partly on what we expect to see. Those findings will be discussed later in this article. For now, it is useful to note that unconscious inference and direct perception are not necessarily mutually exclusive, as one could accurately describe how some perceptual functions work, while the other describes the remaining functions.

TOP-DOWN AND BOTTOM-UP PROCESSING

Top-down and *bottom-up* processing are terms that describe two ways in which perception could operate. In all likelihood human perception involves a mixture of the two. Let us begin with bottom-up processing, which is the more straightforward of the two.

Bottom-up Processing

Bottom-up processing begins with distal stimuli, which project proximal stimuli to the senses. The senses transduce (i.e. convert) the stimuli into neural codes, as for example when rods and cones in the retina convert incoming light into voltage differences within the photoreceptors (light-sensitive cells) – differences that ultimately result in neural firings (action potentials). These neural responses feed into other neurons that are organized to detect specific patterns. For example, if three rods arranged in a straight line on the retina activate one neuron, then if a strip of light is shone into the eye and falls exactly on those three rods, this would activate the neuron as much or more than would any other visual stimulus. We could then regard this neuron as a 'detector' for (or internal representation of) line segments of just the right orientation and position, and in fact neurons of this type have been discovered in the visual system of primates. In any case, perception in this scheme operates strictly bottom-up processing in that the proximal stimulus triggers a chain of events that reliably leads to an accurate perception. The flow of information processing proceeds strictly in the bottom-up direction, from the sensory receptors toward higher centers in the brain, with no signals traveling back in the top-down direction.

Top-down Processing

In top-down processing, the flow of information is reversed, at least in part, from bottom-up processing. Imagine closing your eyes and forming an image of your childhood home or of your grandmother. (Admittedly not all of us will be able to do this, but most can with little trouble.) If you succeed in this effort, your resulting experience – better regarded as imagery than as perception – will clearly be from the top down, since your sensory receptors (in the retina) are receiving no stimulation. In dreams, the images can be so vivid and convincing that we may even cry out in our sleep when the plot in the dream takes a terrifying turn. This tells us that top-down processing can sometimes yield results similar to and as realistic as those obtained from bottom-up processing.

In practice, top-down processing need not be so extreme as in dreams or hallucinations, where none of the information comes from our senses. Instead, consider a system that processes a little information from the senses, makes an inference about what may be out there in the world, and then proceeds to (1) fill in some of the missing information (recall the models of dinosaurs in museums of natural history, where most of the skeleton is plaster of Paris) and (2) generate hypotheses about what other sensory information might confirm or refute the current hypothesis or inference.

There is much evidence to support top-down processing, but none is more impressive than the subjective contours discovered by Gaetano Kanizsa and illustrated in Figure 6. Here we can see shapes that are not objectively present in the figure, such as the central 'square' that we can detect in this figure. We can also see brightness differences that are not objectively present (the central 'square' appears to be darker than its surround).

According to the principle of unconscious inference, these figures contain clues that are consistent with the presence of a square – clues such as dots coming to an abrupt halt (being truncated) in the middle of space, and edges that are separated but collinear (i.e. they line up exactly despite a physical separation). Although subjective contours could be detected by bottom-up mechanisms such as collinearity detectors, some subjective contours appear or disappear when viewers are given different instructions on how to interpret the image. Perhaps you can make the subjective square in Figure 6 vanish for yourself simply by prolonged viewing of or staring at certain areas. Our perceptual system may have evolved to treat such cues as evidence for the existence of a central figure, and now it proceeds with confidence to fill in the rest of the square, creating edges and brightness differences along the way. This 'filling in' is a good example of top-down processing that occurs in normal, awake

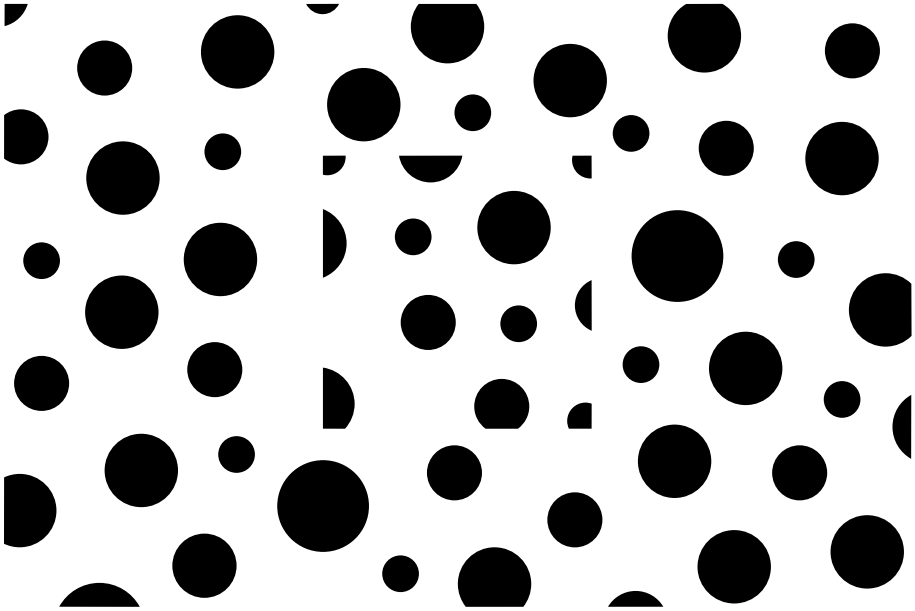

Figure 6. Subjective contours, discovered by Gaetano Kanizsa. The square patch floating in the center of this painting is illusory.

individuals perceiving the world around them. Visual experiences with the eyes closed, as in dreams or hallucinations, are more purely top-down in origin.

CONSTANCIES

As perceivers, we are more often interested in the constant, enduring properties of the distal stimulus than in the fluctuating and often accidental properties of the proximal stimulus. That is, we care more about the 'true' color of grandmother's sweater than about the hue it happens to assume when she walks out of bluish fluorescent light into yellowish natural sunlight. We care more about the objective shape of a door – normally a rectangle – than about the momentary trapezoidal shapes it projects to our eyes as we look at it from various angles.

The human perceptual system is equipped with clever and useful compensatory mechanisms to help us to achieve these constancies. These mechanisms embody a built-in understanding of the various couplings that pervade our perceptual world (e.g. that as an object moves away from us, the size of the image that it projects to our eyes diminishes; that as an object rotates in depth before us, the shape that the object projects changes in a regular manner; that as the illumination falling on an object increases, the amount of light it reflects to our eyes also increases). Thus if we stand next to a lamp and watch as a book is carried towards us, we are not fooled into thinking that the book is getting larger or brighter, nor are we deceived into thinking that the book is changing shape if it is rotating in depth as it approaches us.

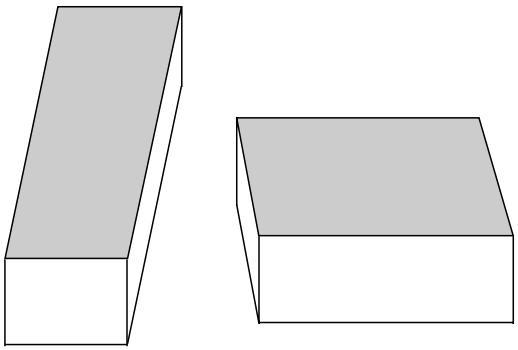

Figure 7. The Shepard box top illusion, caused by the functioning of our shape constancy mechanisms.

The constancies can exert powerful effects on our perceptions, as is illustrated in Figure 7. Look at the two objects depicted in this figure and compare the shapes of their top surfaces. Although they appear to be quite different, they are in fact identical in shape. The reason why they appear so different is that constancy mechanisms in our visual system allow us to look beyond the shape that three-dimensional objects project onto our two-dimensional retinas and focus instead on what the

original three-dimensional shape must actually be. Thus if one were to go about constructing two physical boxes that, if photographed, would produce a picture like that shown in Figure 7, one would discover that the two boxes would indeed need to have quite different-shaped tops. In a sense, our perceptual systems help us to work backwards from the proximal stimulus to our real object of interest, namely the distal stimulus.

CONTEXT EFFECTS

One of the most pervasive properties of human perception is that the appearance of any one stimulus is strongly dependent on the context in which it appears. As we noted above, most people would look short when surrounded by tall basketball players. However, context effects go far beyond perceptions of size. They influence almost every property to which we are sensitive.

Let us consider some examples. The first, which dates back at least to John Locke in 1690, involves the context of time rather than of space. In this demonstration, you begin by filling three bowls with water – one with hot (but not too hot!) water, a second with cold water, and a third with a lukewarm mixture of hot and cold water. Next, put one hand in the hot water and the other in the cold water, and leave them there for a minute or two, just long enough for them to adapt to the temperature. Then quickly plunge both of your hands into the lukewarm bowl. If you are like others, you will find that the lukewarm water feels cool to the hand that has been in hot water, whereas it feels warm to the hand that has been in cold water. The result is a paradox of sorts – you know that both of your hands are immersed in the same water, but it feels quite different to the two hands, because each hand perceives its current temperature in the context of what came before.

A second example involves context in space rather than in time, and is illustrated in Figure 8. Here the same gray patch looks lighter when placed on a dark background, and darker when placed on a light background. As with the two bowls demonstration, context leads to enhanced contrast, magnifying the difference and making us more aware of changes in our surroundings.

Figure 9 shows some additional examples of context effects. In Figure 9(a), a given stimulus can look like the letter B or the number 13, depending on whether you attend to the surrounding digits or the surrounding letters. In Figure 9(b), a curved line can look like the letter C or like a nose, depending on what surrounds it. In Figure 9(c), we are more likely to perceive a diamond as a tilted square when it is placed in a particular configuration of other diamonds.

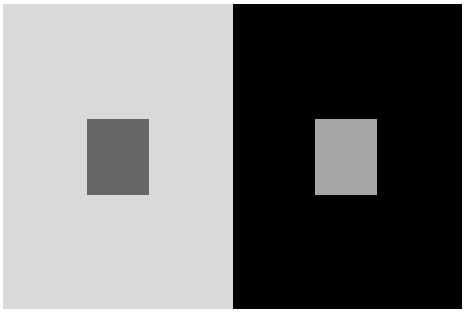

Figure 8. Simultaneous contrast, in which a given shade of gray looks darker on a light background and lighter on a dark background.

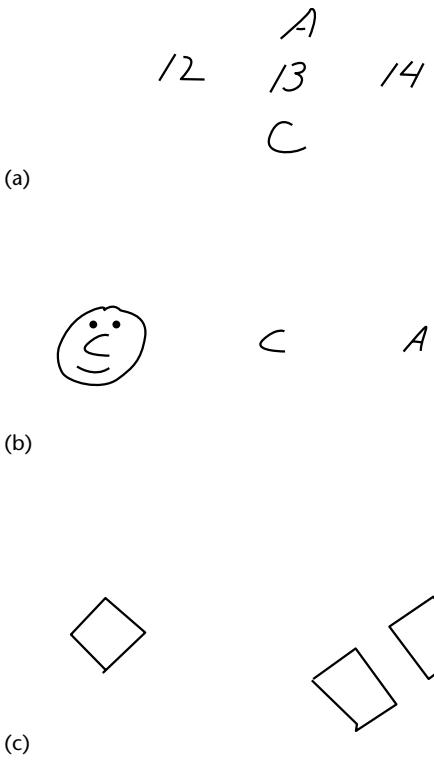

Figure 9. Context effects in visual perception. (a) A given figure can look like a letter or a number depending on whether one attends to the vertical elements or the horizontal elements of the display. (b) A given curve can look like the letter C or a nose, depending on the context. (c) A diamond can look like a tilted square in the right context.

One attempt to explain such context effects is known as Gestalt psychology, which is noted for claiming that, in perception, the whole is more than the sum of its parts. (More accurately, Gestalt psychology claims that the whole is simply *different*

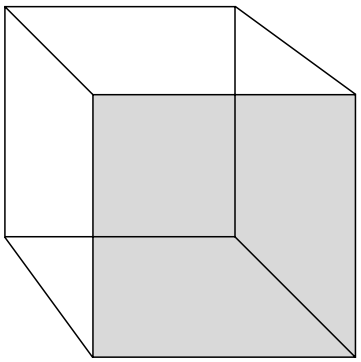

Figure 10. The Necker cube, which can be seen in either of two orientations.

to the sum of its parts.) According to the Gestalt approach, our primary perceptual experience is the configuration of or interrelationships between elements in the stimulus, rather than the elements themselves. Consider a melody as a set of relationships between musical notes. If we transpose a melody into a different key, the melody will remain the same even though all of the notes will have been changed.

Gestalt psychologists developed a number of principles that were intended to explain certain compelling perceptual phenomena. These include perceptual grouping (where physically separate elements in our field of vision appear to form clusters or groups), figure–ground segregation (where we must decide which side of an edge represents an object near to us and which side represents the distant background) and multistability (in which a pattern such as the Necker cube in Figure 10 appears to flip as one looks at it for an extended period of time). One general principle of Gestalt psychology is that we tend to organize our percepts into the simplest possible configuration (e.g. seeing four dots arranged in a square configuration as indeed forming a square or a circle, rather than forming more complex shapes that might also connect the four dots). Although there is much evidence to support a simplicity principle in perception, much evidence also points to an alternative notion that originated with Helmholtz. That notion, known as the likelihood principle, holds that our percepts are organized so as to maximize the chances of their being accurate, whether they are simple or not.

DISORDERS AND TREATMENTS

Our perceptual systems are sometimes described as 'transparent' because when they are operating correctly we hardly notice that they are there. We see through them as if they were clear glass. It is only when they fail us or act abnormally that we become acutely aware of their presence instead of taking them for granted. Losses in vision range from common and readily corrected refraction (focusing) errors such as myopia or astigmatism to partial or complete blindness. Likewise, losses in audition range from mild hearing loss and tinnitus (a ringing in the ear) to profound deafness.

In addition to these losses of our ability to perceive or resolve faint stimuli, there are other types of blindness that involve selected subsystems of perception. Those maladies in turn have taught us much about the way in which these systems work in healthy, intact individuals. Perhaps the commonest of these losses is color blindness, a genetically linked disorder that mainly affects males. Color-blind people rarely lack color vision altogether. Rather, they fail to see certain colors properly or at all. The most frequent type is red–green color blindness, but there are over a dozen other forms of this disorder. Importantly, red and green wavelengths of light also mix to form white (although red and green paints do not mix to form white paint, because paints are pigments that absorb light, so their combination is subtractive rather than additive as with lights). If we stare for a long time at a bright red square and then look at a plain white page, we see a green after-image (and conversely we see a red after-image after staring at a green square). The accumulation of evidence from diseases and disorders such as color blindness alongside the evidence from illusions such as colored after-images has contributed greatly to our scientific understanding of the way in which normal color vision works. With recent improvements in neuroimaging that allow us to identify areas of brain activation, researchers in cognitive neuroscience have learned much about the way in which vision and the other senses operate in the brain.

In addition to color blindness, researchers and physicians have documented blindness for motion, for stereoscopic depth, and even for stimuli as specific as faces. In the latter disorder, known as prosopagnosia, individuals with otherwise normal vision have great difficulty in recognizing the faces of people, even if they are famous or family members. Recent research using neuroimaging techniques (e.g. positron emission tomography and functional magnetic resonance imaging) supports the notion that specialized centers in the visual areas of the brain underlie the perception of motion and of faces, and that damage to those

areas can produce these forms of blindness. (*See* **Prosopagnosia**)

In addition to these disorders, there are others that are even more surprising and revealing with regard to the underlying processes of perception. For example, patients with blindsight can point accurately to the location of objects that they claim they cannot see. In typical cases, patients have an area of their visual field, known as a scotoma, where they cannot see light. In some respects scotomas are like the blind spot that we all possess in each eye, namely a tiny region lacking photoreceptors in which we cannot detect light, but a scotoma can be much larger, taking up half of the visual field or more. When their vision is tested, these patients detect perfectly well lights that are flashed in the functioning areas of their field of vision, but they fail to detect lights that are flashed in their scotoma. If they are asked to guess where these lights appeared, they are understandably reluctant to do so (the very question seems ridiculous), but their judgments turn out to be quite accurate. This suggests that the portion of their visual system that determines where objects are situated is separate from the portion that identifies objects and produces the conscious experience of perception.

Perception: The Ecological Approach

Introductory article

M T Turvey, University of Connecticut, Storrs, Connecticut, USA

CONTENTS

The ecological approach to perception is a theoretical perspective on how animals, including humans, can be aware of their surroundings. It emphasizes the relevance of activity to defining the environment to be perceived.

INTRODUCTION

Perception refers to how animals, including humans, can be aware of their surroundings. The ecological approach to perception refers to a particular idea of how perception works and how it should be studied. The label 'ecological' reflects two main themes that distinguish this approach from the establishment view. First, perception is an achievement of animal–environment systems, not simply animals (or their brains). What makes up the environment of a particular animal – cliffs, caves or crowds – is part of this theory of perception. Second, perception's main purpose is to guide activity, so a theory of perception cannot ignore what animals do. The kinds of activities that a particular animal does – how it eats, moves and mates – are part of this theory of perception.

Including the environment and behavior as important parts of perceptual theory, rather than as afterthoughts, is clearly different from theories that start inside the eye (or the ear or the skin); but it is not necessarily controversial. None the less, the ecological approach is considered controversial because of one central claim: perception is direct. To understand the claim, and why some might consider it troubling, we have to contrast it with the more traditional view. Most scientists believe that perception begins with faulty input. For example, when objects in the world reflect light, the pattern of light that reaches the back of the eye (the retina) has lost and distorted much of the detail. The job of perception, then, becomes one of correcting the input and adding meaningful interpretations to it so that the brain can make an educated guess, an inference, about what caused the input in the first place. This traditional view is labeled as indirect perception because the animal's awareness of the world is a result of these intermediary steps. A theory of direct perception, in contrast, argues that the intermediary steps are only needed if the scientist has described the input incorrectly. Including the environment and activity in the theory of perception allows a better description of the input, a description that shows the input to be richly structured by the environment and the animal's own activities. This means that the intermediary steps are not needed and perception is direct.

GIBSON'S CONTRIBUTION

The ecological approach to perception originated in the work of the American psychologist James J. Gibson (1904–1979). Two biographical facts were important to shaping his theory. As the young son of a railroad employee in America's Midwest, he had spent many hours on trains watching the world flow by. He noticed that from a vantage point in the locomotive looking forwards the flow was outwards; from the caboose looking rearwards the flow was inwards. Here was the seed of his notion that the light that comes to our eyes is reliably structured by activity – structured light can be rich and meaningful. Many years later, after he had established a career as a perceptual psychologist, Gibson took time away from his college teaching position to spend 4 years as a scientist with the aviation psychology program during the Second World War. There he realized that the practical problems of takeoffs and landings, and pursuit and evasion, which could not only be mastered by 18-year-old pilot trainees but also performed routinely by birds and bees, had little to do with the physiology of the eyeball. Here was the seed of his notion that perceptual theory should try to explain

real-world behaviors (and not simply human behaviors). (*See* **Gibson, James J.**)

Upon resuming his job as a college professor, Gibson set about challenging the assumptions that he thought sat unexamined in most laboratory work, including his own. He argued that perceivers are aware of the world, not of their own sensations, and perception theory should respect that. Gibson's reformulation of the problem of distance perception illustrates the essence of what developed into his ecological approach. For centuries, scientists believed that 'distance is not perceivable by eye alone'. Indeed, if objects are treated as isolated points in otherwise empty space, then their distances on a line projecting to the eye are indistinct: each stimulates the same retinal location. Gibson dubbed this formulation 'air theory' (A in Figure 1) and argued that it was inappropriate for addressing how we see. His alternative was 'ground theory', which emphasized the contribution of a continuous background surface to providing rich visual structure (G in Figure 1). The simple step of acknowledging that points do not float in the air but are attached to a surface introduces a higher-order property, the gradient, which opened up the new possibility that perception might be veridical, that is, about facts of the world.

Gibson began to emphasize the enriching role of movement in perception. Once more, an ecological solution to an old problem is instructive. This problem concerned how a perceiver could distinguish object motion from his or her own motion. The puzzle arises because of the traditional assumption that the cue to perceived motion is the stimulation of successive retinal locations. An object moving from left to right fixated by a stationary eye will stimulate retinal receptors A, B, C, then D. That same object fixated by an eye moving from right to left will also stimulate retinal receptors A, B, C, then D. Since the retinal input is ambiguous, it must be compared with other input having to do with whether any muscle commands had been issued to move the eyes, the head or the legs. In the absence of counteracting motor commands, object motion is concluded; in the presence of such commands, the retinal signals would be counteracted, allowing the alternative conclusion of self-motion. Another possibility is that the observer is moved passively under somebody else's power (as in a train) so that other input and even knowledge must be taken into account. Gibson suggested an elegant alternative solution: overall, or global, change in the pattern of light is specific to self-motion; local change against a stationary background is specific to object motion. This simple insight (echoing the experience of the young Gibson riding the rails) opened a new field of research devoted to uncovering the structure in changing patterns of light: optic flow.

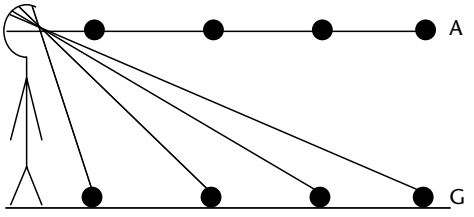

Figure 1. The distances of four points in the air (A) are indistinct because their projections are onto the same retinal location. As texture elements on the ground (G), the gradient of their projections distinguishes their relative depth.

OPTIC FLOW AND THE VISUAL GUIDANCE OF LOCOMOTION

Optic flow refers to the patterns of light, structured by particular animal–environment settings, available to a point of observation. The goal of optic flow research is to discover particular reliable patterns of optical structure, called invariants, relevant to guiding activity. Outflow and inflow are distinct forms of optic flow (distinct flow morphologies) that tell us whether we are moving forwards or backwards. As scientists consider how that flow is structured by the variety of clutter that we encounter as we move around – doorways, hillsides and the like – they discover invariants specific to those facts as well (Figure 2).

In order to effectively guide their activities, animals need to know more than simply what they are approaching. They also need to know how they are approaching – are they moving too fast? – and whether they need to adjust that approach: should they slow down? Turn? As a busy waiter rushes towards the swinging door of the restaurant kitchen, he makes subtle adjustments to his behavior in order to control his collision. He needs to maintain enough speed to push through the door but not so much that he crashes into it. Effective behavior requires that he should know when a collision will happen (so he does not slow down too early) and how hard the collision will be (so that he slows down enough). Optical structure relevant to these facts has been identified and provides examples of quantitative invariants. The optical quantity called τ is specific to when a point of observation will contact an upcoming surface. Consider the rectangular contour in Figure 2(a). As the waiter approaches it, its optical projection

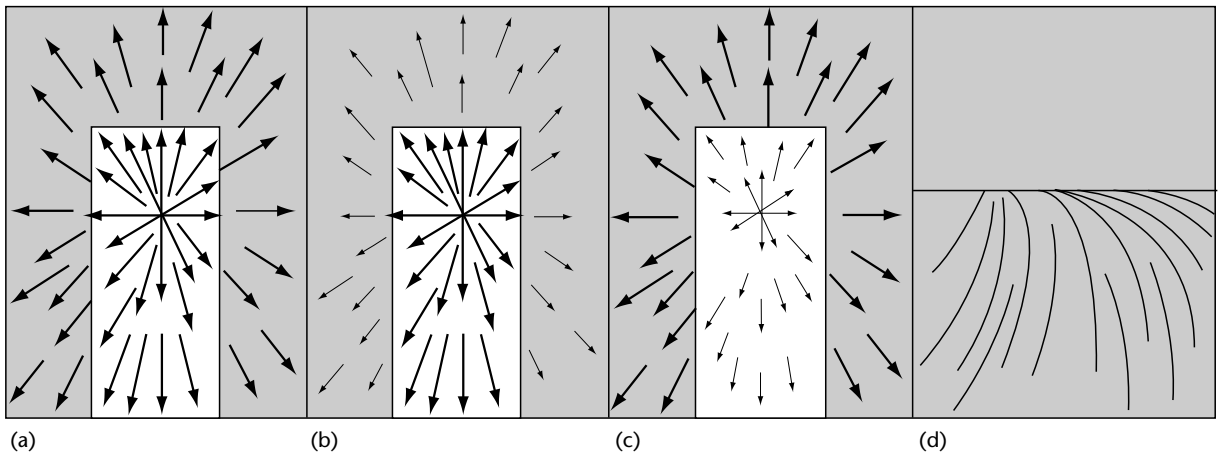

Figure 2. (a) Global optical expansion, which accompanies forward locomotion, is represented as a velocity vector field radiating from a focus of expansion. Smooth flow specifies approach to a flat surface. (b) Faster expansion inside a contour specifies an obstacle. (c) Faster expansion outside a contour specifies an opening. (d) Curvilinear flow specifies direction of heading.

magnifies. The speed of approach affects the rate of expansion, that is, the change in optical area per unit time. The quantity τ is given by the inverse of the relative rate of this expansion – how long will it take until there are no units of time left. As he slows down (or speeds up), the rate at which τ approaches zero changes. The rate of this change (that is, the derivative of τ) is specific to how severe the collision will be. It essentially quantifies for a moving observer (the waiter) whether his kinetic energy is being reduced (by braking) at a rate sufficient to stop movement before contact occurs.

The preceding descriptions of global optical structure refer to situations in which the observer is approaching a surface. However, they are also relevant to a surface, such as a projectile, approaching the point of observation. Local disturbances of optical structure relevant to the guidance of interceptive behavior can also be described in terms of τ and its derivative, specific to when and how hard a collision will be. Other optical quantities are relevant to moving the perceiver (or the perceiver's hand or racket) into a position to intercept (or avoid) the projectile. Moreover, the same invariants are available to the family dog catching a ball, a chickadee landing on a bird feeder, and a bumblebee searching for pollen. Although these creatures have obviously different visual systems and brains, the information relevant to guiding their behaviors is the same. Invariants of tissue deformation and sound compression waves reveal the same richness that has been found in optical structure. Of course, while all creatures need to perceive things such as openings and obstacles to locomotion, what counts as an opening necessarily differs. How perception is 'personalized' is addressed in Gibson's notion of affordances.

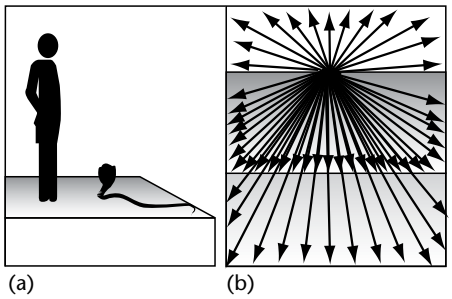

Figure 3. (a) A brink in the path of locomotion presents different behavioral possibilities to animals of different sizes and locomotory styles. (b) For an animal with legs, the ratio of flow above the horizontal contour of the brink relative to the rate of flow below scales the brink to the animal's eye height, specifying whether it can be descended safely.

AFFORDANCES

In highlighting the relevance of optical structure to whether an activity is possible ('Is the ball catchable?') the preceding examples introduce what might be the most radical contribution of this theory: behavioral possibilities are perceived. Gibson coined the word 'affordances' to refer to the possibilities for action of a particular animal–environment setting. They are what an arrangement of surfaces means to an animal. Affordances are usually described as '-ables', as in 'catchable', 'pass throughable', 'climbable', and so on. Whether

a ledge, for example, is a stepping-down place or a falling-off place is not determined by its absolute size or shape but how it relates to a particular animal, including that animal's size and agility, and style of locomotion (Figure 3(a)). Gibson proposed that such activity-relevant animal–environment relations are specified in the optics (Figure 3(b)).

Through their research on affordances, Gibson and his followers 'ecologize' the traditional problems of size, distance and shape perception. They manipulate aspects of the environment (such as the height of a flat surface, or the distance of a target) and ask people to evaluate whether a certain behavior would be possible. Instead of asking for estimates of size or distance in absolute units, they ask (for example) whether the surface could be climbed or the target could be reached. Ideally, experimenters would prefer that people's responses be as natural as possible (that is, without making conscious decisions). When the technology allows, therefore, active behavioral adjustments are recorded. Either way, we have learned that children, adults and the elderly all perceive possibilities for, and restrictions on, activity. They are well aware of behavioral category boundaries (this is climbable; that is not). Even though the absolute boundary – measured in centimeters – differs for people of different sizes, the functional boundary – scaled by something like the person's eye height – is the same. If the eye height is manipulated in some way (e.g. by having the person wear platform shoes or by surreptitiously raising the floor of the room they view through a window) it has predictable consequences for their affordance evaluations.

In summary, the theory of affordances is radical because it treats relational properties as objective: the relation between the ledge size and animal size in Figure 3 exists even when it is not being perceived. Moreover, such relational properties are considered more fundamental to describing environments and understanding perception than the objective primary properties studied so far by physics. According to this ecological theory, meanings are directly perceptible. The wide-ranging species inhabiting our planet, from simplest bacterium to human, do not invent meanings (by conception), they discover them (by perception).

Perception, Gestalt Principles of

Intermediate article

James T Enns, University of British Columbia, Vancouver, British Columbia, Canada

CONTENTS

Gestalt principles of perception are those aspects of perception that cannot be defined in terms of smaller, constituent elements. Gestalt *is a German word which translates in English as whole, configuration, or pattern.*

WHOLES AND SUMS OF PARTS

The visual world we experience is of people, trees, buildings, coffee cups, and other objects. Yet, light shining onto the eye from these objects produces regions of abrupt changes in luminance and color (edges), regions of gradual changes (shading), and regions of relative uniformity (shapes). The problem of how the brain analyzes these sensory events so as to provide us with the experience of objects is the problem of *perceptual organization*.

Perceptual organization was first identified as a central problem by the Gestalt school of psychology in the 1920s. Among the most influential in this school were Max Wertheimer, Kurt Koffka, and Wolfgang Köhler. They emphasized that the perceived object is different from, and sometimes even more than, the sum of its sensory parts. Modern researchers tend to divide perceptual organization into the smaller subproblems discussed below.

Edge Perception

Edges are the building blocks of vision. When eye movements are prevented, so that edges are no longer stimulating the eye over time, we quickly lose all visual experience. Figure 1 allows you to experience something like a stabilized image by staring at the center dot for about one minute. As you stare at the dot, the fuzzy gray border will begin to disappear because it stimulates a part of your eye that is sufficiently distant from the high-resolution centre that it is unable to register this fuzzy edge. As far as your brain is concerned, the fuzzy border no longer exists, and so the brain concludes that the light gray region (which is defined by a sharp border) is continuous.

Edges interact in cooperative and competitive ways (Field and Hayes, 1993). This can be seen at work in Figure 2, where a large O-shape has been drawn in two ways. In Figure 2(a), the easily seen O is defined by line segments whose extensions form a continuous curved arc. In Figure 2(b) the same O-shape has been drawn, using the same number of line segments, but the line segments now lie at a 90-degree angle to the arc of the curve. The O is now very difficult to see and you will have to inspect individual segments to confirm it. This illustrates the cooperation that exists between nearly continuous edges and the competition that exists between edges of different orientation.

Feature Extraction

When observers are asked to respond rapidly to image features, it is apparent that certain features

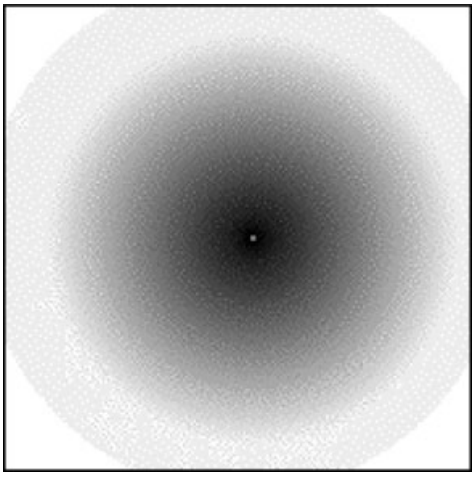

Figure 1. Stabilizing a fuzzy edge on the retina. Stare at the central dot for about a minute with one eye. The fuzzy inner edge will soon disappear and be replaced by a uniform light gray.

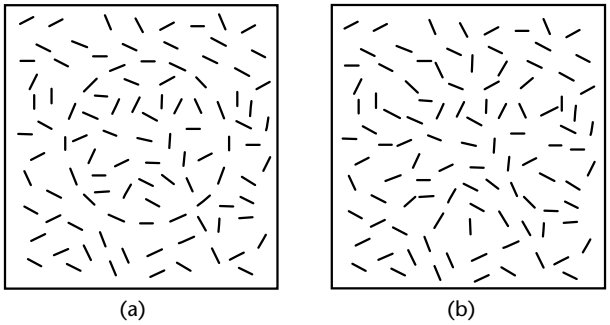

Figure 2. O-shaped configurations defined by (a) nearly continuous line segments, and (b) the same number of line segments oriented at 90 degrees to the continuous curve.

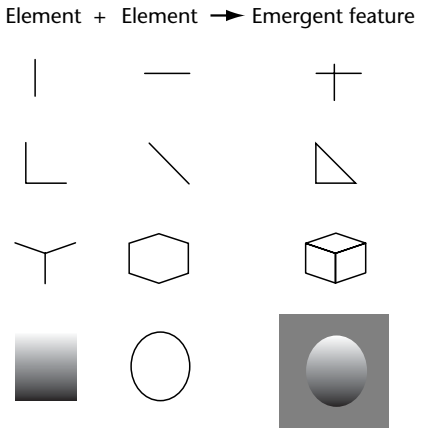

Figure 3. Component elements that create emergent features when combined.

are more basic, including luminance, color, the principal axis of a shape, and shape curvature. Tasks that require observers to respond rapidly to arbitrary combinations of these features are generally done slowly and with many errors (Beck, 1982; Julesz, 1984; Treisman, 1986). However, there are some combinations that do permit rapid analysis. These are *emergent features* since they form *gestalts* that cannot be predicted from the component features (Pomerantz, 1986). Examples are shown in Figure 3 (Enns and Rensink, 1991; Nakayama and Silverman, 1986; Ramachandran, 1988).

Figural Assignment

The assignment of some shapes as belonging to objects that are important to the observer and other shapes as belonging to the background is one of the crowning achievements of vision. It permits actions that are appropriate to objects in the

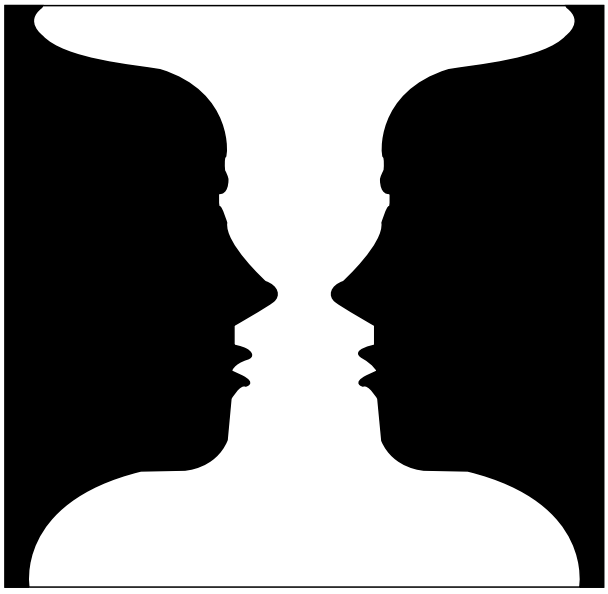

Figure 4. A display that can be seen either as a pair of black faces or as an ornate white vase.

environment, based solely on vision. Some of the complexities involved in the analysis are illustrated in Figure 4, a version of the ambiguous face–vase figure made famous by Rubin (1921). Observers of this display may see a pair of silhouette faces gazing at each other or they may see an ornate vase. The two interpretations also alternate in consciousness over time, illustrating that the assignment of *figure* and *background* is a product of brain processes, and not one determined by the image.

Three-dimensional Structure

Once a three-dimensional interpretation has been made of the figures in an image, the object can be acted upon by the motor systems of the organism. The leading theories in this area have proposed that shapes in the image are assigned to *volumetric primitives*, or simple, convex solids that comprise the three-dimensional building blocks of vision (Biederman, 1987).

PERCEPTUAL FIELD

Perceptual field has two distinct meanings for Gestalt perception. An older sense derives from the early Gestalt theories of brain processes as analogous to electrical force fields. As illustrated in Figure 5(a), Gestalt theories claimed that a single dot viewed on an otherwise blank page, in analogy to a charged particle, had a force that spreads out uniformly in all directions. They hypothesized that

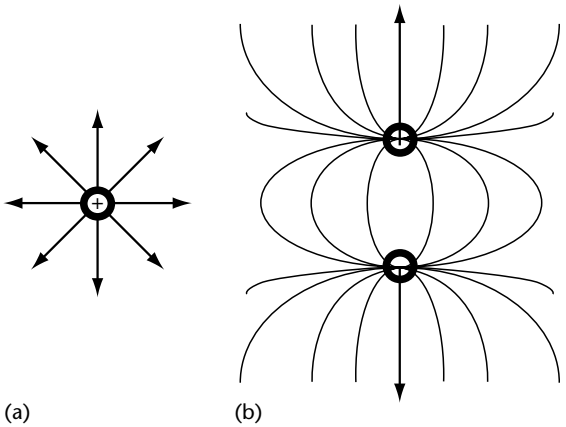

Figure 5. (a) A single particle with a positive electrical charge. (b) The same particle along with a nearby particle with a negative charge. Lines illustrate the electrical field forces.

if a second dot were added, as in Figure 5(b), the two fields of energy would interact. The Gestalt psychologists hoped that such neural interactions would begin to explain perception. However, this theory failed because neuroscientists were unable to find brain mechanisms that followed these patterns. Instead, the dominant metaphor for neurons is the electronic circuit, which means that neurons can perform simple arithmetic operations. In the modern view, neurons do interact with one another in excitatory and inhibitory ways but these interactions do not resemble the spread of energy around magnetic dipoles.

A second sense of *perceptual field* refers to the spatial region over which vision functions. Only a subset of the entire field of view is at any moment contributing to the performance of the task. Some researchers refer to this as the *useful field of view*. Consider how the perceptual field differs depending on the task. If the task is to detect a bright light flashed anywhere in the visual field, the visual field is usually estimated to be almost 180 degrees wide and 100 degrees high. However, if the task is to read letters in a standard row of text, without moving the eyes, then the perceptual field may shrink to only 4–6 degrees wide.

Modern research emphasizes the role of *attention* in perception. Where an observer attends, and what the observer expects to see there, has a powerful effect on what is seen. This dynamic aspect of perception is studied in tasks where observers are asked to detect changes in scenes that are separated by a shift in viewpoint (Simons, 2000) or a short temporal interval (Rensink *et al*., 1997). The main finding is that observers are 'blind' to changes in objects they were not attending to. In other studies, observers perform a visually demanding task and then are suddenly and briefly shown a surprise stimulus. The detection of these unannounced stimuli is so infrequent that the term *inattentional blindness* has been coined (Mack and Rock, 1998). These studies emphasize the 'piecemeal nature' of perception (Hochberg, 1982) and that very little of the available information is consciously registered (Shapiro, 1994).

GROUPING

Which parts of an image belong together and which belong to different objects? This is the problem of grouping that early Gestalt psychologists are best known for. Wertheimer (1923) went so far as to call his answers 'laws', since he believed them to be as reliable as other physical laws. Today reseachers tend to use the term *principle* to reflect their important, but not absolute, influence on perception.

The classic Gestalt principles were illustrated using the elements of dots and line segments. They included the principle of *proximity* (elements that are relatively close tend to be seen as belonging to the same perceptual unit), *similarity* (elements that are relatively similar tend to be seen as belonging together), *good continuation* (elements following a simple curve will tend to be grouped together), *common fate* (elements with common motion direction will tend to cohere), and *closure* (elements which enclose a region will tend to be seen as belonging to the same figure).

Although these principles operate reliably when applied to the drawings of Gestalt psychologists, they are difficult to apply in other settings. There are several reasons for this failure. First, the 'elements' of perception were never defined. Unfortunately, natural images are not coded in the sharply defined dots and lines used in the drawings of Gestalt researchers. Second, the features to which 'similarity' and 'common direction' should be applied were not defined, making the basis of similarity unclear. Third, the spatial region over which the laws applied was not defined. It was simply assumed that each drawing in its entirety would submit to the principles in a coherent manner. This ignores the importance of attentional limits on perceptual field size (Hochberg, 1982).

Some limitations of the classic Gestalt view are being addressed by modern research. For instance, one proposal defines the elements of an image as regions of *common brightness* (Palmer and Rock, 1994). Elements so defined are then grouped further based on a principle of *common region*

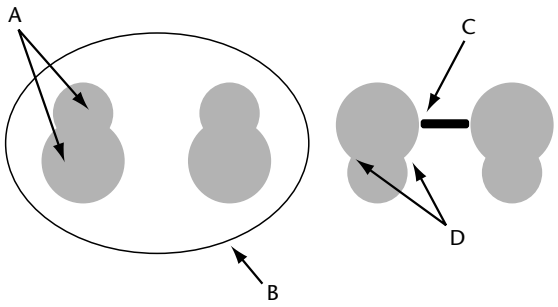

Figure 6. Illustrations of several new principles of grouping (Palmer and Rock, 1994). (A) Common brightness: the two 'bubbles' are grouped because they share brightness. (B) Common region: the two pairs of bubbles are grouped because they are enclosed by a common outline. (C) Element connectedness: the pairs of bubbles are grouped because they are joined by a bar. (D) Image segmentation based on concavities: the two bubbles are seen as separate objects because of the concavities in the surrounding edge.

(elements located within the same enclosed region of space will tend to be grouped) and *element connectedness* (elements in physical contact with other elements will tend to be grouped). However, the initial elements defined by common brightness may also be parsed in greater detail, using the heuristic of segmentation at *regions of deep concavity*. Examples of these principles are shown in Figure 6.

PROXIMITY

An important question for modern research is the perceptual space in which grouping occurs. For example, is the relevant distance for grouping by proximity the retinal image or distance in three-dimensional space? This question has been studied by creating a dot lattice using luminous beads attached to threads, as shown in Figure 7 (Rock, 1997). If observers see the dots as lying in a plane perpendicular to the line of sight, then grouping is influenced primarily by the proximity between dots as measured in the retinal image. On the other hand, if they perceive the dots as part of a surface receding in depth, then the apparent proximity of the dots on the surface determines whether row or column grouping is seen. Related experiments have studied the relations between perceived proximity and the perceptual completion of partially occluding objects. In all cases, it is clear that grouping mechanisms based on proximity work in cooperation with other processes such as depth perception. Similar findings have been reported for grouping by temporal proximity (Lee and Blake, 1999).

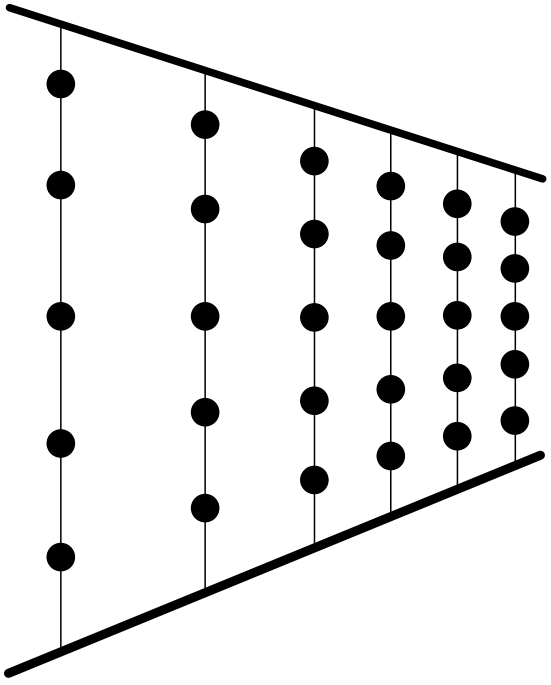

Figure 7. Grouping by proximity depends on whether lattices such as these are seen as lying perpendicular to the line of sight or as receding in depth.

SIMILARITY

Whereas early Gestalt researchers assumed that similarity was based on such obvious properties as color, brightness, and shape, more recent studies have shown that this too is task-dependent. Consider, for example, whether an L-shape or a tilted T-shape is more similar to an upright T-shape. When observers are shown this triplet of elements in isolation, they tend to agree that the tilted and upright Ts are more similar to each other than either one of these two is to the L-shape. However, as shown in Figure 8, when large numbers of these shapes are used to form a texture, borders are formed where regions of uniform elements meet one another. Now it is clear that the strongest border lies between the upright Ts and the tilted Ts (Beck, 1982). This demonstrates that similarity varies with the visual task. Seeing a dense texture of elements leads to an emphasis on differences in element orientation, whereas seeing elements in isolation permits an analysis of the spatial relations among component segments.

In studies of perceived brightness and similarity, it has been shown that grouping depends on the

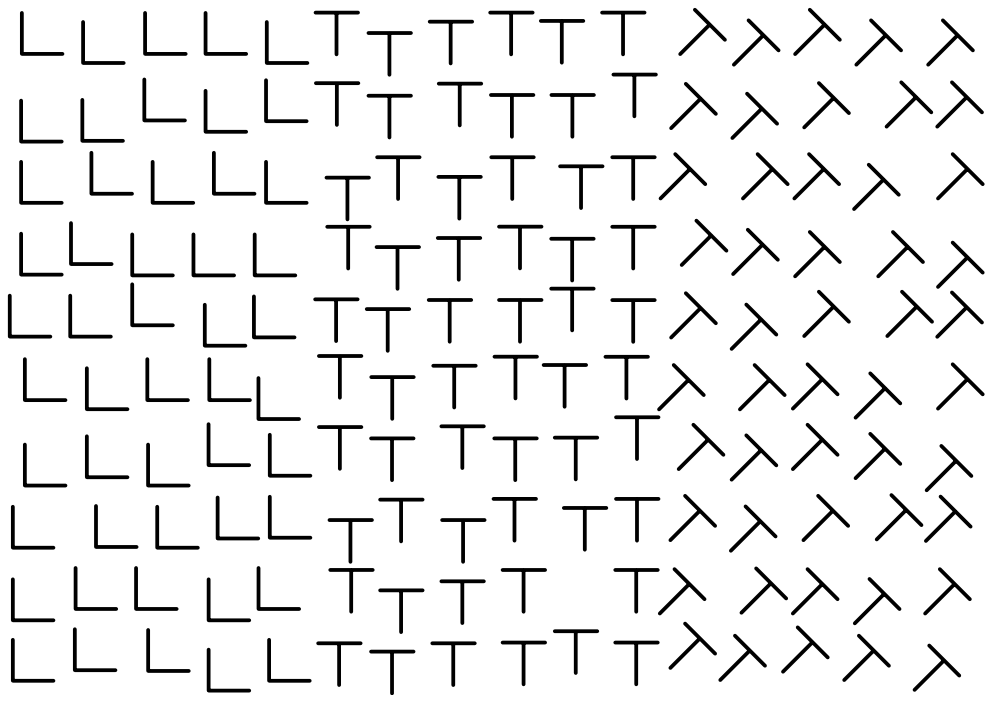

Figure 8. Grouping by similarity in dense textures follows different rules from grouping by similarity of individual texture elements.

apparent brightness, not on the physical luminance intensities of elements (Adelson, 1993; Rock, 1997). This means that observers take into account the role of shadows and assumed light sources in their evaluation of similarity based on luminance. As such, it also demonstrates once again that visual grouping does not operate in isolation from other perceptual processes, especially those involved in the interpretation of an image as being generated by light reflecting from three-dimensional surfaces.

Perception, Haptic

Introductory article

Roberta L Klatzky, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA
Susan J Lederman, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

CONTENTS

Haptic perception is that derived from the sense of touch.

INTRODUCTION

The word 'haptic' comes from a Greek term meaning 'able to lay hold of'. Another word of Greek origin, 'stereognosis', is often used synonymously, particularly in medical contexts. Haptic perception is based on combined sensory inputs from the skin, muscles, tendons, joints and mucosae exposed to the environment (particularly in the mouth). Although these inputs could arise passively, as when an object is pressed against the skin, more commonly they result from active, purposive touch. Special receptors in these sites respond to stimulation from external surfaces or from a person's own movement. Receptors that lie within the skin (cutaneous) include mechanoreceptors, which respond to pressure; thermal receptors, which respond to thermal changes; and nociceptors, which respond to high-intensity, noxious stimulation such as sharp pricks, extreme pressure or very hot or cold surfaces. The word 'kinesthesis' is used to describe perception based on mechanoreceptors in muscles, tendons and joints (and also in the skin of the hand), which give rise to perceived movement, position or strain in body parts.

The cutaneous receptors comprise four types, as defined by the size of the skin surface over which they detect stimulation (receptive field size) and by how quickly they cease firing when stimulation remains constant (rate of adaptation). For example, a class of mechanoreceptors called slowly adapting type I (SA-I) has a small receptive field and adapts slowly, so that it identifies a small area of skin and gives a sustained response when pressure is applied there. These attributes enable it to provide information about small raised patterns that might be touched with the fingertip, like a letter of the Braille alphabet. In contrast, another class of mechanoreceptor, called fast-adapting type II (FA-II), has a large receptive field and stops responding quickly unless mechanical contact changes. This class of receptor responds best to stimuli that repeat rapidly, like the throat of a cat as it purrs. The two remaining classes of mechanoreceptor are rapidly adapting with small receptive fields (FA-I), and slowly adapting with large receptive fields (SA-II). The receptors in muscles and tendons appear to provide information about the positions and movements of the joints. Receptors in the tongue and oral cavity allow people to discriminate food texture, viscosity and temperature, and contribute to the enjoyment of eating.

Much psychological research has investigated the minimum amount of cutaneous stimulation that leads to a conscious sensation – the threshold. Thresholds have been measured, for example, to determine sensitivity to warmth or pain, presumably tapping the inputs from thermoreceptors and nociceptors, respectively. The spatial resolution threshold can be measured by the minimum detectable gap between two points pressed into the skin. Cutaneous thresholds vary somewhat with factors such as air temperature, whereabouts on the skin the stimulus occurs, and the area of skin contacted. Kinesthetic thresholds such as the minimally detectable change in the position of a finger have also been determined. Like most sensory modalities, the haptic system exhibits a general decrease in sensitivity, or heightened thresholds, as people age. Threshold-level responses have implications for haptic perception more generally, as they indicate the intensive, spatial and temporal sensitivities of the system.

HAPTIC PERCEPTION OF SPACE WITHIN REACH OF THE HANDS

In general, perception is not veridical; systematic errors arise. People visually perceive objects at a

distance as nearer than they are (foreshortening). Similarly, various illusions and distortions have been found when people feel shapes in the space within reach of their hands. Some illusions found in touch have counterparts in visual space perception. An example is the Müller–Lyer illusion, in which a horizontal line looks shorter when arrow heads are presented at both ends than when the arrow fins are presented at both ends. Another illusion found in both vision and touch is the oblique effect: it is easier for people to judge the orientation of a rod that is oriented vertically or horizontally than when it is oriented at an oblique angle (such as 45° from the vertical). The analogy between these effects across vision and touch suggests that they might be based on a common underlying representation of space, which can be formed from viewing objects or from feeling them. However, the haptic perceptual system appears capable of producing a variety of representations for any one spatial object, because the way in which the stimulus is explored can have a pronounced effect on the extent of these illusions.

The movements used in exploring space can directly produce some distortions in its perception. For example, when people move their finger from a starting point to a stopping point along an indirect path, the length of their movement affects their estimate of the straight-line distance between the two points. The longer the indirect path from start to end, the longer the direct distance between these points is estimated to be. Another movement-based distortion in haptic space perception is the radial/tangential illusion. Movements towards and away from the body (radial movements) are estimated as being longer than equally long movements made from side to side (tangential movements). One cause of this distortion may be that movements in the two directions take different lengths of time to produce.

HAPTIC PERCEPTION OF TWO-DIMENSIONAL PATTERNS

Most people are familiar with the Braille symbols that can be found in printed media for people with visual impairment and often in elevators and other public facilities. These are examples of two-dimensional patterns that can be presented through touch. Tangible patterns can be relatively small in scale, fitting within a single fingertip, or larger, in which case the pattern must be explored by moving the fingers over it.

Fingertip-size patterns include raised stationary forms, such as Braille, or vibratory stimuli presented by pins that move up and down against the skin. The ability to identify vibratory patterns depends on several factors, including the skin site that is stimulated (the finger or the back, for example), the number of pins in the display, and – when two patterns are presented in succession – by the temporal and spatial relationship between them. Larger patterns, which are traced by the fingers, have often been used as graphic displays for people with poor sight. For example, a line drawing of an object can be converted to a raised, tangible form by a special duplicating machine. The ability to interpret raised drawings of common objects through touch is far below the level that can be achieved with vision. One reason is that the contours being felt must be stored in memory and integrated over time and space. Experience with raised pictures appears to contribute to success in identifying them, as does past visual experience. One strategy that is used to identify tangible patterns without sight is to convert them to a spatial image, which appears to be easier for people who were previously sighted.

PERCEPTION OF OBJECTS AND THEIR PROPERTIES

People are capable of naming familiar, common objects by touch alone with virtually no error, within a few seconds of contact. They do so by perceiving the object's properties – its shape, hardness, and so on. They interpret what they perceive in the context of their knowledge about objects and expectations about what is likely to occur in a given situation.

The nature of people's physical interaction with the world – how they explore and how objects contact them – is critical to what is perceived about an object. People use specialized patterns of touching, called 'exploratory procedures,' in order to determine particular object properties. For example, in order to perceive the roughness of an object's surface, people typically would rub the object. Haptic exploratory procedures have been identified for a variety of other object properties, such as weight and hardness (Figure 1). The exploratory procedure that people choose to use voluntarily, when trying to learn about some property, is also generally the most effective means because it enhances the relevant perceptual information. Rubbing an object, which people spontaneously do when trying to perceive roughness, has been found to heighten the responses of mechanoreceptors that are known to provide information about surface texture.

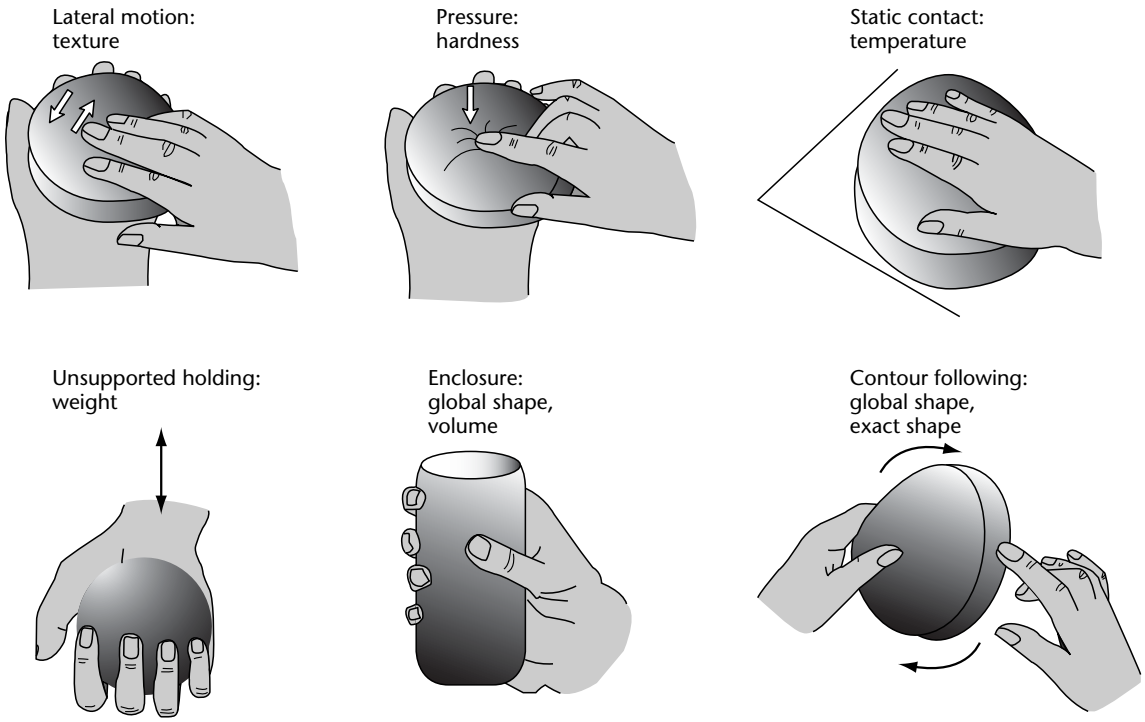

Figure 1. Exploratory procedures and associated object properties. From Lederman and Klatzky (1987); copyright Academic Press, with permission.

Not all properties of an object are equally available through touch. In general, vision and touch provide complementary information about the world, the visual system being more effective at providing information about an object's geometry (size and shape), and the haptic system being more effective at providing information about an object's material properties (roughness, hardness and apparent temperature). The relative availability of object properties can be measured with a haptic search task, in which participants indicate whether a target feature can be found in a display presented to the fingertips. The display incorporates not only the target, if present, but a number of distractor features. For example, the target might be a rough surface presented among smooth surfaces. The time to decide if the target is present is a measure of how quickly the property can be perceived. Material properties tend to be detected relatively quickly, and the time it takes is independent of the number of fingers being stimulated. Such properties are said to 'pop out' of the display. In contrast, haptic searches that involve discrimination between spatial arrangements on the fingertip, such as searching for a horizontal bar among vertical bars, tend to show a pattern of slower response time which increases with the number of fingers stimulated. This finding indicates that processing resources must be directed to each finger.

HAPTIC MEMORY

Two types of memory task have been studied extensively by cognitive psychologists. Explicit memory tasks require people to say directly what they remember about some past event. Implicit memory tasks look for a change in performance in some task, due to the individual having experienced the past event. Research on memory for words and pictures has shown that some manipulations that profoundly affect explicit memory tasks do not have an effect on implicit tasks. For example, thinking about the meaning of a visually presented word while studying it enhances later performance in an explicit test in which studied words must be recalled. However, if the test is implicit – for example, participants must identify words that are flashed briefly – words that were previously viewed will be identified better than unstudied words, regardless of the manner of study.

Comparable distinctions between implicit and explicit memory have been demonstrated in haptic memory experiments. In one experiment,

participants were asked to study a series of tangible forms by touch and then were given either a recognition test (explicit), in which they had to discriminate previously studied forms from novel items, or a test in which they were asked to feel and then draw a series of forms as accurately as possible. The recognition test was affected by whether the participant studied the form in a meaningful way (thinking up some use for an object with that shape) or a nonmeaningful way (counting the number of horizontal and vertical lines in the form). However, the drawing test, which measured implicit memory, was not affected by the task used at study. Evidence of implicit memory has also been found cross-modally – that is, when the participant studied an object by touch and the test object was visual, or vice versa. This indicates that there is a memory trace that can change performance implicitly and is accessible by both modalities.

APPLICATIONS OF RESEARCH

Research into haptic perception leads to several areas of application. Haptically distinguishable cues can be incorporated into the design of handles, knobs or dials, helping to make instruments easier to operate by touch. Haptic stimulators have been used in devices for deaf people, with the goal of helping them disambiguate lip movements. More recently, devices that send forces and vibrations to the hand have been connected to computers. These devices can be used to create haptic virtual worlds, where the forces simulate objects and events that do not physically exist. Similar force-feedback devices can be used to convey the results of real but remote manipulation, such as would occur during telesurgery.

Perceptual Learning

Introductory article

Manfred Fahle, University of Bremen, Bremen, Germany

CONTENTS

Perceptual learning leads to relatively permanent and often very specific improvements in solving perceptual tasks as a result of preceding experience and training. It seems to involve even rather peripheral parts of the central nervous system, such as the primary sensory cortices.

INTRODUCTION

Training and learning improve the performance of humans in a large number of cognitive, motor, and perceptual tasks, as has been known for centuries. Here, we will deal with improvements of *perception* caused by learning. Perceptual learning is defined as a rather permanent and specific change in the perception of and reaction to external stimuli based on preceding training or experience with these stimuli. One factor discriminating perceptual learning from other types of learning is its high specificity, discovered only in the early 1990s. A second difference is that improvement in perceptual learning is generally not based on conscious insight that could be communicated to others, but seems to happen subconsciously, in contrast to explicit forms of learning. Perceptual learning may be regarded as a new subtype of implicit learning and seems to involve a number of different levels of the cortical hierarchy, from higher, cognitive levels down to primary sensory areas, with strong involvement of attention and other top-down influences. The involvement of the low levels of cortical information processing sets perceptual learning apart from most other forms of nonmotor learning and has revolutionized our views regarding the plasticity of these early levels in adult humans.

DEFINITIONS: LEARNING, ADAPTATION, PLASTICITY, AND RELATED TERMS

Learning, of course, may be used as a general notion for all lasting changes in behavior or sensation based on prior experience and/or insight, based on the acquisition and storage of information. Perceptual learning is a specific case, characterized by being restricted to sensory information and by proceeding usually without subjective insight into what exactly is changing during the process, as is typical for implicit forms of learning. This distinguishes perceptual learning from insightful, cognition-based changes in the understanding of facts or relations and from explicit forms of learning. 'Plasticity' stands for changes on both the functional and the anatomic level of the central nervous system which lead to a better adjustment to the outer world or to compensation of defects. The term 'adaptation' denotes a short-term adjustment of the working range of a sensory system, often without any long-term consequences, which is its main difference from perceptual learning. An example is the adaptation to the prevailing light intensity. Two special cases of adaptation are 'saturation' and 'habituation': they denote transient decreases of sensitivity as a result of (usually repeated and/or strong) stimulation. In a way, after-effects are a third special case of adaptation. They are either of retinal origin (after-images) or else cortical origin, mostly due to neuronal fatigue and often caused by antagonistic neuronal mechanisms. Other forms of adaptation are 'sensitization', an increased response after a recent strong stimulation, and 'priming', a latent facilitation of a stimulus–response pair. 'Maturation' and 'development'

relate to changes in function and nervous system structure that – unlike learning – are based mainly on genetics and not on the individual's interaction with the environment.

EXPERT PERCEPTUAL SKILLS

Perceptual learning is not just a phenomenon occurring under restricted laboratory conditions – though it is most often studied this way to better isolate the influence of specific parameters. In everyday life, too, training will improve performance in a multitude of perceptual skills, ranging from visual over acoustical to gustatory (taste) and olfactory (smell) abilities. Expert perceptual skills reach astonishing levels and give testimony of what subtlety of discrimination can be obtained through training, for example in discriminating between simple (such as vernier targets – see below) and complex visual objects (such as CT-scans of normal versus pathological brains), attributing a few bars of music to the corresponding composer, or determining the chateau and year of origin of a wine. All these feats result from long training periods and would be impossible for anyone untrained.

VERNIER ACUITY AND OTHER HYPERACUITIES

To monitor the progress of perceptual learning, it is advisable to use a perceptual function that is easily quantified, gives reliable results, and is very sensitive to change of performance level. These requirements favor perceptual tasks that are complex enough not to be ultimately limited by the optics of the eye or the retinal receptor mosaic, but that are genuine tasks of the cortical machinery – yet mostly achieved by relatively peripheral parts of this cortical machinery, in order to be as independent as possible from higher cognitive processes. Even untrained observers yield amazingly low discrimination thresholds for a number of visual spatial tasks that are known under the heading of hyperacuities. Examples include stereoscopic depth perception, curvature detection, bisection (Figure 1(e)), and vernier discrimination (Figure 1(b)). For example, in vernier discrimination, where subjects have to discriminate between offsets to the right versus offsets to the left in lines with tiny breaks, even thresholds of untrained observers are usually around 20 arcsec, that is below the diameter and spacing of foveal photoreceptors (i.e. the light-receiving elements at the center of the retina). Trained observers may achieve thresholds down to about 2 arcsec, hence vernier discrimination is quite finely tuned but nevertheless open to considerable improvement through training. Hence it is a sensitive measure of perceptual learning, and therefore a large body of experiments has investigated perceptual learning using these hyperacuity tasks.

SPECIFICITY OF LEARNING

It has been known since 1980 that improvement in many of these tasks is rather specific for basic stimulus attributes such as stimulus orientation or position in the visual field. Fiorentini and Beradi, in 1980, found that the improvement through training in discriminating between complex grating stimuli disappeared after rotation of the stimuli by 90 degrees (Figure 1(a)). The same was true for a vernier discrimination task (Figure 1(b) (c)), and even a two-dot stereoscopic depth discrimination task improved for horizontally separated dots through training with these stimuli, only to return to baseline performance when the dots were separated vertically rather than horizontally.

The improvement through training was, moreover, specific for the visual field position that was used during training, both for vernier discrimination (Figure 2(a)) and for texture segregation. Training of a vernier discrimination task at an eccentric field position improved performance significantly within less than 1 hour of training, but if the stimulus was transferred to another position of equal eccentricity, improvement of performance disappeared.

Improvement obtained through training was even (at least partly) specific for the eye used during training: in a texture discrimination task where the subjects had to detect a figure on a background based on the orientation of stimulus elements (Figure 2) no transfer of improvement occurred after monocular training to the eye covered during training. The same specificity for the trained eye holds true for vernier discrimination tasks.

The possible artefact in some of these experiments is that observers may undergo motor learning: they might improve their fixation stability or/and the quality of accommodation. To test this possibility, observers were sequentially tested with a three-dot vernier (Figure 1(d)) and a three-dot bisection task (Figure 1(e)). In both of these tasks, the position of the middle one of three dots differs by less than one photoreceptor spacing from its position in the other task. Observers improved for both of these tasks, but there was no transfer of

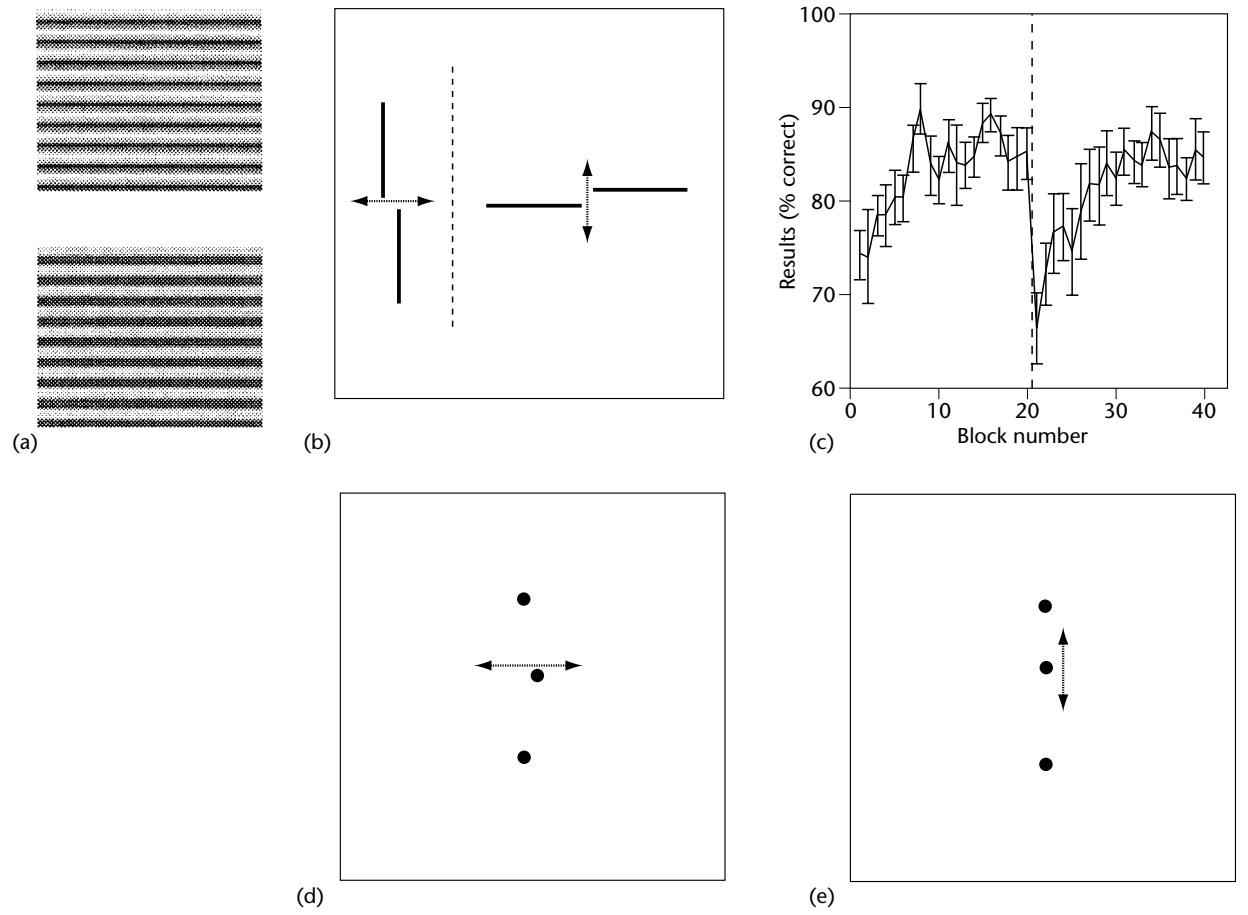

Figure 1. (a) Complex grating patterns as used by Fiorentini and Beradi (1980) to investigate orientation specificity of perceptual learning. Observers learned to discriminate between the two gratings displayed. (b) A vernier discrimination task: is the lower (or left-hand) segment offset to the right or to the left (or up or down) relative to the upper (or right-hand) one? (c) Improvement through training in a vernier discrimination task, within one hour of training, disappears after stimulus rotation by 90 degrees (after Poggio *et al*., 1992). (d) Three-dot vernier task: is the middle dot offset to the left or to the right relative to an imaginary line through the endpoints? (e) Three-dot bisection task: is the middle dot closer to the upper or the lower dot?

improvement, indicating that perceptual learning is not (mainly) based on motor learning, since any form of better fixation or accommodation should have transferred between these tasks. Hence, the specificity for both orientation and the trained eye indicates that the neuronal changes underlying perceptual learning may occur on the level of the primary visual cortex, since only there, neurons are specific both for the eye and for stimulus orientation, while they are not orientation-specific for all more peripheral levels and generally not eye-specific for all more central levels. Specificity of improvement is strongly diminished or disappears altogether for relatively easy tasks. A plausible explanation is that for easy tasks, there is no need to modify peripheral levels of sensory information processing; rather, it suffices to make better use of the information supplied by these 'early' levels.

ROLE OF ATTENTION

Given the above statement that perceptual learning is based most likely on changes on rather peripheral cortical levels of information processing such as the primary sensory cortex, the influence of attention not only on performance but also on speed of learning may be surprising at first sight, but it is a fact. Several independent investigations found that mere presentation of a stimulus that is not attended to improves long-term performance only marginally, or not at all. Hence, there must be strong top-down influences from more 'upstream' parts of the cortical hierarchy that select which

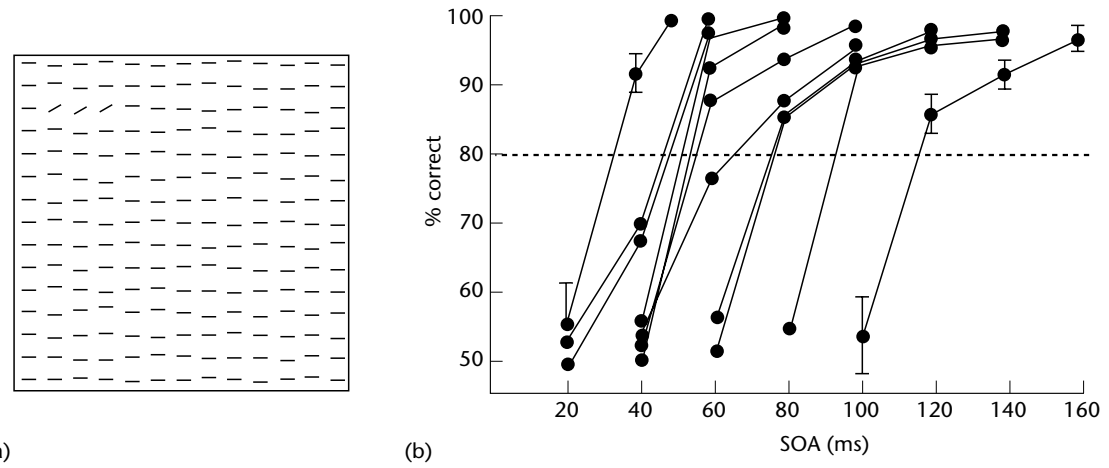

Figure 2. Improvement through perceptual learning in a figure–ground discrimination task based on orientation differences (after Karni and Sagi, 1991). (a) Observers had to discriminate the target defined by the three elements of deviating orientation. (b) Initially, stimulus onset intervals (SOAs) between the stimulus (a) and a subsequent mask had to be longer than 100 ms for the observer to discriminate the target, while less than 40 ms was sufficient after training.

features of the stimulus are attended to, and only those features seem to be effectively learned. Another indication for top-down influences is the fact that after a few clearly above-threshold presentations of the critical feature (hence after stimuli that are easily categorized), observers seem to gain some form of knowledge about which features of the stimulus to attend to and considerably improve performance within a short time.

ROLE OF FEEDBACK

Stimuli usually contain several features, and the number of features increases with the complexity of the stimulus displayed. How does the visual system know which features to attend to? As we just saw, top-down influences such as 'attention' probably play a major role here. Another top-down influence is error feedback. While perceptual learning is certainly possible even without error feedback, it seems to be faster when error feedback is provided. This feedback can be rather sparse, for example, taking the form of a percentage score of correct responses after each block of presentations. Here, the feedback cannot serve as a teacher signal – as in most neuronal network models – since it does not supply information about individual trials, and hence the observer cannot reliably classify stimuli as correctly or incorrectly answered on the basis of this block feedback. A second argument against error feedback serving as a teacher signal is the finding that training is still effective even if half of the error signals are omitted, i.e. feedback is only partial; if the feedback system served to categorize individual stimuli, half of the stimuli misclassified initially by the observer would be 'ratified' by the (missing) error signal – causing large problems for simple neuronal networks. Manipulated error feedback, for example random feedback signals completely unrelated to the observer's performance, can effectively block improvement, and the observer's performance fluctuates strongly but without any clear net improvement.

NEURONAL MECHANISMS AND MODELS OF PERCEPTUAL LEARNING

In the late twentieth century, the primary visual cortex was considered to be plastic only during childhood when it was optimized to become a perfect first filtering stage for visual information processing. In adults, however, the primary visual cortex should be 'hard-wired' in order to prevent changes made in response to one perceptual task from decreasing efficiency of this first filtering stage for other types of stimuli. How then can the statement above be true, that perceptual learning is so specific that it has to (at least partly) rely on changes as early as the primary visual cortex? The answer has also been given above, at least implicitly: the changes on the level of the primary visual cortex might be realized by top-down influences. Thus, the adaptation could be switched on for the appropriate class of stimuli only and hence would not interfere with the processing of other types of

stimuli. Following this hypothesis, plasticity of the primary visual cortex in adults would not interfere with formerly learned tasks.

Apart from the psychological evidence, such as stimulus specificity, there is also electrophysiological evidence for a change of the primary visual cortex following training. On the level of sum-potentials in humans, field distributions over the occipital skull change after training in a vernier discrimination task, especially for the evoked potentials with very short latencies. And on the single cell level, animal studies demonstrate pronounced changes of receptive field positions of neurons in cortical area 17 after lesions of the retinal input.

In summary, the experiments on perceptual learning demonstrate that the primary visual cortex, even of adult humans and animals, is still capable of plastic changes, that these changes underlying perceptual learning seem to be controlled mainly via top-down influences, and that perceptual learning involves several levels of cortical information processing. The results thus indicate that information processing in the visual system is not realized by strictly feedforward connections but that feedback loops play an important role for optimal perceptual performance.

Performance

Introductory article

Dirk Kerzel, Justus-Liebig-University, Giessen, Germany
Wolfgang Prinz, Max Planck Institute for Psychological Research, Munich, Germany

CONTENTS

Human performance is a field of research focusing on the study of elementary sensorimotor skills in well-defined task environments that require fast and accurate responses. Among other things, processes related to the initiation and interruption of responses in single and dual tasks, such as motor planning, response selection, response execution, and response inhibition are investigated.

INTRODUCTION

Human performance is a field of research in which elementary sensorimotor skills are studied. These building blocks of human behavior involve sequences of an external stimulus and an observable action in response to the stimulus, with a well-defined relation between stimulus and action. That is, people are instructed to emit a specified response once a certain stimulus appears. Additionally, they are put under pressure to respond rapidly and without errors. Typically, the experimenter measures both the speed and the accuracy of responses in different conditions. As these aspects of human behavior are relevant to industrial productivity and safety, research on human performance was initially closely related to applied questions such as the design of dashboards or workplaces.

STARTING AND STOPPING ACTIONS

Indicators of Response Preparation

There are many indicators that bear witness to cognitive processes related to a response before that response is visible to an observer. If the electrical activity of the brain is measured by electrodes attached to the scalp, it can be observed that the brain potential on the side of the head opposite to where a response is about to be executed becomes more negative than the potential on the same side. For instance, if a person is instructed to press a left key, the electroencephalogram shows that the brain potential on the right side is more negative than that on the left. This phenomenon is called 'lateralized readiness potential' (LRP) because it has been shown to be involved in response preparation. Notably, the LRP may occur even slightly before the person is consciously aware of intending to execute the action. Thus, physiological events in the brain (at least occasionally) precede our awareness of action plans. At a peripheral level, the electromyographic activity at the muscle rises about 50 ms before the muscle actually moves. Finally, the observable response is emitted. The time between stimulus onset and onset of the associated response is the reaction time (RT). It is common practice to draw conclusions about motor preparation or planning from the analysis of psychophysiological indicators and RT. Any one of these indicators is incomplete as it never captures all aspects of motor planning; however, as a sum, they may be used to derive models of cognitive motor planning. By far the most widely used of these indicators of human performance is the RT. Different types of reaction time may be distinguished. If there is only one possible stimulus and only a single response associated with it, the observed latencies are simple RTs. If there is more than one stimulus, and several associated responses, choice RTs are measured. Typically, choice RTs are longer than simple RTs.

Simple Reaction Time

Simple RT is usually of the order of 200 ms, but the exact time depends on a number of factors. On the stimulus side, it has been shown that the intensity of the signal affects simple RT. The higher the intensity of the stimulus, the faster the response. For instance, bright targets yield faster RTs than dim targets, and loud sounds yield faster RTs than soft ones. Also, stable characteristics of the person affect

simple RTs. Simple responses of young and alert persons are faster than those of older and less alert persons. The degree of preparation is a further determinant of simple RT. Generally, increasing the level of preparation by presenting a warning signal speeds up simple RTs. However, the ability to maintain a high degree of preparation is limited. When the time between the warning signal and the stimulus is long, the beneficial effects of the warning signal disappear. Further, simple RT increases with uncertainty about the time when the stimulus will appear. Responses are faster if the person is sure about when the signal will occur than when the time of signal presentation is uncertain. Finally, simple RT depends on the effector that is executing the response. The larger the mass of the effector, the longer the response latency. For instance, lifting the finger is faster than flexing the elbow, and flexing the elbow is faster than flexing the shoulder. The reason for these differences may be electromechanical factors related to the size of the effectors, not the programming of the response: the time between stimulus presentation and the first electromyographic activity at the peripheral muscles is the same for all effectors, such that the central processes related to motor programming do not differ. Only the time between the first electrical activity at the muscle and the muscle movement differs as a function of effector.

Choice Reaction Time

Choice RT differs from simple RT in that a response has to be selected from an array of alternative responses (two at the minimum). A large variety of responses is available. For instance, the experimenter may ask for key presses on a keyboard with four keys arranged in a square, or for joystick movements to the left, right, up and down, or for verbal responses such as 'yes' and 'no'. In choice tasks, the stimuli are mapped onto responses: that is, the stimulus determines which response has to be executed. Usually, the mapping of stimuli onto response is conveyed by verbal instruction. For instance, the digit 1 appearing on a computer screen may require a joystick movement to the left, and the digit 2 may require a joystick movement to the right. Choice reaction time is longer than simple reaction time because the response in a choice task cannot be as well prepared as the response in a simple task.

The number of response alternatives in choice tasks has been shown to affect directly choice reaction time. Choice reaction time increases with the number of response alternatives: when people are asked to press one of n keys laid horizontally out in front of them whenever one of n lights located directly above the keys is turned on, RTs increase with n. The relation between n and choice reaction time follows a nonlinear function that has become known as the Hick–Hyman law. It states that choice reaction time increases linearly with the logarithm to the base 2 of the number of response alternatives (n). With an increase of 1 in the logarithm, the response time increases by about 150 ms. (*See* **Action**)

Stimulus–Response Compatibility

It is commonly observed that the speed of a choice response depends on how responses are mapped onto stimuli. Generally, the more natural or intuitive the mapping, the faster the responses. For instance, responses are fast when a left stimulus has to be responded by a left response and a right stimulus by a right response, but slow when a left stimulus has to be responded by a right response and a right stimulus by a left response. The former mapping is referred to as a compatible mapping. Stimulus–response compatibility may lead to violations of the Hick–Hyman law. When the assignment of responses to stimuli is extremely compatible, for instance when the tactile stimulation of a finger has to be responded to by depressing the stimulated finger, no increase of choice RT with the number of alternatives is noted. (*See* **Action**)

Sequences of Responses

The previous sections were concerned with a single action as a response to a stimulus. In this section, sequences of actions that follow an external stimulus are discussed. *A priori*, two ways of handling motor programming of a sequence of movements may be distinguished. First, the programming may be done in advance, and the program is only executed once the response is initiated. In this case, a motor output buffer is needed that retains the sequence of motor commands. Assuming that motor commands have to be loaded into the buffer one after the other, the time to load the buffer with commands increases with the required number of commands. Second, movement programming may be restricted to one movement at a time, such that in a sequence of actions, programming and execution alternate. In this case, no effect of number of movements on the reaction time of the first response should occur. The empirical research

suggests that the truth lies in between these extreme views. In support of prior programming, it was observed that the reaction time to initiate a movement sequence increases with the number of movements that have to be executed. For instance, lifting a finger is faster than grasping a tennis ball, which in turn is faster than grasping the tennis ball twice. Note that the question is how fast these movement sequences are initiated – that is, how fast a home key is released before the sequence is executed – not how long the sequence lasts. A similar slowing with increasing number of movements has been observed with sequences of key presses, spoken syllables and written letters. In support of the ongoing programming view, the reaction time of individual movements in a sequence varies as a function of their serial position. At some serial positions, reprogramming of the upcoming movements is necessary, which slows down the response. Thus, sequences of movements cannot be fully pre-programmed, suggesting that the motor output buffer has a limited capacity.

Stopping an Action

Many situations require people to stop their ongoing actions. The successful operation of a stop process may be just as important for survival as the ability to initiate an action quickly. In stop-signal experiments, participants are given a primary task to perform and a stop signal is intermittently presented telling them not to respond on that trial. One may think of the processes related to the stop signal and those related to the primary task as independent sets of processes that are contestants in a race: if the primary task process finishes before the stop-signal process, the response is executed, but if the stop-signal process finishes before the primary task process, the response is inhibited. Studies using the stop-signal paradigm revealed that the stopping of actions does not differ substantially between individuals, strategies or tasks. The latency of inhibition is of the order of 200 ms. Also, the stop-signal paradigm allows for the evaluation of ballistic processes involved in action execution. Ballistic processes cannot be inhibited once they begin; rather, they must run to completion. Little evidence for ballistic processes was obtained. For instance, one might assume that during typing, whole words are programmed, and the typing of the word sequence is ballistic. This is hardly the case. When typists were given an auditory stop signal during typing, they were able to stop typing after a single keystroke, regardless of word boundary (the only notable exception being 'the').

ERRORS OF PERFORMANCE

Errors are usually not independent of the speed with which an action is performed. When errors and reaction time both follow the same pattern across conditions, it might be concluded that performance was affected by the experimental variation. For instance, in an easy condition, fast responses and few errors may be observed, whereas in a difficult condition, slow responses and many errors occur. In this case, one might attribute differences in performance to the difficulty of the conditions. However, if errors and reaction time do not follow the same pattern, strategic decisions of the participant, not the properties of the experimental conditions, might account for the observed performance. If people opt for a daring response strategy, their responses are fast, but they make many errors. Alternatively, they may choose a cautious response strategy, implying that their responses are slow and few errors occur. In other words, participants may trade off speed and accuracy.

At least two types of errors may be distinguished: choice errors and serial order errors. If people select the wrong response from an array of possible responses, this is called a choice error. Serial order errors occur when a correct response is selected, but it is emitted at the wrong position. The exchange of speech sounds such as 'The queer old dean' instead of 'The dear old queen' show that we sometimes confuse the serial order of initial consonants. Also, these errors tell us that we store motor programs for a series of actions. In sum, errors of performance are another measure to characterize human performance in addition to reaction times.

COMBINING BEHAVIORS

Coarticulation

In a stream of actions, it is often efficient not to wait for one action to end before another is initiated. Coarticulation refers to simultaneous motion of effectors that makes a series of movements more efficient. It denotes that an upcoming action is prepared while another action is being performed. Such a strategy reduces latency of actions, and it leads to the combination of behaviors that are adjacent in time. The term 'coarticulation' was coined with respect to speech production, but the phenomenon encompasses other types of movements as well. For instance, finger movements during typing show that the fingers are not at rest until the previous keystrokes have been finished; rather, the hands move to their target positions ahead of

time, allowing for fast typing rates. (*See* **Speech Production**)

Bimanual Rhythmical Movements

In the case of coarticulation, the simultaneous motion of two effectors is a by-product of efficient motor performance. However, it is also common to intentionally perform two movements at the same time. In particular, the production of rhythmical patterns involves simultaneous bimanual movements. However, research shows that our ability to perform two independent rhythmical movements with two effectors is very limited. A famous example may illustrate this point. The index fingers are flexed or extended resulting in a movement that resembles tapping (e.g. on a table top). Two basic relations between the movement of the two index fingers may be distinguished: left and right index fingers are flexed and extended simultaneously, which is referred to as in-phase pattern. In the anti-phase pattern, one index finger flexes as the other extends. When in-phase and anti-phase movement patterns are performed at a moderate speed, and the speed is subsequently increased, a striking difference emerges: whereas the in-phase pattern is stable across different movement speeds, the anti-phase pattern breaks down at fast speeds and a switch into the in-phase pattern occurs because it is easier in terms of the emerging perceptual or motor pattern. Thus, performance in tasks that involve continuous action of two effectors is severely limited.

DOING MORE THAN ONE THING AT ONCE

Dual Task Performance

In everyday life it is common to see people perform two different activities at the same time. Driving a car does not prevent people from having a conversation, and eating potato crisps does not keep them from watching television. Usually people do not experience any difficulty in concurrently carrying out two tasks, unless the tasks are intellectually challenging or physically impossible. Contrary to this belief, laboratory studies show that performing even simple tasks concurrently causes interference between the two tasks – that is, one of the tasks is performed less efficiently in terms of response time or proportion of errors.

The Psychological Refractory Period

In one important experimental design used to investigate dual task performance, observers are presented with two stimuli in succession, S1 and S2. The stimuli may be auditory, visual or even tactile, and they do not have to be presented within the same modality (e.g. an auditory S1 may be combined with a visual S2). The stimuli S1 and S2 are temporally separated by a variable stimulus onset asynchrony (SOA). Typically, the SOA varies between 0 ms and 1000 ms. Before the experiment starts, the participant is instructed to respond to S1 with a response R1, and to S2 with a response R2 (Figure 1). By far the most common responses are key presses because they can be easily recorded on a keyboard. Other responses include vocal responses, eye movements or foot movements. Again, R1 and R2 do not have to originate from the same effector (e.g. a manual R1 may be combined with a vocal R2). A large number of mappings between stimulus and response are possible

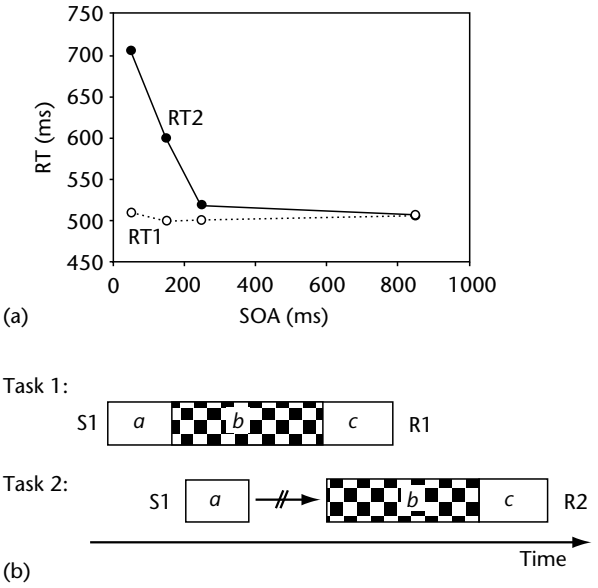

Figure 1. (a) The psychological refractory period effect. The reaction time for the first task (RT1) is unaffected by the stimulus onset asynchrony (SOA), whereas the reaction time in the second task (RT2) is longer at shorter SOAs. (b) The central bottleneck model of dual task performance. Cognitive processes *a*, *b* and *c* intervene between stimulus presentation S and response execution R, in two tasks. Process *b* (checkerboard region) is a bottleneck because it cannot begin in task 2 until the corresponding part of task 1 is complete. Process *b* has been associated with response selection.

and a fair percentage of them have already been tested. However, the main finding is robust across a large number of possible combinations of stimuli and responses: the time elapsing between the onset of S1 and the execution of R1 (RT1) varies little as a function of SOA between S1 and S2. In contrast, the time between onset of S2 and execution of R2 (RT2) increases dramatically when the SOA between S1 and S2 is made short. This finding is referred to as the psychological refractory period (PRP) effect. The PRP effect is the slowing of performance in one (or sometimes both) of two speeded tasks when the two tasks are performed at approximately the same time.

Other Dual Task Situations

Contrary to our everyday experience, the PRP effect shows that performance in two apparently easy tasks is slowed if they are performed at the same time. However, there are also dual task situations in which no interference between the two tasks occurs. When participants are engaged in a task without response uncertainty, such as repetitive finger-tapping or saying 'the' repetitively, there is almost no slowing of concurrent speeded responses in a different modality or of mental operations such as counting. Also, when there is no speed pressure on a perceptual judgment, it does not suffer from a speeded response in another modality. For instance, unspeeded visual identification of a letter is not affected by the approximately simultaneous response to an acoustic signal. Taken together, these findings suggest that the important distinction between dual task situations that show indications of interference and those that do not is whether both tasks or only one task requires a speeded response. Generally, whenever a rapid decision about a response has to be made in two approximately simultaneous tasks, interference results; otherwise, dual task interference is less likely and may be attributable to factors that are unrelated to the execution of the two tasks.

Models of Dual Task Performance

A widely accepted account of dual task performance, and in particular the PRP effect, is based on the assumption of a central bottleneck. A mental process *b* is considered a central bottleneck if (1) *b* is necessary for the completion of both tasks involved in a dual task situation, and (2) *b* may only be used by one task at a time. In other words, when a task (T1) lays claim on *b*, *b* cannot be used by another task (T2). Rather, T2 has to wait for *b* to be released from T1. Only after *b* has been released from T1 can T2 be completed. A central processing bottleneck would explain the PRP effect in the following way: when S1 is presented, the execution of the first task, T1, is initiated. Because S2 is presented after S1, execution of T2 is initiated after T1. Therefore, T1 claims *b* before T2 tries to. Consequently, with short intervals between S1 and S2, T1 may still occupy *b* when T2 is ready to use *b*. As a result, responses to S2 are delayed. With long intervals between S1 and S2, responses to S2 are faster because T1 has already released *b*, such that T2 has free access to it.

Considerable debate has focused on the nature of the central bottleneck. During the execution of a task that requires a particular response when a particular stimulus is presented, different processing stages may be identified: perceptual identification of the stimulus, selection of the correct response, and execution of the response. The central bottleneck may be located at any of these stages. Over the years, evidence has accumulated that the central bottleneck is located at the stage of response selection – that is, at the stage at which we decide whether to press the left or the right key, or whether to say 'a' or 'b' in response to a given stimulus.

The hypothesis of a central bottleneck in response selection has been criticized, on the grounds that the instructions in experiments on the PRP effect gave performance in T1 priority over performance in T2. That is, participants were asked to emit R1 before R2, possibly forcing them to use a bottleneck mechanism to postpone information processing for T2, so that responses to S2 did not occur before those to S1. Alternatives to the central bottleneck approach assume that the scheduling of processes in the PRP paradigm is under strategic control. That is, participants voluntarily decide to complete stimulus identification and response selection for T1 before tackling T2 because of the higher priority of T1, and not because of a structural bottleneck that forces them to do so. If participants had been given different instructions, they might just as well have scheduled response selection for T1 and T2 to occur at the same time (in violation of the second condition for a central bottleneck).

Phenomenology, Psychological

Advanced article

Michael Kubovy, University of Virginia, Charlottesville, Virginia, USA

CONTENTS

Phenomenology is the study of how the world (material, mental, or cultural) appears to me. Given the common view of scientific observation as objective, unaffected by a point of view, it is natural that controversy exists over the role of phenomenology in science.

INTRODUCTION

The debate over the role of phenomenology in science (Roy *et al*., 1999) can be understood with the help of a diagram (Figure 1) that shows the three facets of cognitive theory – a theory of the brain, a theory of how the mind performs its computations, and a theory of experience – and the links between them. The controversy has focused on the link between the computational and the phenomenological mind. Skeptics have claimed that there is an unbridgeable 'explanatory gap' (a term coined by Levine (1983)) in this link. An early exponent of this position was Thomas Nagel (1970), who eloquently raised doubts about the possibility of ever incorporating phenomenological data into cognitive science.

Those who believe that the explanatory gap is unbridgeable give two reasons. The first reason is that theories of the phenomenological mind are inevitably based on private data: I cannot tap into the experience of another person. In contrast, theories of the computational mind are, generally speaking, based on public data that we obtain from psychological experiments. The two can therefore never meet. But the argument from privacy alone is not sufficient to warrant the skeptical view of the explanatory gap. If you had reasons to believe that another person's experiences were the same as yours, you would not care that they are inaccessible. The argument is parallel to the following one. Because you have reasons to believe that the text of a book remains the same when the book is closed, you do not care that it is inaccessible when it is closed.

Thus, to argue for the explanatory gap, the skeptic requires a second argument: the argument from subjectivity. It claims that different sentient beings must have different experiences. So even if you could tap into a bat's experience of the world, the experience would be unfathomable, since bats, for example, catch insects so differently from the way you do. But could we sidestep skepticism by capitulating on the bat front only, while denying that the argument from subjectivity holds among humans? The skeptic would reply that humans too experience things differently from each other, because they are of different sexes, because they grew up in different cultures, or simply because they are different people.

We will not try to resolve this issue on philosophical grounds. Instead, we present a phenomenological analysis to illustrate how a cognitive psychologist might deal with these issues. In working through this example we will follow Husserl (see Moran, 2000, chapters 2–5), as interpreted by Sartre (1948) and Ihde (1977)).

MENTAL IMAGERY

In the 1970s and 1980s, following the groundbreaking work of Shepard and Metzler (1971) (see also Shepard and Cooper, 1982), there raged a debate over the nature of mental imagery. We will follow Kosslyn's (1994) account. The two camps in this debate defended two different kinds of mental representations that could underlie mental imagery (Kosslyn, 1994, p. 5):

- *Propositional:* 'A propositional representation is a "mental sentence" that specifies unambiguously the meaning of an assertion. Such a representation must contain a relation … [which] ties together two or more … arguments.'
- *Depictive:* 'A depictive representation is a type of picture, which specifies the locations and values of configurations of points in a space. … [D]epictive representations convey meaning via their resemblance to an object, with parts of the representation corresponding to parts of the object.'

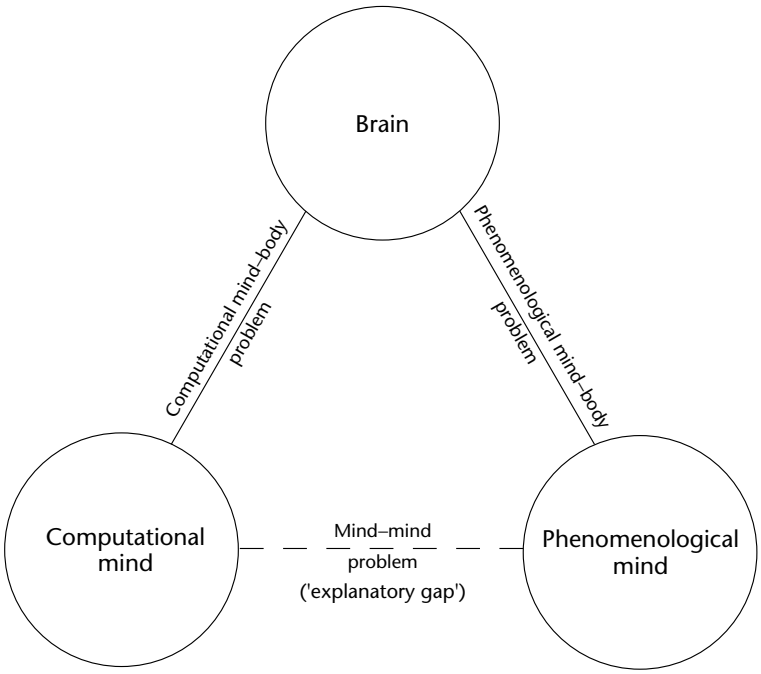

Figure 1. The three facets and the three linkage problems of cognitive science, and the explanatory gap. (Adapted from Jackendoff, 1987.)

At the end of his survey, Kosslyn concludes that mental images 'rely … on depictive representations'. He also effectively sidesteps the following challenge offered by Pylyshyn (1973, 1981). If a mental representation is depictive, it must be depictive for someone or something, perhaps the eye of a homunculus. But if we accepted that, we would then fall into an infinite regress, because we would have to explain how this homuncular eye works. Kosslyn replies that he is under no obligation to answer Pylyshyn's question about imagery. We know that the visual system contains depictive representations: the existence of multiple retinotopically organized maps has been well established (Wandell, 1999; Zeki, 1993; Livingstone and Hubel, 1988). Yet no one asks who or what looks at these retinotopic maps. Kosslyn argues that imagery relies on depictive representations because, firstly, 'imagery and perception share common mechanisms', and secondly, the mechanisms underlying perception are depictive. He concludes that Pylyshyn's homunculus argument about imagery is no more justified than such an argument about visual perception.

Now for a little exercise in imagery. Think of the home you live in. How many windows can one see on the facade of the house? This is a question that most people answer willingly. (Many people make small pointing gestures while they count.) Once you have counted, ask yourself: where were you standing when you counted? Most people answer with no hesitation.

Before we examine our exercise, let us mention a fundamental proposition of phenomenology: all experience is the experiencing of something (Moran, 2000, pp. 16–17). This 'aboutness principle' suggests that the structure of an experience is '*experiencing* → *experienced*', where the → represents the 'aboutness' relation.

If you think back on what you just did, you will recognize that during the exercise you were conscious of the facade, not of an image of the facade. In this respect, imagining is no different from perceiving. How, then, do they differ? As Sartre (1948) observed, when you perceive the facade, you experience it as present, but when you imagine it, you experience it as absent. Just as Jastrow's (1900) drawing (Figure 2) remains unchanged whether you see it as a duck or as a rabbit, the facade is the same, whether you see it, and therefore experience it as existing, or imagine it, and therefore experience it as absent.

What we have learned (following Ihde, 1977, chap. 2) can be summarized by two schemata: '*seeing* → *facade*' and '*imagining* → *facade*'. Thus both experiences are experiences of the same thing, the facade.

Our observation regarding the difference between seeing and imagining the facade can be

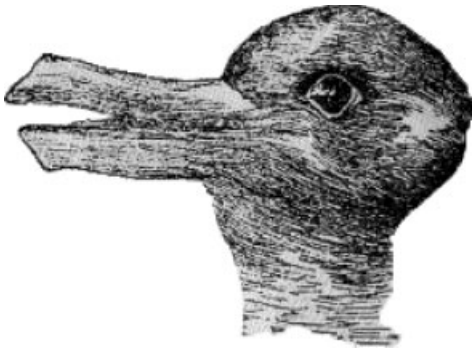

Figure 2. The duck-rabbit. (Adapted from Jastrow, 1900.)

represented by the contrast between '*seeing: experiencing as present → facade*' and '*imagining: experiencing as absent → facade*'.

Finally, having observed that you knew where you stood while counting the windows, we infer that this act of imagining contains an experiencer, which we denote '(I)'. So we can write: '*(I) imagining: experiencing as absent → facade*'.

A theory of mental imagery must take account of these observations. But current theories do not. Regarding the fact that you knew where you stood when you counted windows, perhaps we need a theory of embodied imagination (perhaps in the direction proposed by Ballard *et al*. (1997)), according to which imagining a visible object is a partial reenactment of many of the bodily activities involved in perceiving something, not just an activation of the visual system.

INTERSUBJECTIVITY AND EXPERIMENTAL PHENOMENOLOGY

The issue of subjectivity would not come into play in our phenomenological analysis unless someone who did our exercise challenged our observations. For example, you could tell me that you actually did not know where you stood while you were counting the windows; that when I asked, you inferred your position from the fact that you could see the whole facade. Of course, such a challenge would also bring to the fore the problem of the privacy of experience: I could not challenge your assertion. It is precisely here that other methods of research would come into play. One could not resolve a disagreement over the source of people's phenomenological intuitions within the domain of phenomenology. It is only by assuming that the links among the three facets of cognitive science are intact that progress can be made. To exclude phenomenological methods just because

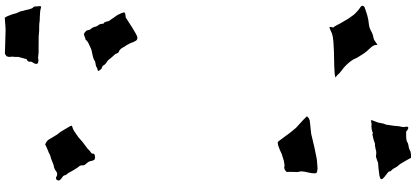

Figure 3. Grouping. (Adapted from Köhler, 1947.)

they do not bear a seal of infallibility is to ensure the existence of an explanatory gap.

Thus the key to the use of phenomenological observation is 'intersubjectivity' (Husserl, 1967), i.e. an agreement among individuals about the nature of their experience. The Gestalt psychologists – who were the ones who imported phenomenology into psychology – took it for granted that phenomenology was not a study of the subjective. For example, Köhler (1947, p. 142, emphasis mine) writes of Figure 3:

> The reader has before him two groups of patches. Why not merely six patches? Or two other groups? Or three groups of three members each? When looking casually at this pattern *everyone* beholds the two groups of three patches each.

Phenomenology has given rise to a research methodology, sometimes known as 'experimental phenomenology', which differs from conventional psychological experiments as summarized in Table 1 (Bozzi, 1989, chap. 7). This methodology is appropriate for the kind of phenomenological exploration we carried out above.

OPPOSITES

For an example of the application of Bozzi's method, we turn to the research of Savardi and Bianchi (2000) on psycholinguistics and the experience of space. They claim that opposites structure our experience, no less than unity, identity, or similarity.

The research was conducted with a group of undergraduate students of industrial design at the Politecnico di Milano (the Milan Institute of Technology). They met in groups of three once a week in three-hour sessions to exchange observations about their experience of space. They were asked to find all the words (in everyday Italian) they needed to exhaustively describe any space or spatial relation. They produced 74 adjectives or adverbs. Upon examination of these words, Savardi and Bianchi found that each word had its opposite within the set (see Table 2).

Once they had obtained these opposites, Savardi and Bianchi assumed that these were the endpoints

Table 1. Comparison of conventional and phenomenological experiments. (Adapted from Bozzi, 1989.)

	Conventional	*Phenomenological*
Environment	isolated (e.g. a laboratory)	any (preferably not a laboratory)
Participants	kept naive about the topic or purpose of the research	told everything
Task	well-defined	jointly defined by participant and researcher
Participants' response	often the first that comes to mind	may transcend their first impression, and thus provide information about their solution space
	may not be modified	may be reconsidered
	either correct or incorrect	always valid
	unambiguous, or filtered into a set of mutually exclusive and collectively exhaustive *a priori* categories	classified only after all the data have been examined

Table 2. Thirty-seven pairs of opposites, grouped by cluster. A disk represents a singular pole. A solid line turning into a dashed line represent an unbounded polarity. A solid line that ends with a vertical tick represents a bounded polarity. A rectangle represents a single intermediate state. Short vertical ticks between the endpoints represent multiple intermediate states (Adapted from Savardi and Bianchi, 2000.)

Dimension	*Representation*	*Dimension*	*Representation*
Cluster 1		*Cluster 2*	
regular–irregular		moving–still	
symmetric–asymmetric		open–closed	
complete–incomplete			
straight–curved			
ordered–disordered			
supported–unsupported			
bounded–unbounded			
Cluster 3		*Cluster 4*	
full–empty		obtuse–acute	standing–lying		uphill–downhill	
vertical–horizontal		convex–concave	
top–bottom		divergent–convergent	
beginning–end		right–left	
floating–sunken		rounded–angular	
upright–upside down			
inside–outside			
Cluster 5		*Cluster 6*	
above–below		far–near	in front of–behind		long–short	
		wide–narrow	
		thick–thin	
		high–low	
		broad–narrow	
		many–few	
		large–small	
		dense–sparse	
		fat–thin	
		simple–complex	
		deep–shallow	

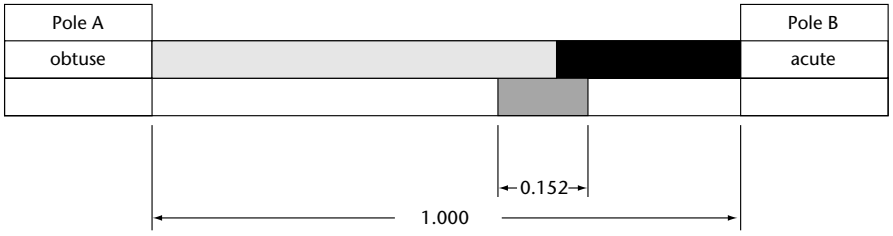

Figure 4. Fragment of the table used by Savardi and Bianchi (2000). It is shown as it might look after having been filled by participants.

of dimensions. To understand these dimensions, they explored the characteristics of things that are at neither pole of these dimensions. They gave the participants a table (Figure 4) that listed the 37 dimensions defined by their endpoints, or poles. About the 'obtuse–acute' dimension they were told to think of the space between the poles as a scale that represents 'all possible visual experiences of things that you would call "obtuse" or "acute" or anything in between'. For each pair, there were two scales. On the first scale, they were then told to mark the boundary between things they would call 'obtuse' and things they would call 'acute'. On the second scale they were asked to indicate the bounds of a range that would straddle the boundary marked on the first scale. This range was to represent the things they would neither call 'obtuse' nor 'acute'. The participants were reminded that the boundaries they were asked to place should not represent the number of things that are obtuse, acute, or in between, but rather the number of ways there are to be obtuse, acute, or in between.

Having obtained these judgments, they computed the proportion of the dimension covered by the 'in between' region (15.2% in Figure 4), and then computed what fraction of the remainder was given to each pole. They found that, on the average, only 12% of our experience of space is intermediate. They then performed a hierarchical cluster analysis of these judgments, and found that the dimensions fell into three classes: strongly polarized (19 dimensions), moderately polarized (13 dimensions), and weakly polarized (5 dimensions). For the strongly polarized dimensions, such as 'moving–still', each polar adjective either holds or not, there are no names for intermediate states, and the poles cover the entire range of possible states. For the moderately polarized dimensions, such as 'vertical–horizontal', there are names for intermediate states. Finally, for the weakly polarized dimensions, such as 'full–empty', each polar adjective either holds or not, there are no names for intermediate states, and the poles cover only the extreme states.

Savardi and Bianchi then performed a hierarchical cluster analysis of the asymmetry of the dimensions, and further classified the dimensions, as shown in Table 2. After several more steps, they produced a taxonomy of spatial concepts, also shown in this table.

Two remarks should be made here. Firstly, phenomenological research is similar to protocol analysis, which involves the use of verbal reports as data, and is often used in research on problem-solving (Simon and Kaplan, 1989), and to other non-experimental research methods (Smith *et al.*, 1995). Secondly, phenomenology should not be confused with introspectionism as practiced by early psychologists such as Titchener. In fact, any account of the introspectionists' methods (e.g. Lyons, 1986), and their methodological assumptions, will confirm that introspectionism is closer to contemporary experimental psychology than to phenomenology. Indeed, overall, introspective research is well described by Bozzi's list of features of conventional psychological experiments (Table 1).

The application of phenomenology to cognitive science is not restricted to the type of exercise we engaged in earlier and the type of work Bozzi described in his valuable discussion of 'Interobservation as a Method of Experimental Phenomenology', as summarized in Table 1 (Bozzi, 1989, chap. 7). We therefore turn to a discussion of a methodology that draws upon psychophysics and phenomenology, which Kubovy and Gepshtein (2002) called 'phenomenological psychophysics'.

PHENOMENOLOGICAL PSYCHOPHYSICS

Palmer (2002) in a discussion of demonstrations of grouping (such as Figure 3) writes that, they are 'a useful, but relatively blunt instrument for studying perceptual organization' because they have a

subjective basis. Pomerantz and Kubovy (1981, p. 426) had similar concerns:

> [T]he pragmatic streak in American psychology drives us to ask what role … experiences, however compelling their demonstration, play in the causal chain that ends in action. Thus we ask whether such phenomenology might not be a mere epiphenomenon, unrelated to behavior.

The standard solution to this problem is to use objective behavioral tasks:

> [I]f we can set up situations in which we ask subjects questions about the stimulus that have a correct answer, and if organizational processes affect their judgments (and so their answers), then the experimentalists' skepticism about the importance of organizational phenomena should be dispelled.

Can one determine whether an experience is epiphenomenal? For example, can perceptual organization be studied by embedding it in an experimental task for which responses can be judged to be correct or incorrect, i.e. a traditional psychophysical task? This involves, as Palmer says, 'changing what is actually being studied from subjective grouping to something else'. What does this transformation of one task into another entail, and what does it achieve?

As an illustration of traditional psychophysics applied to a problem in perceptual organization, consider the experiments in which Palmer and Bucher (1981) studied the pointing of equilateral triangles (Figure 5(d)). The equilateral triangle at the bottom of the left panel of Figure 5(d) appears to point about equally often at 60°, 180°, or 300°. Suppose you were shown this triangle, and asked to report which way it is pointing. The bottom section of the left panel of Figure 5(d) shows the triangle you see. Its background is white, indicating that it represents a public event. The middle section represents the three possible ways in which you could see the triangle pointing. Its background is gray, indicating that it represents a private event, your experience. The top section represents your response. Since you could see the triangle in one of three ways, you are asked to choose one of these alternatives, i.e. to make a three-alternative forced choice (3AFC). The bottom, middle, and top sections of the panel are connected by white arrows; they represent a presumed temporal and causal order. The structure of this task is summarized in Figure 5(b); it is the structure of a phenomenological psychophysics task.

Now suppose you were asked a different question: is the triangle pointing to the right or left? This is what Palmer and Bucher (1981) asked. In the left panel of Figure 5(c), the bottom section shows the triangle, and the left side of the middle section shows the ways you could see it. But since you were not asked which way it was pointing, the phenomenology is somewhat more involved than in the first example. If you spontaneously saw the triangle pointing horizontally, you could answer the question just by deciding whether it was pointing left or right, which requires some effort. But if you spontaneously saw it pointing in another direction, to answer the question you would have to relinquish that view of the triangle, so that you could see which way it would point were it pointing horizontally (right side of the middle section of the panel). This is not always easy to do. We can call this effort 'perceptual work'. This work is represented by the doubled-headed arrow in the middle section. Here you are asked to make a two-alternative forced choice (2AFC), and your reaction time (RT) is recorded. The structure of this task is summarized in Figure 5(a); it is the structure of a traditional psychophysics task.

As opposed to phenomenological psychophysical tasks, traditional psychophysical tasks are indirect. This idea is illustrated in Figures 5(a) and 5(b). In natural viewing conditions, as well as in the tasks used in phenomenological psychophysics, certain aspects of the visual scene ('stimulus' in the figure) lead to a corresponding percept by means of a private perceptual process. The latter is labeled as a 'spontaneous perceptual process' in the figure to emphasize that the process occurs naturally, just as it does when the observer views a stimulus outside the laboratory. The experimental phenomenologist strives to devise experimental conditions that ask observers to give reports that are as close as possible to the way they would describe their experiences outside the laboratory.

We now come to the crux of the Palmer and Bucher experiment, and to the resolution of the issue of epiphenomenality. If you align three equilateral triangles along a common axis of mirror symmetry tilted at 60° (Figures 5(c) and 5(d), right panels), they appear to point most often at 60°. Palmer and Bucher were interested in the effect of this context on the pointing of triangles. They used the traditional psychophysics task described in the preceding paragraph, and found that observers were slower to decide whether the axis-aligned triangles point to the right or to the left than to decide whether the isolated triangle does. The pointing induced by the common axis forced the observers to do more perceptual work than in the case of the single triangle. It is this perceptual work that persuades us that neither pointing nor

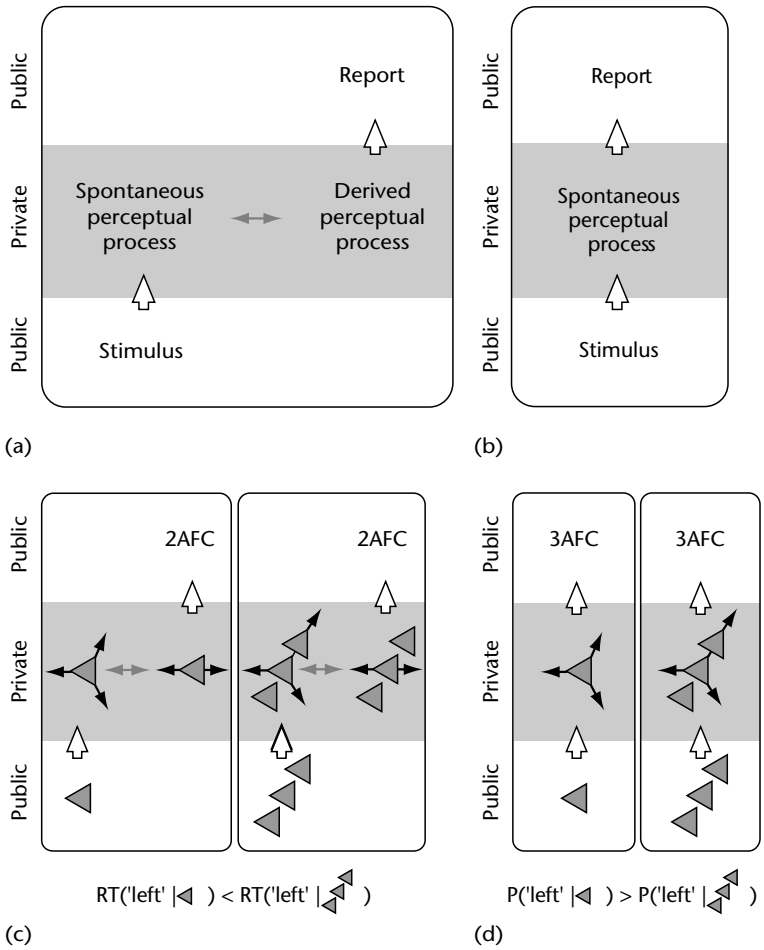

Figure 5. Comparison of the processes that take place in an observer engaged in different types of experimental procedures. The hypothetical events that are not public are marked by a gray band. The procedures of traditional psychophysics force the observer to do 'perceptual work' (horizontal arrows), i.e. to transform their experience in order to meet the requirements of the procedure. Thus they engage perceptual processes additional to the procedures of phenomenological psychophysics. In that sense, the latter are more direct than the former. (a) Traditional psychophysical procedure. (b) Phenomenological psychophysics procedure. (c) The experiment of Palmer and Bucher (1981) as a traditional psychophysical procedure (2AFC). (d) Hypothetical study of pointing using phenomenological report (3AFC).

the effect of a common axis is epiphenomenal (or purely subjective).

Epiphenomenality cannot be refuted with phenomenological methods. However, having established that the effect of a common axis on pointing is not epiphenomenal, one can explore the effect directly, i.e. phenomenologically, without forcing observers to do perceptual work (Figure 5(c), right). For example, one could use a phenomenological psychophysics procedure with a three-alternative forced choice (3AFC) in which the observer's task is to report (by pressing one of three keys) in which direction the middle (or single) triangle is pointing (Figure 5(c): '$P(X)$' stands for the probability of percept X). This is a phenomenological report because the three report categories offered to the observers agree with the three likely spontaneous organizations of the stimulus.

In traditional psychophysics the natural perceptual experience is transformed. It is transformed by asking observers to judge certain aspects of the stimulus, thus engaging mechanisms not normally involved in the perception of natural scenes. Or the perception of the stimulus may be hindered, either by adding external noise to the stimulus or by presenting the stimulus at the threshold of visibility. It is not clear whether such transformations of perceptual experience are indispensable in studies of perception.

The inferences involved in the interpretation of psychophysical studies of perception would not make sense without assuming the existence of a

spontaneous perception, which could have led to a phenomenological report. They are an indirect assessment of perceptual processes. We do not suggest that tasks that have correct and incorrect responses are useless after one has established that a perceptual phenomenon is not epiphenomenal. These tasks may give us important information about the underlying process. But indirect psychophysical methods have no intrinsic advantage over phenomenological methods.

CONTENTS

Jean Piaget established an important approach to the study of mental development. He distinguished a series of stages of cognitive development and outlined a process of change through which children actively create a new type of intelligence at each stage. New tools, in contextual and cultural analysis, dynamical systems theory, and neuroscience, are helping to realize his goal of connecting developmental stages with processes of growth.

INTRODUCTION

Jean Piaget advanced one of the most important endeavors in cognitive science: the analysis of the development of the mind. Working in what he called genetic epistemology (study of the genesis of knowledge), he described cognitive development richly and argued compellingly that children and adults build understanding and knowledge through their own activities in the world. In his constructivist view, people stand between nature and nurture when they act on objects, events, and people: through coordinating those activities, people drive the development of their own individual intelligences, as well as the collective intelligence of human cultures. Piaget's emphasis on people as agents constructing their own reality contributed to the birth of cognitive science and established firmly the argument that children build their intelligence through their own activities. They are neither 'tabulae rasae', shaped entirely by their environment, nor unfolding flowers determined entirely by their genes, but dynamic agents connecting themselves with their worlds.

In the 1920s, Piaget began the effort to explain human action and thought with analysis of how children act on things in their environment and thus learn about world and self. In this early work, and in the extensive developmental research that followed it, he emphasized two principles: firstly, that each individual actively constructs knowledge; and secondly, that the organization of that construction moves systematically through stages based on qualitative transformations of the mind. Piaget's work engendered and influenced much research and theory in the second half of the twentieth century, some building upon his work and some opposing it. By the end of the twentieth century, new findings and concepts about developmental processes, context, culture, and brain functioning had made it possible to study the transformation and development of concepts and skills in ways that built on Piaget's work and went beyond it. Areas that Piaget could only speculate about have become focuses of active research.

THE BASIS OF KNOWLEDGE IN ACTION ON THE WORLD

Jean Piaget and his wife Valentine, a psychologist, created the foundation of Piaget's theory of cognitive development by building on their detailed observations of how their own infants acted with objects and events. Piaget's book *The Origins of Intelligence in Children*, published in 1936, focused on his first principle: how infants construct their activities and knowledge with real objects in particular contexts, learning, for example, how to make a mobile move in the crib or how to make the mother return after she walks away. In *The Construction of Reality in the Child* published in 1937, Piaget emphasized his second principle: how infants' skills develop through a sequence of stages that are defined by patterns of action and appear across different domains, especially those of objects, space, causality, and time. Piaget's

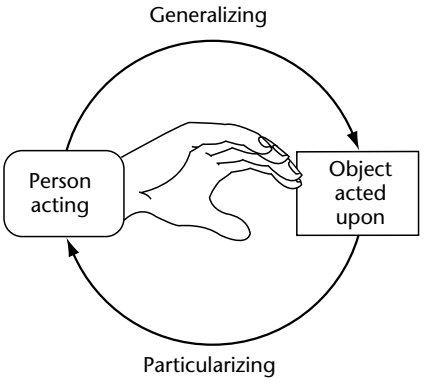

Figure 1. Piaget's 'knowing circle': understanding objects through acting on them. A person acts on an object, event, or person, and thus comes to know it by adapting his or her actions to it. Piaget called the generalizing aspect of a knowing action 'assimilation', and the particularizing aspect 'accommodation'.

long-term goal was to integrate the two principles, bringing together person and environment in a single framework.

Piaget's model for the process of development was equilibration, whereby children's activities in the world involve a continual reciprocal collaboration between person and object, as shown in Figure 1. A child acts on an object in a specific context: for example, picking up a toy rattle in her hand from her crib, shaking it, and hearing a rattling noise. In this action – a 'scheme', in Piaget's terminology – she uses her grasping, manipulating, and listening in a general way to act on the rattle, and she adapts those activities to the particular properties of the rattle, including its graspability and its capacity to make noise. The generalizing role of action is what Piaget called 'assimilation', and the particularizing role of adapting to the object is what he called 'accommodation'. Figure 1 shows how assimilation and accommodation work together simultaneously in action to produce knowing. This equilibration enables a person to function in and adapt to an environment, or context. The person and context exist together as integral parts of each other in intelligence.

An infant builds up each action scheme by repeatedly trying out an action with a particular object, such as the rattle. Piaget called this repetitive process a 'circular reaction', following the American psychologist James Mark Baldwin. Through repetition and variation, the baby learns how to control the action in that context, and then works to extend it to other contexts and build a more generalized scheme. Eventually this process leads to equilibrium, in which a knowledge scheme fits an object and context so well that activities are stable and well adapted, as when an infant can manipulate a rattle at will to produce its rattling sound.

Piaget hypothesized that the strongest form of equilibrium is structured by logic, which children gradually construct from their activities, producing a series of qualitatively distinct stages of intelligence. According to Piaget, logic has an intrinsic stability to it because it involves coordination of diverse activities in a single system without contradiction. At the same time, all knowledge schemes – even logical ones – include the seeds for further development. An existing scheme leads a child to recognize limitations in his or her knowledge, pointing to things that he or she does not understand. Stimulated by such 'disequilibria', people move on to build new knowledge upon the foundations of existing knowledge.

QUALITATIVE CHANGES IN INTELLIGENCE PRODUCED BY ACTION ON THE WORLD

Piaget described a series of 'stages' or 'periods' in the development of intelligence (see Table 1). He also described substages within each stage. When the stages and substages are used as tools for describing the qualitative changes in intelligence, their number depends on how fine-grained a description is required; but when analyzed in terms of logic, they are more precise and fixed.

These broad stages are often called periods. Three of the four periods involve different types of logic. The periods build on each other, forming a hierarchy in which each higher form of intelligence includes the earlier ones – similar to the way in which a body is composed of organs, organs are composed of cells, and cells are composed of organic molecules. Piaget concentrated on knowledge about the physical world in his research, but other researchers have elaborated Piaget's concepts to apply to knowledge of people as well. For example, Lawrence Kohlberg described the development of moral judgment through stages related to Piaget's.

In the first period, characterized by sensorimotor intelligence, infants understand their worlds through direct actions and perceptions, such as grasping, moving, looking, and listening. The stages of infant development show gradual coordination and differentiation of these actions to produce successively more sophisticated systems, which culminate at 1 to 2 years of age in what Piaget called *the logic of action*: infants can find

Table 1. Piaget's four main stages of intelligence

Stage	*Schemes*	*Problems dealt with*	*Type of logic*	*Age*
Sensorimotor	Actions	Acting on world, including objects, space, causality, and time	Logic of actions, such as movement in space	Infancy: 0–2 years
Preoperational	Representations	Symbols, including thought, language, imitation, and play	No logic, but egocentric, illogical thought	Early childhood: 2–6 years
Concrete-operational	Operations on representations	Classes, relations, and numbers	Logic of mental actions on representations (concrete operations)	Middle childhood: 6–12 years
Formal-operational	Operations on operations	Abstract and hypothetical thinking	Logic of the hypothetical and possible (formal operations)	Adolescence and adulthood: beyond 12 years

objects that are hidden, recognizing their permanence; and they can find their way around in space, relating multiple paths to get back to the same location in a system of spatial displacements. Piaget proposed that this logic of action is the culmination of development in infancy and that it creates a powerful equilibrium in intelligence. At the same time it launches a new form of intelligence, and many disequilibria.

In the second period, young children use this new form of intelligence: preoperational intelligence, the capacity to represent objects, people, and events in the mind. Representations are actions that children do in their minds without needing to carry out the overt actions or perceptions, such as when a 3-year-old girl pretends that a doll is her friend Jennifer taking a bath and also describes the activity in words ('Jennifer is wet in the bathtub'). Although these representations are based in the logic of action, the logic is only in the actions, not in the representations. The thought of such children is mostly illogical, involving frequent contradictions, and egocentric. This leads to disequilibria, which in turn lead to a new kind of logic and intelligence.

Concrete-operational intelligence is the logic of concrete operations on representations, in which a child can combine several representations in his or her mind, coordinating characteristics of an object that can change or compensate for each other. For example, a child with preoperational intelligence believes that when a ball of clay is elongated into a sausage shape, it becomes bigger. A child with concrete-operational intelligence understands that the reduced width of the sausage compensates for its increased length, so that the total amount remains the same. Similarly, children become able to take other people's concrete perspectives and coordinate them with their own, moving from egocentrism to 'perspective taking'.

In the fourth and final period, the adolescent or adult with formal-operational intelligence is no longer limited to the actual and concrete but can mentally coordinate the world of possibilities, creating a logic of the hypothetical by representing operations on concrete operations. Like the scientist performing an experiment, the formal-operational thinker can systematically consider all possible causes and outcomes of a situation in relation to a hypothesis or question. Such a person may be able to solve problems like getting a stalled car to start, explaining the results of a combination of chemicals, or evaluating the morality of hurting one person in order to help another.

VARIATION, DYNAMICS, AND CATASTROPHES

There are many variations in cognitive development that go beyond Piaget's descriptions. Much of what people know and believe does not seem to fit the logical structures that Piaget described, and even for tasks that do involve logic, people show wide variability in development – much more than Piaget's theory can explain. Many researchers have described patterns of *décalage* or unevenness, in which, for example, understanding of conservation of amount of clay develops at a different age from other kinds of conservation understanding. In particular, the skills of young infants sometimes show knowledge of objects, space, causality, and number that are more advanced than Piaget described.

Variability is also evident within individuals. The stages that a person demonstrates in one assessment session greatly depend on the immediate contextual support, showing a wide 'developmental range'. The term 'levels' is often used instead of 'stages' to reflect this variability. For instance, young adults may exhibit advanced formal-operational thinking when supported by questions and prompts from a knowledgeable teacher, but revert to concrete-operational thinking without that support. Research inspired by James J. Gibson, Lev Vygotsky and others has shown how the physical and social worlds respectively support cognition and development. This work explains much of the variability that posed problems for Piagetian theory.

Until recently, the main focus of research and theory has been the stages of development rather than the processes of equilibration. The new understanding of contextual support is one of several new tools that make it possible to integrate processes of development with stages. Mathematical techniques for describing nonlinear dynamical change (including theories of chaos, catastrophe, and complexity) provide powerful tools for analyzing growth processes, such as Paul van Geert's nonlinear mathematical model of Piaget's equilibration. Under many different growth conditions, the model produces three or four stages of development, as Piaget posited; at the same time, it produces pervasive and interesting patterns of *décalage* and variation.

Other research has established clear empirical criteria for emergence of a stage, and conditions under which development shows stages. Kurt Fischer has found that children's skills show sudden spurts with the emergence of a new stage or level, but only under conditions of high contextual support, not in most ordinary activities. Contrary to Piaget's hypothesis, developing skills do not all fit a single logical structure, but instead they develop independently along separate strands (domains) in a developmental 'web', as illustrated in Figure 2. However, concurrent change to a new level does occur across many strands for activities with high contextual support (as shown by the time zones marked by boxes in Figure 2). The changes can include not only spurts in skill but also joining of domains or separating of strands into distinct domains.

Although no structures have the universal applicability that Piaget sought for logic, Robbie Case has shown that some 'central conceptual structures' generalize broadly across relevant, limited domains. The best-documented example is

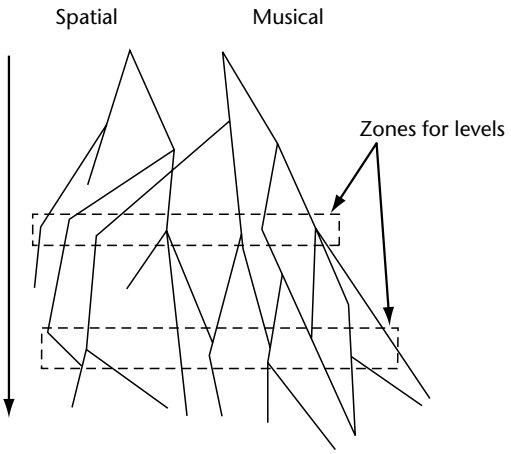

Figure 2. Developmental web showing emergence of two levels in two domains. People develop along many independent strands even within a coherent domain, as illustrated for spatial skills and musical skills. Simultaneously, performance under optimal conditions shows clusters of discontinuous changes across many strands within a zone, marking a new developmental stage or level, as indicated by the boxes.

the number line, which frames number in terms of a geometric line divided into segments by units, a structure that is strongly supported in language and cultural practices.

Fischer, Case and others have also shown that children develop through several substages for each general stage, with substages marked by spurts under high support. These substages explain many of the findings that abilities develop earlier or later than Piaget thought. Neuroscience research suggests that neural networks in the brain are reorganized at each substage and stage, as reflected by changes in patterns of electrical activity and blood flow in the cerebral cortex. Mathematical models of neural networks have many of the properties of development that Piaget postulated, including dependence on activity, sensitivity to contextual support, and occurrence of relatively abrupt reorganizations.

CONCLUSION

Piaget characterized development of intelligence in terms of two broad principles: that children construct knowledge and skill through acting on objects, people, and events in the world; and that their intelligence moves through a series of qualitative reorganizations that build on each other hierarchically and are markedly different from each other. The processes of change involve equilibration, whereby a person acts on objects using

existing schemes (activity structures), gradually achieving relatively stable knowledge states. Each such state leads to recognition of things that are confusing or not understood, and thus drives the person towards new knowledge.

Piaget's broad principles of equilibration and stages continue to frame most current research in cognitive development. Although Piaget dealt only broadly with important issues such as context, dynamical systems, and the brain, his framework is remarkably consistent with recent directions and findings in cognitive science and developmental neuroscience. Piaget's analysis of the development of intelligence still defines most of the basic questions and concepts that drive research in these fields.

Post-traumatic Stress Disorder

Introductory article

Rachel Yehuda, Sinai School of Medicine, New York, New York, USA

CONTENTS

Post-traumatic stress disorder is an anxiety disorder in which an individual's ability to function is impaired by emotional responses to memories of a traumatic event.

INTRODUCTION

The diagnosis of post-traumatic stress disorder (PTSD) first appeared in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* in 1980. This disorder develops in response to a terrifying event or ordeal that has been experienced, witnessed or learned about. The event is usually life-threatening or capable of producing bodily harm, and typically involves interpersonal violence or disaster. Examples of such events include rape, assault, torture, car or plane crashes, or being exposed to earthquake, tornadoes or floods. What these events have in common is their ability to cause feelings of intense fear, horror or helplessness. This response can lead to a cascade of adverse psychological reactions that can result in substantial disability.

In the field of mental health, professionals have been slow to recognize that the psychological effects of traumatic experiences can be long-lasting. Prior to the establishment of the diagnosis of PTSD, stress-related symptoms tended to be viewed as transient, and not requiring intensive treatment. This view was in keeping with the pervasive feeling in society that, with time, people ought to be able to 'get over' the effects of a traumatic experience, and to move on without noticeable impairment. Accordingly, those who did develop long-term symptoms following trauma were perceived as being constitutionally vulnerable. The diagnosis of PTSD has permitted greater understanding of the impact of traumatic events in precipitating long-term psychological symptoms, and has created a model that allows systematic hypothesis testing about the nature of adverse consequences following trauma. In the 1990s scientific developments led to a better understanding of the etiology of PTSD, the course of the disorder, and the biological changes associated with its development.

CLINICAL FEATURES

Post-traumatic stress disorder is classified as an anxiety disorder according to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), and defines a syndrome in which a person is unable to modulate emotional responses to memories of a traumatic event. The disorder can affect many aspects of a person's life, particularly day-to-day functioning, quality of life, and relationships. Three symptom clusters are associated with PTSD:

- Reexperiencing the event through distressing images, unwanted memories, nightmares or flashbacks of the event that cause distress and attendant physical symptoms such as palpitations, shortness of breath and other manifestations of panic.
- Avoidance of reminders of the event, including people, places or things associated with the trauma, and becoming emotionally numb, constricted or generally unresponsive to the environment.
- Hyperarousal, reflected by physiological symptoms such as insomnia, irritability, impaired concentration, hypervigilance and increased startle responses.

The disorder can cause impairment, and in some cases substantial disability, in social, occupational and interpersonal domains.

People who develop PTSD usually begin to show signs of anxiety and emotional withdrawal in the immediate aftermath of the traumatic event. Neither trauma survivors nor their families are particularly alarmed by such symptoms immediately after the event, believing them to be normal responses that will pass with time. Indeed, most trauma survivors wait for several weeks or months

before contacting a physician in order to give themselves time to resolve their traumatic reactions on their own. Ultimately, the failure of post-traumatic symptoms to improve spontaneously, and the increasing disability caused by sleep disturbance, panic and depression, cause people to seek professional help.

The response that is perhaps most detrimental in the long run to trauma survivors is that of avoiding talking or thinking about (i.e. 'processing') the event. Most experts assert that giving trauma survivors a forum to discuss the event and their resultant feelings about it promotes recovery by minimizing avoidance. However, since talking about the event may be distressing, both survivors and those who are there to listen to them are often content to avoid such discussions. Yet PTSD symptoms can be ameliorated once the survivor actively confronts the feelings of fear and vulnerability associated with the traumatic event.

ETIOLOGY

Studies of the prevalence of PTSD have demonstrated that this condition is the fourth most common psychiatric disorder, afflicting 7–14 percent of the population at some time in their lives. The nature of the trauma experienced seems to be the single most significant factor in the etiology of PTSD. Events involving interpersonal violence, such as torture, rape, assaultive violence and combat, are more potent agents in the causation of PTSD than experiences such as motor vehicle accidents and natural disasters. The former events produce PTSD in as many as 50–75 percent of trauma survivors, whereas the latter result in PTSD approximately 10–25 percent of the time. For specific events, dose–response relationships have been observed between degree of exposure and incidence of PTSD.

The observation that for any given trauma only a subset of those exposed will develop chronic PTSD has led to the search for other risk factors that contribute to the development of (or recovery from) this disorder. In addition to the nature and severity of the traumatic event, previous exposure to stress or trauma, particularly in childhood, a history of psychological and behavioral problems, and familial factors such as parental PTSD and family history of anxiety and depression, have been noted as risk factors. Gender also appears to be a potent risk factor for the development of this disorder, with studies consistently demonstrating it to be doubly prevalent in women.

Epidemiological studies have identified clusters of risk factors that are clearly interrelated. For example, lower levels of education and income, differences in ethnicity, poverty, and lower intellectual functioning have been identified as risk factors for the development of PTSD in the wake of a traumatic event. However, these variables are also associated with a greater exposure to some kinds of traumatic events, such as assaultive violence.

A history of family instability is associated with increased incidence of PTSD, and numerous studies have indicated that familial psychiatric history may place an individual at higher risk. In particular, parental psychopathology and/or PTSD appears to be a highly specific risk factor for the development of PTSD in offspring. It is not clear whether the tendency to develop PTSD is genetically inherited. An intriguing finding in a study on soldiers, examining PTSD in monozygotic (identical) twins, demonstrated that as much as 30 percent of some PTSD symptoms were present in both the combat-exposed twin and his nonexposed co-twin. However, this finding leaves open the possibility that either genetic or shared environmental influences may contribute to vulnerability for this disorder.

The development of PTSD may also be associated with how the survivor interprets the traumatic event in the context of preexisting ideas about personal safety. Individuals who believe that they can no longer be safe after experiencing a traumatic event, for example, may be more likely to develop chronic PTSD following a trauma. In addition, interpreting initial symptoms such as intrusive thoughts and hypervigilance as a sign of falling apart or being permanently altered for the worse may serve to maintain them. Since ideas about the world and one's ability to cope with adversity are often shaped by prior experience, this may in part explain why exposure to earlier adversity places an individual at risk at greater risk for developing PTSD following exposure to a later event. Unfortunately, little is known about resiliency factors that prevent the development of PTSD or increase recovery once this condition develops.

COURSE OF THE DISORDER

The symptoms of PTSD do not necessarily become more severe as time passes. However, the failure of the trauma-related symptoms to remit often results in a cascade of secondary behavioral, emotional and personality problems. People who develop PTSD are also more likely to develop other psychiatric disorders – such as mood, personality and eating disorders – and substance dependence.

Post-traumatic stress disorder can remit spontaneously or following treatment. However, the likelihood of developing a recrudescence of symptoms increases upon further exposure to stress or trauma.

The course of PTSD may thus vary considerably from person to person, taking acute, chronic or intermittent forms. Although in the majority of PTSD cases symptoms show immediate onset following the trauma, sometimes onset may be delayed. Delayed onset is usually stimulated by an environmental trigger. For example, a woman who was sexually abused as a 5-year-old might not develop PTSD at the time of the event but as an adult, triggered by her daughter's fifth birthday. A combat veteran might develop symptoms in response to hearing about the outbreak of a war decades later. Retirement can be a trigger of post-traumatic symptoms in elderly people traumatized decades earlier, if the survivor had used a lifelong pattern of keeping busy with work as a way of delaying thinking about the traumatic event and resultant feelings associated with it.

Community studies have indicated that the nature of the symptoms experienced changes over time, with intrusive symptoms being particularly prominent in earlier stages of the disorder, and avoidance and arousal being more significant later on. Treatment can influence the course of PTSD. Many treatment approaches have been demonstrated as effective in reducing PTSD symptoms, even to the point of achieving remission. Psychotherapeutic or counseling methods, such as cognitive-behavioral therapy including exposure and anxiety management treatments, have been shown to be effective: these methods encourage trauma survivors to talk about their traumatic experiences, and to view direct confrontation of frightening emotional memories as essential for symptom resolution. Medications such as antidepressant and anticonvulsant drugs have also been shown to be effective, and the use of two selective serotonin reuptake inhibitors has been approved by the US Food and Drug Administration for the treatment of PTSD. Usually some combination of psychotherapy and medication is required for the best possible treatment outcome.

NEURAL AND HORMONAL CORRELATES

Alterations have been observed in hormonal systems involved in the body's response to stress in PTSD. These alterations include increased concentrations of noradrenaline (norepinephrine) and an amplified reactivity of noradrenergic receptors, increased thyroid hormone levels, and increased reactivity of the hormones of the hypothalamic–pituitary–adrenal (HPA) axis. Anatomical changes occur in two major brain structures – the amygdala and hippocampus – that are directly involved in fear responses and in the acquisition of traumatic and emotional memories. The amygdala and hippocampus are important target organs in both initiating and terminating biological stress responses; changes in their activity in PTSD may be linked to other chronic, stress-related alterations in hormones and neurotransmitters.

It is important to understand that the alterations observed in PTSD do not uniformly resemble those associated with stress. One of the more unexpected findings has been the observation of low cortisol levels in some studies of chronic PTSD, even decades after trauma exposure. These and other findings have led to the idea that the development of PTSD may be facilitated by a failure to contain the normal stress response at the time of the trauma, resulting in a cascade of biological alterations that lead to intrusive, avoidance and hyperarousal symptoms.

The normal fear response is characterized by a series of biological reactions, initiated by the amygdala. Activation of the sympathetic nervous system and the release of adrenaline (epinephrine) allow the organism to increase its physiological capacity for 'fight or flight' in response to threat, and facilitate consolidation of the threat memory. The simultaneous activation of the HPA axis, culminating in the release of cortisol, helps contain the neural, defensive stress reactions. As stress-activated biological reactions are restricted, elevated cortisol levels also suppress the further release of cortisol through negative feedback inhibition on the pituitary, hypothalamus, hippocampus and amygdala.

Prospective biologic studies have begun to demonstrate that individuals who develop PTSD or PTSD symptoms appear to have smaller cortisol increases in the acute aftermath of a trauma than those who do not develop this disorder. Furthermore, those who develop PTSD show higher heart rates in the emergency room and 1 week after the trauma compared with those who ultimately recover, suggesting a greater degree of sympathetic nervous system activation. These findings imply that the actual biological response to acute trauma may be different in people who develop PTSD, some changes being typical and others atypical of the 'normal' stress response. These data offer an intriguing opportunity for developing hypotheses about processes in the early aftermath of trauma

that appear to forestall recovery and prevent the natural restitution of the stress response.

One model explaining the development of PTSD following trauma proposes that the increased sympathetic nervous system activity leads to an exaggerated response by this system to the trauma, manifested by an increased concentration of adrenaline. This in turn initiates a process in which traumatic memories become 'overconsolidated' or inappropriately remembered owing to an exaggerated level of distress. The primary mechanism through which adrenaline facilitates memory formation is by maintaining organisms at a high level of arousal. If cortisol failed to adequately shut down adrenaline production this arousal might be prolonged, and the consolidation of the memory facilitated. The increased distress every time there are traumatic reminders would further activate stress-responsive systems, resulting in secondary biological alterations associated with anxiety and hyperarousal. Although there may be other biologic pathways leading to PTSD, the above appears to be a promising candidate.

Prejudice

Intermediate article

William von Hippel, University of New South Wales, Sydney, Australia
Steven Fein, Bronfmann Science Center, Williamstown, Massachusetts, USA

CONTENTS

Prejudice is conscious or unconscious animosity towards members of other groups. Although far fewer people openly express dislike of other groups today than in the past, unconscious forms of prejudice are still common, and have a subtle influence on how people treat each other.

ROOTS OF PREJUDICE

There are many different forms of prejudice, and many causes of it. Prejudice is often connected with stereotypes and inter-group attitudes. (*See* **Stereotypes**; **Attitudes**)

One of the most important roots of prejudice, and perhaps the principal reason why prejudice is so universal and resistant to change, is that people are often motivated to see other groups in a negative way. This motivation may stem from a desire to gain from, or maintain the tangible rewards associated with, power over other groups. For example, when two groups are competing against each other, one group may derogate the other in order to justify taking aggressive action against it. Members of a dominant group may exhibit prejudice towards a weaker group to reinforce the status quo, whereas members of the weaker group may use hostility towards the dominant group in order to rally their group to challenge the status quo. In a classic field experiment conducted at a summer camp, the psychologist Muzafer Sherif and his colleagues (Sherif *et al*., 1961) found that creating competition between two groups of boys quickly led to intense hostility between the groups. Once these groups were induced to share common goals, however, the hostility just as quickly subsided.

Even if there is no conflict between groups, inter-group prejudice can spring from group members' desire to feel good about themselves. Social identity theory (Tajfel and Turner, 1986) proposes that in addition to the sense of self people derive from their personal qualities, they also gain a sense of self from their group memberships. Thus, people tend to feel better about themselves when their groups are held in high esteem. Because prejudice towards other groups results in the perceived relative elevation of one's own group, social identity theory suggests that prejudice can make people feel better about their groups, and therefore about themselves.

Despite these positive effects of prejudice on self-esteem, in contemporary times it is often the case that awareness of one's own prejudice can actually make one feel worse, rather than better, about oneself. It is the current social unacceptability of prejudice that often (although not always) causes prejudice to express itself through subtle, unconscious processes. The remainder of this article focuses on these processes.

UNCONSCIOUS PREJUDICE

Much like the bacteria that have mutated in response to the use of antibiotics, prejudice has changed dramatically in western society over the past fifty years. At a conscious level, people have become less likely to show 'old-fashioned' prejudice. For example, few now advocate the exclusion of minorities from their workplace or country (Schuman *et al*., 1997). Instead, most people voice egalitarian ideals; and if they do show negativity toward minorities, it is expressed in terms of resentment at unfair advantages, for example.

In contrast, unconscious prejudice is quite common (e.g. Fazio *et al*., 1995). This prevalence of unconscious prejudice in the absence of the conscious variety has led some psychologists to propose that most North Americans and Europeans are secretly bigots. Although this characterization is probably untrue, research does support the notion that prejudice tends to be learned at a young age and can be very difficult to change (Devine *et al*., 1991). Indeed, when psychologists Anthony Greenwald and Mahzarin Banaji

developed a measure of unconscious prejudice and created websites that enabled people to test themselves on their measure, they found that well over half of the hundreds of thousands of white respondents showed unconscious prejudice towards blacks (Nosek *et al*., 2002). Their measure relies on differences in the time it takes to make certain judgments (the difference between prejudiced and unprejudiced individuals is measured in milliseconds). The test is available on the internet (Nosek *et al*., 2002). Unconscious prejudice emerges with similar prevalence in other experiments, with other measures, and with samples that are not web-based or self-selected.

These findings do not mean that the advances in race relations and civil rights that have occurred since the Second World War are illusory. As Philip Tetlock (1994) noted, 'we have come a long way from the Selma, Alabama of 40 years ago if we now have reached the point in our history when white racism must be measured in milliseconds'. Tatlock is undeniably correct, as almost every indicator of race relations today shows a dramatic reduction in prejudice compared with the recent past. It is now clear that Americans have largely accepted the fact that their egalitarian credo must apply to blacks as well as whites. The depth of this change in American attitudes is apparent from the words of Ellis Cose, writing in *Newsweek*: 'If you are touched at all by American culture, your idol is likely to be black.'

In a very important way, however, Tetlock is also wrong. Just because prejudice must often be measured in milliseconds does not mean that it has only negligible effects. On the contrary, the sort of subtle, unconscious prejudice that exists today can be almost as disruptive as its more blatant precursor. For example, research indicates that people who test high on measures of unconscious prejudice are more likely to be selectively rude to minorities than people who test low on these measures (Sekaquaptewa *et al*., 2002). Such individuals deny that they are behaving rudely – indeed, they probably do not know it themselves – but a variety of behavioral measures show important differences in how they respond to members of different groups.

THE ROLE OF AMBIGUITY

These findings might lead one to ask whether we should really be concerned about the possibility that an unconscious 'bigot' might be a little unfriendly when interacting with minorities. After all, this seems much preferable to a world where a person who openly hates blacks, for example, can engage in socially sanctioned beatings and lynchings. No one is required to be friendly to everyone, so why should we worry if some whites unintentionally show a little extra rudeness or displeasure towards blacks?

Unfortunately, in some ways, the subtle effects of unconscious prejudice are more pernicious than the obvious effects of blatant prejudice. Society at large tends to recoil from the latter, and we feel sympathy for its victims (this response to blatant prejudice is what made the civil rights movement in the United States so effective). On the other hand, when prejudice is subtle and its effects ambiguous, we tend to doubt or deny it, and grow weary of claims (and claimants) of its existence.

Consistent with this argument, a number of experiments have shown that when people are in situations in which their negative behavior could easily be interpreted in terms of prejudice, they go out of their way to behave in an egalitarian fashion, often unintentionally favoring members of minority groups (Dovidio and Gaertner, 1998). This sort of 'bending over backwards' – whereby people are biased in favor of minorities – is quite common, as people use such circumstances to demonstrate to themselves and others that they harbor no prejudices.

These experiments also demonstrate, however, that unconscious prejudice influences behavior when the situation provides the necessary excuse. As a consequence, those who regularly are on the receiving end of prejudice learn that it can be hard to identify. For example, imagine a black student who is evaluated negatively by a white teacher. The student is confronted with two possible explanations: 'I did a poor job' versus 'the teacher is biased'. Even when the student is rated positively, the student is again confronted with two possible explanations: 'I did a good job' versus 'the teacher is bending over backwards so as not to look prejudiced'. As psychologists Brenda Major and Jennifer Crocker (1993) have demonstrated, because there is usually no way to distinguish between these alternative explanations, blacks are often unsure whether they can believe the evaluations of whites. The result is a lack of trust between blacks and even well-meaning whites. This lack of trust can become especially acute when whites are in the role of supervisor or teacher, and blacks are in the role of employee or student, leading to a breakdown in communication that both sides find frustrating and difficult to overcome. See Cohen *et al*. (1999) for one solution to this problem.

SITUATIONAL DETERMINANTS OF UNCONSCIOUS PREJUDICE

Lest one conclude that unconscious prejudice only ever manifests in subtle ways, it is worth noting that it can also have dramatic effects. Because unconscious prejudice is usually stationed only just outside the spotlight of attention, it is ready to manifest itself in conscious thought and behavior on a moment's notice when it becomes socially sanctioned or psychologically salubrious. Consider, for example, the reaction of most United States citizens to the terrorist attacks of 11 September 2001. Within moments of learning who the perpetrators were, many found themselves possessing and expressing a strong dislike for Arabs and Muslims. Because this enmity was now perceived to be socially acceptable, racist statements that would otherwise have remained hidden became commonplace. Indeed, the numbers of verbal and physical attacks on Arabs and Muslims increased in many western countries. Clearly such discriminatory behavior would hardly be tolerated or expressed during peacetime, but, as many experiments and natural situations have shown, conflict brings unconscious prejudices and generalized dislike of other groups to the surface.

It is not only dramatic events like wars that bring unconscious prejudices to the fore: mundane situations can have the same effect. For example, people are particularly likely to denigrate others when they are feeling bad about themselves. This behavior can be functional for people who are feeling low, as it changes their point of reference. In order to feel better about oneself (in relation to others), one can either raise oneself above others or lower others below oneself. Because it is easier to denigrate others than to improve oneself, the method of putting other people down in order to restore one's own self-esteem is popular and effective. Furthermore, this process can be particularly successful when the denigrated target is an entire group of people, because under this circumstance, looking down on others leads a person to feel better than an entire segment of the population.

A series of experiments examining this idea has demonstrated that even people who show no prejudice under normal circumstances will discriminate against a variety of different groups (e.g. gays, Jews, Asian Americans, African Americans) when they are led to feel bad about themselves (Fein and Spencer, 1997; Spencer *et al*., 1998). In these experiments, college students (predominantly liberal) were told either that they had performed very well or that they had performed very poorly on an intelligence test. When the students thought they had done well, they were magnanimous in their evaluations of others. In contrast, when they thought they had done poorly, they became selectively nasty towards members of other groups – for example, showing dislike toward blacks and Jews but not towards whites and Christians. In effect, the students were consoling themselves with thoughts like 'I may not have done well on that test, but at least I'm not Jewish.' Indeed, the more prejudice they showed, the more they restored their sense of self-worth.

These findings suggest that prejudice may be difficult to eradicate in part because it can be rewarding, making people feel better about themselves at the expense of others. However, to the extent that people internalize goals of egalitarianism, and see connections and similarities between their own groups and other groups, the rewards of prejudice may diminish, compared with the rewards of fairness.

CONTENTS

Priming is a process involved in memory and in the preparation of responses to coming events. Anomalies in priming have been identified in some kinds of psychopathology, especially in the schizophrenias. Studies of priming by psychopathologists have been primarily interested in priming as a technique for the investigations of the influence of the activation of associations to a presented stimulus upon responses to subsequent stimuli. In this respect their purposes have differed somewhat from those of cognitive scientists interested in dissecting the components of normal cognition.

INTRODUCTION

When the occurrence of a specific stimulus event (A) indicates an increased probability that it will be followed by a second specific event (B), the second event is likely to be perceived and responded to more rapidly and accurately than if it had occurred without the prior occurrence of A. This sequence is an example of 'priming'. The appearance of A (the 'prime') affects the readiness of the individual to respond to B (the 'target'). B may be a repetition of A. It is not necessary that the individual have consciously noticed the appearance of A. It is sufficient to demonstrate priming if we can show that the response to B is faster, more accurate, and more adaptive than it is when it is not preceded by A.

Priming occurs on the basis of predictable sequences that have been experienced in the past and have been stored in memory. The sequences may consist of spoken or written words, pictures, signs, or indeed any events that can be perceived, processed, and stored. Research into priming and psychopathology is conducted on the basis of hypotheses about how sequences are stored in the brain and how deviant brain functioning may affect priming. Defective priming can lead to maladaptive behavior, and for this reason the process has been studied intensively in patients with serious psychopathology. These include patients with major psychotic disorders such as schizophrenia, as well as patients with known brain pathology including Alzheimer's disease.

INHIBITION

Excitation and Inhibition in the Brain

The activity of the neurons, the nerve cells of the brain, can be classified in many ways. One fundamental distinction is between excitatory and inhibitory activity. The neurons of the brain are constantly active when we are awake and when we sleep. For the brain to function effectively it is essential that patterns of excitatory activity that are appropriate to the tasks of the moment can operate without disruption from irrelevant surrounding activity. This is achieved by the action of inhibitory neurons that suppress the activity of potentially disruptive excitatory cells. Adaptive regulation of inhibitory and excitatory activity appears to be located in the dorsolateral prefrontal cortex of the brain (Brodmann areas 9 and 46). Patients with lesions in the prefrontal cortex have difficulty in excluding distracting stimuli in the environment. They are therefore impaired in their ability to maintain sustained attention to a specific task, particularly if the task requires a time delay before the appropriate response can be made. There are resulting disturbances in language, the control of motor behavior, and in decision-making.

The Association Network

Our present understanding of this process of inhibition in relation to priming can be illustrated with the concept of the association network. Words (pictures, odors, music, etc.) are connected by interlinked associations. When I ask somebody to tell me the first word that comes into her head when I say 'cat' she may respond with 'mouse' or some other relevant associated word. For her, the word 'cat' has primed the association to 'mouse'. The

response will be rapid and direct and usually unaccompanied by conscious intervening reflection. The linkage is robust. But if the same individual takes her cat to the veterinarian to report that it is sick, she does not say 'My cat mouse is sick'. The strong association does not disruptively enter into her consciousness and language because the now irrelevant cat–mouse link has been inhibited. Inhibition of this kind does not occur as a conscious act but is an integral component of the production of organized thought and speech. If the inhibitory process were defective such intrusions might well enter into actual speech, which would then become incoherent.

It is useful to consider the association network around a particular word, picture, or other class of stimulus as having a central node (e.g. a specific word) and a series of branching links extending in three dimensions connecting at various points with other networks. Any one element may be a member of several networks. The content of a network is determined by individual experience; the fact that members of a culture will have many common experiences means that normative associative links may be found with some frequency in different persons. This makes it possible to study priming experimentally in the general population and people with psychopathological conditions.

FACILITATION

Semantic Priming

One method commonly used to study priming employs the technique of semantic priming, and particularly the task of lexical decision. In the lexical decision paradigm the researcher presents the participating patient with a rapid sequence of two separate strings of letters appearing successively on a computer screen. The first string of the pair is the prime. It is replaced by the second, the target. The patient is to decide whether or not the target is a real word. Pressing a keyboard key marked 'Yes' signals that it is a word, pressing one marked 'No' that it is not. The reaction time (R/T) and accuracy of response are recorded. Typical sequences might be TABLE – KROD (word – nonword), GRAX – BOAT (nonword – word). Word–word pairs are either associated, as in DOCTOR–NURSE, or nonassociated, as in TAXI–NURSE.

Studies of the general population show that R/T in response to the target in associated word pairs is significantly greater than in nonassociated pairs. For example, the word NURSE would be recognized more quickly following DOCTOR than following TAXI. The gain is interpreted as due to the automatic activation of the associated target by the prime, making recognition more immediate. The resulting difference in recognition time between the two conditions is termed 'facilitation'. Facilitation scores are computed by subtracting the mean R/T to associated pairs from that for the nonassociated pairs. The greater the difference, the more facilitation. Facilitation is most marked when the time interval between the appearance of the prime and the target is brief. Short intervals – typically of 250 milliseconds are more likely to produce facilitation than longer intervals, such as 800 milliseconds. Variations in the lexical procedure include the use of phonological ('clang') associations, such as PANG – SANG, or orthographic similarity such as CONFESS – CONFUSE.

Schizophrenia

Clinical observers of the behavior of schizophrenia patients have long pointed out that associations often intrude into their spoken and written language. One proposed explanation of this is that inhibitory processes that normally prevent this are defective. Thus activated associations are not inhibited but disrupt the coherence of the utterance, as in the example 'My cat mouse is sick' mentioned above. Intrusion of associations into utterance is extremely rare in normal speech or writing; presumably this reflects the greater effectiveness of inhibition in the normal case. In the light of this, we might expect that the patients will show greater facilitation (hyperfacilitation) than nonpatient controls. Research has shown this to be the case, particularly with patients who exhibit disturbed language. The evidence also suggests that the hyperfacilitation is more characteristic of patients the onset of whose illness has been recent. With increasing years of illness, the effect disappears and, in some patients, reverses itself – the associated pairs producing slower R/Ts than the nonassociated. This effect appears to be independent of the increasing chronological age of the patients.

Other priming paradigms for lexical decisions exist. One approach presents a degraded target word for recognition. The patient presses the key to receive increasing components of the target until the patient recognizes it correctly. Schizophrenia patients correctly identified the associated target at lower levels of clarity than were required by the control participants. There was no difference in performance under other condition. The hypothesis behind this investigation proposes that as the task is essentially one of matching the degraded

pattern of elements of the prime against the stored image of an actual word, the schizophrenia patients had the advantage of matching it against the actual association activated by the prime, while the controls did not. Another method employs word pronunciation (WP), where the patient reads the target word aloud, rather than simply pressing a key. This technique produces lower levels of facilitation generally and is less likely to elicit hyperfacilitation in patients.

Negative Priming

In some settings the appearance of an initial event (A) has the effect that the next event in sequence (B), one that would ordinarily elicit a specific response, is followed by a different or diminished response or no response at all. In effect, this requires that the normal response to B must be inhibited (not facilitated) when A has preceded it. In semantic priming this would be demonstrated when responses to associated prime–target sequences are slower or less accurate than to associated prime–target sequences.This is found in some chronic schizophrenia patients and in some patients with bipolar affective disorder.

INDIRECT PRIMING

Our understanding of associational networks is that they may be linked to each other through a series of connecting overlapping associations. For example, if the word RIVER primes the association WATER, and WATER primes WASH, which then primes SOAP, we have a sequential series of associative links which are moving progressively further away from the original prime. It is relatively easy to elicit this kind of chaining by the simple instruction to the participant to associate sequentially to his own responses. We may also demonstrate the pervasiveness of such links by asking a participant to connect two unrelated words by a chain of plausible intermediate associations. Given the task of finding a link between, let us say, TIME and GRASS, we might get TIME–CLOCK–HAND–FOOT–YARD–GRASS.

The existence of such sequences raises the question whether a prime might facilitate a target word that is two or more links away from it. In the example above, would the prime word CLOCK facilitate the target word FOOT? Psychopathologists refer to this as 'indirect priming'. The psychopathologist Eugen Bleuler first described the phenomenon in clinical cases in 1911. He used the term 'mediated' association, and this term is in current use in investigations of 'implicit' memory in normal populations. In contemporary experimental studies of psychopathological samples, the term 'indirect priming' is commonly employed. When it occurs it is regarded as evidence of relatively uninhibited excitatory activity. In schizophrenia patients indirect priming has been demonstrated in this way, but it is rare in nonpsychiatric comparison groups or in depressed patients.

Polysemous Priming

Many words or icons have more than one meaning. Such words are termed 'polysemous'. Their different meanings may be quite unrelated and each meaning has its own network of associations. English is replete with such examples. Consider the various meanings of such words as 'bank', 'stock', 'seal', 'pen', 'bark', and 'yard'. Effective thinking and communication requires that we do not confuse the possible meanings when we are trying to understand a speaker or trying to frame an utterance for others to understand. Under these circumstances the meaning (and its associations) that is not relevant to the utterance are inhibited.

In many polysemous words one meaning is more common than the others. If we ask for first associations to 'Stock' from stockbrokers we will likely get a different response than if we ask in a farming community. If, however, we have defective inhibitory processes the association to the dominant meaning may intrude into an utterance intended to convey a nondominant meaning. This happens in some utterances by schizophrenia patients, and produces what is termed 'tangential thinking', as in 'The notary put a seal on a document but it swam away'. It is evident that a chain of indirect priming has been activated by the polysemous word 'seal'. This is also found in some schizophrenia patients, suggesting again a defect in selective inhibition.

SUMMARY

Disturbances in the balance of excitatory and inhibitory processes in the neurons give rise to disturbances in language and thought in some forms of psychopathology. These disturbances may appear as the intrusion of associations into spoken or written utterances and/or difficulty in following a connected sequence of discourse. The effects seem to arise from a defect in the processes of selective inhibition and have been reported most often in patients with schizophrenia. They may appear in patients with bipolar affective disorders.

Priming

Introductory article

James H Neely, University at Albany, State University of New York, New York, USA

CONTENTS

Priming is a change in the response to a stimulus (the target) due to a recent exposure to it or a similar stimulus (the prime).

INTRODUCTION

This article will consider how our responses to the multitude of stimuli that we encounter every day depend not only on our accumulated learning about those stimuli, but also on our most recent exposure to them or to related stimuli. Priming is defined as a change in the response to a stimulus (the target) due to a recent exposure to it or a related stimulus (the prime). It has been studied extensively with diverse procedures.

1. When completing a word fragment such as *a---e* with an English word, people are more likely to respond with *amble* if they have recently seen that word. This occurs even if days separate the presentation of the prime *amble* and the target word fragment. (*See* **Memory: Implicit versus Explicit**)
2. When solving the problem $3 \times 8 = ?$, people are faster if two to nine problems ago they received $3 \times 8 = ?$ as a prime, but are slower if they received the related problem $3 \times 6 = ?$ as a prime, relative to when they had been primed with totally unrelated problems.
3. When asked to describe a picture of a dog chasing a cat, people are more likely to say 'A cat is being chased by a dog' if they recently heard the word 'cat', and are more likely to say 'The dog is chasing the cat' if they recently heard the word 'dog'.

SHORT-TERM PRIMING IN WORD-RECOGNITION TASKS

Because studies of priming have been so diverse and extensive, this article will focus on short-term priming effects in word-recognition tasks. In these tasks, a reader responds as quickly as possible to a single target letter string either by pronouncing it aloud or by pressing one of two keys to indicate (1) whether it is a word or a non-word (a lexical decision task) or a noun or a verb, or (2) whether its referent is pleasant or unpleasant, animate or inanimate, larger or smaller than a soccer ball, or is a member of a specific semantic category such as *fruit*. Because errors are rare, researchers focus on the person's reaction time (RT) to the target. The prime that precedes the target can be either (1) a clearly visible word, presented for 0.05–2 s, that the reader is told to read silently or (2) a word that is presented for a very brief duration (< 70 ms), and which is immediately followed by a visual mask. With such masking the reader cannot identify the prime, and even claims to be unaware of its presentation. The time interval between the prime's onset and the target's onset, known as the stimulus onset asynchrony (SOA), is typically varied between 100 and 2000 ms to control the length of time for which the person can think about the prime before the target appears. (*See* **Word Recognition**)

With these procedures, priming effects are computed by subtracting RTs to targets when the prime and target are somehow related from RTs to targets that follow an unrelated prime. When people attend to the prime, most priming effects are positive (i.e. RTs are quicker after related than after unrelated primes). However, when people ignore the prime and attend (respond) to some other simultaneously presented stimulus, priming effects are often negative. This article will focus on studies in which the prime is attended to and the prime and target are presented alone.

A VARIETY OF PRIME–TARGET RELATIONS PRODUCE PRIMING

Most short-term word-priming studies have used pronunciation or lexical (word/non-word) decision

tasks. Unsurprisingly, repetition (e.g. *dog dog*) priming effects are positive and larger than other priming effects, and even with masked primes they are large. In orthographic priming, the prime and target share many of the same orthographic (letter) units, whereas in phonological priming their pronunciations share many of the same phonological (sound) units. Although most orthographically related primes and targets are also phonologically related, and vice versa (e.g. *tribe tripe*), one can find 'pure' orthographically related items that are phonologically unrelated (e.g. *dough cough*), and 'pure' phonologically related items that are orthographically unrelated (e.g. *eight ate*). Interestingly, orthographically related and phonologically related primes facilitate target processing to a greater extent when they are masked. In fact, when an attended unmasked prime is orthographically/phonologically related to the target, priming can be negative for lexical decisions, especially when the prime is less common than the target (e.g. *waif wait*). For unmasked primes, negative priming can also occur for 'pure' orthographically related items (e.g. *dough cough*).

In semantic priming, the prime and target are similar in meaning (e.g. *lion tiger*). In associative priming, they are associatively related (e.g. *blood red*), which means that when people are asked to free associate (i.e. give the first word that comes to mind) to the prime, they often give the target. As with orthographic and phonological relationships, it is difficult to isolate semantic and associative relationships. However, some researchers have claimed to do so by using 'pure' semantically related items such as *goat lion* (when given *goat*, few people give *lion* as an associate) and 'pure' associatively related items such as *snow ball*. However, the concept of a 'pure' semantic relationship is questionable because mediating associations may exist for semantically related items (e.g. 'animal' for *goat* and *lion*). Semantic/associative priming effects are consistently positive for unmasked primes, but sometimes do not occur (or are even negative) for masked primes, even under conditions that yield large positive repetition priming effects.

There are two other less extensively investigated types of associative priming. In backward priming (e.g. *baby stork*), the prime (*baby*) is often given as an associate of the target (*stork*), but the target (*stork*) is rarely given as an associate of the prime (*baby*). In mediated priming, the prime and the target are neither semantically related nor directly associated in either direction, but are linked via their sharing an association with a third mediating word (e.g. *lion stripes*, with 'tiger' as the mediating associate). At long SOAs, positive backward priming occurs for lexical decisions but not for pronunciation, whereas positive mediated priming is easier to obtain for pronunciation than for lexical decisions.

Morphologically related primes and targets share the same base morpheme. A morpheme is the smallest possible unit of meaning. For example, *unpainted* contains the base morpheme *paint* plus two morphemic affixes (i.e. *un* (not) and *ed* (past participle)). When morphologically related primes and targets are also orthographically, phonologically and semantically related (e.g. *heavy* and *heavier*), it is difficult to know whether priming is based solely on shared morphology. However, morphological priming is not merely an orthographic, phonological or semantic priming effect, because priming occurs for irregular morphologically related primes and targets that are not orthographically or phonologically related (e.g. *buy bought*), even under conditions that eliminate semantic/associative priming. (*See* **Morphology**)

In the rarely studied syntactic priming effect, RTs are faster when the related prime and target form a syntactically well-formed pair (e.g. *angry cup*) than when they do not (e.g. *anger cup*).

FACILITATION AND INHIBITION AND THE TIME COURSE OF PRIMING

RTs are faster when *dog* is primed by *cat* rather than by *wall* either because *cat* facilitates the processing of *dog*, or because *wall* is instead (or also) inhibiting the processing of *dog*. To measure facilitation and inhibition, one needs a 'neutral' prime such as ******, *XXXXXX* or the word *ready*. If RTs for targets following a word prime are faster than RTs for targets following the neutral prime, facilitation has occurred. If they are slower, inhibition has occurred. Facilitation and inhibition effects have most often been examined for semantic/associative priming effects. Related primes typically produce facilitation, and at SOAs as short as 50 ms. However, inhibition from unrelated primes occurs only when most of the related primes and targets in the experiment are related but not strongly associated, and only at SOAs of 300 ms or longer. Only repetition and morphological priming effects consistently occur when up to 2–3 min and many unrelated words intervene between a single prime and the target. Although there have been a couple of reports of semantic/associative priming from multiple primes lasting that long, semantic/associative priming typically survives for only a few seconds when unrelated words intervene between a target and its single related prime.

AUTOMATIC AND STRATEGIC PRIMING

Priming is said to be automatic if it (1) occurs quickly (at SOAs of 250 ms or less), (2) yields facilitation from related primes but no inhibition from unrelated primes and (3) occurs unintentionally without the prime even being attended to or entering awareness. In contrast, strategic priming (1) occurs only at SOAs of 300 ms or longer, (2) often yields inhibition from unrelated primes as well as facilitation from related primes and (3) depends on the reader being aware of the prime and intentionally using it to aid the processing of related targets. Most experiments designed to separate automatic and strategic mechanisms have examined semantic/associative priming. (*See* **Automaticity**)

At SOAs of 250 ms or less, which do not allow the reader enough time to use the prime to invoke strategies, semantic/associative priming seems to be automatic for the following reasons.

1. As the proportion of related prime–target pairs increases, priming does not increase as it would if the person was becoming more likely to use the prime to invoke strategies to aid the processing of the more likely related targets.
2. Priming effects are due to facilitation from related primes, but not to inhibition from unrelated primes.
3. Even when word targets that follow a category-name prime such as *body* are highly likely to be words selected from the category *building parts*, the *body* prime produces facilitation for rarely occurring 'unexpected' related targets such as *arm*, but not for frequently occurring 'expected' but unrelated targets such as *door*.

At SOAs of 300 ms or longer, which provide enough time for strategic processes to be engaged, priming seems to be strategic for the following reasons.

1. Priming now increases as the proportion of related prime–target pairs increases.
2. Facilitation from related primes when most of the related primes are not strongly associated.
3. When building part targets are highly likely to follow the prime *body*, the *body* prime now produces inhibition rather than facilitation for 'unexpected' related targets such as *arm*, and facilitation for 'expected' but unrelated targets such as *door*.

Although the distinction between automatic and strategic priming is well accepted, there is controversy over whether automatic semantic priming occurs when people are truly unaware of the prime.

MODELS OF PRIMING

According to one popular account, automatic semantic priming is mediated by activation that spreads within a lexical network of interconnected memory nodes corresponding to the individual words that a person knows. A prime word's presentation automatically activates its node, and this activation spreads via associative links to preactivate the node of a semantically related target, making it easier to process when it is presented. The concept of spreading activation is used in many theories designed to explain a large number of cognitive phenomena in addition to priming. (*See* **Semantic Networks**; **Spreading-activation Networks**; **Lexicon, Computational Models of**)

Strategic semantic priming occurs when a person uses the prime to generate an expectancy set containing potential targets that are related to it. The target is first searched for in this expectancy set. If it is not found there, the complete search of lexical memory that always occurs following neutral primes is then initiated. If most of the related primes and targets are strongly related, the expectancy set is small. Thus facilitation from related primes is large because the target is found quickly in a small expectancy set, and inhibition from unrelated primes is small because the unsuccessful search of a small expectancy set only slightly delays the search of lexical memory. When most of the primes and targets are weakly related, the expectancy set is large. By the previous reasoning, this causes facilitation to be small and inhibition to be large.

Spreading-activation and expectancy accounts of semantic priming assume a search process that operates on individual nodes which correspond to each word that a reader knows. More recently, connectionist 'neural-net' models of lexical memory have been developed in which orthographic, phonological and semantic 'features' are connected to each other and to response features via other 'content-free features' (called hidden units) through excitatory and inhibitory connections. However, because these models have only very recently been applied to a very limited number of priming phenomena, their adequacy as models of priming remains unclear. (*See* **Connectionism**; **Distributed Representations**)

PRIMING AS A METHODOLOGICAL TOOL

Priming is also commonly used as a methodological tool. For example, because automatic

priming presumably occurs only for prime–target relationships that are directly represented in lexical memory, priming has been used to study the representational structure of bilingual lexical memory. It has also been used to study individual differences. For example, in some cases cognitive deficits due to normal aging, stroke, Alzheimer disease's and psychopathology seem to be due to a strategic processing deficit, while in other cases they appear to be due to a deterioration of the lexical network itself. Finally, priming has been used to examine differences in the brain's two hemispheres with regard to the types of information that they have directly represented in them and the types of strategic processing mechanisms that they control. (*See* **Language and Brain**; **Brain Asymmetry**; **Priming in Psychopathology**)

Problem Solving, Psychology of

Introductory article

Laura R Novick, Vanderbilt University, Nashville, Tennessee, USA

CONTENTS

Problem-solving is the process by which a person represents the goal to be accomplished, determines a procedure for reaching the goal, executes that procedure, and evaluates the success of the solution attempt.

INTRODUCTION

Much of human activity involves problem-solving. In school, the algebra teacher assigns the end-of-chapter problems for homework. On family game night, players must decide what move to make in chess, what word to write in Scrabble, or whether to build houses in Monopoly. In the world of work, a travel agent may need to coordinate plane flights for people living in two different states in the USA who wish to fly to Scotland together; a cognitive psychologist may want to design an experiment to study some aspect of problem-solving; and an architect may attempt to design an award-winning building. What all these examples have in common is that there is a goal to be achieved (solving the algebra problem, writing a high-scoring word, finding convenient and reasonably priced plane flights), and the solution that achieves that goal is not already known. If the solution can be retrieved from memory (e.g. if an adult is asked to multiply 5×7), there is no problem to be solved.

MODEL OF PROBLEM-SOLVING

Problem-solving consists of three general stages: understanding, production, and judgment. Each of these stages, in turn, involves several specific processes.

Understanding

The outcome of the understanding stage is a representation of the problem. This representation reflects the solver's understanding (correct or incorrect) of the information given and the goal to be achieved. The importance of constructing a good representation for successful problem-solving will be considered in a later section. The processes involved in understanding the problem include: (a) identifying the initial state of the problem; (b) identifying the solution criteria; (c) determining the constraints imposed on the solution attempt; and (d) comparing the current problem with problems encountered previously.

Consider the algebra word problem shown in Figure 1(a). Letting N denote the price of the notebook and P the price of the pencil, the initial state of the problem is: $N = 4P$, $P = N - 30$. In this domain, the solution criterion is straightforward: the correct

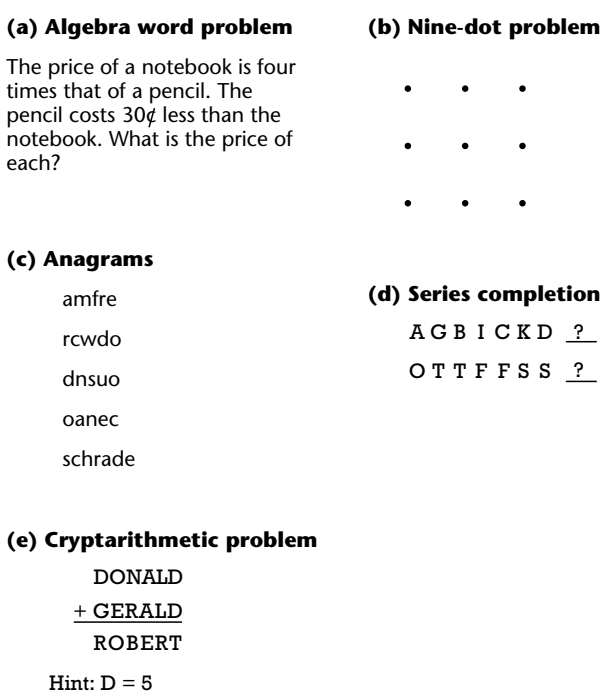

Figure 1. Examples of five types of problems.

answer has been found if both equations yield valid arithmetic statements when the derived values of N and P are substituted for the variables. Figure 3 at the end of the article gives the answer to this and all other problems in Figures 1 and 2.

To think about task constraints, it is useful to consider another example – the nine-dot problem illustrated in Figure 1(b). The goal is to connect the nine dots with exactly four straight lines without lifting one's pencil from the paper. Try to solve this problem before reading further.

The difficulty most people encounter when they try to solve this problem is that they assume that the lines cannot go outside the boundary of the imaginary box surrounding the dots. With this constraint, which is incorrectly imposed by the solver and is not part of the definition of the problem, the problem cannot be solved.

One's understanding and solution of a current problem may be guided by its similarity to a problem encountered previously. In such cases, psychologists talk about people solving problems by analogy. This topic will be considered in a later section.

Production

The outcome of this stage is a candidate solution to the problem. How the solution is generated depends on the type of problem to be solved. Two general strategies – search and analogy – will be considered in later sections. Broadly speaking, the solver applies operators (e.g. moving pegs, adding numbers) to the elements of the problem in order to transform or rearrange the information given into the solution or to induce the structure of the information given. For example, in an anagram (see Figure 1(c)), one must rearrange the letters to form a word in English (or another language). In a series completion problem (see Figure 1(d)), one must figure out the pattern in order to predict the next item in the sequence.

Often, generating a solution requires one to retrieve relevant facts and procedures from long-term memory. Consider the cryptarithmetic problem shown in Figure 1(e). The goal is to substitute a different number (0–9) for each letter to create a valid addition problem. A hint is given that the letter D has the value of 5. To solve this problem, one must retrieve addition facts (e.g. $5 + 5 = 10$) and procedures (e.g. only the one's digit of an answer is written below the line; the ten's digit is written at the top of the next column as a carry).

Generating a solution is more difficult, and the solution attempt more error-prone, when one must do all the work in one's head, in what cognitive psychologists refer to as working memory. It is harder to perform operations on the contents of working memory and maintain the outcomes of prior operations in working memory than to do the same on paper. To illustrate this, imagine being given a 'running' arithmetic problem in which you must perform the arithmetic operations in the order they are stated. For the first problem, $8 + 16 \times 3$, you are allowed to use pencil and paper. So, you add 8 and 16 and write down the answer, 24. Then, again on paper, you multiply 24 by 3 to get 72. For the second problem, $5 + 18 \times 4$, you must perform all the computations in your head (i.e. in working memory). Clearly, the second problem is harder, and you are more likely to get it wrong.

Many times, solvers store in long-term memory the procedure used to solve a problem. This information may enable them to use the current solution attempt to help solve related problems in the future, through analogical problem-solving.

Judgment

The outcome of this final stage is a decision that the problem has been solved or that more work is needed. Two processes are involved. One is to choose a rule for determining that a sufficient match exists between the candidate solution produced in the production stage and the goal specified in the understanding stage. Often this is fairly trivial. For anagrams, for example, the rule is that the anagram has been solved if the letter rearrangement the solver generated matches a word in his or her mental dictionary. For some problems, however, it is much more difficult to choose a decision rule. This will be the case when the goal is ill-defined – for example, to design an award-winning building – or when an optimum solution is not possible – for example, if one has a limited amount of money and cannot afford all of the car features one wants.

The second process is to compare the candidate solution to the solution criteria. Continuing with the anagram example, one compares the generated solution to words in one's mental dictionary. If a match is obtained, the anagram is solved. Otherwise, one tries to find a different arrangement of the letters that in fact is a word.

REPRESENTATION

Problem representations depict a solver's understanding of the structure of the problem to be

solved. They can be distinguished in a variety of ways. They can be constructed and stored internally in working memory, or they can be constructed and stored externally – for example, as a drawing on paper. As noted earlier, problem-solving is facilitated when representations can be stored and manipulated externally. A second important distinction is that representations may resemble their physical referents (e.g. a drawing of a pulley system is similar in appearance to the object it represents), or they may be more abstract and symbolic (e.g. a hierarchy diagram depicting the sequence of games in a basketball tournament looks nothing like the tournament). Finally, representations may be diagrammatic/pictorial or verbal.

It is often possible to represent the information in a problem in multiple ways. Consider the problem stated in Figure 2(a). Figures 2(b)–2(d) provide examples of three types of external representations that solvers might construct for this problem: (b) verbal shorthand (partially complete); (c) Venn diagram; and (d) network (partially complete).

(a) Problem statement:

A third-grade teacher asked her students to raise their hands if they collect rocks. She repeated the question for shells and for key chains. The following students raised their hands for each question:
Rocks: Harry, Francesca, Aaron, Joseph, Marcus, Elana, Quentin, Naomi, Rebecca, Stephanie, William, Derek, Gillian, Courtney.
Shells: William, Oliver, Kayla, Gillian, Elana, Aaron, Teondria, Stephanie.
Key chains: Victoria, Courtney, Leah, Quentin, Francesca, Elana, Marcus, Stephanie, Oliver, Benjamin
Three students never raised their hand: Isaac, Ursula, Pavel.
What percentage of the class collects rock and shells but not key chains?

(b) Verbal representation

rocks only: Harry, Joseph, Naomi, Rebecca, Derek
shells only: Kayla, Teondria
key chains only: Victoria, Leah, Benjamin
rocks & shells only: Aaron, William, Gillian
etc.

(c) Venn diagram representation (d) Network representation

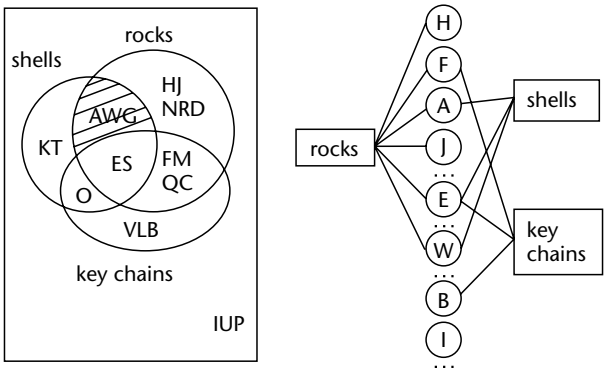

Figure 2. An illustration of different types of representations constructed for a single problem.

Many studies have shown that the type of representation constructed for a problem affects the ease or likelihood of solution: performance is facilitated when the structure of the representation corresponds well with the structure of the problem. Thus, a critical aspect of successful problem-solving is selecting, and then constructing, the most appropriate type of representation for the problem at hand. Often, solvers devote insufficient attention to this step, jumping straight from reading the problem to trying to get the answer – that is, to the production stage.

According to folk wisdom, visual representations are superior to verbal ones. As the oft-repeated Chinese proverb tells us, a picture is worth ten thousand words. Research supports the folk wisdom, as many studies have documented the benefits of pictures and diagrams for successful problem-solving. Abstract diagrams, in particular, are important instruments in the toolbox for thought. Such diagrams include, among others, Venn diagrams, hierarchies, matrices, and networks (sometimes called path diagrams).

PROBLEM SPACE, SEARCH, MEANS–ENDS ANALYSIS

Allen Newell and Herbert Simon referred to the solver's internal representation of a problem (and related context) as a problem space. In their view, a problem space has four major components: (a) an initial state of knowledge, specifying what the solver knows about the problem before trying to solve it; (b) a goal state, specifying the final state of knowledge to be reached; (c) operators, which produce new knowledge states when applied to existing knowledge states; and (d) a set of intermediate knowledge states, which result from applying the operators. Given this type of representation, solving a problem involves searching for a path through the problem space that connects the initial state to the goal state, going through some sequence of intermediate states. (*See* **Newell, Allen**; **Simon, Herbert A.**)

Consider the Tower of Hanoi problem. There are three pegs sticking up from a board. On the leftmost peg are three disks of differing sizes, with the largest disk on the bottom and the smallest disk on top. The goal is to move this tower to the rightmost peg. There are two constraints on the moves: (a) only one disk can be moved at a time, and (b) a larger disk cannot be placed on top of a smaller

disk. There are 27 different ways the three disks can be arranged on the three pegs. Solving this problem can be conceptualized as searching for a path through these 27 knowledge states that connects the initial state to the goal state. Try to find the shortest solution path, which involves only seven moves, before reading further.

Solvers may use any of a variety of search strategies to decide what operator to apply next. The simplest, but least effective, strategy is to pick an operator randomly. A more sophisticated strategy is known as hill-climbing, in which, for each move, the solver picks the operator that generates a new knowledge state that most closely resembles the goal state. This strategy is better than random guessing, because it allows the solver to look one move ahead. Often in problem-solving, however, one must backtrack a little to move forward, and in these cases hill-climbing will not lead to successful solution. An even more sophisticated strategy is means–ends analysis with subgoals.

The basic idea with means–ends analysis is to compare the current state to the goal state in order to select an operator that will reduce the difference between them. A critical aspect of this strategy is the setting of subgoals. Often, the solver is blocked from applying the best operator (e.g. because of the constraints of the problem). In that case, the solver sets a subgoal to remove the block. The current state is then compared to the subgoal state, and an operator is selected to reduce the difference between them. Additional subgoals may need to be set before an appropriate operator can be applied. (*See* **Means–Ends Analysis**)

Consider again the Tower of Hanoi problem. Because the largest disk must be placed on the bottom of the rightmost peg to build the goal tower, the best operator to apply is to move that disk from the leftmost peg to the rightmost peg. However, the two disks resting on top of that disk prevent that course of action. Therefore, the solver must set a subgoal to move the top, two-disk tower to the middle peg. To satisfy this subgoal, the solver must move the medium-sized disk to the middle peg. But, the smallest disk is in the way and prevents application of this operator. So another subgoal is set to move that disk out of the way. This subgoal can be satisfied directly, by moving the smallest disk to the rightmost peg, which then enables the remaining subgoals to be satisfied in reverse order. Continuing in this manner, the problem is easily solved.

ANALOGY

General-purpose strategies such as hill-climbing and means–ends analysis work well when solvers do not have specific, domain-relevant knowledge to guide their solution attempt. Often, however, solvers do have more specific knowledge available. This may be because they have solved a similar problem in the past or because they have acquired some expertise in the domain. Analogical problem-solving will be considered in this section and expertise in the next.

Analogical problem-solving involves four subprocesses: retrieval, mapping, inference, and adaptation. First, one must retrieve a relevant example problem. Solvers usually select a problem whose story line is similar to that of the current, or target, problem. For example, algebra students given Target Problem 1 in the middle of Table 1 for homework might look for a related example problem encountered earlier in the chapter, such as the first problem in the table. (Solvers who are relatively expert in a domain can often identify analogous problems without such overt similarity between them.) Then, the mapping process identifies correspondences between elements in the two problems. For example, 'washing the windows' maps onto 'mowing the lawn', '3.75 hours' maps onto '42 minutes', and 'Max' maps onto 'Sarah'.

The solver uses the mapping, along with links connecting elements of the example problem to elements of that problem's solution, to generate inferences concerning the solution to the target problem. For example, the fact that one multiplies the reciprocal of 42 times the unknown number of minutes worked in the example problem suggests that one should similarly multiply the reciprocal of 3.75 times the unknown number of hours worked in the target problem. If the two problems are structurally identical (i.e. isomorphic), like the example problem and Target Problem 1, these inferences should enable solution of the target problem. But if the two problems are only similar, the adaptation process will be needed to modify some of the inferences or to generate new inferences to account for the unique aspects of the target problem's structure. For example, two adaptations are needed to solve Target Problem 2 in Table 1 by analogy to the example problem. First, the right-hand side of the equation should be 1/2 rather than 1, because the couple works together to complete only half the job. Second, distinctive labels must be used to represent the amount of time worked by

Table 1. Algebra word problems to illustrate analogical problem-solving

Example problem with solution

It takes Sarah 42 minutes to mow the lawn, whereas her younger brother, Adam, requires 63 minutes to do that same job. How long will it take to mow the lawn if the two children work together?

$$\left(\frac{1}{42}\right)X + \left(\frac{1}{63}\right)X = 1 \rightarrow \left(\frac{3}{126}\right)X + \left(\frac{2}{126}\right)X = 1$$

$$\left(\frac{5}{126}\right)X = 1 \rightarrow 5\,X = 126 \rightarrow X = 25.2 \text{ minutes}$$

Target Problem 1 – isomorphic to example problem

It takes Max 3.75 hours to wash the windows of his house. His wife, Jessica, needs 4.25 hours to do that same job. How long will it take to wash the windows if the two of them work together?

Target Problem 2 – similar to example problem

It takes Max 3.75 hours to wash the windows of his house. His wife, Jessica, needs 4.25 hours to do that same job. Jessica washes half the windows on Saturday. On Sunday, they work together to complete the job, but Jessica starts half an hour after Max. How long will each person work on Sunday?

Max and by his wife (e.g. 'X' and 'X − 0.5', respectively), because they do not work for the same amount of time.

EXPERTISE

When cognitive psychologists moved from studying problem-solving using puzzles such as the Tower of Hanoi and those illustrated in Figures 1(b)–1(e) to using subject-matter domains such as mathematics and physics (e.g. Table 1), the importance of considering domain expertise became clear. Research on expertise in many domains (e.g. physics, mathematics, computer programming, X-ray diagnosis, chess, basketball) has identified several important differences between experts and novices that have an impact on problem-solving.

Perhaps most importantly, experts and novices in a domain differ with respect to the types of features they focus on in their representations of problems in that domain. Novices tend to focus on what are referred to as superficial features of the domain, such as the particular objects and terms mentioned in the problem and the way the question happens to be phrased. Thus, for example, when asked to sort a set of mechanics (physics) problems according to how they would be solved, undergraduates who have done well in an elementary physics course sort by the types of objects described, making separate piles for spring problems, pulley problems, inclined plane problems, etc. In contrast, experts focus on the underlying structure of the problems, in particular, how the objects are related to each other, regardless of what the objects are. Given the same sorting task, physics graduate students group the problems according to the physics principle required for solution – e.g. conservation of energy or Newton's second law – even if that means putting a spring problem, a pulley problem, and an inclined plane problem together. Thus, acquiring expertise in a domain involves learning the important distinguishing features of problems in that domain.

This representational difference has important ramifications for problem-solving. On the one hand, because the structure of a problem is what determines how to solve it, experts are more successful than novices at devising solution procedures from scratch. They are also more successful than novices at analogical problem-sol ving, because they are: (a) more likely to retrie ve a structurally similar (i.e. relevant) example problem; (b) more successful at constructing the mapping between the target and example problems; and (c) more successful at adapting the example problem's solution procedure, if necessary, to fit the unique requirements of the target problem. On the other hand, experts' solution attempts are less affected than those of novices by superficial characteristics of problems. For example, although both highly skilled and less skilled anagram solvers require more time to solve pronounceable than unpronounceable anagrams (e.g. *aftin* versus *infta, koech* versus *oekch, tarms* versus *rtmsa*), the negative impact of this superficial characteristic is much greater for novices (the solutions are 'faint', 'choke', and 'smart', respectively).

Experts also have better memory for, and can more quickly recognize, meaningful patterns of information within their domain of expertise. Finally,

experts and novices often differ in how they approach the task of problem-solving. Novices tend to reason backwards from the desired goal (e.g. the conclusion to be proved in a geometry problem or the variable to be solved for in a physics problem), often using a general-purpose strategy such as means–ends analysis. In contrast, experts tend to reason forwards from the information given (i.e. the initial state), based on their knowledge of the structural relations among important concepts in the domain, relations that have been learned through prior experience reasoning backwards. It makes sense, therefore, that experts revert to reasoning backwards when they encounter novel problems.

The transition from novice to expert is gradual. Problem-solvers at intermediate levels of expertise typically show patterns of performance that are intermediate between those of novices and experts.

INSIGHT

The discussion so far has considered problem-solving to be a deliberate, effortful, and consciously accessible means for proceeding incrementally from the initial state to the goal state. Although this characterization captures people's intuitions concerning many of their problem-solving attempts (e.g. solving the algebra word problems in Table 1), there are exceptions. Sometimes, people have the impression that a solution has simply popped into mind suddenly, seemingly out of nowhere, without any accompanying awareness of having made incremental progress towards the goal. The phenomenological experience in such cases is one of 'aha!' Perhaps you generated such a solution to one of the anagrams in Figure 1(c). Problems that often lead to 'aha' solutions (e.g. anagrams), or that lead to such solutions after the solver has restructured the problem in an appropriate way (e.g. the nine-dot problem in Figure 1(b)), have been referred to as *insight* problems.

Psychologists have long been interested in whether insight (sometimes called 'pop-out') solutions are fundamentally the same as or qualitatively different from noninsight solutions. The Gestalt psychologists explained the sudden emergence of the insightful solution and the accompanying 'aha!' sensation by the sudden reorganization of one's understanding of the problem. For example, they suggested that solution of the nine-dot problem could be obtained easily if one's understanding of the problem were restructured to allow the lines to go outside the boundary of the dots.

More generally, there are four components to the Gestalt view of insight problem-solving: (a) solution to the problem is prevented initially by fixation on an inappropriate organization (i.e. representation) of the problem; (b) removal of the fixation leads to a sudden restructuring of the problem; (c) the new (restructured) representation leads to the sudden emergence of the solution; (d) the restructuring process is different in kind from the type of process used to solve noninsight (e.g. search) problems. That is, what happens outside of conscious awareness mimics solvers' conscious experience.

Modern views have questioned whether restructuring necessarily leads to immediate solution, that is, to insight. For example, for the nine-dot problem, even after realizing that the lines may extend outside the boundary of the dots, one must still search in the new problem space for a solution, much like one searches for a solution to noninsight problems (e.g. the Tower of Hanoi). Modern research has also called into question the Gestalt claim that the restructuring arises full-blown. Although the solution may pop into mind suddenly, solution-relevant information appears to accumulate gradually outside of awareness. For example, highly skilled anagram solvers can reliably determine whether a string of five letters can be unscrambled to form an English word (e.g. 'dnsuo', 'injto', and 'amfre' can, but 'ynsil', 'ocjeu', and 'cofen' cannot) within half a second, and their performance on this solvability judgment task improves as the time available to make a decision increases, from half a second to a second, even when the available time is too short to enable them to unscramble the solvable items (i.e. the anagrams).

The results of recent research suggest that although both pop-out and search solutions rely on the gradual accumulation of partial information, there may be some merit to the Gestalt claim that pop-out solutions are different in kind from search solutions: pop-out solutions may result from the solver attempting to satisfy the many, sometimes conflicting, constraints on problem solution *in parallel* (i.e. simultaneously) and outside of awareness; in contrast, search solutions appear to result from trying to satisfy the same constraints *sequentially* (i.e. one after the other) and consciously.

Recent research also suggests that there may be a link between insight solutions and expertise: at least in some domains (e.g. anagrams), pop-out solutions are much more common among experts. And there may be a transition from primarily sequential to greater parallel processing with increasing expertise.

CONCLUSION

Problem-solving consists of three general stages: (a) understanding, which results in a representation of the problem; (b) production, which results in a candidate solution; and (c) judgment, which results in a decision as to whether the problem has been solved or more work is needed. Understanding is arguably the most important stage, because the type of representation constructed affects the ease or likelihood of solution. Among external representations, visual ones are often superior to verbal ones. Problem representations held in memory are sometimes referred to as problem spaces. Problem-solving is often conceptualized as a process of searching through a problem space for a path connecting the initial state to the goal state. An important search strategy is means–ends analysis with subgoals. Sometimes, solvers attempt to solve a current problem by making an analogy to a structurally similar problem encountered previously. Experts in a domain have a problem-solving advantage over novices because (a) their problem representations highlight solution-relevant structural features rather than solution-irrelevant superficial features, and (b) they more quickly recognize meaningful patterns within their domain of expertise. Sometimes, problem solutions seem to pop into mind suddenly, without any accompanying awareness of the process by which they were generated. Current research suggests that such insight solutions, like noninsight solutions, are preceded by the gradual accumulation of partial information relevant to solution.

Prototype Representations

Intermediate article

James A Hampton, City University, London, UK

CONTENTS

Prototype representations represent classes in terms of their central or most typical example – the prototype – rather than in terms of an explicit definition of the class boundary. Classification is based on whether similarity to the prototype is above some threshold criterion value.

INTRODUCTION

Psychological models of conceptual knowledge and knowledge of word meaning both require an internal representation of the world in the mind. Models or systems of representation vary in their level of complexity. At the simplest level are exemplar storage systems, in which individual experiences of objects are each stored, and categorization of novel instances proceeds by comparison to previously encountered exemplars. At the most complex level are systems for representing complex knowledge incorporating causal explanations of how individual attributes of an object class relate to each other. Prototype representations lie in the middle of this complexity dimension. The central notion is that we abstract a generic representation or prototype of a class (such as *fruit*) from our experience with many examples. This representation may be more or less structured, but does not contain information about specific individuals. Deciding that a novel instance is of a particular type involves a decision about how closely it matches the prototype for the class.

This form of representation gives rise to two phenomena. First, the membership of the class is graded in terms of typicality: those instances that match the prototype well (such as an apple) will be considered more representative or typical than those that match poorly (such as a coconut). Second, because the borderline of the class is not well specified, there may be instances which are neither clearly in, nor clearly out of the class (such as tomatoes or olives). This vagueness in the application of the category is a key aspect of prototype representations since it maps onto the acknowledged vagueness of the meaning of most nouns and verbs in natural language.

HISTORICAL DEVELOPMENTS

Early theories of semantic and conceptual representation tended to assume that a conceptual category was defined in terms of a set of singly necessary and jointly sufficient defining features – a view known as the Classical View of concept structure. It can be seen in analyses of the meaning of such words as 'Uncle' or 'Cousin', which can be defined in terms of a small set of dimensions.

One of the first appearances of the notion of prototype was a classic study by Posner and Keele (1968). Their study investigated the learning of novel stimulus classes through trial and error. Rather than investigating the learning of different forms of definitional rule, Posner and Keele taught people to differentiate stimulus classes that were based on small distortions of a random array of dots. In general terms a prototype can be thought of as a point in 'stimulus space'. Each exemplar of a category can be described in terms of its position along a number of orthogonal dimensions (for example its size, orientation, color, etc.). By plotting the dimensions in a multidimensional space, the exemplars can be placed in the space according to their coordinates on each dimension, and distance in the space can then be mapped onto the similarity between exemplars. This spatial representation is the stimulus space. The prototype is then defined as the centre of gravity of the set of exemplars in the space – the (possible) exemplar that has maximum overall similarity to all of the surrounding exemplars.

(Where a stimulus is not describable in terms of continuous or dichotomous dimensions, then this spatial model breaks down, and other ways of defining the prototype are used, such as taking the prototype to be the possible exemplar that has the most commonly occurring values on each feature or dimension.)

Prototype representations have in common that they are limited to representing classes that are linearly discriminable. That is to say that it is possible to discriminate between members and nonmembers in terms of some simple additive combination of the features or dimensions. Probability of an item being categorized in a prototype class should be expressible as a positive function of its similarity to the prototype and as a negative function of its similarity to the prototypes of other contrasting categories. This constraint has been used to argue that natural biological categories are not represented by prototypes. For example, it is claimed, a creature such as a whale is more similar to the prototype for fish than is a creature such as a seahorse, and yet while the whale is not a fish, the seahorse is.

The primary development of prototype theory is largely due to the work of Eleanor Rosch and Carolyn Mervis in the 1970s. Rosch (working initially as Heider) first developed the notion of 'natural' prototypes in the context of color and geometric figures. She showed that in the color spectrum there were certain hues that were naturally considered 'good examples' of a color term such as 'red', and others that were atypical. In her work with a primitive society – the Dani of New Guinea – Rosch was able to show that even though the group had no language term for 'red', they found color categories based on a 'good' red easier to learn than color categories centred around a 'poor' or atypical red. (More recent research has questioned this result.) According to Rosch, certain visual forms and colors form natural (universal) cognitive reference points or prototypes. Work in comparative linguistics confirms this notion. Whereas the boundaries between color terms vary widely across languages, the choice of the most central hue for a color term shows much closer agreement.

FAMILY RESEMBLANCE STRUCTURES: WITTGENSTEIN AND ROSCH

In subsequent work with Mervis, Rosch extended the notion of prototype concept to include more complex natural categories such as biological and artifact kinds (birds, fish, fruits, tools, furniture etc.). In developing the notion, they referred to a philosophical analysis given by Wittgenstein (1953) in his *Philosophical Investigations*. Wittgenstein spent many years worrying over the relation between word meaning and the underlying logic of thought and language. Towards the end of his life he came to the view that words do not correspond directly to the logical terms of propositions, but that the meaning of a word is defined instead in terms of the complex pattern of use that it has in language. He pointed out, for example, that one cannot specify just what all the activities that we call 'game' have in common, since for any possible relevant defining feature (e.g. 'games are all competitive') clear counterexamples could be found (ring-a-rosy is a children's game that is not competitive). Games, he said, are like members of a family. There are clear resemblances amongst the members of a family, but there may be no single distinguishing feature that would pick out the whole family from everyone else.

Rosch and Mervis (1975) took this notion and developed it into the Prototype Theory of Concepts (PTC). According to PTC, a concept such as 'game' is defined in terms of a number of features, such as *competitive* or *has teams*, and membership in the class of games involves possessing a sufficient number of these features. Their theory was equivalent to a classification system known as *polythetic* classification in theoretical taxonomy. The theory proposes that because different features or dimensions of objects are correlated within a domain, objects naturally fall into similarity clusters. For example, the domain of creatures having a beak is correlated with laying eggs and flying, while having a scaly skin is correlated with having cold blood and teeth. Prototype representations capitalize on these intercorrelations amongst features by drawing clusters of intercorrelated features together into a prototype of, say, birds or reptiles. However, because the correlations are imperfect, knowing that an object is in a particular class would not tell you just which set of the prototypical features it would possess.

Evidence for their theory was obtained as follows. They presented subjects with members of categories such as birds or fruits, and had them list properties or features of those members. Other subjects then decided the extent to which each member possessed each feature. A tally was computed of the degree to which each member shared features with each other member. This 'family resemblance score' was shown to correlate well with independent judgments of the typicality of each member. Using a more direct method of

interrogating subjects about the features that they thought relevant to defining each category, Hampton confirmed that the number of shared features predicts typicality. He also showed that it could be used with some degree of accuracy to determine whether an item was considered to be a category member or not, and the speed with which the decision was made (Hampton, 1979).

The novel feature of PTC as applied to word meanings is that, unlike traditional lexical semantic analyses of meaning, a feature may be part of the 'definition' of a term even though it is not true of all the things covered by the term. Analyses of prototype effects in any domain typically involve showing four types of effect: (a) there is no explicit definition to be given in terms of a conjunction of defining features; (b) features (e.g. that birds can fly) are listed as important to the concept's meaning even though they are not in fact common to all members of the category; (c) there are clear differences in the 'representativeness' or typicality of different category members; and (d) there are differences in the degree to which different items may actually be considered to belong in the category – that is to say, the category borderline is vague or fuzzy.

Rosch, Mervis, and others extended the exploration of prototype effects into many different areas. Prototype effects have been found in the learning of novel categories based on prototypes, the speed and accuracy of categorization, the strength of inductive inferences based on a typical as opposed to an atypical category member, and the differential build-up and release from proactive interference in short-term memory studies. An example of the predictive power of PTC is a study of categorization by Hampton (1982). One consequence of defining category membership in terms of a 'sufficient number' of the prototype features is that one may find a hierarchy of classes (A is a kind of B; B is a kind of C) for which the transitive inference (A is a kind of C) does not hold. Hampton confirmed the existence of such sets. For example 'car-seat' was categorized as a chair, and 'chair' was categorized as furniture, but 'car-seat' was not considered to be furniture.

Another closely related example of the use of prototype representations in reasoning is the conjunction fallacy, in which people erroneously use similarity to a prototype to estimate probabilities of class membership.

PTC as proposed by Rosch is not in itself a psychological model of concept representation, but is more a way of drawing together a large set of phenomena. More precise models for representing and learning prototype concepts have since been developed. While PTC has undoubtedly had a great influence on the understanding of concepts and word meaning, it is important to note that few theorists still regard it as adequate as a basis for conceptual representation. Murphy and Medin (1985) developed a critique of the theory from the point of view of the lack of constraints that it provides on the notion of feature or similarity. They argue that one cannot define similarity without making prior assumptions about the relevant dimensions of difference amongst a set of stimuli, and that these assumptions come from a much more sophisticated understanding of the domain in question. Concepts have to be seen in the context of a broader domain 'theory' in which they play an explanatory role. This view, sometimes known as the 'theory theory', has been widely endorsed by developmentalists studying children's concepts (e.g. Carey, 1985; Keil, 1989).

IMPORTANCE OF PROTOTYPE THEORY FOR INVESTIGATIONS INTO WORD MEANING

Evidence for prototype effects in word use and word meaning is easy to find. In addition to the intransitivity of categorization, the perceived strength of inductive arguments is also affected by typicality differences. Even when told that all members of a broad category have some property, people feel more confident about concluding that a typical subclass would have it, than that an atypical subclass would. People are aware that the more typical an example, the more likely it is to possess all the prototypical features of the class.

Demonstrations of the vagueness of category borderlines are particularly important in studies of word meaning. It can be argued that all natural language terms (that is, excluding terms in axiomatically defined systems such as mathematics) are vague to some degree. Judgments on whether to call a man tall, whether to call a geological formation a mountain, or whether to call a particular organism a dog, may all be a matter of debate. There is some evidence, however, that with biological kinds as opposed to artifacts or social categories, people are less willing to agree that the boundaries of the class may be vague, and instead assume that there is some essential constitutive property, known perhaps only to experts. For example, people may assume that 'arthritis' refers to some well-defined condition with a unique identifiable cause, whereas in fact it simply means inflammation of the joints.

A simple way to account for the ubiquitous vagueness of natural language terms is through Wittgenstein's basic insight that, as Rosch puts it, we can 'judge how clear a case something is and deal with categories on the basis of clear cases in the total absence of information about boundaries' (Rosch, 1978). Prototype representations can be held independently of a rule for determining the category boundary.

Take an example such as 'murder'. Most people's understanding of the meaning of this word in English is based on prototypical examples – the classical murder mystery type of murder in which one individual deliberately and intentionally kills another through their own direct physical action, with some clear motive such as revenge, jealousy, or personal financial gain. A prototype analysis of the concept would involve gathering a list of all such features from a sample of English speakers and putting them together to generate a prototypical or paradigm case. From this prototype one can then invent different possible scenarios in which one or more of the standard features are missing. These might include cases where the killing occurs through failing to act, cases where the victim may be considered a borderline case of being a person (as in abortion), or cases where the motives are not self-serving (as in euthanasia). The doubt and debate that is engendered in this series of 'moral dilemmas' are evidence of the multidimensional nature of the concept itself and the vagueness that results from representing clear cases, but not clearly representing the class boundary.

The problems of vagueness in language use provide a good argument for a clear differentiation between concepts and word meanings. Osherson and Smith (1981) and a number of philosophers have argued that our ability to understand and to use logic in our thinking and speaking is itself evidence that concepts cannot be vague prototypes. Osherson and Smith, for example, argue that there is no workable logic for handling logical combinations of vague concept terms such as 'striped apple' or 'pet fish'. Typicality in these complex concepts is not a simple function of typicality in the original sets, since a guppy or a goldfish may be a clear example of a pet fish, but atypical as either a pet or a fish. Work on conceptual combination arising from Osherson and Smith's paper has shown that the combination of prototypes does obey some constraints, although there is also evidence that broader world knowledge is involved in determining the meaning of complex noun phrases. The difficulty is that if concepts are to be components of thoughts, then the way in which they combine should follow the simple rules of logic. Since prototypes are mostly noncompositional, it is argued that they cannot serve the necessary function of being the building blocks for a compositional theory of thought.

Another important critique of PTC was offered by Armstrong *et al*. (1983), who asked subjects to give typicality ratings to exemplars of well-defined categories such as 'even number'. The degree of inter-subject agreement on the typicality of numbers such as 2, 18, or 574 was as great as that for the typicality of different fruits or different items of furniture. From this result they argued that typicality effects *per se* were not strong enough evidence to support the conclusion that a concept had a prototype representation. At the very least, their demonstration makes the point that determining the membership of a class need not involve the same information as judging what is typical of that class.

Prototype theory has been applied to the analysis of a wide range of semantic domains. Labov demonstrated how the use of simple terms such as 'cup' and 'bowl' could be mapped into a stimulus space involving dimensions of size, shape, and use of containers (Labor, 1973). Cantor and colleagues have applied the analysis with success to person perception, personality traits, psychological situations, and psychiatric diagnosis (Cantor and Mischel, 1977). Coleman and Kay showed graded structure in the types of speech act that would be categorized as 'lying' (Coleman and Kay, 1981), and Hampton applied it to abstract terms such as 'Art' and 'Science', although interestingly some other terms like 'Rule' and 'Instinct' did not show prototype structure (Hampton, 1981).

PROTOTYPES IN LINGUISTICS, AND RADIAL CATEGORIES IN WORD MEANING

Cognitive linguistics has embraced the notion of prototypes for analysis of word usage and word meaning. Most notable has been the work of George Lakoff, whose book *Women, Fire, and Dangerous Things* (Lakoff, 1987) presents a detailed account of prototype effects, which are viewed as reflecting the underlying idealized cognitive models that we use to represent the world. According to Lakoff, prototype effects can be identified not only in lexical meaning, but also in phonology, morphology, and syntax. For example, even syntactic classes such as noun may be based around prototypes. Some nouns (typically referring to concrete objects) show a wider range of

allowable syntactic manipulations than do others. Membership in the category appears to be graded – some words are more 'nouny' than others.

Lakoff distinguishes a number of different sources of prototype effects in lexical semantics. One case is where a number of related cognitive models cluster within the same domain. For example, the concept 'mother' really involves a cluster of concepts including giving birth, being the genetic parent, nurturing the child, and playing the relevant family role. Surrogate, adoptive, foster, and egg-donor mothers fit one or another of these models. Prototype effects result from the different applicability of the cluster of models to different cases.

Lakoff takes the analysis further with his discussion of 'radial categories'. These are clusters of meaning in which the application of a term has come to be extended to a range of other cases through a nonarbitrary but yet unpredictable process of chaining. For example, in Japanese, there is a noun classifier 'hon' which is used most commonly to describe long thin objects. By radial chaining it is also used for associated nouns such as martial arts contests using staffs or swords, hits in baseball, telephone calls through long thin wires, injections using long thin needles, and so forth. According to Lakoff the best explanation for the diverse range of nouns that take 'hon' is in terms of chains of association in which a central case (e.g. a long thin staff) becomes extended to a secondary case (e.g. a martial arts contest) and from there to a case at third remove such as a judo contest (similar to a martial arts contest, but now lacking the long thin staff). The process of chaining has also been shown to affect categorization in the learning of novel categories.

One consequence of radial category structure is that the original notion of representing a concept with a single prototype and an allowable degree of distortion is no longer adequate. Because the radial extensions take the meaning along chained paths in unpredictable ways, one can no longer expect the application of a term to occupy a linearly discriminable region of the stimulus space. A good demonstration of the complexity of radial categories is Malt's analysis of the use of the word 'water'. Malt asked a group of students to judge the extent to which a range of liquids such as lemonade, dishwater, rain, etc. contained H_2O. There was surprisingly little correlation between the estimated proportion of H_2O and the appropriateness of the term 'water' for referring to the liquid. Use of the term was affected by a number of other factors such as how the liquid was used, and whether other more appropriate labels for it existed (Malt, 1994).

As another example of prototype effects in language, Lakoff also reports an extensive analysis by Brugman of the different uses in English of the spatial preposition 'over'. Although at first sight a word with only one meaning, a careful analysis reveals a host of different but related senses – moving above and across (jumping over), being above (hovering over), covering up (painting over), to name but three. It is argued that the way in which word meanings form an interconnected network of related senses shows a particular form of prototype structure that is endemic to natural languages.

ACQUISITION OF PROTOTYPE CATEGORIES

The acquisition of prototype categories has been studied in two different ways. First there have been extensive studies of how adults (and children) learn novel categories based around a prototype structure. The domains used include a wide range of materials such as stick figures, random shapes, simple geometric figures, lists of disease symptoms, random strings of letters, or schematic scenes. Prototype models make the specific prediction that even if not presented in training, the prototype stimulus itself will always be at least as fast and as accurately classified as other category members. The main competitor to prototype theory for category learning is the Generalized Context Model (GCM) which assumes that individual exemplars are stored without any abstraction of the prototype. Across a range of experiments, the GCM has been developed into a highly successful predictor of a range of results, and frequently outperforms prototype models in predicting behavior. However, the two approaches are perhaps best seen as variants of a more general model. Both learn the statistical properties of the stimulus input, in a way that could easily be modeled by a neural net with a hidden layer of nodes between the input of features and the output of category membership. As the hidden layer becomes more restricted, so the ability to retain individual exemplar information is lost and abstraction of a prototype becomes more important.

The second way in which the acquisition of prototypes has been studied is through the study of children's early use of words. Keil and Batterman (1984) presented children with a range of concepts such as 'island' or 'uncle', and tested how they would categorize novel examples. Younger

children aged 4–5 years tended to categorize on the basis of surface appearance – for example, an 'uncle' is an adult male who gives you presents on your birthday. Older children changed to using more definitional information – for example, allowing that if your grandmother had a young male child then that could still be your uncle. Keil accounted for this change by suggesting that children start out forming similarity-based prototype concepts for the meaning of these terms based on the examples that they have experienced. It is only later, as they start to develop causal explanatory principles for organizing their knowledge, that they switch to the correct adult usage of the terms.

CROSS-LINGUISTIC ANALYSES

Schwanenflugel *et al*. (1991) review the influence of cultural and linguistic differences on word meanings and concepts. The culture and language into which a child is born present her with a system of cutting up the world and labeling it which requires attention to the correct attributes and dimensions, and learning of the appropriate underlying theories and models of different domains.

Studies of ethnobiological terms (words for biological kinds) suggest that all cultures divide up the natural world in similar ways, and have labels corresponding roughly to the level of species. In other domains there are, however, important cross-cultural differences in how language divides up the world. For example, Polish has no word corresponding to the English word 'disgust', and English no word corresponding to the German 'Gemütlichkeit' (although it could be translated as 'comfortableness', 'cosiness', or 'amiability' to convey the idea). Although sometimes taken as evidence that thought is thereby constrained by language, the fact that we frequently adopt useful terms from foreign languages into our own vocabulary suggests that the constraint can be overcome. A language that lacks a term for a particular concept is very similar to an individual language speaker whose vocabulary in her native language is limited. There is always the possibility of extending the expressive range of one's language.

A study by Malt *et al*. (1999) investigated the domain of container names in English, Spanish, and Chinese Mandarin. In one task, participants were given a set of photographs of a wide variety of different containers (boxes, cartons, bottles, jars, etc.) and had to say what they would call them. The results showed almost no relationship between one language and another. Three different containers may all be given the same label in one language, yet have three different labels in another. However, when another group of participants rated the similarity of each container to the others, there was far greater agreement between the different language groups. It is therefore clear that the effects of language and the effects of the cultural environment in which a person lives may be independent of each other. Rated similarity was based on a shared experience of the appearance and use of a particular container, whereas the label given to it was highly idiosyncratic to the particular language being spoken.

Another case in which languages differ markedly is in the use of spatial prepositions such as 'in', 'over', or 'through' in English, which according to Lakoff form radial categories of meaning. Even European languages with common roots such as French, Italian, and Spanish have very different ways in which these terms map onto the world, and learning their use requires attention to subtly different conceptual distinctions in each language.

Psychoactive Drugs

Introductory article

Deepak Cyril D'Souza, Yale University School of Medicine, New Haven, Connecticut, USA
John Harrison Krystal, Yale University School of Medicine, New Haven, Connecticut, USA

CONTENTS

Psychoactive drugs are chemical substances that influence the mind or mental processes by their effects on brain chemical messengers.

INTRODUCTION

The psychoactive effects of a drug are the sum of its effects on the brain, the characteristics of the individual and the setting in which the drug is used, resulting in wide interindividual differences in subjective drug effects. The immediate and long-term effects of a drug differ, as do the effects of short-term and chronic use. The descriptions that follow focus on the immediate effects of short-term psychoactive drug use.

Despite differences in their mechanism of action, chemical structure and behavioral effects, most psychoactive drugs that are misused share the capacity to increase levels of the chemical messenger (neurotransmitter) dopamine in the nucleus accumbens, a region that is believed to be a critical part of the reward pathway of the brain.

DOPAMINERGIC STIMULANTS

Dopaminergic stimulants include amphetamine, related compounds (such as methylphenidate and ephedrine) and cocaine. Cocaine blocks the reuptake of the neurotransmitters dopamine, serotonin and noradrenaline (norepinephrine); amphetamines increase the release of dopamine, noradrenaline and serotonin in addition to blocking the reuptake of these neurotransmitters. Thus, the common net effect of amphetamine and cocaine is an increase in the availability of synaptic dopamine, serotonin and noradrenaline. This explains why these drugs produce similar effects.

Amphetamines

Amphetamines can be used orally, by smoking or by injection. Amphetamines produce a 'rush' – an orgasm-like state, followed by a state of euphoria, a feeling of well-being, alertness, and increased energy and self-confidence that could enhance vocational or social activities, which could last for hours following a single dose. As an individual increases the use of the drug and expands the number of settings in which the drug is used, conditioning occurs – that is, the drug's effects (euphoria and increased energy) become associated with the setting in which the drug was consumed. Conditioning has been postulated to contribute to drug craving and relapse to addiction. With continued repeated consumption, dependence may develop. Some individuals start to binge – bursts of repeated consumption spanning hours to a few days – and this pattern of use may be associated with the symptoms of paranoid schizophrenia. Bingeing is followed by a 'crash' phase or withdrawal syndrome characterized by depression, agitation, anxiety and low energy followed by insomnia and fatigue, culminating in increased appetite and hypersomnolence. In the immediate abstinence period, individuals will experience effects opposite to those of amphetamine along with an intense craving to use the drug. With extended abstinence from the drug, conditioned urges and craving undergo gradual extinction.

Cocaine

Cocaine is derived from the coca plant and is used in the form of a hydrochloride salt or as a free base ('crack'). It is consumed intranasally by 'snorting' or sniffing a 'line', by smoking the free base, or

by intravenous injection. The duration and onset of the effects of cocaine depend on its route of administration. Smoking or intravenous injection produces rapid and accentuated effects in comparison with intranasal use. Since the euphoric effects of a single dose of cocaine last only about an hour, individuals will repeat its use several times in succession within a day. These properties of cocaine are probably the basis of its extremely high reinforcing properties. The effects of cocaine are similar to those of amphetamines except that they are of much shorter duration. As a result of the differences in duration, cocaine is associated with greater repeated use and amphetamine is associated with a longer withdrawal syndrome. So powerful is the direct stimulation of the reward pathway by cocaine that everything else in life becomes irrelevant to the cocaine user. The reinforcing effects of cocaine are strong enough to severely disrupt the social and vocational functioning of the individual.

The dopaminergic stimulants are associated with tolerance, intense psychological dependence and withdrawal. In addition, amphetamines and cocaine may be associated with sensitization.

CAFFEINE

Caffeine, the principal active ingredient of coffee, is perhaps the most widely used psychoactive drug. Caffeine is also present in a wide range of beverages and foods (tea, cocoa, chocolate, colas), prescription medications, over-the-counter analgesics and appetite suppressants. Caffeine produces its effects by blocking adenosine receptors.

At moderate single doses (100 mg) caffeine produces a state of enhanced attention and alertness. Higher (> 250 mg) or repeated doses can produce restlessness, nervousness, excitement, insomnia, agitation, increased energy, a feeling of inexhaustibility, muscle twitches, diuresis (urination), palpitations, increased heart rate and blood pressure, and tremor. Caffeine is associated with physical dependence and a withdrawal syndrome; the latter begins 24–48 h after the last dose and is characterized by lethargy, irritability and headache.

NICOTINE

Nicotine, the active ingredient of tobacco, produces its psychoactive effects through agonist effects at brain nicotinic acetylcholine receptors. Tobacco can be smoked in the form of cigarettes or cigars, or used as snuff which is either insufflated or held between the cheek and gums.

Nicotine has effects that are in some aspects similar to the classic dopaminergic stimulants. In nicotine-dependent individuals (smokers), nicotine produces euphoric and anxiolytic effects, and increases arousal and alertness within seconds. Nicotine-dependent individuals liken its effect to those of amphetamines, but milder. In individuals not dependent on nicotine (e.g. novice smokers), nicotine produces symptoms of dizziness, light-headedness, vertigo and at higher doses nausea and vomiting. It may increase the speed and accuracy of motor activity and may improve the capacity of the brain to process information. Nicotine is associated with physical dependence and a withdrawal syndrome that begins within hours of the last dose and is characterized by mood changes (irritability, anger, anxiety, depression), cognitive changes (drowsiness, fatigue, difficulty concentrating) and physical symptoms (insomnia, hunger, constipation, sweating).

CLASSICAL SEROTONERGIC HALLUCINOGENS

Drugs such as lysergic acid diethylamide (LSD), dimethyltryptamine (DMT), mescaline, derived from the peyote cactus, and psilocybin and psilobin, both derived from 'magic mushrooms' (*Psilocybe mexicana*) produce their psychoactive effects by partial stimulation of the 5-HT_{2A} subtype of serotonin (5-hydroxytryptamine, 5-HT) receptors in the brain. While these drugs may differ in the onset, duration and intensity of effects, their acute behavioral effects are similar. Initially LSD produces somatic symptoms including paresthesias (tingling of the extremities), dizziness, weakness and tremor. This is followed by perceptual alterations including blurring of vision, illusions, visual hallucinations, less discriminant hearing, and altered time perception. Dream-like imagery may develop when eyes are closed. Sensory inputs sometimes become mixed, so that people report 'seeing' sounds or 'feeling' colors (synesthesia). This is accompanied by changes in emotions: several emotions may occur at once, or emotions may become intensified and change rapidly. Depersonalization (the feeling of being separated from oneself) and difficulty separating self from environmental stimuli may occur. Finally, cognitive disturbances are generally mild and rarely include impaired memory, difficulty with attention and concentration. Individuals may report the capacity to gain greater introspection and reveal new 'insights' about themselves, leading to the reputation that these drugs are 'mind revealing' (or 'psychedelic').

Tolerance to the physical effects of these drugs develops rapidly. However, these drugs are not associated with dependence or withdrawal and have low reinforcement liability relative to stimulants.

SUBSTITUTED STIMULANT-HALLUCINOGENS

Drugs such as methylenedioxymethamphetamine (MDMA, 'ecstasy'), *N*-ethyl-3,4-methylenedioxyamphetamine (MDEA), 2,5-dimethoxy-4-methylamphetamine (DOM), methylenedioxyethylamphetamine (MDA, or 'Eve'), and methylenedioxyamphetamine (MDA) are synthetic compounds based on the amphetamine molecule; they are both stimulants and hallucinogens. Though intranasal use has been reported, these drugs are typically ingested orally. The psychoactive properties of these drugs appear to be related to some combination of effects on both serotonin and dopamine release, and partial agonist effects at 5-HT_{2A} (serotonin) receptors. The psychoactive effects begin with a mild 'rush' followed by other stimulant-like effects including euphoria, increased self-confidence and decreased appetite. The use of MDMA reportedly makes people feel more 'open' or more 'connected' to others. Like serotonergic hallucinogens, these drugs produce perceptual alterations (heightened sensory perception, illusions, hallucinations), difficulty concentrating and changes in mood (calmness, or anxiety and panic). Other effects include ataxia (instability of gait), insomnia, jaw clenching (bruxism) and muscle rigidity. It is possible that MDMA and MDA cause irreversible damage to brain serotonin neurons.

There is little information about whether these drugs are associated with tolerance, dependence or withdrawal. However, since they share some properties with amphetamines, one would predict tolerance, dependence and withdrawal to their stimulant-like effects.

CANNABIS

One of the oldest and most widely used psychoactive drugs, cannabis is derived from the flowers and leaves of the plant *Cannabis sativa*. Delta-9-tetrahydrocannabinol (THC) is the principal active ingredient, but there are more than eighty other cannabinoids present in cannabis which may also contribute to its effects. While usually smoked, cannabis is sometimes incorporated into confections and eaten. The application of hydroponics and the use of cloning appear to have increased the THC content of cannabis by up to ten-fold. Delta-9-tetrahydrocannabinol produces its psychoactive effects by actions at brain cannabinoid receptors.

Cannabis intoxication begins about 5–10 min after smoking and includes changes in mood, perception and cognition. The effects of cannabis may last 1–2 h, but its constituents remain in the body for several days. The initial phase of intoxication consists of euphoria which may be accompanied by uncontrollable laughter and a feeling of hilarity. This is followed by a phase of feeling calm, relaxed, mellow, passive, apathetic and drowsy. Sometimes individuals may feel anxious and, rarely, may experience panic attack-like symptoms. The perceptual alterations induced by cannabis include a heightened sensitivity to all sensory modalities; colors and sounds seem brighter and richer, and details previously unappreciated become obvious. This may also be accompanied by a sense of greater insight or self-revelation. There is distortion of time sense (time feels slowed down), spatial sense, and body image. Individuals feel as if they are separated from the experience, watching themselves as distant observers (depersonalization). Hallucinations and synesthesias are rare. The cognitive effects include impairment of short-term memory, free recall, difficulty concentrating, difficulty keeping track of thoughts, rapid flow of ideas and poor judgment. Paranoia (irrational suspiciousness or distrustfulness) is not infrequently observed, but frank psychosis is uncommon. Other effects include motor incoordination, increased appetite, increased heart rate and conjunctival injection (redness of eyes).

There appears to be some evidence suggesting tolerance to some (though not all) of the effects of cannabis, and increasing amounts of evidence suggesting the presence of a mild and subtle, but definite, cannabis withdrawal syndrome.

OPIOIDS

The opioids include the natural compounds (opium, morphine, heroin) isolated from the poppy plant (*Papaver somniferum*), and synthetic compounds such as pethidine, fentanyl, oxycodone and codeine. Opioids produce their psychoactive and physiological effects through actions at delta (δ), kappa (κ) and mu (μ) opioid receptors located in the brain and other systems in the body. The prototypical opioids are agonists for the μ opioid receptors. However, they vary in their affinity for the various subtypes of opioid receptors

and for their agonist/antagonist effects at these receptors.

Opioids can be smoked, used orally, or intranasally, or injected. Especially when injected, they produce an intense 'rush' followed by euphoria, a reduction in anxiety, elevation of mood, drowsiness, and a feeling of tranquillity. At high doses consciousness may be impaired as well as regulation of respiration. Opioids have powerful analgesic (pain-killing) effects and also depress the brain center that regulates respiration. Other effects include nausea and vomiting, narrowing of the pupils, alterations in temperature regulation and disruption of hormone release. This state lasts about 3–5 h. At typical doses, opioids do not appear to significantly impair cognition or perception. Sometimes heroin is combined with cocaine ('speedball') to produce a 'rush' which addicts claim feels better than either drug alone.

Tolerance to the psychoactive effects of opioids develops rapidly with repeated dosing. The need to avoid unpleasant withdrawal symptoms (dependence) is significant. The combination of tolerance and dependence make opioids extremely reinforcing. Approximately 8–10 h after the last dose,

Table 1. Properties of psychoactive drugs

Drug	*Mechanism of action*	*Route of administration*	*Tolerance*	*Physical dependence*	*Withdrawal*
Dopaminergic stimulants					
Amphetamine, methylphenidate	Stimulates dopamine and noradrenaline release and blocks dopamine, serotonin and noradrenaline reuptake	PO, S, IV	++	+	+/−
Cocaine	Blocks dopamine, serotonin and noradrenaline reuptake	PO, S, IN, IV	++	−	+/−
Caffeine	Blocks adenosine receptors	PO	+	+	+
Nicotine	Stimulates nicotinic acetylcholine receptors	IN	+	+	+
Classical serotonergic hallucinogens					
LSD, psilocybin, mescaline	Partially stimulate 5-HT_{2A} receptors	PO	+	−	−
Substituted stimulant-hallucinogens					
MDMA (ecstasy), MDEA (Eve), MDA	Stimulate dopamine and serotonin release, and partially stimulate 5-HT_{2A} receptors	PO	+/−	?	?
GABA-mediated sedative-hypnotics					
Benzodiazepines, barbiturates	Facilitate $GABA_A$ receptor function	PO	+	++	++
Alcohol (ethanol)	Facilitates $GABA_A$ receptor function, inhibits NMDA receptor function	PO	+	++	++
NMDA antagonists					
PCP (angel dust), ketamine (special K)	Inhibits NMDA receptors		−	−	−
Cannabinoids					
Cannabis, hashish	Stimulate cannabinoid receptors	PO, IN	+	−	+
Opioids					
Opium, heroin, morphine	Stimulate μ, κ and δ opioid receptors	PO, S, IN, IV	+	++	++

GABA, γ-aminobutyric acid; 5-HT_{2A}, 2A subtype of serotonin receptor; IN, intranasal; IV, intravenous; LSD, lysergic acid diethylamide; MDA, 3,4-methylenedioxyamphetamine; MDEA, *N*-ethyl-3,4-methylenedioxyamphetamine; MDMA, *N*-methyl-3,4-methylenedioxyamphetamine; NMDA, *N*-methyl-D-aspartate; PO, per oral; PCP, phencyclidine; +, present; −, absent; +/−, equivocal; ?, questionable; S, smoking.

symptoms of opioid withdrawal syndrome set in. The withdrawal syndrome, which can persist for over a week, is characterized by dysphoria (feeling 'down'), yawning, lacrimation (tearing), rhinorrhea (sniffles), sweating, gooseflesh, chills, nausea, vomiting, abdominal cramps, diarrhea, muscle and bone pains, high blood pressure, increased body temperature and restless sleep. A secondary phase of this withdrawal syndrome lasting up to 30 weeks is characterized by low blood pressure, reduced heart rate, dilatation of the pupils, and decreased body temperature.

NMDA ANTAGONISTS

Drugs such as phencyclidine (PCP, angel dust), ketamine (special K) and thienyl phencyclidine (TCP) were originally developed as anesthetic agents. These drugs produce their effects by blocking the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. Interestingly, alcohol is also thought to produce some of its psychoactive effects by a similar mechanism – however, since it also facilitates γ-aminobutyric acid (GABA) receptor function, it is discussed in the next section. Phencyclidine can be inhaled, smoked, consumed orally or injected. The effects occur within minutes of smoking the drug, and include initial euphoria, followed by perceptual alterations (feelings of detachment, distortion of body image, heightened sensitivity to sounds and images, illusions, hallucinations) and cognitive deficits (disruption of memory, difficulty in planning, impairment of judgment, difficulty with abstract thinking, difficulty concentrating and maintaining a train of thought). Other effects include numbness, paresthesias, unsteady gait and slurred speech. The effects of PCP have been likened to the symptoms of schizophrenia, and in rare instances PCP use may be associated with a psychotic syndrome that outlasts intoxication.

There is little evidence to suggest that the misuse of these drugs by humans is associated with tolerance, dependence or withdrawal.

GABA-MEDIATED DRUGS

The drugs referred to collectively as 'sedative hypnotics' include alcohol, barbiturates, benzodiazepines, meprobamate and chloral hydrate among others. These drugs are usually consumed orally and the effects tend to be biphasic: at low doses or soon after consumption the effects are predominantly stimulatory (euphoria, reduction in anxiety, disinhibition of impulses, lability of mood, talkativeness), whereas later on or at higher doses, depressant (drowsiness, amnesia) effects emerge. These drugs also disrupt memory and in some instances can induce black-outs or periods of total amnesia. Other effects include slurred speech, incoordination, unsteady gait, and nystagmus. At high doses or when used in combination these drugs can depress the brain center that regulates respiration and can also lead to coma.

The GABA-mediated drugs are associated with tolerance, physical and psychological dependence, and a clear withdrawal syndrome. The latter is characterized by anxiety, tremulousness, nausea and vomiting, transitory illusions and hallucinations, weakness, sweating, changes in blood pressure and heart rate, headache and insomnia, which begin within hours of the last drink. The withdrawal syndrome may progress to delirium tremens 2–3 days after drinking stops and may culminate in convulsions.

The properties of the above-mentioned drugs are summarized in Table 1.

Psycholinguistics is the scientific study of the production and comprehension of language.

INTRODUCTION

Psycholinguistics is a branch of cognitive psychology that deals with the production and comprehension of language. It emerged in the early part of the 1950s, as the thinking of psychologists was shifting from behavioristic views towards the 'cognitive revolution'. Although psycholinguists initially concerned themselves with exploring the psychological aspects of Noam Chomsky's work in linguistics, the field has grown to embrace a wide range of methodologies and theoretical approaches to studying the development of language (how do children learn language?), the comprehension of language (how do we understand conversations, novels, lectures, and more?), the production of language (how do we produce spoken and written language), and the loss of language (such as occurs with brain damage or stroke).

PSYCHOLINGUISTIC METHODS

Psycholinguists are first and foremost scientists who use experimental methods to test their ideas about how language works. The following are the more common methods used in the field.

Self-report/Behavioral Methods

These methods are commonly referred to as 'offline' measures because the measurement is not taken directly while the participants are comprehending or producing language. One example of such a task is a 'cloze procedure' task (e.g. fill in the blank: 'Megan walked _____.').

Reading Time/Reaction Time Methods

Time-based measures (i.e. measuring how rapidly a participant can perform a task) are by far the most common set of methods used by psycholinguists. Typically, researchers use computers to display words or sentences to research participants, and then time how long it takes for the research participants to read what was presented on the screen. This type of experiment can be used to measure how long it takes a person to read each word in a sentence, or how long it takes to read the entire sentence. By looking at which words and sentences are read comparatively quickly or slowly, researchers can make inferences about the nature of the processing involved in reading what was presented.

Variants of this methodology time responses to particular stimuli, rather than recording the time it takes to read, *per se*. Two widely used variants on this method are the probe response task and the lexical decision task. In the former case, research participants are often presented with a word and asked to determine as quickly as possible if it is related to a sentence or story they had just read. In the latter case, research participants are presented with stimuli, and they must decide as quickly as possible if the stimulus is a word or not (e.g. 'bank' is a word, whereas 'blick' is not). As before, the pattern of response times can be used to test predictions generated by different theories. Both reading time and reaction time methodologies (as well as all the methods discussed subsequently) are considered 'online' measures because the measurement is taken while language is being processed.

Priming Experiments

Priming experiments are a special type of reaction time experiment. In these experiments, subjects are presented with a stimulus (called a 'prime'), which is hypothesized to speed their response to a subsequently presented stimulus (called a 'target'). For example, presenting the word 'doctor' (prime) will

speed responding to the word 'nurse' (target), but will not speed responding to the word 'tiger'. Priming experiments are often used to test hypotheses about how word meanings relate to each other, and how information is organized in the brain.

Eye-tracking Methods

Since the 1980s, a popular method in the field has been tracking the movement of a research participant's eyes as the participant reads words, sentences, or passages, or inspects visual displays. Eye-tracking involves the use of lasers. These methods allow researchers to measure how long readers spend viewing each word they read, and when and if readers go back to re-read earlier parts of sentences. Eye-tracking also allows researchers to measure what objects in the environment research participants look at when they are listening to language. This method helps explain what happens at the earliest stages of language comprehension.

Event-related Potential (ERP) Methods

One way of determining what the brain is doing as it processes language is to use ERP methods. ERP studies examine the patterns of electrical activity in the brain as the subject is presented with various types of stimuli. These studies allow researchers to get a general sense of what parts of the brain are active when language is processed, and to determine what types of language present the brain with processing difficulty.

Neuroimaging Methods

Neuroimaging methods encompass a family of techniques that can be used to determine somewhat precisely what areas of the brain are active during the processing of different types of language, and at different stages of language processing. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) are common brain-imaging methods. Most of the techniques in this category exploit the increased flow of blood to active brain regions to determine which parts of the brain are used in particular types of processing. As ERP and neuroimaging techniques have become more widely available, the field has witnessed a growth in the number of researchers who use several methods cooperatively to draw more precise conclusions about how language is processed.

HISTORICAL DEVELOPMENT OF THE FIELD

Origin in the 1950s

Although many consider the 1957 publication of Noam Chomsky's book *Syntactic Structures* to mark the birth of psycholinguistics, the field was formally christened 4 years earlier. In 1953, Cornell University hosted a conference of linguists and psychologists who wished to bring their fields together to address issues of common concern. It was here that the term 'psycholinguistics' was coined. Despite the resolve of the members of this conference, however, it wasn't until the publication of Chomsky's work that psycholinguistics gained wide recognition as a field in psychology.

Chomsky's early work in linguistics was critical for the development of psycholinguistics in two ways. First, his linguistic theory (called 'transformational generative grammar') used a mathematical system of notation to create a precision previously unknown in the field. The importance of this idea cannot be underestimated, as one crucial factor that kept 'cognitive' terms out of behavioristic theory was the lack of precision with which many terms (such as 'attention') could be defined. With a precise linguistic theory in hand, psychologists could now explore the workings of language in a more exact, scientific manner. Chomsky's second contribution to the rise of psycholinguistics was his review of noted behaviorist B. F. Skinner's work *Verbal Behavior*. In the review, Chomsky took Skinner to task for presenting an oversimplified view of language acquisition based on the behaviorist principles of reward and punishment. This review made it clear to psychologists that a new approach to the study of language, and to the study of cognitive processes, was required.

1960s: Psycholinguists Work to Verify Linguistic Analyses

Through the latter part of the 1950s and much of the 1960s, psycholinguists worked to develop theories of language processing based on Chomsky's generative grammar. To illustrate, consider Chomsky's proposal that each sentence has a *deep structure* (a structure that translates the meaning of the sentence into a syntactic form) that can be transformed in a number of ways to produce various *surface structures* (roughly, the actual order of the words in the sentence). A deep structure such as 'Mike kicked the ball' could be produced without transformation (leaving it as it is), or with one

transformation, rendering the sentence as 'The ball was kicked by Mike'. Both versions of the sentence have the same deep structure (and, hence, the same meaning), but are produced with different surface structures. In pioneering psycholinguistic work, George Miller and colleagues demonstrated that the response time to simple sentences like those presented above was related to the number of transformations required to get from the surface form to the deep structure. Thus, all things being equal, it takes longer to read a sentence with one transformation ('The ball was kicked by Mike') than to read a sentence with no transformations ('Mike kicked the ball').

1970s: Separation from Goals of Linguistic Theory

Towards the end of the 1960s, psycholinguistics began to broaden in scope. Inspired by the theory of information processing that was developing throughout cognitive psychology, psycholinguists began to move away from the notion that language processing was best understood with respect to linguistic theory, and towards the notion that language processing could be characterized in terms of the types of information processing that computers performed. The predicate calculus system of representation presented in Miller and Johnson-Laird's seminal work *Language and Perception*, as well as proposition-based theories of language processing, were characteristic of this new approach. To contrast this new approach with that taken in the 1960s, consider again the difference between the two versions of the 'Mike …' sentence presented earlier. The early psycholinguists attributed the longer reading time of the passive version of the sentence to the presence of a transformation that needed to be performed in order to recover the deep structure of the sentence; the more recent theorists proposed that the difference in reading time was due to the more complicated propositional structure associated with the passive sentence.

1980s: Preoccupation with Modularity and 'Early Is Interesting'

Although theories of language processing moved away from a strict reliance on linguistic and philosophical analysis, central issues from those fields continued to be important to psycholinguists. A prime example is the question of whether language could be considered a 'modular' cognitive structure. Jerry Fodor presented a strong statement that certain aspects of language processing, such as the recovery of the syntactic form of a sentence, are performed by specialized cognitive machinery without influence from other structures or sources of information. Thus, the syntactic form of a sentence would be computed without recourse to information such as the meaning of the words in the sentence. This idea, which was known as 'modularity', was hotly debated throughout the latter part of the 1970s, and the early to mid-1980s.

Interest in the modularity of language was fueled in part by the advent of technology that allowed researchers to get finer-grained measures of the time it takes to read words and sentences than had been possible before, as well as by the advent of devices that allowed one to track the eye movements that individuals made while reading. With these powerful tools, psycholinguists attempted to ascertain whether sentences were initially processed with respect to syntax only (the 'language is modular' position), or with respect to multiple sources of information, such as syntax and meaning. As the debates intensified, there was great interest in obtaining data on how people processed sentences at earlier and earlier stages of the comprehension process, based on the belief that questions about modularity could be answered conclusively by figuring out what people did first when reading.

1990s: Investigation of Constraint Satisfaction Models and Other Approaches to Psycholinguistics

As the 1980s ended, interest in the modularity issue waned. This was in part because the imagination of psycholinguists was captured by the investigation of constraint satisfaction theories of language processing. Constraint satisfaction theories proposed that language comprehension involves the rapid use of mutually constraining sources of information, such as knowledge about syntactic structures and word meanings. With the development of computer-based neural networks, it became possible to develop sophisticated models of constraint satisfaction theories, and much effort was directed towards developing computer simulations of language processes. These new theories emphasized the notion that language processing is nonmodular. They also diverged from past work in psycholinguistics by drawing not from Chomskyan theories of linguistics, but from alternative approaches to characterizing the structure of language (e.g. head-driven phrase structure grammar).

One further development in the 1990s deserves mention. Several researchers are now approaching language processing based on the idea of embodied cognition. While only in its infancy, this work has shifted the focus away from studying how a reader generates the structure of the language, and back towards how meaning is generated from language. This recent development, along with constraint satisfaction theories and attempts to use neuroimaging to study language processing, promise to move psycholinguistics in interesting new directions in the future.

CONTENTS

Experimental methods in psychology are the procedures used to isolate the effects of manipulations on behavioral measures.

USE OF EXPERIMENTS IN PSYCHOLOGY

Experimental methods have been associated with psychology since the field's beginnings. The founding of psychology as a science is usually dated to 1879, when Wilhelm Wundt established the first laboratory devoted to experimental investigation of psychological phenomena. This association of psychology with the experimental method and its emphasis on control of the environment is what enabled the discipline to make the claim of being a science. The scientific approach provides a more objective method for establishing facts and evaluating alternative possible explanations. Throughout its history, experimentation has remained the central method of psychology, although it has not been without its critics, and non-experimental methods such as naturalistic observation and survey research have come into increasingly wide use.

Experiments can be conducted with humans or animals. The specific population that is studied will depend on several factors, including the topic with which the research is concerned, the theoretical predispositions of the researcher, the specific methods that are feasible with a particular population (e.g. humans cannot be lesioned, but non-humans cannot provide verbal reports), and the fact that more control can be exerted over a laboratory animal's history and environment than can be extended over a human's. Much psychological research in the late nineteenth century used human subjects, in part because researchers had an interest in the subjective experience of perceptual events. Beginning in the early twentieth century with the behaviorist movement, the use of animals increased. Because the learning and conditioning principles studied by the behaviorists were considered to be generalizable across species, much of the research focused on rats and pigeons, animals that can be studied easily.

Research on humans continued to be conducted throughout this period, but a major renewal of interest occurred with the advent of contemporary cognitive psychology in the 1950s. Most experimental research on humans is conducted in laboratory settings with undergraduate psychology students. One concern with such research is the extent to which the principles derived from it generalize to other populations and beyond the laboratory. Therefore, human populations other than undergraduate students are also sometimes tested. For example, there is now a large literature on expert–novice differences, in which performances and strategies of experts in a domain such as chess are compared with those of novices. Comparisons across different human and non-human populations are essential in many areas of research. Developmental psychologists compare experimental results across different age groups or over a period of development to evaluate the course of development throughout the lifespan. Comparative psychologists study a range of species, including humans, using similarities and differences across species to draw conclusions about general and species-specific behaviors.

In the last quarter of the twentieth century there was increasing concern with ethical principles in experimentation. All research must first be

approved by an institutional review board. This board determines whether the costs and benefits of a proposed research project justify its being conducted. If an experiment poses more than minimal risk for humans or hazard to non-humans, the procedure must be strongly justified by the researcher, who must ensure that precautions will be taken to minimize the risk to the subjects. There are guidelines that prescribe ethical principles for human and non-human research. Humans must give their informed consent to participate after being told about the general nature of the experiment, and they must be provided with a more detailed debriefing about the purpose of the study upon completion of their participation.

CONTROL IN PSYCHOLOGY EXPERIMENTS

Many properties vary simultaneously in the world, making it difficult to determine the causal relationships among them. In an experiment, the basic idea is to control those properties, or variables, that are not of interest to the experimenter and to isolate the critical ones. One or more variables (the 'independent' variables) are manipulated, and their effects on behavioral or psychophysiological variables (the 'dependent' variables) are measured. The question of interest is whether, and how, the conditions defined by the values of the independent variables influence the dependent variables. Often a researcher wants to test implications about hypothetical constructs that are not directly observable, and these constructs must be mapped to observable variables. This mapping yields 'operational definitions' of the constructs in terms of the operations the researcher uses to manipulate and measure them. For example, if the goal of an experiment is to determine whether learning of a repeated sequence of events occurs without awareness, the researcher must decide on appropriate measures of 'learning' (e.g. faster response speed on a repeated sequence than on a random series) and 'without awareness' (e.g. inability of the participant to verbalize whether a sequence is present). Debates in many areas of research center around the appropriateness of various operational definitions of the theoretical constructs.

When conducting research, the values of the variables must be measured accurately. All measures consist of two components: true measure and error. For example, on a recognition memory test, in which a 'yes' or 'no' response must be given regarding whether each test item was seen in a previous list, the proportion of correct responses reflects both the accuracy of memory and whether lucky guesses are made when the person is unsure. Two people with the same exact accuracy of memory may show different proportions of correct responses on the memory test. A reliable measure will give the same or similar values every time. A valid measure will reflect what it is intended to measure. For example, if repeated measurements were made of the duration of a stimulus that is displayed for exactly 1 second, a timing device that consistently read 1.5 s would be reliable, but it would not be a valid measure of the stimulus duration. The concept of two components of measures, true and error, is central to the logic of the inferential statistical methods that are used to decide whether independent variables affect dependent variables.

A good experiment controls extraneous variables that could produce differential effects on the dependent variable across conditions. When the extraneous variables are not controlled, they are said to be confounded with the independent variables. When a systematic confounding is present, the experimental results could be a consequence of the confounded variables and not the independent variables. Control of extraneous variables may be accomplished in several ways, such as holding a variable constant or distributing its effects equally across conditions. It is important to eliminate confounds because a researcher can only claim that the independent variable caused any observed differences on the dependent measure when there are no alternative explanations. A well-controlled experiment with no obvious confounds is said to have high internal validity because the researcher can be relatively confident that the independent variable caused any observed effect on the dependent variable.

An example of a poorly designed experiment with many confounds is the single-group pre- and post-test design. With this design, the researcher measures the dependent variable before and after manipulating the independent variable and compares the pre-test and post-test values. The goal is to attribute any differences in the dependent measure to the effect of the independent variable.

At first glance, this design seems like a good one, because performance on the post-test can be compared with performance on the pre-test as a control condition. However, this design does not control variables adequately. Suppose a researcher tests the hypothesis that consuming caffeine (a stimulant) prior to an examination decreases performance. The researcher has the students in a class

take one version of an examination and, afterwards, drink a cup of caffeinated coffee. A second version of the examination is then administered, and the scores on it are found to be 20 percent lower than those on the first version. Is it appropriate for the researcher to conclude that consuming caffeine before an examination decreases performance? The answer is 'no' because the experimental design did not control for confounding variables. Several factors other than consumption of caffeine could have caused the lower scores on the second examination: the second version may have been more difficult than the first; the students may have been more fatigued by the time they took the second examination, and consequently may not have tried as hard; the act of consuming the coffee itself may have affected the students' performance. A better experimental design would use a second group of students who received decaffeinated, rather than caffeinated, coffee. This group could provide a control for the confounds described above. In a double-blind design, neither the researcher conducting the experiment nor the student knows whether they are receiving caffeinated or decaffeinated coffee. In addition, half of the students should receive the second version of the examination for the pre-test and the first version for the post-test, so that the averages for the pre- and post-tests would reflect equal contributions from the two versions. With this two-group pre- and post-test design, the three alternative causes described above for the difference between pre- and post-test results can be ruled out if the group that received the caffeinated coffee shows the difference in performance between the pre- and post-tests but the group that received the decaffeinated coffee does not.

For control procedures of this type to be effective, the independent variable must be the only variable that systematically distinguishes the two groups. In other words, the groups must be equivalent in other respects, subject to the laws of probability. If this is the case, then statistical tests can be performed that enable the researcher to evaluate whether the mean difference between the groups can be attributed entirely to chance or is large enough to suggest a systematic difference due to the independent variable.

BETWEEN-SUBJECTS AND WITHIN-SUBJECTS DESIGNS

An independent variable can be manipulated either between subjects or within subjects.

For a between-subjects design, different groups of participants receive each condition, or value of the independent variable. There are two permissible methods for assigning the participants to the different groups. The simplest is random assignment, in which each person is arbitrarily assigned to a condition. The justification for random assignment is that the groups will be equivalent within chance limits for all subject variables (i.e., subject characteristics) because only chance determines who gets assigned to which condition. The second method is to match the groups according to subject variables known to be correlated with the behavior of interest. For example, one might wish to match groups or individuals in a memory experiment according to intelligence quotient (IQ) scores to ensure that the groups are closely equated on this characteristic.

To illustrate these two methods, we will assume that there are only two groups, *A* and *B*, and that 40 participants are being tested. With random assignment, only chance determines whether a participant will be put in group *A* or group *B*, with the constraint that 20 participants should be in each group. To match the two groups on IQ, participants are ranked from high to low and usually matched in pairs. The researcher randomly assigns one of the two members of each pair to group *A* and the other to group *B*. Thus, as with random assignment, there are 20 participants in each group, but each is participant is paired with another who scored similarly on the IQ test. Both procedures allow the researcher to assume that the two groups are equivalent within chance and that the independent variable is the only factor that systematically distinguishes them. The major benefit of the matching procedure is that it reduces the chance, or error, component of the measurements. In other words, if IQ score is highly correlated with memory ability, then the average memory ability for the subjects in the two groups is more likely to be highly similar if the matching procedure was used than if only random assignment was employed. A consequence of this reduction in chance variability is that it is easier to detect any effect of the independent variable on the dependent measure.

Regardless of which method is employed, if a statistically significant difference between the two groups is detected, this difference can be attributed to an effect of the independent variable because it is the only factor systematically distinguishing the two groups.

For within-subjects, or repeated-measures, designs, each participant is tested in all experimental

conditions. In the example above, 20 participants would be tested, rather than 40, to obtain 20 scores in each condition. This illustrates one advantage of using a within-subjects design: fewer participants are needed because each participates in all conditions. More importantly, this design is more sensitive than a between-subjects design to differences between conditions, because it effectively matches all conditions precisely on all possible subject variables (i.e. each subject contributes a score to each condition).

There are also disadvantages of using within-subjects designs. There may be order effects, whereby the order of the conditions affects the dependent variable. If these are likely to be present then a within-subjects design would be inadvisable. In addition, there can be general practice or fatigue effects, whereby previous exposure to the task affects the dependent measure. The general effects can be controlled by counterbalancing the order in which the conditions are presented, so that, in the example, half of the participants receive condition *A* first and half condition *B* first. With complete counterbalancing, all possible orders of presentation are included in the experiment, thus averaging out general practice and fatigue effects.

Thus, there are trade-offs between the different research designs. The choice of design should be determined by a clear understanding of the objectives of the experiment. Whether a between- or within-subjects design is preferred depends on the goals of the experimenter and on the nature of the experiment being conducted. Within-subjects designs require fewer participants and are more sensitive to effects of the independent variable. However, within-subjects designs cannot be usedwhen there is a possibility of differential 'carry-over' effects, or effects that are influenced by exposure to the previous conditions. In addition, within-subjects designs cannot be used when any experimental manipulation causes permanent changes in the subject (e.g. brain lesion).

COMPLEX DESIGNS AND INTERACTIONS

Most research uses complex designs in which two or more independent variables are manipulated. The conditions comprise all combinations of the values of the independent variables. All variables can be manipulated either between subjects, in which case the number of groups will equal the number of conditions, or within subjects, in which case there will be only one group. In mixed designs, one or more variables is between subjects and one or more is within subjects. The caffeine example above was a mixed design in which the type of coffee (caffeinated or decaffeinated) was a between-subjects variable and whether the examination was pre-test or post-test was a within-subjects variable. In mixed designs, the number of groups is the number of between-subjects conditions.

The advantage of manipulating more than one independent variable is that interactions can be studied. This is important because the effects of a variable often depend on other variables. For example, consuming a stimulant like caffeine, which increases levels of arousal, may enhance performance of a simple task but degrade performance of a complex task. In this case, the effect of caffeine interacts with that of task difficulty. In a design with two independent variables, regardless of whether they are manipulated between or within subjects, one can look at main effects of each variable as well as their interaction. A variable has a main effect if there is a difference in the dependent measure as a function of its values when averaged across all values of the other independent variable. An interaction occurs if the effect of one variable is different in magnitude or direction for different values of the other variable. If a variable has a main effect but no interaction, then this effect generalizes across values of the other independent variable. If it has a main effect but also an interaction with the second independent variable, the effect of the variable must be examined at each value of the other variable.

STATISTICAL SIGNIFICANCE TESTING

The purpose of statistical tests in experimental psychology is to determine whether observed differences in the dependent measure for each condition are due to the manipulation of the independent variable or to chance error. Significance testing is used to determine whether the difference in the dependent measure is larger than that expected due to chance. In significance testing, there are usually two hypotheses: the 'null' hypothesis and the alternative one. The null hypothesis usually states that the manipulation of the independent variable had no effect on the dependent one. The alternative hypothesis usually states that the manipulation of the independent variable had an effect on the dependent one. If there is evidence that the difference between groups is larger than that due to chance alone, then the null hypothesis is rejected in favor of the alternative one.

Before conducting an experiment, the researcher selects an 'alpha' level, which is the probability

level required for significance. Most researchers use an alpha level of .05, which means that if there is less than a 5 percent chance that the results were due to random error, the researcher concludes that the difference is significant, or that there is an effect of the independent variable. If the probability is greater than .05 that the difference between conditions could result from chance alone, the null hypothesis is not rejected. Because of the arbitrariness of the choice of alpha, some psychologists have criticized the use of null hypothesis testing and recommended other methods, such as the use of confidence intervals for reaching decisions.

There are four possible outcomes of significance testing (see Figure 1). First, the null hypothesis that there is no difference between the groups may be accepted (or, more accurately, not rejected), when in reality there is no difference (correct decision). Second, the null hypothesis may be rejected when in reality there is not a difference between the groups ('Type I error'). Third, the null hypothesis may be accepted when in reality there is a difference ('Type II error'). Finally, the null hypothesis may be rejected when in reality there is a difference (correct decision). When the .05 alpha level is used and the analysis shows that there is a significant difference between groups, the decision to reject the null hypothesis will lead to a Type I error 5 times out of 100. The probability of a Type II error occurring when the statistical test leads to acceptance of the null hypothesis is more difficult to specify because it depends on factors such as the size of the measurement error and the number of subjects tested. If an effect size of interest, and error variability for the analysis, can be estimated, a power analysis can be performed to determine the sample size needed to be reasonably sure of detecting an effect of the independent variable if one is really present.

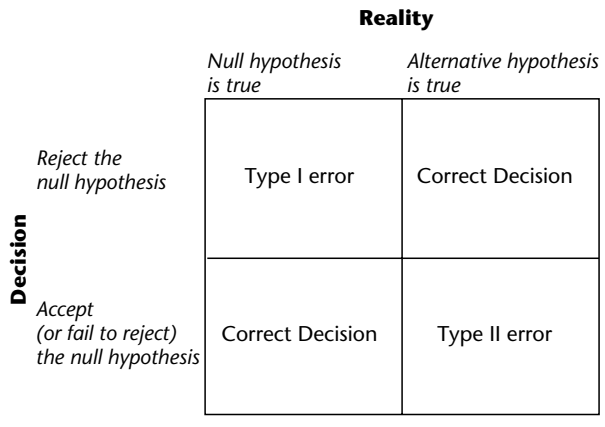

Figure 1. Decision matrix for statistical significance testing.

VARIETIES OF SCIENTIFIC METHODS

According to a popular point of view, the major feature that distinguishes science from other activities is its method, the scientific method. The scientific method is commonly identified with hypothesis testing. According to this approach, first introduced by William Whewell in about 1850, an empirically testable hypothesis is formulated on some basis. A prediction from the hypothesis is derived and then tested by designing a suitable experiment. If the experimental finding is consistent with the prediction, the hypothesis is retained. Otherwise, the hypothesis is rejected. This formulation may be found in virtually all of the widely used methodology textbooks written for undergraduate psychology students.

However, hypothesis testing is not as simple and clear-cut as is suggested by most methodology textbooks in psychology, because of what has come to be known as the Duhem–Quine thesis. This thesis rightly suggests that when a hypothesis is subjected to experimental test, numerous additional propositions are simultaneously under test. Thus, failure to confirm the hypothesis may be due to one or more of these additional factors. For instance, is the measuring instrument (Geiger counter, maze, paper and pencil test) an appropriate vehicle for testing the hypothesis? It may be insufficiently sensitive to test the hypothesis. Is the measuring instrument in good working order? It may be improperly calibrated. Is the prediction drawn from the hypothesis a valid one? For example, by emphasizing some neglected aspect of the hypothesis, a somewhat different prediction may follow. Can the prediction be rendered consistent with the data by making an additional modest assumption? As many historians of science have suggested, much good science has resulted from individuals resolutely holding on to a supposedly disconfirmed hypothesis by making such additional assumptions.

It is possible to object to equating science with hypothesis testing for the following reason: other methods have led to successful and useful scientific theories. For example, some useful theories, called explanatory theories, have been devised by explaining already known phenomena, rather than predicting new ones. A recent example of this is plate tectonics in geology. That theory, which was based exclusively on already known phenomena when initially formulated, was viewed quite

unsympathetically by American geologists who favored the hypothesis testing approach. European geologists, who were much less wedded to hypothesis testing, were much quicker to embrace plate tectonics.

Behaviorism is a set of broad assumptions that has led to the formulation of many individual theories, ranging from Tolman's cognitive behaviorism to Skinner's radical behaviorism. More recently, cognitive psychology has similarly given rise to a variety of theories. Broad approaches such as behaviorism and cognitive psychology have been called, variously, paradigms, research programmes, and research traditions. Needless to say, perhaps, broad research traditions such as behaviorism and cognitive psychology have had a great influence on the theory and practice of experimental psychology. Yet at the time of their introduction they were not able to explain many interesting phenomena; nor did they give rise to many novel, confirmed predictions. Their original acceptance could be likened to the acceptance of a promissory note, which promises a big pay-off in the future. Clearly, the ability to explain existing phenomena or to predict new ones is not the only factor in shaping interesting scientific research. At least as important is the capacity of an approach to attract adherents because of its promise of leading to fruitful discoveries.

Thus, major components of the scientific method include, in addition to hypothesis testing, explanatory theories that apply themselves, at least in their initial stages, to already known phenomena, and broad viewpoints, known variously as paradigms, research programs, or research traditions, that are accepted at first on the basis of their perceived ability to solve interesting scientific problems. If we view science in this broader perspective, it becomes apparent that different scientists will have different thresholds for accepting or rejecting theoretical propositions. For example, a few scientists will be quick to accept, at least tentatively, a new theory that appears to them to be promising; while other scientists may hold onto a theory long after most others have abandoned it. Of course, many intermediate positions are possible. History teaches that which possibility turns out to be correct in a particular case will depend on a variety of circumstances that can only be determined on the basis of additional research.

Psychophysics

Introductory article

Daniel Algom, Tel Aviv University, Ramat-Aviv, Israel

CONTENTS

Psychophysics is the scientific study of the relation between stimulus and sensation, and therefore its study concerns fundamental questions of psychology and cognitive science.

INTRODUCTION

Psychophysics is the scientific study of the relation between stimuli and sensations. According to the consensual view in psychophysics, the human perceptual system is a measuring instrument whose sensitivity to changes in the environment can be quantitatively analyzed. Of the many aspects of impinging stimuli and the corresponding sensations, three stand out and have received much attention. First, the system's response must exceed that triggered by a critical stimulus intensity – threshold – for any sensation at all to be experienced. Second, when a stimulus more intense than the threshold impinges on the sense organ, its intensity must be increased by a critical amount – the difference threshold – for the person to sense a just noticeable difference (JND) in sensation. Finally, of paramount importance is specifying the functional relation between stimulus magnitude as assessed by the instruments of physics and sensation magnitude as assessed by the *scaling* of people's perceptions.

Before describing each of these traditional problem areas, the fundamental finding of psychophysical research should be appreciated: a human being is not a perfect measuring instrument, infinitely sensitive to changes in the impinging stimuli. High levels of refinement are thus required of the methods and theories of psychophysics in their quest to unravel the operational characteristics of the human perceptual system.

ABSOLUTE THRESHOLD AND SENSITIVITY

The absolute threshold, the smallest amount of stimulus energy necessary to produce sensation, specifies the sensitivity in a given sensory modality. Despite the appealing simplicity of the concept of threshold, its measurement poses difficult problems. First, the absolute threshold is not a rigidly fixed value because both sensitivity and the intensity of a nominally invariant stimulus fluctuate irregularly over time (the latter variation refers to quantal fluctuations). Second, the threshold also varies with changes in the conditions of stimulation. For example, to produce threshold sensation in vision requires substantially more energy at one wavelength than at another. In general, the senses are not uniformly sensitive over their respective ranges of detectable energy.

There is no answer to the simple question 'how sensitive is the eye to light?' The sensitivity of the eye cannot be gauged by a single threshold because it depends on the conditions of stimulation such as prior exposure of the eye to light, and the wavelength, area, and duration of the stimulus. In contrast, the sensitivity of the eye under optimal conditions of stimulation can be determined. In order to see, it is necessary for only one quantum of light to be absorbed by a single molecule of photochemical pigment in each of five to 14 receptors in the retina. The maximum sensitivity of the eye is constrained only by the limit imposed by the nature of light. The ear nearly matches that remarkable sensitivity: under optimal conditions, the eardrum has to move a distance less than the diameter of a hydrogen molecule for a sound to be heard. Given its dependence on the conditions of

stimulation, the absolute sensitivity of a perceptual system is best described by examining the relations between the threshold and the various stimulus dimensions that affect its value.

Given the variability, the threshold must be measured statistically. For instance, it can be calculated as that level of energy detected on half the stimulus presentations. This definition is adopted in the *method of constant stimuli* in which fixed stimulus levels are presented many times in an irregular order. In the *method of limits*, stimuli are presented in order of increasing or decreasing magnitude until the observer modifies her or his responses from 'not perceived' to 'perceived' in an ascending series, or from 'perceived' to 'not perceived' in a descending series. The average value of the reversals defines the threshold. Finally, in the *method of adjustment* the observer sets the level of the stimulus so that it is just perceptible. The threshold is the average of several settings. The three methods, known as the classical psychophysical methods, have been in widespread use ever since their inception by Gustav T. Fechner, the founder of psychophysics in the nineteenth century.

Novel methods include variations on the classical ones. In the *staircase method*, a variation on the method of limits, stimulus levels around the threshold are made weaker when the observer detects them and made stronger when they go undetected. Hence, the method is adaptive and saves time because stimuli much below or above threshold are never presented. In the *threshold tracking method*, the observer maintains just perceptible intensity of the stimulus as it continuously changes on another dimension such as frequency. Individuals differ greatly in how much they tend to report the presence of sensation when no stimulus is present, a tendency referred to as 'response bias'. Methods of *forced choice*, in which the observer *must* select on each trial that time interval or location that contains the stimulus, control for response bias, as do the methods based on the theory of signal detectability (TSD) that include presentations of *catch trials* containing no stimuli. Within the framework of TSD, separate and pure measures have been developed for sensitivity and for response bias.

DIFFERENCE THRESHOLD, SENSORY RESOLVING POWER, AND WEBER'S LAW

The difference threshold (DL for the German *Differenz Limen*), the smallest detectable change in energy, specifies the resolving power of a given sensory system. It is the stimulus increment, ΔI, required to produce a JND in sensation. Because the difference threshold is as variable as the absolute threshold, the same methods of measurement are adapted to specify its value. Using the *method of constant stimuli*, for instance, the observer reports on each trial whether a stimulus (selected from a set of predetermined levels) is stronger than the invariant standard stimulus. The difference threshold can be defined as half the distance between the levels reported stronger than the standard on a quarter and on three-quarters of the presentations. The stimulus level that is perceived to be stronger than the standard as often as not, is defined as the point of subjective equality (PSE), and the difference between the PSE and the standard stimulus is a psychophysical quantity called the 'constant error'.

Applying the method of constant stimuli (or any other method) recurrently, DLs can be specified for several stimuli taken as standards. Does the DL remain invariant at different intensities along a given continuum? Ernst H. Weber discovered that it does not. According to Weber's law, the DL depends on the starting intensity in a linear manner such that $\Delta I = cI$, where ΔI stands as before for the stimulus increment necessary to produce a JND when added to the starting stimulus level I; c is a constant known as Weber's fraction. Dividing both sides of the equation by I gives what is perhaps the better-known form of Weber's law, $\Delta I/I = c$, where $\Delta I/I$ is again Weber's fraction. Weber's law states that the minimum change in stimulus intensity that can be noticed is a constant fraction of the starting intensity of the stimulus. To be discriminable, the intensities of two stimuli must differ by an amount that is proportional to their absolute level.

Weber's fraction differs for different sensory reactions, which means that sensory systems differ in their resolving power. The constant is less than 1 percent for pain, about 4 percent for visual length and heaviness, approximately 8 percent for brightness and loudness, and can be as high as 20 percent for saltiness. Weber fractions thus vary over an order of magnitude across the full range of human sensory systems.

Because the Weber fraction is a dimensionless number, sensory systems can be directly compared on resolving power (it is impossible to perform a meaningful comparison of sensitivity because the absolute thresholds do carry various physical dimensions). Gauged by the Weber fraction, pain is more acute than the perception of length, which in turn is more acute than either brightness or loudness.

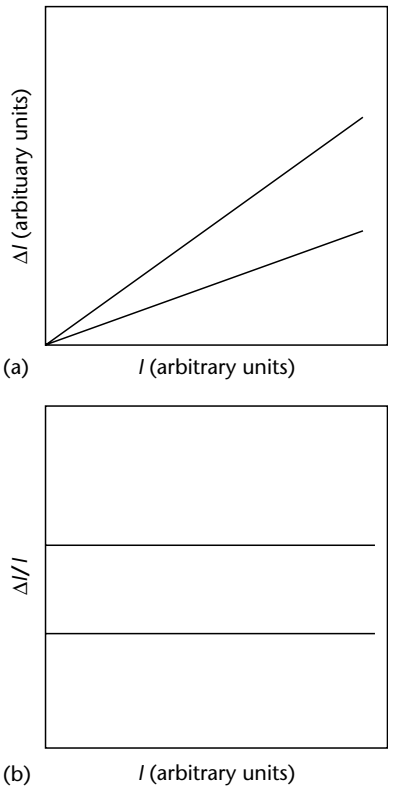

Figure 1. Two characterizations of Weber's law for two sensory continua: (a) the DL (or ΔI) as a function of stimulus intensity I, or (b) the Weber fraction, $\Delta I/I$, as a function of I. In both characterizations, the lower functions mark finer resolving power (i.e. smaller Weber fractions).

Figure 1 shows two characteristic renditions of Weber's law. From its inception in the nineteenth century, Weber's law has been repeatedly tested, and has been to shown to hold remarkably well over most of the dynamic ranges of the respective sensory continua. Deviations occur at very low intensities (in the vicinity of the absolute threshold) and at extremely high intensities. Weber's law remains the oldest, broadest, and most useful empirical generalization in the behavioral sciences.

PSYCHOPHYSICAL SCALING: FECHNER'S LAW AND STEVENS' LAW

Fechner used Weber's relativity principle, namely that DLs are proportional to stimulus intensity, in deriving his psychophysical law, the first explicit, quantitative statement relating sensations to stimuli.

Fechner complemented Weber's law by assuming that all JNDs comprise equal increments in sensation magnitude regardless of the size of the DL in physical units. Therefore, the JND can serve as a unit of sensation. According to Weber's law, pairs of stimuli discriminable by single DLs are separated by different physical increments, although the ratios, I_2/I_1, $I_3/I_2, \ldots I_n/I_{n-1}$, are equal. According to Fechner, these stimulus ratios correspond to equal *increments* in sensation because the respective JNDs are equal in magnitude. As a result, a geometrically spaced series of values on the physical continuum gives rise to an arithmetically spaced series of values on the psychological continuum. This relation defines the logarithmic function, and Fechner's law accordingly is $R = M \log (I/I_0)$, where R is sensation magnitude, M is the constant of proportionality, and I_0 is the threshold. Fechner's law implies that equal *ratios* of stimulus magnitude produce equal *differences* in subjective magnitude; hence, as is apparent in Figure 2, sensation magnitude increases as a negatively accelerated function of stimulus intensity.

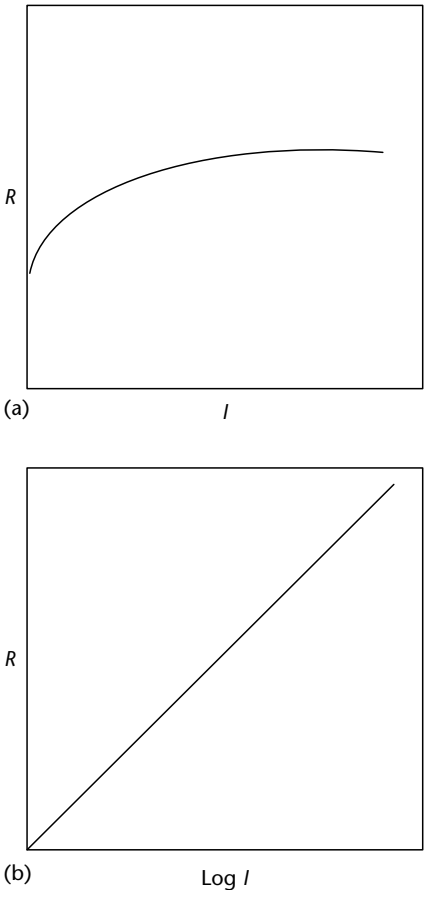

Figure 2. Two characterizations of Fechner's law. (a) Sensation magnitude R increases as a negatively accelerated function of stimulus intensity I. (b) When stimulus intensity is plotted logarithmically the function appears as a straight line.

Following Fechner's law, actual scaling requires determining I_0 and ΔI in the laboratory through the classical psychophysical methods. For suprathreshold scaling, the observer has to arrange stimuli in equal-appearing intervals, or to rate or classify them in equally spaced categories. The hallmark of these methods is that the observer merely matches or orders stimuli on a continuum (by responses such as 'greater', 'smaller', or 'equal'). These responses avoid many of the pitfalls associated with 'direct' numerical responses. Their validity is guaranteed by their extreme familiarity and simplicity.

It is important to distinguish between the laws of Weber and Fechner (there exists no Weber–Fechner law). Weber did not refer to a concept of sensation magnitude or sensation difference in his law. The sole psychological component in Weber's law is the observer's indication of when two stimuli are discriminably different. Yet Weber's law is silent on the crucial question: 'What sensation is felt at a given JND?' It was Fechner who created the notion of sensation magnitude and assumed that all JNDs were subjectively equal, thereby conceiving a truly 'psycho-physical' relation.

Fechner's logarithmic law has had a profound influence in science, from promoting the decibel scale, which is a logarithmic scale of (sound) energy, to aiding in the development of measures of pain such as the dol scale, to quantifying the results of electrical recording from receptors. Nevertheless, the universal validity of Fechner's law has been challenged. For one objection, reports by expert observers – acoustical engineers – judging the relative loudness of sounds did not agree with the logarithmic function. For another, the adaptive value of a logarithmic function for pain is questionable, given the paramount importance of good discriminability at high levels (the logarithmic function, in contrast, implies good discriminability at low levels). Finally, applying direct numerical estimates of the magnitudes of sensations typically yields power functions of intensity rather than logarithmic functions of intensity. Capitalizing on these results, S. S. Stevens has proposed the power function as *the* psychophysical law, replacing Fechner's logarithmic formulation.

According to Stevens, $R = kI^b$, where b and k are constants. The size of the exponent b varies from one continuum to another, subject, of course, to the conditions of stimulation. Exponents can take on values that vary from much smaller than unity (0.33 for brightness) through near unity (1.0 for perceived length) to much greater than unity (3.5 for the perceived intensity of alternating electric current). The power functions for such continua are depicted in Figure 3; the same functions become straight lines when plotted in logarithmically spaced axes because the logarithmic form of the power law is $\log R = \log k + b \log I$. The slopes of these linear functions correspond to the values of the respective exponents.

Assuming that a rule like Weber's law also holds for sensation results in the psychophysical power law. According to Ekman's law, JND is not constant but rather a linear function of sensation magnitude such that $\Delta R = gR$, where g is a constant, Ekman's fraction (which may or may not equal Weber's fraction for a particular modality), and ΔR is the increment in sensation that is just noticeable when added to starting sensation R. Assuming the validity of Weber's law for values of the stimulus and

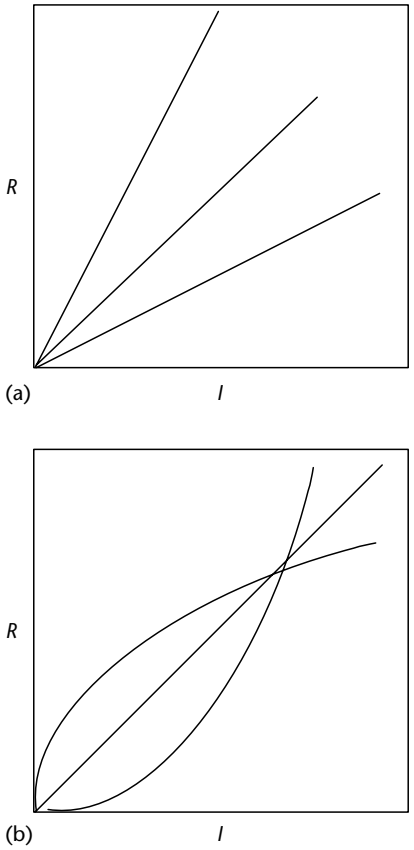

Figure 3. Two characterizations of Stevens' power law. (a) The power functions appear linear on double logarithmic coordinates, with the slopes corresponding to the respective exponents of the power functions. (b) Plotted on linear coordinates, the form of the functions is greatly influenced by the size of the exponent. An exponent of 1.0 corresponds to a linear function; an exponent smaller than 1 corresponds to a concave down function; an exponent greater than 1 corresponds to a concave upward function.

the validity of Ekman's law for values of the sensations, a geometrically spaced series of values on the physical continuum gives rise to a geometrically spaced series of values on the psychological continuum. This relation defines the power function with the exponent b reflecting the ratio of the respective fractions of Ekman and Weber.

In contrast to the Fechnerian approach, the methods of scaling advocated by Stevens are direct. Chief among the latter is *magnitude estimation* in which the observer is required to make direct numerical judgments of the stimuli in proportion to their sensory magnitudes. If one stimulus feels twice as strong as does another, the observer should give them numbers standing in a 2 to 1 ratio. The experimenter may provide the starting stimulus (standard) and assign it a certain numerical value (modulus) such that numbers are assigned to subsequent stimuli relative to the value of the modulus. The most popular method, however, is free magnitude estimation in which stimuli are randomly presented and the observer assigns numbers to them in proportion to the magnitudes of the respective sensations. No standard is provided and the observer is able to establish her or his own modulus. Other direct scaling procedures include *magnitude production*, in which the observer adjusts the level of the stimuli in proportion to numbers called out by the experimenter, and *absolute magnitude estimation*, in which the observer is asked to assign a number to each stimulus in a unique fashion, independent of the values of the other stimuli (hence, the resulting scale is an absolute one that cannot be transformed in any way).

In *cross-modality matching* (CMM) the observer is not required to make numerical judgments. The task is to set the magnitude of sensation in one modality equal to that presented in another modality. For instance, the observer might be asked to adjust the intensity of a vibration on the fingertip to that produced by a sound presented by the experimenter. If power functions are valid descriptions for vibration and for sound, then plotting the matching stimulus levels of the two modalities through CMM results in a power function with an exponent that is the ratio of those for vibration and sound. This result has often been confirmed in the laboratory. Stevens sought to use CMM to validate magnitude estimation and the associated power law. However, results of CMM predictable on the basis of the power law are better considered successful tests of transitivity or internal consistency. A good case can be made for magnitude estimation comprising a special case of CMM in which the observer matches number magnitude to that of the stimuli on the tested continuum. Consequently, any continuum could be substituted for numbers as the standard continuum to measure sensation magnitude on all of the other continua.

CONCLUSION

The implicit assumption that people are able to assign numbers to stimuli in a manner proportional to their inner sensations has been increasingly challenged in modern psychophysics. If it is not the case, then it is illegitimate to treat R as true numbers, let alone introduce them to quantitative, functional relations. Stevens' power law conflates the function relating stimulus intensity to sensation magnitude (the psychophysical function) and the function relating sensation magnitude to the observable verbal response R (the response function). Specifying the former as a power function strongly depends on the unjustified assumption that the latter is linear with zero intercept. The psychophysical function thus is indeterminable when a single stimulus factor is considered, as is usually the case in standard magnitude estimation scaling. Advanced multidimensional models have been developed in modern psychophysics to provide the necessary constraints for deriving and validating the 'true' psychophysical function.

Quantitative Reasoning

Introductory article

Kristy vanMarle, Yale University, New Haven, Connecticut, USA
Karen Wynn, Yale University, New Haven, Connecticut, USA

CONTENTS

Quantitative reasoning refers to human and non-human animals' sensitivity to and ability to represent different types of numerical information, including both discrete and continuous quantities, and to perform mental operations over these representations.

INTRODUCTION

The ability to mentally represent number and quantity is one of the human species' greatest assets. It has led to the development of our formal system of mathematics, which has enabled the advancement of our species throughout much of its recent history. As an abstract, logical system, mathematics allows us to represent both physical and abstract entities. This article will discuss how numerical information is represented in the human mind, and how the mind uses these representations to carry out basic numerical computations such as simple addition and subtraction. Recent research suggests that our sensitivity to number may be an evolved capacity and one that we share with other animal species.

THE NEUROPSYCHOLOGY OF NUMBER PROCESSING

The psychologist Stanislas Dehaene formulated a model of number processing, which currently dominates the study of numerical cognition. According to this model, humans' number knowledge is comprised of three representational systems, occupying distinct areas of the brain. Although these systems represent numerical information differently, they are interconnected, and function together, under normal circumstances, to support the numerical abilities of humans.

The 'verbal number' system is located in the language area of the left hemisphere of the brain. It represents numerical information linguistically, including both spoken and written number words. It also represents well-learned arithmetical facts, such as addition and multiplication tables learned by rote, and supports multidigit calculations, which require both the recall of memorized facts and the visuospatial representation of numbers. The 'visual Arabic numeral' system, located in the occipito-temporal region of both hemispheres, represents the visual forms of Arabic numerals. Note that not all cultures use the Arabic form of numbers in their written language. Presumably this area of the brain would represent the written form of numerals whether it be Arabic or otherwise. However, as the known data implicating this area of the brain have been tested only with Arabic numerals, we will continue to refer to it here as the 'visual Arabic numeral' system. A 'magnitude' system, located in the inferior parietal cortex regions of both hemispheres, represents numerical information in the form of magnitudes. It gives us our sense of quantity – the meanings of numbers – and therefore supports our ability to compare two numbers, perform approximate calculations, and so on. Empirical findings support the idea that such processes rely on a magnitude representation of number. For example, in the 'distance effect', adults become faster at saying which of two numbers is larger as the proportionate difference between the numbers increases. This is consistent with a magnitude representation of number, which predicts (as explained below) that as the proportionate difference between two numbers becomes smaller, it becomes more difficult to compare them.

Since these three systems are interconnected, activating the representation of, say, 'seven' in the verbal number store automatically activates both the visual Arabic form '7' and the magnitude representation of the number 7. Nevertheless,

neuropsychological evidence clearly indicates that these systems are both functionally and anatomically distinct: they are disrupted by damage to different areas of the brain, and if one system is damaged, the functioning of the remaining two systems is often preserved.

Studies of patients with brain damage support the existence of distinct neural circuitry underlying each of these different systems. For example, there are patients with left-hemisphere injuries affecting their language areas who show deficiencies in understanding number words and performing simple rote calculations such as 'eight plus nine' or 'six times four'. However, they remain able to recognize Arabic numerals, make magnitude judgments (e.g. whether 3 is larger than 7), and even compute approximate results of numerical calculations – for example, judging correctly that '$2+2=9$' is false, while erroneously judging that '$2+2=5$' is correct. In contrast, there are patients with damage to the inferior parietal cortex (where the magnitude number system is located) who can recognize written and spoken number words and Arabic digits, but have lost their sense of magnitude. These patients can recite arithmetic facts, such as multiplication tables, but cannot say, for example, whether 3 is larger or smaller than 7.

The fact that patients with left-hemisphere damage may show impaired ability to recognize and produce verbal number words, yet still be able to judge approximate magnitudes and visually recognize Arabic numerals, suggests that the damaged (but not the preserved) abilities rely on areas of the brain within the left hemisphere. Similarly, the fact that patients with damage to the inferior parietal cortex show impaired performance on tasks requiring magnitude judgments, but retain the ability to recognize verbal and written numbers as well as Arabic numerals, suggests that the damaged (but not the preserved) systems reside in the inferior parietal cortex.

Brain imaging studies with normal adults reveal that tasks involving exact calculation recruit different brain areas from those involving approximate calculation. Specifically, the left and right parietal lobes show more activation for approximate than for exact calculation, while the left inferior frontal lobe shows the opposite pattern. And studies with bilingual subjects indicate that precise number facts are represented in the language in which they are learned, while approximate number facts, which engage subjects' sense of magnitude, seem to be represented in a format that is independent of language.

Taken together, this evidence provides strong support for the existence of distinct systems of numerical knowledge and processes. Note that two of the components in the model, the verbal number system and the Arabic numeral system, consist of knowledge that must be learned. The magnitude number system, however, is thought to be an innate, evolved capacity. If so, we would expect to find evidence of it in non-human animals and prelinguistic infants.

NUMERICAL ABILITIES OF ANIMALS AND HUMAN INFANTS

Many studies have documented extensive numerical abilities across a wide range of warm-blooded vertebrate species. Many animals, including rats, pigeons, parrots, raccoons and chimpanzees, are able to respond on the basis of number of stimuli, whether the stimuli are visual or auditory events, objects in the world, or actions of the animal itself (such as presses of a lever), and whether the stimuli are simultaneously or sequentially presented. Moreover, animals trained to respond to number of one kind of stimuli show generalization to stimuli of other kinds. A model of a magnitude number mechanism was developed by Warren Meck and Russell Church, to account for animals' numerical abilities. On this model, the magnitude number mechanism can be thought of as a small container into which units of water can be added – one unit for each item counted. The subsequent fullness of the container represents the total number of items counted. The discriminability of two numbers relies on the proportionate, rather than the absolute, difference between their values. Consequently, it is easier to discriminate smaller numbers (e.g. 2 and 3) than larger numbers with the same absolute difference (e.g. 12 and 13).

Predictions derived from this model have been tested with prelinguistic humans to investigate the nature of their numerical abilities. The majority of infant studies conducted recently have used looking time as a dependent measure. There are two basic paradigms: habituation, and violation of expectation. In habituation studies, infants are presented repeatedly with a particular stimulus until they become familiar with it. When an infant's looking time decreases, according to a predetermined criterion, the infant is considered to be 'habituated', and is then presented with new instances of the habituated stimulus interspersed with instances of a novel stimulus; the infant's looking time to each is measured. If infants can discriminate between the habituated and the novel stimuli,

then their looking time should recover (i.e., increase) for the novel stimulus, but not for the habituated stimulus.

In violation-of-expectation studies, there is no habituation phase: the infant is simply presented with trials consisting of series of events, the outcome of which is sometimes an 'expected' one (e.g. '$1+1=2$') and sometimes an 'unexpected' one (e.g. '$1+1=1$'). If infants have expectations about the outcome that should obtain in a particular event, then they should look longer at outcomes that do not match their expectation.

If human infants possess the same magnitude number system as do non-human animals, they should show similar numerical abilities. In particular, infants' ability to discriminate two numbers should depend on their proportionate, not their absolute, difference; and infants' numerical abilities should apply to a wide range of entities (auditory, visual, etc.).

Experiments have shown that infants are sensitive to numerical quantity. They can discriminate between both small and large numbers of items, and, as predicted by the model, their ability to discriminate two numbers depends on their proportionate difference – infants can discriminate 2 items from 4 items, 8 from 16, and 16 from 32, but under similar conditions fail to discriminate 8 items from 12 items or 16 from 24. Moreover, their numerical abilities are abstract: infants can enumerate visual objects, collections of objects, events (e.g. jumps of a puppet), and auditory stimuli.

Recent studies recording infants' event-related potentials – which measure activity across different areas of the brain in response to stimuli – reveal that when making numerical discriminations, infants' parietal cortex is highly activated. This is the area of the brain that is responsible for the magnitude sense of number in adults. Further studies have shown that infants can do more than discriminate numbers: their numerical representations can also be used to perform simple numerical operations such as addition and subtraction. When 5-month-old infants are shown an object placed on a stage and then hidden behind a screen, and then shown another object placed behind the screen, they expect two objects to be revealed when the screen is removed, and will look for longer if one or three objects are revealed. Similarly, if shown two objects that are then hidden behind a screen, and then shown one of them being removed, infants expect one object to remain and will look for longer if two are revealed behind the screen.

Similar studies conducted with non-human primates show that they possess similar abilities. Both rhesus macaques and cotton-top tamarins respond as do human infants when shown addition and subtraction situations as described above: they look for longer at incorrect outcomes than at correct ones. For example, when rhesus monkeys were shown one eggplant placed out of sight in a box, and then shown another eggplant also placed in the box, they expected two eggplants to be in the box, and looked for longer if only one was revealed.

ABILITY TO REASON ABOUT CONTINUOUS QUANTITY

Humans – and other animals – can represent continuous as well as discrete quantity: the height of a table, the volume of a piece of cake, the weight of a child, the duration of a sound. Research indicates that the ability to represent continuous quantities is also present from an early age. Infants under 6 months of age can discriminate between objects that differ in their amount of surface area. They can also represent the height of an object, the distance traversed by an object, and the duration of an event. Indeed, some experiments intended as investigations of infants' numerical discriminations (e.g. between different numbers of items) may have inadvertently been testing their ability to measure and distinguish continuous quantities (e.g. total area): in these studies, continuous quantities were confounded with discrete quantities (because a greater number of items always had a greater total surface area). However, recent studies testing infants' numerical abilities while strictly controlling for continuous variables have shown clearly that these abilities are distinct. Infants can represent both continuous quantities, such as the total surface area of elements in a display, and discrete quantities, such as the number of elements in a display.

Thus, from a very early age – long before any formal schooling, and even before any language comprehension – humans have distinct systems for quantitative reasoning. Empirical results with infants suggest at least two basic representational systems for quantity (discrete and continuous), but there may well be many more. It is implausible that all of our representations of continuous quantities are subserved by the same mental structures. For example, we would intuitively expect that our processes for representing an object's speed, the height of an object, the duration of an event, and the weight of an object are quite distinct. However, little is known about the cognitive systems that represent and reason about these kinds of continuous quantities. To obtain a richer understanding of

the full range of humans' quantitative abilities, and the relationships between these different quantitative systems, will require rigorous empirical investigation of these abilities.

CONCLUSION

In conclusion, there is a great deal of evidence supporting at least three components of number processing. Neuropsychological evidence shows that verbal number knowledge, visual recognition of the Arabic numerals, and our sense of numerical magnitude, while interconnected in normal humans, are functionally and anatomically distinct. Moreover, the magnitude number mechanism is special in that it is an evolved mechanism that humans share with other animals, and that is independent of language and learning. It gives us our sense of quantity, allows us to understand relationships between different quantities of items, and underlies our ability to perform simple numerical operations. Empirical findings with adults, prelinguistic infants, and nonhuman animals converge to support this claim. Further research is necessary to determine in more detail the functional parameters of the analog magnitude mechanism, and how all three systems interact throughout development to form human adults' numerical abilities.

Rational Models of Cognition

CONTENTS

Rational models of cognition attempt to explain the function or purpose of cognitive processes.

CONSTRAINTS ON MODELS OF COGNITION

A scientific explanation of psychological, biological, or social phenomena can take one of two complementary forms. The first is mechanistic: phenomena are explained by analysing their internal causal structures. The second is purposive: phenomena are explained in terms of their purpose, what problems they solve.

In biology, purposive explanation concerns the function of biological structures and processes (e.g. the function of the heart is to pump blood). The same style of explanation is applied to animal behavior (e.g. the function of building nests is to provide a safe shelter for eggs). In the social sciences, 'rational choice' explanation views people as having the purpose of maximizing their 'utility', given the constraints imposed by their environment. Moreover, in everyday life, we explain each other's behavior by giving reasons for why this behavior 'makes sense', given our desires and our beliefs.

In cognitive science, however, mechanistic explanation has been predominant. Computational models, whether symbolic or connectionist, have focused on specifying architectures and algorithms for cognition; and experimental work has been oriented towards mechanistic questions, such as the limits of human memory, or the number of, and interconnections between, memory stores. The picture of the cognitive system that emerges from this focus on mechanistic explanation is as an assortment of apparently arbitrary mechanisms, subject to equally arbitrary limitations, with no apparent rationale or purpose.

By downplaying purposive explanation of cognition, cognitive science may have been missing an essential source of constraints on cognitive models: namely, that in many domains, cogntion appears to be extremely well adapted to the challenges that it faces. In perception, motor control, language processing, common-sense reasoning and decision-making, the cognitive system reliably (though not infallibly) handles perceptual and cognitive problems of great complexity, typically under conditions of uncertainty. The cognitive system can learn to deal with a remarkably broad range of challenges, both natural and artificial, from unicycling to backgammon to musical composition. And the cognitive system acquires, stores and retrieves a rich understanding of the everyday world. It seems plausible that, as for other biological structures, this success is not accidental. It seems more likely that the cognitive system is superbly adapted to serve practical and computational ends. Thus, cognitive models should, ideally, not just fit the empirical data, but also, where possible, make sense as solutions to adaptive problems that the cognitive system faces.

CHARACTERIZING RATIONALITY IN HUMAN COGNITION

Rational models of human cognition aim to explain the function or purpose of human behavior or the cognitive processes underlying it. An idealized methodology for providing such explanation is given in Anderson's (1990) notion of 'rational analysis'. This methodology has six steps:

1. *Goals*. Specify precisely the goals of the cognitive system.
2. *Environment*. Develop a formal model of the environment to which the system is adapted.
3. *Computational limitations*. Make minimal assumptions about computational limitations.
4. *Optimization*. Derive the optimal behavior function.

5. *Data*. Examine the empirical evidence to see whether the predictions of the behavior function are confirmed.
6. *Iteration*. Repeat, iteratively refining the theory.

The idea is that a rational model explains behavior as an optimal (or nearly optimal) attempt (step 4) to achieve certain goals (step 1), in the context of a particular environment (step 2), and with possibly limited computational resources (step 3). The project is empirical, in two senses. First, the goals, environment, and computational limitations can only be determined empirically. Second, the goal of a rational analysis is to explain patterns of empirical data. So, an optimal system for some aspect of categorization or reasoning is only of interest if it captures empirical data on how people do categorize or reason. As with any empirical scientific project, there may be a continuous adjustment of all the elements of the explanation, in order to obtain the most compelling relationship between theory and data (step 6).

How can this 'rational' style of explanation relate to, and potentially constrain, a mechanistic cognitive model? The answer is that the mechanistic cognitive model can implement the computations specified by the rational model (or, at least, some approximation to them). Thus, building a rational model complements, rather than displaces, traditional mechanistic modeling in cognitive science.

Rational models have been developed, more or less independently, in a number of contexts. One tradition, mentioned above, is 'rational choice' explanation, which, in its classical form, assumes that individuals make decisions in order to maximize their expected utility (or, in some biological contexts, to maximize their number of viable offspring). Rational choice explanation is the foundation of modern economics, and has applications in animal behavior, sociology, and political science. In cognitive science, rational models have been developed for specific cognitive processes in perception, categorization, reasoning, problem solving, memory, and language processing, rather than for the whole individual. We will discuss work in this tradition below; related approaches have also been developed independently in the study of vision (e.g. likelihood and simplicity models in perceptual organization, ideal observer models, and the computational level of explanation (Marr, 1982; Pomerantz and Kubovy, 1986)).

Many rational models, including those described below, use a particular theorem of probability, Bayes' theorem. Given two states A and B, the *joint* probability $P(A \,\&\, B)$ is the probability that both A and B are true; and the *conditional* probability of A given B, written $P(A \mid B)$, is the proportion of the probability associated with B that is also associated with A. So by definition, $P(A \mid B) = P(A \,\&\, B)/P(B)$ and $P(B \mid A) = P(A \,\&\, B)/P(A)$. Putting these together, and rearranging, we obtain Bayes' theorem:

$$P(B|A) \;=\; \frac{P(A|B)P(B)}{P(A)} \tag{1}$$

This simple theorem has considerable application, not only in building rational models of cognition, but also in statistics and the philosophy of science.

BAYESIAN MODELS OF CATEGORIZATION

Formulating a rational model of categorization requires specifying a goal or purpose which categorization is presumed to serve. Anderson (1991) makes the natural assumption that the goal of categorization (step 1) is to predict unknown features of objects from known features. He assumes, further, that the environment consists of classes characterized by a probabilistic relationship with a set of features (step 2). Specifically, given a class C_i, the assumption is that for each feature F_j, there is a probability $P(F_j \mid C_i)$ that a item of category C_i has the feature F_j; and, crucially, that this probability is *conditonally independent* of the other features that item has (formally, this means that $P(F_1 \,\&\, \ldots \,\&\, F_n|C_i) \;=\; \prod_{j=1}^{n} P(F_j \mid C_i)$). Here, we shall assume that step 3 is null: no specific computational constraints are needed. Given these assumptions, what is the optimal way of predicting unknown features from known features (step 4)?

Rather than follow Anderson's precise formulation, for clarity we follow a simpler analysis. Suppose we know that an item possesses a set of features $F_1, \ldots F_n$, and want to know $P(C_i \mid F_1 \,\&\, \ldots \,\&\, F_n)$ for each category C_i. That is, we want to know the probability that the item belongs to category C_i. Bayes' theorem gives:

$$P(C_i \mid F_1 \,\&\, \ldots \,\&\, F_n) = \frac{P(F_1 \,\&\, \ldots \,\&\, F_n \mid C_i)P(C_i)}{P(F_1 \,\&\, \ldots \,\&\, F_n)} \tag{2}$$

$$= \frac{P(C_i) \prod_{j=1}^{n} P(F_j \mid C_i)}{P(F_1 \,\&\, \ldots \,\&\, F_n)} \tag{3}$$

where the simplification follows because of Anderson's crucial assumption that features are conditionally independent. Finally, suppose we

want to predict an unknown feature F_{n+1}. If we knew that the item belonged to category C_i, then the probability of F_{n+1} would simply be $P(F_{n+1} | C_i)$. But we know $F_1, \ldots F_n$, rather than the category, so we must predict F_{n+1} by summing these conditional probabilities, weighted by the probability of each C_i, given the known features $F_1, \ldots F_n$. Thus,

$$P(F_{n+1}|F_1 \,\&\, \ldots \,\&\, F_n) = \sum_i P(C_i|F_1 \,\&\, \ldots \,\&\, F_n) P(F_{n+1}|C_i) \quad (4)$$

Bayesian models of categorization, of various forms, have been used to capture empirical data on categorization (rational analysis step 5) (Anderson, 1991), as well being widely applied in artificial intelligence and machine learning.

BAYESIAN MODELS OF BELIEF REVISION

Bayesian models are also widely used in understanding reasoning and belief revision. In artificial intelligence, there has been a substantial shift from logical to Bayesian views of how beliefs should be revised in the light of new knowledge. According to the logical viewpoint, knowledge is encoded as a set of axioms and their deductive consequences. New knowledge (for example, derived from perception or language) is encoded in new axioms; and the new knowledge state consists of the larger set of axioms and their deductive consequences. This approach runs into difficulties where new and old knowledge appear inconsistent, because, in most logical systems, all propositions (and their negations) follow from a contradiction, leading to potential inferential chaos. There have been numerous ingenious attempts to combat this difficulty. But the Bayesian approach aims to avoid it entirely, by assuming that 'knowledge' is only probabilistic – or more accurately, by modeling belief revision in terms of probability theory. In the probabilistic framework, outright contradictions need not occur (what was previously probable simply becomes much less probable). Pearl (1988) and others have shown how to build parallel distributed computational mechanisms for probabilistic reasoning for belief revision. These models depend, crucially, on making independence assumptions between pieces of information, in just the way that we assumed above that features were conditionally independent given the relevant category. For example, effects are typically viewed as conditionally independent given their causes.

A similar shift from logic to probability theory has been advocated in the psychology of reasoning. It has been argued that various apparent experimental demonstrations of irrationality can be reinterpreted. For example, Oaksford and Chater (1994) have argued that searching instances which confirm a conditional rule 'if A then B' is rational from a probabilistic perspective, because a confirming instance can substantially raise the probability that the statement is true. Yet on a traditional viewpoint in the psychology of reasoning, searching for confirmatory evidence is misguided, because general statements cannot be logically derived from their instances – the next observation could always be a refutation. Thus, the human tendency to seek confirming evidence may appear irrational from a logical perspective, but entirely rational according to a Bayesian rational analysis. (*See* **Reasoning**)

EMPIRICAL EVIDENCE FOR AND AGAINST RATIONALITY

The case noted above highlights the difficulty of interpreting empirical evidence for or against rationality: the interpretation depends on the theoretical perspective adopted. But it might seem that rational models of cognition do not usefully contribute to the debate on whether people are rational, because they seem to assume the idea of the rationality of cognition from the outset. The approach seems to presuppose rationality, regardless of any empirical evidence that might be collected. The picture is, however, not so straightforward.

First, the dictates of a rational cognitive model will typically only be implemented approximately. These approximations will result in irrational behaviour. For example, Chater and Oaksford have given a Bayesian rational model of how people reason with syllogisms (e.g., 'all X are Y, all Y are Z, therefore, all X are Z'). Where there is a probabilistically valid conclusion for a syllogism, the heuristics generally generate it successfully; but they also generate other conclusions, giving 'irrational' answers for syllogisms where no conclusion follows.

Second, there is an important distinction between the rationality of specific cognitive processes and the rationality of the whole person, which is comprised of the interaction of innumerable cognitive processes. For example, the tendency of the cognitive system to pay attention to relative rather than absolute magnitudes may be highly adaptive in encoding information about the external world

(because many aspects of the world are 'scale-invariant' (Chater and Brown, 1999)). But this may give rise to irrationality in risky decision-making, where, for example, the difference between prizes of \$0 and \$10 may be viewed as far less significant than the difference between prizes of \$90 and \$100 (Kahneman *et al*., 1982) – even though the differences are objectively the same. In general, we might conjecture that specialized cognitive processes might exhibit greater 'rationality' than the whole individual. This is because specialized processes need only be adapted to some relatively narrow class of tasks (e.g. interpreting stereoscopic disparities between the two eyes, segmenting the visual field) which has been encountered throughout an individual's life, and perhaps also through millions of years of evolutionary history. The whole person, on the other hand, must cope with an endless variety of tasks (e.g. making financial decisions), for which neither experience nor evolution may provide much guidance. If this is the case, then rational choice explanation, as described above, may seek support from human rationality just where it is weakest – a disturbing reflection from the point of view of the foundations of economics.

Third, the attempt to apply rational models of cognition can be viewed as a way of measuring the degree of rationality of the cognitive system. The rationality of thought and behavior can only be assessed against a standard of 'correct' performance. But to choose an appropriate standard of correct performance, we need to have decided what computational function the cognitive system is attempting to perform – and this is the goal of rational analysis. We cannot merely stipulate the standards against which cognition should be measured. If we do so, we run the risk of, for example, condemning people as irrational because they fail to reason logically, when they are reasoning quite rationally according to the dictates of probability, as noted above. Thus, far from presupposing human rationality, the project of building rational models of cognition should provide a test for when and to what degree people are rational.

Reaction Time

Intermediate article

James T Townsend, Indiana University, Bloomington, Indiana, USA

CONTENTS

Reaction time is, along with accuracy, the most important dependent variable employed in experimental cognitive psychology and perhaps in all of experimental psychology.

INTRODUCTION

Reaction time (RT) – also called response time – refers to the time taken by a person (called a 'subject' or 'participant') to perform some task in an experiment. The experimental psychologist must manipulate aspects of the experiment in order to discover important characteristics of behavior and psychological processes, and to test theories or models of performance. Variables in the experiment that are manipulated by the experimenter are called 'independent variables'. Examples include the various aspects of the stimulus (something presented to the participant), the details of the task requirements, and even environmental variables such as the illumination in the experimental chamber.

Reaction time is, in contrast, a dependent variable, because it (like the accuracy of the response) is recorded by the experimenter and used to draw conclusions of psychological interest. Reaction time is used, for instance, to study the characteristics of the psychological system within the participant that is performing various kinds of perceptual, mental and motor tasks. Professional RT analyses depend on an understanding of statistics, experimental design, and often mathematical modeling. This article will attempt only to give a feel for the topic. This entails some sacrifice of detail and precision.

STATISTICAL PROPERTIES OF RT

One of the very first problems that a psychologist must face is that human behavior is virtually always probabilistic, or statistical; that is, it varies according to the laws of chance. This chance, probabilistic, or equivalently, statistical, aspect is present in everything from the behavior of a single neuron all the way up to complex mental operations and actions. Hence, RTs are never the same from trial to trial. The scientist collects a series of them over the experimental session and plots the results in the form of a so-called *frequency function*. The underlying variable is called the 'variate'. In the present case, the variate is RT. The RTs are segregated into small bins, say of about 0.01 seconds each, and then the number of RTs within each time bin is plotted (usually standardized by dividing by the total number of RTs accumulated in the experiment). The result is the RT frequency function.

The *cumulative frequency function*, where the frequencies are summed from the smallest value of RT up to an arbitrary level, is also very useful. Thus, the value of the cumulative frequency function at, say, $RT = 1\,s$, measures how many RTs were at or below 1 second.

These functions show the likelihood of a particular RT for a given experimental condition. They provide the basis for all other analyses and conclusions regarding the experimental results (Wenger and Townsend, 2000).

The *mean*, giving the central tendency of a frequency function, and the *variance*, indicating the variability in the data, are the most important and often-employed statistics. They are used, along with standard statistical assumptions, to investigate hypotheses about mental processes, often employing statistical techniques such as the *t*-test, analysis of variance, and so on. For instance, an experimental group given a special kind of treatment in a memory experiment (e.g., a drug, or extra learning trials) may perform a memory task faster than the control group, as revealed by its mean RT being lower in a statistically significant fashion. Such statistical inference, involving only means and variances, provides the basis for much of modern cognitive psychology and other branches of psychology.

However, there are other statistics or statistical functions of the variate that are considerably more

powerful (Townsend, 1990; Townsend and Ashby, 1983). In fact, there exists a hierarchy of statistical functions organized according to their logical strength. The 'hazard function' reveals the chance that the subject will react in the next instant, given that he or she has not ret reacted. The 'likelihood function' is a ratio of two separate frequency functions evaluated at any particular value of RT. We will next illustrate this and the other statistics within a realistic example.

Suppose that a psychologist is interested in testing the effectiveness of a drug intended to facilitate memory search. Naturally, she wants to make sure the treatment is more effective than no treatment or a placebo. She administers the real drug and a placebo to two different groups, measures their RTs in a memory-search task, and plots the frequency function. Then, the various statistical functions noted – mean, cumulative frequency function, hazard function, and likelihood function – differ in their power to discriminate between the two groups. The mean is, of course, simply the arithmetic average of the sampled RTs. It can be written as $M = \Sigma_i P_i \times RT_i$ where P_i is the proportion of RTs that fall into the i^{th} time bin and RT_i is the reaction time at the i^{th} bin. The greek letter sigma (Σ) simply tells us to sum up the values of the multiplication just to the right ($P_i \times RT_i$). And, the subscript 'i' is the index over which we form the sum. Next, the cumulative frequency function, $F(RT_i)$, is the sum of the frequencies from the smallest time bin up to and including the j^{th}, $F(RT_i) = \Sigma_i^j P_i$, where i runs from 1 up to j, where j is less than or equal to the last index value (standing for the largest value of RT found in the current experiment). The hazard function at time RT_i is just $h(RT_i) = P_i / (1 - F(RT_i))$.

All of these statistics can be compared for the real drug vs. the placebo group. In fact we could write M(DRUG) and M(PLACEBO), $F(RT_i;DRUG)$ and $F(RT_i;PLACEBO)$, and $h(RT_i;DRUG)$ and $h(RT_i;PLACEBO)$, and then see which is bigger, the real drug statistics or the placebo statistics, or if they are basically the same. If M for the real drug group is smaller than that for the placebo group then that suggests that the drug group is performing faster than the placebo group. However, this inference of the real drug group being faster than the placebo group will be supported in an even stronger manner if F is always bigger for the real drug group and even stronger than either M or F, if h is larger for the real drug group than for the placebo group. Finally, the likelihood function is composed of a ratio of P_i for the real drug group over the P_i for the placebo group, which might be expressed as $P_i(DRUG)/P_i(PLACEBO)$. If that ratio, increases as RT grows (the same thing as the index i getting bigger) then that provides the strongest evidence of all for the true drug group being faster than the placebo group, indicating effectiveness of the pharmaceutical. Again, it is important to understand that the likelihood increasing implies the hazard function ordering, that is if $P_i(DRUG)/P_i(PLACEBO)$ increases as i increases, then it follows that $h(RT_i;DRUG) > h(RT_i;PLACEBO)$, where '>' is the 'greater than' relation, for every value of i. Similarly, if $h(RT_i;DRUG) > h(RT_i;PLACEBO)$, then the result that $F(RT_i;DRUG) > F(RT_i;PLACEBO)$ for every value of i is forced to occur. Any of these findings implies that $M(DRUG) < M(PLACEBO)$. Finally, as mentioned earlier, none of these implications works in reverse. For instance, the ordering in h does not force the likelihood function to be increasing and so on. That is what we mean by the indicators differing in the power of what they say about the data. Such results are not only important for ordinary inference about experimental conditions: internal cognitive mechanisms make predictions that permit their testing against other hypothetical mechanisms only if their variables are ordered in a relatively strong way (Townsend, 1990a).

MODEL TESTING

Model testing can be roughly divided into two categories, which we shall discuss. We must begin by defining the terms 'parameter' and 'free parameter'. A parameter is a variable in a quantitative model that must be given an exact value in order for the model to make numerical predictions. A simple example is the prediction that the dependent variable y is a linear function of the independent variable x: $y = ax + b$. Here, the slope a and the intercept b are the parameters. Before they are given exact values, they are considered free parameters. After being assigned values, they are no longer free.

Fitting the Model to the Data

The most common approach to model testing involves estimating free parameters so that the predictions of the model are as close as possible to the data. Then, the fit of the model – that is, how well the model predicts the data – is assessed.

There are almost no cases in psychology where parameters can be assigned numerical values before running the experiment. With some methods of fit, the assessment of how well a

model predicts the data can be done quantitatively, with the null hypothesis of the predictions not being significantly different from the data being explicitly tested. However, in a number of important cases, there is no way to statistically test the degree of fit. Another problem with fit strategies is that the more sparse the data (e.g., fewer trials or subjects), the more likely the model is to fit acceptably, even if the method of fit allows a statistical test. This makes it difficult to adequately test a model. The reasons are fundamentally the same as for the fact that a small sample size gives less power to reject the null hypothesis in ordinary statistical inference. One helpful strategy is to compare the fits of two or more competing models. This is especially useful where no statistical assessment of fit is available.

Within the model-fitting approach, one must distinguish between the simple positing of a particular probability or frequency function for the processing time of one or more hypothesized subtasks, and a processing model that is based on higher-order psychological hypotheses. Frequency functions that have been proposed for processing times, and sometimes for the complete RT probability law, include the 'ex-Gaussian' (the convolution of an exponential with a Gaussian frequency function), the exponential itself, and the gamma or general-gamma (identical with a convolution of exponentials with the same or different parameters, respectively) (Luce, 1986).

When constructing a process model for a psychological phenomenon, one may employ particular frequency functions in the model, but usually one also has to hypothesize an architecture of separate individual sub-processes, rules of interaction, and input and output. One of the most basic questions is whether processing is serial or parallel – that is, are any two sub-processes operating at the same time, or only one at a time? For instance, it has been proposed that when people search their memories for specific information, the search involves examination of each of the individual items in memory one at a time – in other words, serially (e.g., Sternberg, 1969). However, others have suggested that instead, this type of search might take place in a parallel fashion (see, e.g., the review in Townsend (1990)). In this type of search, all the items could be examined simultaneously, that is, in parallel.

Suppose two sub-processes are arranged in a serial fashion with processing durations T_1 and T_2 and that there is also a set of other residual subprocesses that we can combine into the single variable T_0. Note that these must be random variables, since RTs are never perfectly constant from trial to trial. Then, the overall RT can be expressed as $\mathrm{RT} = T_0 + T_1 + T_2$. If, in addition, these random variables are probabilistically independent, then the frequency function of their sum is formed by a mathematical operation called the *convolution* of the individual frequency functions. Furthermore, it can be shown that the mean or expectation of RT is just $\mathrm{E(RT)} = \mathrm{E}(T_1) + \mathrm{E}(T_2) + \mathrm{E}(T_0)$.

Suppose, on the other hand, that the two subprocesses of interest are processed in parallel, but again the residual times are in series with them. Then the total time for completing both, plus the residual time, is the maximum of the two separate times plus T_0; that is, $\mathrm{RT} = \max(T_1, T_2) + T_0$, and $\mathrm{E(RT)} = \mathrm{E}(\max(T_1, T_2)) + \mathrm{E}(T_0)$. Thus, we have already formed two possible models for a mental task that involves two separate sub-processes. Of course, there are other issues or questions about system architecture and processing that can arise in model construction (e.g., Townsend and Ashby, 1983), and the theorist may need to form models of much greater complexity (e.g., Schweickert, 1978; Schweickert and Townsend, 1989).

Qualitative Testing

The second, somewhat less common, approach to model testing is to explore and determine qualitative characteristics that are predicted by a model and then to probe whether and to what extent these are exhibited by the data. By 'qualitative' is meant, for example, inequalities, the general form that functions or graphs should take, and other relationships among various aspects of data. Suppose we are interested in testing a model of choice-responding that says that the mean RT increases with the number of choice alternatives n, in proportion to the logarithm of n plus a constant. That is, $\mathrm{E(RT)} = k\log(n) + C$. Now, one might actually fit this simple model to the RT data and assess the fit, or one could start by checking a qualitative prediction of the model: whether the data curve is concave down, like the logarithm function (and many other functions). If the data curve is not concave down, then the logarithm model (as well as many other models) is rejected (disconfirmed). If the curve is concave down, then it may be reasonable to attempt more precise data fits.

A more powerful kind of qualitative distinction can be found in the discussion above of various types of statistical functions. For instance, a model might predict that the cumulative frequency functions are ordered in a certain way. In fact, it has been found that in memory search experiments, the cumulative frequency functions are indeed ordered in

terms of the number of items that must be searched in memory (e.g., Townsend, 1990b, Figure 3). This ordering implies that in a relatively strong statistical sense (stronger than would follow from an ordering based on mean RT alone, for instance), more items do indeed take longer to search through. Interestingly, it turns out that both serial models and many parallel models can make this prediction.

There is one qualitative approach that was developed in the late 1960s and has evolved into a rather impressive arsenal of related techniques intended to reveal the underlying architecture. The approach began as the 'additive factors method' (Sternberg, 1969; Sanders, 1983). The basic idea is to assume that processing is serial and that each sub-process in a series of sub-processes engaged by a certain task may be associated with an experimental factor that can lengthen or shorten the duration taken by that sub-process to finish its part of the task in the series. For instance, an early sensory sub-process might be affected by stimulus intensity, while a late motor sub-process might be affected by response difficulty. (*See* **Information Processing**)

In an additive factors study, the experimenter manipulates two or more factors intended to target certain sub-processes of interest. Because of the assumed seriality the manipulation of the experimental factors should influence RT in an additive fashion. We can then write $\mathrm{RT}(x_1, x_2) = T_1(x_1) + T_2(x_2) + T_0$, and we have the prediction that $\mathrm{E}(\mathrm{RT}) = \mathrm{E}(T_1(x_1)) + \mathrm{E}(T_2(x_2)) + \mathrm{E}(T_0)$. This prediction can readily be tested in the RT data by standard statistical procedures. If additivity is found then the conclusion is that there do indeed exist two psychological sub-processes, that they operate in series, and that they are suitably affected by the experimental factors. On the other hand, if additivity is not found, then one or more of the experimental factors must affect more than 'its own' sub-process (e.g., stimulus intensity might affect both an early and a late sub-process), or that there are not two separate serially-arranged sub-processes.

The additive factors method was extended over the years by a number of authors to include parallel processes as well as much more complex mental networks (e.g., Schweickert and Townsend, 1989). The point to be made here is that the predicted additivity by serial models, and various kinds of non-additivity by other types of architectures, are all of a qualitative nature. It is not necessary to know exactly what the RTs are, only that, for instance, they obey the additivity property. Of course, it is possible, once one has affirmed, say, the additivity, to attempt to fit particular serial models to the numerical data.

It appears that RT will continue to be one of the most important dependent variables used in studying cognitive processes.

CONTENTS

The psychology of reading investigates the process by which readers extract visual information from written text and make sense of it.

INTRODUCTION

Reading is the process by which a reader extracts visual information from a piece of written text and makes sense of it. Psychologists are interested in questions such as how readers extract this visual information, what writing is, how it relates to speech, and precisely how a reader makes sense of the text during reading. Because children have to be taught to read in a way that they do not have to be taught to speak, psychologists are also interested in how we learn to read and what underlies individual differences in reading skill.

Consider the following passage:

> Clyde did not want to arouse suspicion. So he sat down in the waiting room with his hand over his holster and smiled politely at the other occupants of the room. He thumbed deliberately through the heaps of reading matter on the table until he spotted the latest *Newsweek*. He opened the magazine and then carefully counted the number of bullets it held, waiting to be fired. When the office door opened, Clyde was poised and ready. The magazine was full.

This passage is made up of a series of graphical symbols (letters, words, sentences) that represent a word-by-word transcription of its spoken form. Although all writing systems use graphical symbols to represent the spoken language, they do so in different ways. For example, in the Japanese Kana writing system, the symbols correspond to whole syllables (e.g. the *wait* + the *ing* sounds in 'waiting'), whereas in English, letters or groups of letters correspond to smaller sound units or *phonemes* (e.g. the *w ai t i ng* sounds in 'waiting'). These different systems pose different problems for readers and those learning to read.

WRITING SYSTEMS AND ORTHOGRAPHIC DEPTH

The three main kinds of writing system are *logographic* systems (as in Chinese and Japanese Kanji), *syllabic* systems (as in Japanese Kana), and *alphabetic* systems (as in English, Greek, and Russian). Logographic systems use symbols to represent word meanings, so the symbols – called 'characters' in Chinese – do not map directly onto any sound segments in the spoken language. As a result, readers have to learn thousands of different characters – almost one for each word – to become literate in Chinese. Syllabaries and alphabets have symbols that map onto whole syllables in the first case or phonemes in the second. Because there are many more syllables than phonemes, syllabaries tend to have more symbols (typically 100) than do alphabets (typically 25 to 30). However, even with alphabetic systems, such as written English or Italian, the transparency of the mapping between the letters in the alphabet and the spoken phonemes varies considerably. For example, in Italian there is a very direct and consistent mapping between *graphemes* (letters and patterns of letters) and phonemes (individual speech sounds), whereas in English there is not. Across English words, the same combination of letters may map onto a range of distinct speech sounds (compare the *ou* sound in the words c*ou*nted and thr*ou*gh in the Clyde passage; now consider en*ou*gh and th*ou*gh).

There are various reasons for this difference between the written languages. One reason is that languages like English have tended to import foreign words and retain their original spellings (e.g. 'villa', 'centre'). This means that the grapheme-to-phoneme mappings may be inappropriate for English pronunciation. Another reason is that in some written languages the spelling sometimes reflects the *morphemic* or meaning structure of words

as opposed to their pronunciation. For example in English, 'vine' and 'vineyard' share the same letter pattern *VINE*, which corresponds to the common meaning component of the two words. However, this pattern of letters is pronounced quite differently in the two spoken words. The degree to which the written language reflects morphology as opposed to phonology is called *orthographic depth*. Written languages like Italian have shallow orthographies, whereas written English has a deep orthography. In general, it is more difficult to learn to read in languages with deep orthographies as opposed to shallow orthographies. Also, alphabetic systems tend to be more difficult to learn than syllabaries. (*See* **Reading and Writing**)

PHONOLOGICAL RECODING DURING SILENT READING

Most readers are aware of covertly pronouncing printed words as they read. Many even report experiencing an inner speech that has the appropriate stress, pauses, and intonation patterns for the text being read. The process of translating print to sound has been called *phonological recoding* (also *phonological encoding*, *speech recoding*, *subvocalization*, *inner speech*). It has been argued that phonological recoding limits reading speed to the rate at which we can covertly articulate the words. Indeed, commercial speed reading courses lure their clients by boasting that they can dramatically increase reading speed at no cost to comprehension simply by teaching people to eliminate phonological recoding. However, some psychologists would argue that phonological recoding serves an important, or even necessary, information-processing function in silent reading so that preventing or limiting inner speech would have an adverse effect on reading comprehension. (*See* **Phonological Encoding of Words**)

Psychologists have proposed two possible roles for phonological recoding. According to the first view, readers recode a printed word into the way it sounds as a way of gaining access to the meaning of that word held in memory. So for example, by applying spelling-to-sound rules, the letters *s-a-t* could be mentally converted into their corresponding phonemes /s/ /æ/ /t/, and the phonological code /sæt/ could then be used to access the word's meaning, much as is done during listening comprehension. Evidence for the use of phonological codes to access word meanings comes from demonstrating *homophone* (i.e. words that sound the same) confusion effects. For example, if readers use sound to access meaning, they should be more likely to mistakenly judge a phrase to be sensible if it sounds correct (e.g. 'He thumbed deliberately threw the heaps of reading matter …') than if it does not sound correct ('He thumbed deliberately throw the heaps of reading matter …'). Psychologists agree that *prelexical* phonological codes (i.e. codes accessed before recovering the meaning of the word) are particularly important for beginning readers and unskilled readers who will frequently encounter words that are unfamiliar to them in print (but familiar if recoded into sound). However, psychologists are in some disagreement as to whether fluent adult readers generate prelexical phonological codes during silent reading, or whether they access the meanings of words directly on the basis of the words' visual features. Some researchers argue that skilled readers use the direct visual pathway, others argue that skilled readers use the indirect phonologically mediated pathway, and yet others argue for dual (alternate) pathways to the lexicon.

Regardless of the extent to which skilled readers engage in prelexical phonological recoding, at least some of the inner speech of a skilled reader must be generated *after* lexical access. This is because there is no way to know the appropriate stress and intonation patterns without first interpreting the sentence at several levels, such as determining what the individual words mean and doing at least some preliminary analysis of how the words are semantically and syntactically related to one another. The second view of phonological recoding is that phonological codes are generated after lexical access to help the reader to retain information in working memory (temporary memory) long enough for the higher-level semantic integration to occur. During reading, sequences of words must he held in a temporary storage buffer while the comprehension processes integrate them into a meaningful conceptual structure that can be stored in a more permanent memory.

For example, when first encountering the Clyde passage, most readers probably initially interpreted the word 'magazine' to mean 'reading periodical' because this is the meaning that was strongly primed by the preceding context ('… he spotted the latest *Newsweek*'). However, this meaning is inconsistent with the subsequent text ('the number of bullets it held, waiting to be fired'), and a resolution of the apparent inconsistency requires a reinterpretation of 'magazine' to mean 'bullet chamber'. If recently processed information cannot be stored at least temporarily, the reader would be continually backtracking to reread parts or even whole sentences and passages.

It has been argued that the most stable code in working memory is a sound-based one. By generating speech-based (phonological) codes that are less vulnerable to memory loss, the reader can keep track of exact words rather than rough meanings. Thus, according to this second view, phonological recoding plays an important role in reading by facilitating the storage and integration of successive ideas in a text. Evidence for this view comes from demonstrating that comprehension suffers when readers are required to engage in a concurrent task that interferes with the generation or maintenance of phonological codes in working memory. For example, repeating an irrelevant word such as 'cola, cola, cola' during reading has adverse effects on comprehension, whereas engaging in an equally effortful nonverbal finger-tapping task does not. (*See* **Working Memory**)

METHODS FOR STUDYING READING

There are two approaches to the study of the reading process itself. The first is to investigate what is remembered after reading a text. This can tell us what information a reader gleans from a text and how long it is retained. For example, memory tests show that readers quickly forget the precise wording of a text as they read it, yet they retain the gist. Memory-based measures of reading are called 'offline measures' because they cannot address directly the moment-by-moment decisions a reader makes as he or she is actually reading. For this reason offline measures are generally used only in combination with other more direct measures to investigate the reading process itself.

The second approach is to measure the time readers spend looking at the words and sentences as they read them. Recording a reader's eye-movement patterns is the most direct method. Less direct methods use self-paced reading procedures, which let the participant determine the rate at which written material is presented. The reader might be required to pace himself or herself sentence by sentence, phrase by phrase, or word by word. For example, in the word-by-word procedure, a word is presented, and as soon as the reader has understood it, he or she presses a key to trigger presentation of the next word. The sequence is then repeated until all the text has been read and the time taken to read each word is recorded. Eye-tracking and self-paced reading produce 'online measures', because they reflect the moment-by-moment processing of the text.

During reading the eye moves in a systematic way. There are brief fixations in which gaze stays on the same letter for between 100 and 450 milliseconds. These are interspersed with fast movements called 'saccades' during which the gaze moves to another letter or word of the text. Typically, saccades take only 30 milliseconds to execute and change the position of gaze by about eight letter spaces in the text. For a skilled reader, nine out of ten saccades move the gaze from left to right to sample new material from the text, whereas one out of ten saccades return the point of gaze to previously read material (these are called 'regressions'). Thus, skilled readers typically view all the content words in a text and typically view them in the order that they would occur if spoken. The duration of fixations and the length and direction of saccades (forward or backward movement of the gaze) directly reflect the ease or difficulty of the reading process. Furthermore, they indicate the precise word in the text that is causing reading difficulty because attention is given only to the word currently fixated. (*See* **Visual Attention**; **Eye Movements**)

The limited span of attention during reading can be demonstrated using the *moving window* technique, in which a computer program controls dynamically the window of text presented to the reader as a function of where the subject is fixating. For example, with an asymmetric 12-character window, the four characters to left and the eight characters to the right of where the reader is fixating will be displayed as normal, whereas all the remaining text will be converted into random letters. The window of text together with its surround of random letters then changes as the point of fixation changes (see Figure 1). The window changes do not interfere with normal reading because they occur during saccadic eye movements when no information is taken in from the visual stimulus. As a consequence, readers do not notice that the text in front of them is changing as their eyes move across it.

With the moving window technique, one can reduce the size and form of the text window and measure when it begins to affect reading rate. It turns out that normal reading is quite possible when the window contains only the word currently fixated plus the first three letters of the next word on the line. However, there is a proviso that the material around the window must retain the spaces between the words in the original text. When the window arrangement is reversed so that the window contains random letters and the surround contains the normal text, readers encounter difficulty. With a reverse window of only 11 letters in width, reading becomes almost impossible.

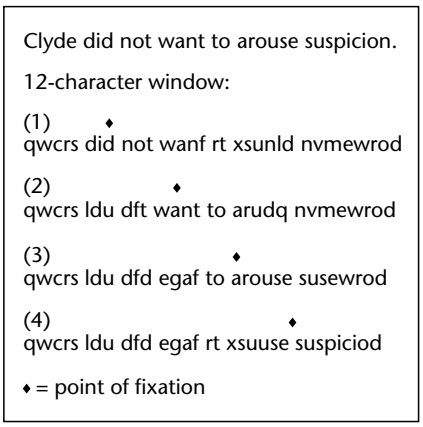

Figure 1. Sequence of presentations for an asymmetric 12-character moving window.

Moving window studies indicate that readers take in information from only a very limited region at any time during reading. This means that any extra time spent fixating the region must reflect processing difficulty associated with that region of text or previous regions not completely processed but still held in memory. Current theories of eye-movement control assume that the programming of where the fixation is to land next is determined on the basis of information about the gross shape of words and spaces to the right of the fixation. This explains why it is important to retain the spaces outside the moving window. In contrast, the decision as to when to launch the eye movement is determined by more immediate processing considerations, such as recognition of the word currently being fixated.

Eye-movement studies confirm that the basic identification of each word and its meaning often occurs during the very first fixation on the word. For example, the first fixation duration is affected by the frequency of the word and whether or not it is ambiguous.

SEMANTIC INTERPRETATION AND INTEGRATION

Moving window experiments demonstrate that words are identified and semantic information extracted before the eye moves on to the next word in a text. But is all this information integrated into the current interpretation immediately or are some processes delayed? The relationship between sampling and processing time is captured by what is called the *immediacy hypothesis*. This states that each word in a text is processed to the deepest level possible (in relation to its meaning, how it relates to the context, and so on) before the reader goes on to the next word.

In general, this hypothesis has been supported. Evidence for immediate contextual effects on semantic interpretation comes from eye-tracking studies in which people read ambiguous words in different contexts. Consider, for example, interpreting the ambiguous word 'magazine' in the Clyde passage. 'Magazine' has a dominant meaning (periodical) and a less dominant meaning (bullet chamber). Eye-tracking studies show that when the prior context favors the less dominant meaning (bullet chamber), readers spend longer fixating the word than when the context favors either the dominant meaning or neither meaning in particular. This suggests that the contextually appropriate meaning of the word is identified before the reader moves on to the next word in the text. Other findings relate to interpreting what are called *anaphors*. These are expressions such as the pronoun 'he' in the Clyde passage whose interpretation depends upon something that has been previously mentioned in the text (i.e., the antecedent mention of 'Clyde'). The difficulty of establishing the appropriate antecedent is reflected in the time spent reading the anaphor itself and the words that immediately follow it. This indicates that at least some aspects of the interpretation of the anaphoric pronoun occur as soon as it is encountered in the text. (*See* **Anaphora, Processing of**)

However, there is also evidence that some semantic processing and integration is left until the reader has completed a whole clause or sentence of text. Hence, readers tend to spend a little extra time looking at the words at the end of a sentence before proceeding to the beginning of the next sentence in the text. This process is sometimes referred to as 'sentence wrap-up'. (*See* **Lexical Ambiguity Resolution**)

INDIVIDUAL DIFFERENCES IN READING ABILITY

There are large individual differences in how well people read. Some adults can read only 150 words a minute whereas others can read 400 words a minute or more. Differences in comprehension ability can be just as large. Good readers not only understand the literal facts in a passage, but they also make the appropriate inferences, attend to how the passage is organized, and appreciate the author's tone and style. By contrast, poor readers may read an entire passage without understanding or retaining even the main point. What accounts for the enormous differences in how fast and how

accurately people can read? Because reading is a complex cognitive skill that draws on many component processes and resources, any of the component processes has the potential for being a source of individual differences in reading ability. Many – but not all – are. Here we consider some factors that do and do not account for the range of reading ability differences that might be encountered in a typical school or university classroom.

Eye-movement control is one component of reading that does not appear to account for individual differences in reading ability. It is not that poor readers display the same pattern of eye movements and fixations as good readers. On the contrary; they make more and longer fixations than do good readers, as well as many more regressions. However, training poor readers to make the eye-movement patterns of good readers does not lead to improvements in their comprehension. Consequently, the erratic and inefficient eye movements of poor readers are thought to be the *result* rather than the *source* of their reading problems. Low-level visual-perceptual processes also do not appear to account for individual differences in reading ability because good and poor readers do not differ in the amount of information they can extract during a single eye fixation. Indeed, almost all reading problems are due to difficulties in recognizing words and comprehending language.

There is relatively strong evidence that word recognition skills contribute to overall reading ability. Poor readers are slower and less efficient at recognizing written words, slower at accessing word meanings from memory, and less skilled at deriving phonology from print. However, the relationship between word recognition skills and reading ability is much stronger for young readers than it is for adults. For example, the speed with which readers can access word meanings from memory accounts for only about 10 percent of the variance in reading ability found in a typical university classroom, and is more related to reading fluency than to reading comprehension.

On the other hand, the higher-level language comprehension processes common to both reading and listening account for much more of the variance in reading ability that one finds in a typical university classroom. Poor readers are at a particular disadvantage when they are required to execute a process that involves integrating newly encountered information with information that was encountered earlier in the text or that must be retrieved from long-term memory. For example, poor readers have problems interrelating successive topics and integrating information to derive the overall gist or main theme of a passage. They have more difficulty identifying the antecedent referent for a pronoun (e.g. determining that the pronoun 'it' in 'it held' refers to the magazine of the gun that Clyde opened); they have more difficulty making inferences (e.g. that Clyde's holster contained a gun; that he removed his hand from the holster); and they tend to make fewer thematic inferences spontaneously during reading (e.g. that Clyde may have wanted to murder someone, that he was in a doctor's office, or perhaps a lawyer's office). All in all, poor readers tend not to demand informational coherence and consistency in a text, and they often fail to detect, let alone repair, semantic inconsistencies (such as the inconsistency between the initially accessed 'reading periodical' meaning for 'magazine' and the subsequent phrase 'held, waiting to be fired…').

Two mechanisms have been proposed to account for why poor readers have difficulty with the integration processes of reading: *working memory capacity*, and *background knowledge*. According to working memory theories of reading ability, poor readers are at a disadvantage at all of the processes that require the integration of newly encountered information with information encountered *earlier in the text* because they have less capacity to keep the earlier information active in temporary storage. According to knowledge-based theories of reading ability, poor readers are at a disadvantage at all of the processes that require the integration of newly encountered information with information that must be *retrieved from long-term memory*, either because they have less background knowledge of the topic being read, and/or because they have less ability to access that knowledge when required. (*See* **Language Comprehension and Verbal Working Memory**)

The existence of individual differences in reading ability has far-reaching educational implications. Because reading is the major medium for acquiring knowledge and skills, poor readers will experience difficulty not only in a literature class, but also in classes as diverse as history, economics, and science.

DYSLEXIA

Dyslexia is the term applied to individuals who have a much more severe reading disability than the poor readers described in the previous section, in the sense that these individuals struggle to decode or recognize even the simplest of words.

Individuals who were previously competent readers but who suffered an impairment of that ability due to brain injury are said to have *acquired dyslexia*. Individuals who failed to attain normal reading skills in the first place are said to have *developmental dyslexia*. (*See* **Dyslexia**; **Developmental Disorders of Language**)

Acquired dyslexia comes in a number of different forms. Individuals with *surface dyslexia* appear to have damage to the direct visual pathway to the lexicon, and so they have to rely on the indirect route of assembling the phonological code by applying spelling-to-sound (grapheme-to-phoneme) conversion rules. They can read regular words (e.g. 'sat' and 'hand') and pronounceable nonwords (e.g. 'flum' and 'pib'), but they have difficulty reading words with irregular spelling patterns (e.g. 'thumbed', 'through'). On encountering the irregular word 'listen', one surface dyslexic misread it as 'liston' (pronouncing the *t* which should be silent), and then added 'the famous boxer' (referring to Sonny Liston, a former boxing champion).

The fact that surface dyslexics have a tendency to regularize irregular words (e.g. to say 'liston' for 'listen') and then to ascribe meaning to the words based on how they sound rather than how they look (to interpret 'listen' as 'Sonny Liston, the boxer') is consistent with the idea that surface dyslexics rely on the indirect phonological route to the lexicon. In contrast, individuals with *phonological dyslexia* appear to have lost their capacity for grapheme-to-phoneme conversions and so they are unable to read pronounceable nonwords and unfamiliar words. However, their direct visual pathway is intact, so they can read (and understand) regular and irregular real words, as long as the words are already familiar to them.

Like phonological dyslexics, *deep dyslexics* have lost the capacity for grapheme-to-phoneme conversion (they cannot read nonwords), and must rely on the direct visual route (they can recognize very familiar words). However, deep dyslexics are thought to have multiple sources of damage because they have a number of other difficulties as well. These include difficulty reading familiar function words (e.g. 'the', 'in'), difficulty reading abstract words (e.g. 'suspicion'), and the propensity to make striking semantic substitution errors (they might read 'ape' as 'monkey' or 'blood' as 'pressure').

It has been estimated that approximately 4 percent of school-aged children have developmental dyslexia in that they have severe difficulty learning to read despite adequate intelligence, vision, and opportunity to learn. Many people are under the misconception that developmental dyslexia is a visual disturbance that manifests itself in the tendency to read letters and words backwards (e.g. to read *d* as *b*, 'was' as 'saw'). However, there is little evidence to support this notion because dyslexic readers make reversal errors no more frequently than beginning readers do. There is still considerable disagreement among psychologists as to the nature of the deficit(s) underlying developmental dyslexia. Nevertheless, there is an emerging consensus that developmental dyslexics do not constitute a homogeneous population, but rather fall into a number of distinct subgroups. Indeed, some researchers have drawn parallels to the different subgroups of acquired dyslexia. For example, approximately 60 percent of developmental dyslexics are like the phonological dyslexics described earlier, in that they have difficulty assembling a phonological code by applying grapheme-to-phoneme conversion rules. However, there are other developmental dyslexics who are more like the surface dyslexics described earlier, in that they are relatively competent at reading phonologically regular words but have severe problems reading irregular words.

CONCLUSION

Reading is a complex skill and particularly so with alphabetic written languages such as English. Although skilled readers can process as many as six words a second, phonological recoding imposes an upper limit on reading rate. Even skilled readers fixate almost all the words in a text and can attend to only one word at a time. Yet, each word is identified rapidly, and, in most cases, its meaning is integrated immediately into the meaning of the passage as a whole.

Since reading is such a complex skill for which we have to receive instruction, it is perhaps not surprising that there are striking individual differences in reading ability. Individual differences arise both within the normal range of readers and in relation to those with specific disabilities such as dyslexia.

Reasoning

Introductory article

Mike Oaksford, Cardiff University, Cardiff, UK

CONTENTS

Reasoning is a mental process by which given information is transformed into a new and more useful form.

WHAT IS REASONING?

Reasoning is an ever-present feature of human life. People are so dependent on the processes involved that they tend to go by unnoticed. But it is simple to demonstrate how much of human behavior depends on reasoning processes. Suppose you see your neighbor arriving home. She passes her garage and looks in to see that the car is gone. When she reaches the door, instead of ringing the doorbell, she takes out her key and opens the door. Why your neighbor broke her habitual pattern of behavior can be explained in an instant: she sees that the car is gone; she therefore infers that someone has driven it away; because she knows that only her partner has the keys, she infers that her partner has driven it away; she further infers that if he is in the car he is not in the house and hence he would not open the door if she rang the bell; consequently she takes out her key and opens the door herself.

In this example, the given information is derived directly from perception (the car was gone) and from prior knowledge (e.g. if the car is gone someone has driven it away). This information is combined, in an inference, to yield new information: someone has driven the car away. The given information can be regarded as the premises, and the new information as the conclusion, of a passage of reasoning. The subsequent steps that lead her to the final conclusion that she must use her key to get in to the house can all be characterized in the same way. For example, the second step involves the inference from the premises

Only if you have the keys you can drive the car.
Only her partner has the keys. (1)

to the conclusion

Her partner drove the car. (2)

So it would seem that even the most mundane passages of human behavior involve complex reasoning processes that involve using given information (premises) to infer new information (conclusions). Since Aristotle, this ability to reason has been taken as a defining quality of humans: humans are rational animals.

However, not every process of moving from given information to new information is reasoning. For example, conclusion 2 above could be replaced with 'Her partner had a cream tea'. This may be new information for her, but it does not seem to be related to the premises in the right kind of way. So the process that leads to the conclusion in a passage of reasoning must depend in some rational way on the premises: if you believe the premises then somehow you must believe the conclusion. Reasoning may be studied in terms of formal logical systems, which mark the beginnings of a true science of cognition. (*See* **Inductive Reasoning, Psychology of**)

FORMAL LOGICAL SYSTEMS

Systems of formal logic began to be developed in the mid-nineteenth century to provide a mathematical theory of how mathematicians should reason. Mathematics is about manipulating symbols according to rules. Thus, someone following the rules of arithmetic knows that if they see '2 + 2' then they can replace those symbols with '4'. This rule can be applied without knowing what the symbols '2' and '+' mean. Systems of such rules are called *formal* systems. Mathematicians and philosophers like Boole, Frege, and Russell realized that the same formal treatment could be applied to passages of reasoning such as that described above. So using the symbol p to stand for 'the car is gone' and q to stand for 'someone has driven it

away', the first inference in the example can be expressed formally as 'if p then q; p; therefore q'. This logical rule is called *modus ponens* (MP). Another similar rule is: 'if p then q; not q; therefore not p'. (Thus, if the car is not gone, you can infer that no one has driven it away.) This is called *modus tollens* (MT). (*See* **Deductive Reasoning**)

These rules can be justified by what the sentences mean. The sentence 'if the car is gone, someone has driven it away' is only definitely false when although the car is gone, no one drove it away. In general, assuming that 'if p then q' is false only when p is true and q is false (and is true otherwise), the formal logical rules MP and MT must be truth-preserving: that is, if the premises are true then the conclusion must be true. Formal logical systems provide a standard against which reasoning can be measured: logic provides a theory of the inferences people should and should not make.

This account of formal logic resolves the problem alluded to above. The process that leads necessarily from premises to conclusion is truth-preserving. The truth of 'if the car is gone, someone has driven it away' and 'the car is gone' convey no information about the truth of 'her partner had a cream tea'; so that conclusion cannot be inferred from these premises alone.

Early psychologists researching human cognition assumed that human adults reasoned logically. Indeed, Piaget placed formal logical reasoning at the pinnacle of his stage theory of cognitive development: according to that theory, logically competent adults began to emerge at about age 11. However, since the work of Peter Wason in the early 1960s, research into the psychology of reasoning has frequently produced results that seem to cast doubt on the ability of human adults to reason logically.

ARE PEOPLE LOGICAL?

Research into the psychology of reasoning has proceeded by developing tasks that have apparently straightforward logical solutions. People's performance on these tasks can then be compared with the logical solution. The most famous such task is Wason's selection task.

Wason's Selection Task

In the selection task, people assess whether evidence is relevant to the truth or falsity of a conditional rule. In the abstract version, the rule concerns cards that have a number on one side and a letter on the other. For example, a typical rule might be 'if there is an "A" on one side (p) then there is a "2" on the other side (q)'. Four cards are placed before the participant, so that just one side is visible, showing an 'A' (p), a 'K' ($\neg p$), a '2' (q) and a '7' ($\neg q$) (Figure 1). Participants select those cards they must turn over to determine whether the rule is true or false.

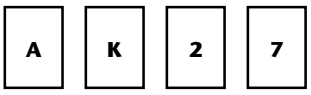

Figure 1. The four cards in a version of Wason's selection task. Each card has a letter on one side and a number on the other. The rule to be tested is: 'if there is an "A" on one side then there is a "2" on the other side'. Subjects must select which cards they need to turn over to determine whether the rule is true or false.

According to logic, only a card with an 'A' on one side but without a '2' on the other side would render this rule false. There are only two cards that could possibly be of this type: the 'A' card could have a number other than '2' on the other side, and the '7' card could have an 'A' on the other side. So people should select the 'A' and the '7' cards to turn over, but not the 'K' or the '2' cards.

These selections are rarely observed in the experimental results. Typical results are: 'A' and '2' (46%); 'A' only (33%); 'A', '2', and '7' (7%); 'A' and '7' (4%), other (10%). Thus, only 4% of participants make the response predicted by logic. Participants typically select cards that could confirm the rule, i.e., the p and q cards. But the choice of the q card is illogical. This is an example of 'confirmation bias'. It would appear that people are not usually logical.

Content Effects

Further experiments have shown that more logic-like performance is observed when real-world content is used. People seem to make more logical (p and not-q) card selections for rules like:

If Johnny travels to Manchester, he takes the train. (3)

If you use a second-class stamp, you must leave the envelope unsealed. (4)

If you are drinking beer, you must be over 21 years of age. (5)

However, this seems at odds with the idea that people use a formal logic that applies independently of content; i.e. regardless of what the symbols mean.

Moreover, not all contents facilitate the logical response. Rules like 3 lead to logical responses less reliably than rules like 4 and 5. The reason for this appears to have little to do with logic. Rules like 4 and 5 are 'prescriptions' for how people should or should not behave; they are not descriptions of the world or of how someone behaves in the world. Discovering that Johnny has traveled to Manchester by car may cast doubt on the truth of rule 3, but finding someone who is drinking beer under the age of 21 does not cast doubt on the truth of rule 5. Rule 5 is in force regardless of the number of people found to be violating it.

Rule 3 is an example of an 'indicative' conditional; rules 4 and 5 are examples of 'deontic' conditionals. Only deontic conditionals appear to reliably produce logic-like performance. However, this is only because the task is no longer one for which standard logic provides the solution. Thus, it still appears that people are not logical.

Everyday Reasoning

Many of the inferences that people need to make in their everyday lives do not conform to logic. Consider the first inference in our example. The premises are

If the car is gone, someone has driven it away.
The car is gone. (6)

The conclusion is

Someone has driven it away. (7)

According to logic, if the premises are true then the conclusion must be true; i.e. the conclusion cannot be false. But this seems to be wrong. For example, although the premise in (6) seems reasonable, the car may have been towed away, disassembled, or even driven away by a trained chimpanzee. Any one of these additional pieces of information would defeat the conclusion that someone drove the car away. Everyday inferences like this are called 'defeasible'. Defeasible inference is at odds with logic, in which additional information cannot overturn the conclusion of a valid inference. (*See* **Frame Problem, The**; **Non-monotonic Logic**)

THEORIES OF REASONING

In the cognitive science of human reasoning there have been many theoretical responses to these findings, each seemingly guided by a different insight. The main theoretical approaches are described below.

Abstract Rule Theories

There are several different 'abstract rule' theories, also known as 'mental logic' theories. These accounts are close in spirit to Piaget, who argued that normal adult human thought was just the operation of formal logic. According to abstract rule accounts, logic and symbolic computation must be at the heart of a well-specified theory of reasoning. However, in modern accounts, people need not possess all the logical inference rules. This should not limit the set of inferences that can be drawn, though some inferences might be more complicated than they would be with a complete set of rules. Furthermore, modern accounts appeal to the distinction between the logic and the control procedure that decides which rules to apply and when. For example, in constructing a mathematical proof it is up to the mathematician to make these decisions. A proof may be shorter or more elegant, depending on the order in which the rules are applied. A computational model of human reasoning must model this flow of control. These control procedures do not have to be as rigid as the logical rules themselves. They might include heuristics (rules of thumb) that suggest applying certain rules at certain stages of a proof.

Thus, abstract rule theories have considerable scope for variation in how they explain people's reasoning behavior. In the Wason selection task (Figure 1), people try to apply logical inference rules to the card sides that they can see to predict what logically should be on the other, unseen side. If people possessed both the inference rules MP and MT, they would turn the p card ('A') expecting to see a q card ('2') by MP, and they would turn the $\neg q$ card ('7') expecting to see a $\neg p$ card by MT. However, if people did not possess the MT rule, then they would only select the p card, as do about 33% of participants.

People often interpret conditionals as 'biconditionals'. For example, they may interpret 'if you have the keys you can drive the car' as entailing also 'if you can drive the car you must have the keys'. This amounts to testing two rules: 'if p then q' and 'if q then p'. The logical rules MP and MT can then also be applied to the second conditional. With only the MP rule available, participants will now select the p and the q cards, as do about 46% of participants. Thus, abstract rule theories appear to be able to explain the main pattern of responses in the selection task.

Abstract rule theories may appear to be less able to deal with content effects and everyday reasoning; but this is not necessarily the case.

Logicians have formulated abstract rule theories that deal with the 'modal' terms, such as 'must', that feature in deontic conditionals. Everyday inference appears more problematic because it seems to rely on an ability to draw inferences using large amounts of world knowledge stored in long-term memory. Logically this means that very large numbers of premises may be involved, leading to an exponential increase in computational cost. Abstract rule theories generally avoid this problem by suggesting that everyday inference is really a form of 'inductive' inference, to do with changing one's beliefs about the world, rather than 'deductive' inference which is dealt with by logic.

Mental Models

Mental models also assume that people are at least in principle capable of logical reasoning. However, rather than reason by applying formal rules to mental sentences, mental models theory argues that people reason over pictorial representations of what those sentences are about. These representations are then manipulated in a search for counterexamples to the conclusion they initially seem to support. For the conditional, this means representing the conditions where it is true. Because people have a limited 'working memory' capacity, they do not represent the complete meaning of a conditional; rather, they have a preferred initial mental model that may be 'fleshed out' if required. (*See* **Mental Models**)

Figure 2(a) shows the initial representation for the conditional 'if p then q'. The three dots indicate that the model may be incomplete. The square brackets indicate that p cannot be paired with any term other than q. Figure 2(b) shows the fully fleshed-out representation, with all the conditions that make the rule true. Figures 2(c) and 2(d) illustrate the corresponding representations for the biconditional.

According to mental model theory, in Wason's selection task, given representation 2(a) only the p card should be turned (because it must have a q on it). The q card need not be turned because it may be paired with other terms that are not represented. However, given representation 2(c) both the p and the q cards should be turned. Given representation 2(b) the p and the $\neg q$ cards should be turned; and given representation 2(d) all four cards should be turned. Thus, mental models theory appears to be able to explain performance in the selection task.

Mental models theory has also been applied to reasoning with deontic conditionals. This involves marking certain mental models as necessary or possible to capture the modal terms used in the rules. Whether mental models can apply to everyday reasoning is less certain. It is argued that the construction of the initial model is determined by world knowledge, and that moreover it may be altered to accommodate additional information. But the processes involved are not clear. This is problematic because recent experiments appear to show that people usually only construct an initial model. If this is the case, then most of the action in human reasoning would appear to be in the construction of this initial model and not in the subsequent manipulation of mental models.

Although mental models may be less precise than abstract rule theories, they give good coverage of the data. Indeed, mental models theory seems to provide the most plausible current account of a range of phenomena in human reasoning. The fact that mental models often only represent what is true leads to the prediction of a range of 'illusory' inferences that people make apparently because of failing to consider the cases that can make a claim false. Mental models theory is currently the most active area of research in human reasoning. (*See* **Spatial Representation and Reasoning**)

Domain-specific Theories

Domain-specific theories are largely inspired by the observation of content effects. The fact that people seem to reason better with deontic conditionals

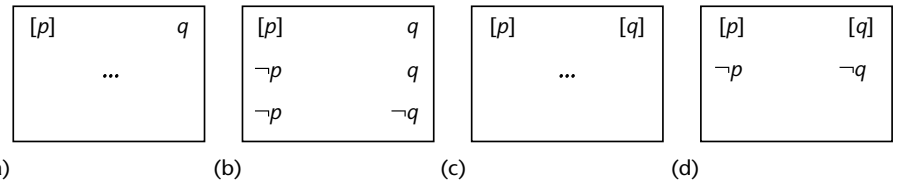

Figure 2. Mental models for the conditional 'if p then q'. Three dots indicate that the model may be incomplete. Square brackets around a term indicate that the term cannot be paired with any term other than the one shown; '¬' indicates 'not'. (a) A simple representation of the conditional. (b) A fully fleshed-out representation of the conditional. (c) A simple representation of the biconditional. (d) A fully fleshed-out representation of the biconditional.

than with indicative conditionals is taken to suggest that people possess domain-specific reasoning mechanisms. There are two varieties of this type of theory. 'Social contract theory' takes its lead from evolutionary psychology. To be part of a social group requires conforming to rules of behavior like rules 4 and 5 above. According to social contract theory, because reasoning about social contracts was so important in early human evolution an innate module evolved to deal with this type of reasoning. One source of evidence for this view is the early emergence of correct deontic reasoning in children. (*See* **Evolutionary Psychology: Theoretical Foundation**)

According to 'pragmatic reasoning schema theory' people possess many domain-specific schemata for reasoning. Each of these schemata contains rules that operate only in its specific domain. For example, rules 4 and 5 both have the same underlying form: they relate a precondition for performing an action to the action. A pragmatic reasoning schema for deontic reasoning contains rules concerning how to draw inferences about preconditions and actions. Such a schema is only triggered if the antecedent and consequent of a conditional can be interpreted as a precondition and an action, respectively. Pragmatic reasoning schemata are generally considered to be learned rather than as innate.

Neither of these two theories has much to say about the standard Wason selection task using indicative conditionals, or about everyday reasoning. This may be because they derive from other theoretical frameworks whose primary concerns lay elsewhere. Social contract theory is seen mainly as a contribution to evolutionary psychology, and researchers in this area are not primarily concerned with creating general theories of reasoning. Pragmatic reasoning schema theory was originally part of a more general theory of inductive reasoning. In the future these theories may be extended to deal with more phenomena in human reasoning. However, one problem is that they do not adopt a theory of the inferences people should make, such as that provided by logic in abstract rule theories and in mental models. Subjects' responses are not shown to be 'correct' (or 'incorrect') according to some theory of the domain (such as logic), so it is difficult to see how they can be generalized to new contexts of reasoning.

Dual Process Theories

Dual process theories have a long history. They suggest a two-way partition in reasoning abilities. This is somewhat similar to the distinction between deductive and inductive reasoning involved by some abstract rule theories. Typically, dual process theories suggest that we do have a (perhaps limited) ability for explicit logical reasoning, which may be embodied in a mental logic or in mental models. However, a lot of reasoning goes on implicitly and is independent of these logical processes. In one version of this type of theory, reasoning in the abstract selection task is largely heuristic. It has been observed that if a rule like 'if there is an "A" on one side (p) then there is not a "2" on the other side ($\neg q$)' is used, people still select the 'A' (p) and the '2' (q) cards; i.e. they appear to ignore the negation. It is argued that people are guided by a heuristic that says that '2' is still the topic of the consequent 'there is not a "2" on the other side', so, regardless of the negation, the '2' card is still selected. This makes sense in everyday discourse, where mentioned information is often still the topic even in a negated sentence: for example, the lateness of the train is still the topic of 'the train is not late'.

Another distinction has been drawn between two types of rationality. According to this account, people are rational in one sense when their reasoning conforms to a normative standard like logic. They are rational in another sense when they reason so as to achieve their goals in the world, regardless of whether their reasoning conforms to a normative standard. Different mental processes are involved in these forms of reasoning.

Much of the evidence seems to support the view that some reasoning is under the guidance of abstract rules while other reasoning is achieved by processes that can be captured in 'neural networks'; i.e., networks of massively interconnected small processors, which imitate neurons in the brain.

According to these theories, most of the reasoning seen in Wason's selection task, content effects, and everyday reasoning are under the guidance of implicit cognitive processes. Perhaps the main problem with this approach is that the nature of the implicit reasoning processes is left obscure. Although one suggestion is that neural networks are involved, no neural network model of any of the passages of reasoning they are supposed to explain currently exists.

Probabilistic Theories

Probabilistic theories start from the intuition that everyday inference cannot be based on logic. According to these accounts, the problems of everyday reasoning arise because people have to

reason about the uncertain world in which they live. Consequently, rather than assume that people are trying to reason logically but have imperfect mental mechanisms for inference, as in abstract rule theories and mental models, it is argued that people are reasoning according to a probabilistic standard. For example, rather than applying logical rules such as MP and MT, people will endorse inferences to a degree depending on the probability of the conclusion given the categorical premise. For MP, this is the conditional probability of q given p ($P(q/p)$). Conditional probabilities for all other inferences can be derived from $P(q/p)$, $P(p)$, $P(q)$. (*See* **Reasoning under Uncertainty**)

Thus, selecting the p and the q cards in the Wason selection task may be the rational thing to do. The only assumption that needs to be made is that $P(p)$ and $P(q)$ are small (this is called the 'rarity assumption'), which has received independent verification. According to probabilistic theories, each card has some probability of being selected, which varies with $P(p)$ and $P(q)$. This can account for the major patterns of card selection. (*See* **Rational Models of Cognition**)

Probabilistic theories have also been applied to content effects. Here it is argued that the materials influence how much people value certain outcomes, like finding people who are trying to violate a rule. The expected value of looking at a card can then be calculated using what is called 'subjective expected utility' theory. This account again predicts the main pattern of results.

Probabilistic theories are relatively new. However, like mental models and abstract rule theories, they have been generalized to the main inference tasks investigated in the psychology of reasoning. These theories deal directly with the uncertainty of everyday inference. Moreover, probability theory may be the right language in which to connect high-level theories of reasoning with the operation of neural networks and ultimately with neural processes in the brain. However, the mental processes that actually implement such models have yet to be specified; and the empirical scope of this approach is currently limited, at least in comparison with mental models accounts. (*See* **Reasoning and Thinking, Neural Basis of**)

CONCLUSION

Reasoning is a vital human ability. It involves transforming given information into a new and more useful form. Computational approaches to cognition provide a mechanistic account of reasoning. However, results in the psychology of reasoning seem to show that people do not reason logically. There have been a variety of theoretical approaches to explain this, each of which begins from some intuition. Some deal with problem cases by drawing distinctions between different kinds of reasoning. It remains to be seen which of these intuitions is the most important in accounting for human reasoning, and hence which theoretical framework will prevail.

Religious Thought

Intermediate article

E Thomas Lawson, Western Michigan University, Kalamazoo, Michigan, USA

CONTENTS

Religious thought is a type of cognitive processing that exploits, and is parasitic on, ordinary cognitive resources by minimally modifying standard conceptions of action and agency. Its cultural transmission is determined by its symbolic evocativeness, its subtle combination of intuitive and counter-intuitive features, and its inferential potential.

INTRODUCTION

While a number of social scientists, psychologists, socio-biologists, philosophers, historians, and cultural critics have occasionally turned their attention to an analysis and explanation of religious thought in the last hundred years or so, only recently have cognitive scientists begun to examine religion. Earlier inquirers in the tradition of William James and his heirs (see Etzel Cardena *et al*., 2000) have focused on the nature, causes, and consequences of religious experience. These studies take such experience to be primarily an affective and emotional matter, quite often far removed from rational thought and in a significant sense antithetical to it. Religious thought, from this point of view was nothing more than a reflection on religious experience, often serving as a rationalization. The real story was to be found at the noncognitive level. One recent example of the 'experiential approach' can be found in the work of James H. Austin (1999), who has investigated the brain processes that putatively account for extraordinary (mystical) religious experiences, often viewed as altered states of consciousness. While such research appears to place the examination of religious thought on a firm scientific footing, it does not have any obvious connection with the widespread generation and reception of religious ideas. Nor does it tell us much about the practice of religious ritual acts, even by those who lay no claim to such mystical encounters.

More recent work in cognitive science has analyzed religious thought through a variety of concepts:

- as an example of an autonomous symbolic mechanism,
- as a system for the representation of action coupled with a conceptual scheme,
- as a set of concepts emerging out of an intuitive ontology that is memorable because of its minimally counter-intuitive properties,
- as a transmissible set of concepts whose transmission is made highly probable because of its frequency correlated with its emotional intensity,
- as an instance of anthropomorphism generated by a hyper-active agency detector,
- and as a difference between on-line and off-line thinking.

Recently experimental studies have put some of these claims to empirical test.

SYMBOLIC THOUGHT

Hints of a cognitive approach to religious thought that focuses upon its symbolic character start with the groundbreaking work of the cognitive scientist Dan Sperber (1975) who argued that religious thought was one aspect of a more general cognitive process of symbolism which he labeled 'creative competence'. Sperber regards symbolism as an autonomous mechanism that, together with perceptual and conceptual processes, contributes to the production of knowledge and the dynamics of memory. Going against the semiological grain fashionable at the time, Sperber argued that symbolism is a typical instance of an inferential process common to all people that is neither analytic nor synthetic. In effect he was claiming that symbolism is a perfectly natural 'instinct'. From Sperber's point of view, symbolism, of which religious thought is an instance, is to be examined as a set of cognitive processes with quite specific products related to but distinct from what he has called 'dictionary' and 'encyclopedic' knowledge. The major objective of Sperber's approach has been to emphasize the continuities between ordinary modes of thinking and symbolic thinking. His

point has been to show that the inferential processes that lead to religious and other symbolic representations, rather than being radically different from the products of our ordinary cognitive resources, engage the same inferential engines that are called into play when presented with half-understood beliefs. Sperber argues that religious thought is a quite specific cognitive process of evocation that triggers specific memories scattered across a number of domains and connects them to each other in quite unusual ways. According to Sperber, then, when human minds are exposed to certain cultural phenomena such as statues of deities, strange behavior, or apparently bizarre beliefs – phenomena which fail to meet the criteria of either definition or description – a symbolic process of evocation becomes activated which establishes unique connections among the representations encoded in human memory. These connections are not required by either dictionary definitions or encyclopedic descriptions, but restless human minds interpret them anyway. By doing so they make the beliefs plausible, the behavior relevant, and the objects salient.

THE REPRESENTATION OF ACTION AND RITUAL FORM

Inspired by Sperber's theory of symbolism, Lawson and McCauley (1990) established the cognitive science of religion by developing an analogy between competence theorizing in linguistics and ritual competence in religious contexts, thus giving theoretical and empirical bite to Sperber's more general notion of 'creative competence'. They argue that just as people possess a tacit knowledge of the structure of their language, so religious participants possess a tacit, noncultural knowledge of their religious ritual system. This tacit knowledge is demonstrated by the people's ability to make judgments about religious ritual forms even when they do not consciously entertain questions about their structure, how well formed they are, their efficacy, repeatability and their reversibility, and clearly have not been instructed in these features by members of their society. Some of Lawson and McCauley's claims have recently been experimentally confirmed (Barrett and Lawson, 2001).

Lawson and McCauley argue that while cognitive scientists have paid a great deal of attention to questions about the cognitive representation of agency (Leslie, 1995), they have paid far less attention to representations of action. Lawson and McCauley think that representations of action are crucial for understanding not only religious ideas but the actions that follow from them. Hence they propose that human beings possess a set of cognitive processes collectively known as an 'action representation system' which, when coupled with a culturally variable conceptual scheme (which provides the content in the action representation system for agent, action, and patient with all their various properties), is sufficient to generate a set of formal descriptions of religious ritual structure.

Lawson and McCauley claim that there are three basic types of ritual forms: special agent, special instrument, and special patient rituals (McCauley and Lawson, 2002). They also argue that ritual actions are systematically connected to each other. Almost invariably any particular ritual act presupposes acts already performed: for example, integration as an adult into a specific cultural community presupposes prior rituals such as initiation and marriage. So the structural description of a ritual would have to include the 'embedded' rituals. A ritual's full structural description would contrast with its immediate, surface description. Whereas in ordinary reasoning such 'embedding' can go on indefinitely (involving either causal reasoning or concatenation), religious reasoning, while engaging the same representational resources, typically involves an endpoint. The 'buck stops' with the gods. Lawson and McCauley also show that rituals in which the 'buckstopping agent' (a culturally postulated superhuman agent) is the actor rather than the patient turn out to be crucial for understanding the differences among rituals. These differences in ritual form play a crucial role in accounting for aspects of cultural transmission.

INTUITIVE ONTOLOGY

Pascal Boyer (1994) has been investigating the underlying properties of the conceptual scheme that informs the action representation system by showing how the variability of religious concepts can be explained by paying attention to the underlying intuitive ontology in terms of which all human beings interpret the world. Boyer argues for the 'naturalness' of religious ideas. Religious ideas are natural in the sense that they exploit our ordinary cognitive machinery for representing the world. He shows how the operation of the intuitive ontology that all human beings employ in their traffic with the world can quite comfortably explain the generation and transmission of religious ideas. These operations involve the violation of aspects of the default assumptions (by either breaching them or transferring them from one

category to another) that our ontological categories typically possess. For example, the category 'artificial object' normally is thought of as having physical properties but not biological or mental qualities. Boyer shows that by transferring the property of intentionality normally associated with the category of 'person' to the 'artificial object' category, we can develop the concept of an artificial object, such as a statue that listens to prayers, that has a psychology. Or, given the category 'person', the default assumptions involving intentionality, biological characteristics, and physical features – violating only the physicality assumption (while maintaining biological and intentional properties) – generate the concept of a person who can be thought of as being alive and having intentions but no body: namely, a spirit. Boyer's point is to show that with only minimal alterations our ordinary ontological concepts are readily available for generating religious concepts. Such minimally counter-intuitive representations are different enough to be interesting and therefore transmissible. Multiple violations, on the other hand, would make the concepts more difficult to represent and, therefore, be less likely to be transmitted.

THE FREQUENCY HYPOTHESIS

Harvey Whitehouse, a cognitive anthropologist who has been doing fieldwork in Papua New Guinea, also has evinced an interest in developing a cognitive account of religious thought. He is particularly interested in how religious systems change, how such changes can be accounted for, what role memory plays in the transmission of religious concepts and the behavior they inform, and the processes by which such concepts are encoded. In Memorable religions (1992), he signaled his interest in giving a cognitive account of cultural transmission. He suggests that frequency is an important variable that accounts for aspects of the transmissibility of religious concepts. The more frequently a religious ritual is performed, accounting for its transmission becomes less of a problem; while if a ritual is performed less frequently, emotional factors are more likely to be involved in ensuring its transmission. His fieldwork seems to confirm his hypothesis and in *Inside the Cult* (1995), he presents a full account of his reasoning.

ANTHROPOMORPHIC THOUGHT

Stuart Guthrie (1993), a cognitive anthropologist, hypothesizes that people explain gods by a hyperactive agency detection device bequeathed to humans by evolutionary forces. He thinks that being able to postulate unseen, hidden agents with very special qualities provides an evolutionary advantage. The interpretation of events in anthropomorphic terms, i.e. as the work of superhuman agents, demonstrates a 'better be safe than sorry' attitude that can enhance the possibility of survival. Hence it is quite understandable that humans not only see faces in the clouds but interpret ordinary events in anthropomorphic ways.

While Sperber, Lawson and McCauley, Boyer, Whitehouse and Guthrie depend primarily on ethnography for empirical support, cognitive psychologists interested in religious thought but with experimental inclinations, and aware of the work of the above-mentioned cognitive scientists, have begun to subject such claims to empirical tests in controlled studies.

EXPERIMENTAL EXPLORATIONS

Cognitive psychologists Justin Barrett and Frank Keil (1996) turn from theoretical analysis to experimental exploration of the empirical dimensions of the cognitive science of religion by proceeding to demonstrate experimentally in a rather clever way that an important distinction needs to be made between theological and religious thought. They demonstrate that theological thought is a far more abstract, 'off-line', mode of reasoning, which requires conscious reflection and explicit instruction for its transmission from generation to generation (much like scientific knowledge). Barrett and Keil show that religious thought is anthropomorphic, 'on-line', and much more directly related to the way that people generally conceive of agents and actions. Thus religious thought is much more like folk science. Their experiments demonstrate that even when people have developed highly sophisticated theological conceptions of deity (including such puzzling notions as atemporality and omniscience), they nevertheless, when required to make rapid judgments, tend to reason about the properties of the gods in the same way that they reason about the properties of the rest of us. The point of the Barrett and Keil study is to show that our ordinary, psychological processes constrain our religious representations. This is one of those areas of thought where not 'anything goes'. Even the gods are represented as being temporally constrained.

Since these initial empirical and experimental studies, further cross-cultural investigations by cognitive psychologists, cognitive anthropologists, and some comparative religionists are being

pursued in order to ensure that investigators overcome unconscious biases about human modes of thought based upon Western examples. Particularly notable for their empirical and experimental cross-cultural studies of the structure of religious thought and its modes of cultural transmission are those of Boyer and Ramble (in press) and Barrett (1998).

Boyer and Ramble's study shows that participants more accurately recall items which violate category-level assumptions than those items which conform to these assumptions. In addition they demonstrate that there is very little cross-cultural difference in the sensitivity to these assumptions.

Barrett's (1998) replication in India of the Barrett and Keil (1996) study shows that whether the subjects are in northern New York or northern India, representations of deities are subject to the cognitive assumptions that govern all intentional agents. Even though the explicit concepts attribute to the deities nontemporal properties endorsed by a given theological tradition, people in both cultural situations nevertheless, in their everyday, 'on-line' reasoning situations, attribute to the gods the same psychological and physical qualities that they attribute to ordinary intentional agents.

Representation Formats in Psychology

Introductory article

Arthur B Markman, University of Texas, Austin, Texas, USA

CONTENTS

Representation formats are specific methods used by the mind/brain to store information for later use.

MODES OF INFORMATION STORAGE

Knowledge representation is at the core of psychological theories. In brief, a representation is some internal state of a cognitive system that carries information that the system uses for thought and action. Representations consist of an internal state (known as the *representing world*) which corresponds to some *represented world*. The format in which knowledge is represented (the way the representing world is set up) has a significant impact on what the cognitive system finds easy to do and what it finds hard to do. For this reason, psychologists have examined a number of different representational formats in order to understand their properties and their suitability for theories of cognitive processing.

This article is organized around two issues. First, proposals about representation have explored how the structure of the representing world influences the ease with which aspects of the represented world can be encoded. Two important dichotomies that have been explored in this context are the distinctions between analog and propositional representations and between localist and distributed representations. Second, research on representation has explored how representational structures allow a cognitive system to go beyond the information present in the environment. This issue will be discussed in the context of scripts and schemas.

ANALOG AND PROPOSITIONAL REPRESENTATIONS

The distinction between analog and propositional representations focuses on how the representing world comes to reflect the structure of the represented world. Analog representations are representing worlds whose natural structure mirrors that of the represented world. For example, an analog clock represents time as the angular distance traveled by a hand on the clock. Time is a quantity, and there are certain relationships that hold between quantities. For example, amounts of time have a transitive structure, so that if event A is longer than event B, and event B is longer than event C, event A must be longer than event C. The angular distance traveled by a hand on a clock is also a quantity, and thus it also naturally displays a transitive structure. For example, if the angular distance traveled by the minute hand of a clock during event A is larger than the angular distance traveled by the minute hand during event B, and the angular distance traveled by the minute hand during event B is larger than the angular distance traveled by the minute hand during event C, then the angular distance traveled by the minute hand during event A must be larger than the angular distance traveled by the minute hand during event C. Thus, angular distance and time share some relationships. Not every relationship in the domains is shared, as angular distance may be traversed clockwise or counterclockwise, but time moves in only one direction.

Analog representations have been used in theories of visual perception and mental imagery. On this view, the representation of visual information has the same structure as the three-dimensional space being represented. Studies examining whether mental images have an analog representation have generally tried to demonstrate that transformations of mental images have the same properties as transformations of real images. For example, classic studies by Shepard and his colleagues found that the amount of time required to rotate a mental image increases with the angle of

rotation, just as the time required to rotate a physical image increases with the angle of rotation.

Propositional representations differ from analog representations in that the relationships among aspects of the representing world are arbitrary. Thus, in order for the representing world to capture relationships in the represented world, these relations must be explicitly defined. For example, a digital clock represents time using numbers as a representing world. The structure of the number system is set up by convention. There is nothing inherent in the shapes of the numbers ('1', '2') that require them to stand for certain quantities. Furthermore, there is nothing in the way numbers are written that determines that 7 is less than 8 or that 8 is less than 9. Thus, the domain of digits does not have a natural transitive structure the way time and angular distance do. In order to use numbers to represent quantities, the relationships among the numbers need to be defined explicitly.

Propositional representations encode complex items such as natural objects or situations using relations among parts. For example, an image of a person might be described as having a head on top of a body. By using this type of representation, the relative positions of the parts can be represented, even when the same object is viewed from different perspectives. Studies examining whether mental representations have a propositional structure typically focus on whether complex objects or scenes are broken down into predictable subcomponents and relations between them. This work suggests that people do tend to divide objects into subcomponents.

In research on visual representation, proposals for analog representations are typically *viewer-centered*. That means that the representation of an object will change when the perspective of the viewer changes. In contrast, proposals for propositional representations are typically *object-centered*, meaning that the parts of objects are represented relative to each other rather than relative to the viewer. Thus, an object-centered representation will not change when the perspective of the viewer changes.

Given that some evidence from visual perception favors analog representations and some favors propositional representations, which type is correct? In all likelihood, both are correct. Analog representations facilitate storage of information about metric properties of objects such as the distances between parts. Propositional representations facilitate storage of relational properties such as the relative position of two parts of an object. Kosslyn has suggested that the hemispheres of the brain may differ in the types of representations they favor, with metric information being stored by the right hemisphere and relational information being stored by the left hemisphere.

LOCALIST AND DISTRIBUTED REPRESENTATIONS

Representations may also be localist or distributed. A localist representation involves a collection of discrete symbols that are used to represent properties. For example, a dog might be described by the properties 'furry, four-legged, barks, loyal'. Each of these features is a symbol that stands for some property that is true of dogs. Each feature is a localist representation, because it has a particular meaning associated with it, and that meaning is distinct from the meanings of other symbols.

At first glance, localist representations appear to be the only obvious way of encoding information. This intuition is driven by the fact that words are symbols just like those in localist representations, and we often derive our intuitions about psychology on the basis of what is easy to verbalize. Indeed, localist representations are important in many theories of language processing.

Despite this strong intuition, even a cursory examination of the brain suggests a different way of representing information. The brain is an organ consisting of a number of different types of cells. One important type, called the *neuron*, is capable of sending electrical signals from one cell to another. The brain carries information on the basis of the pattern of signaling (or *firing*) of a group of neurons rather than in the signals sent by a single neuron. For example, classic work on the visual cortex by Hubel, Wiesel, and their colleagues suggests that there are neurons that fire most strongly (i.e. they send the most signals) for lines of a particular orientation. These neurons will fire somewhat less strongly in the presence of lines that deviate slightly from their preferred orientation, and they will fire very little for lines that deviate a lot from their preferred orientation. Thus, at any given moment, there are a large number of directionally sensitive neurons in visual cortex firing, with some cells sending a lot of signals and others sending very few. The orientation of the line in the environment is determined by the pattern of activation across the set of neurons rather than by the activation of a particular neuron.

There are two advantages of this distributed coding over a localist coding. One is fairly obvious. Cells in the brain are fragile. If a cell dies, the brain's ability to represent information does not

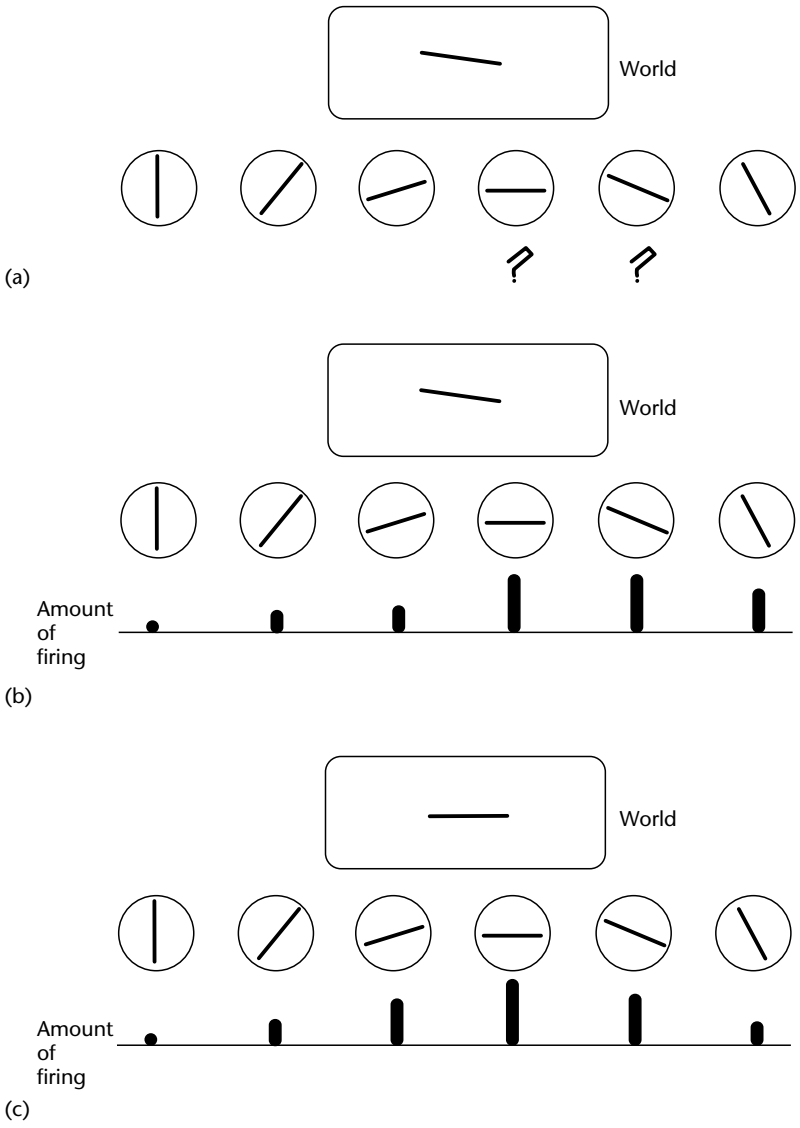

Figure 1. Examples of localist and distributed coding. The circles are representational units for orientation of a line. The preferred orientation of each unit is shown in the circle. In the localist coding (a), each unit represents a different orientation. The maximum resolution of the representation depends on the degree of difference in preferred orientation of neighboring representations. In a distributed coding, (b) and (c), each unit fires to some degree depending on the similarity of the input to the preferred orientation of the unit. The pattern of firing across the units changes even with small changes in the orientation of the line in the world. Thus, the maximum resolution of the distributed representation is actually finer than the difference in preferred orientation of neighboring units.

suffer much, because the pattern of firing across a large set of neurons carries information. This robustness in the face of cell loss is called *graceful degradation*. The second advantage of a distributed coding is more subtle. Imagine a localist coding of orientation like that shown in Figure 1(a). When a line is presented in the world, one (localist) unit will be active. This active unit describes the orientation of the line in the world. Because there are only six different units, the orientation of the line cannot be represented with a high degree of accuracy. The resolution of this representation is only as good as the difference in preferred orientation of neighboring units. In contrast, in a distributed representation, like those in Figures 1(b) and 1 (c), every unit fires to some degree when a line is present, but the amount of firing depends on the similarity of the line to the preferred orientation of the unit. Thus, even small changes in the orientation of a line in the world lead to different patterns of firing of the units. In this way, the system can represent orientations of lines to a finer degree of

resolution than the difference in preferred orientation of neighboring units.

GOING BEYOND THE INFORMATION GIVEN: SCRIPTS AND SCHEMAS

The representations discussed so far are constructed on the basis of information in the environment. In most complex situations, the information needed to understand what is happening in the world must be derived from a combination of what is available in the world and what can be inferred from past experience. For example, consider the following story:

> Sarah went to the restaurant and ordered a salad. She ate it and left.

After reading this story, people typically assume that Sarah was sitting while she ordered and ate, that her order was taken by an adult, and that she paid for the salad. This information is not contained in the story, but rather follows straightforwardly from our previous experiences with restaurants.

There have been many proposals for overarching knowledge structures that can be used to interpret the world. These knowledge structures are called 'schemas' or 'scripts'. At heart, these proposals have a core set of characteristics. First, it is assumed that these structures are built up on the basis of past experience (both personal experience and second-hand experience through narratives). Second, these structures describe the temporal order of events in a situation, which enables people to predict what will occur next. Third, schemas contain causal relations among events that describe not only what sub-events tend to occur in an event, but also why those sub-events occur. These causal relations are important for understanding violations of the typical sequence of events, such as:

> Sarah went to the restaurant and ordered a salad. She took one bite and left without paying.

In this case, most people assume that Sarah was dissatisfied with her order, because paying for the food at the end of the meal is part of the transaction that occurs when going to a restaurant. These deviations from expectations are often the most interesting parts of stories.

In sum, schemas and scripts allow people to go beyond the information that is obviously available in the environment in order to comprehend a new situation. These knowledge structures allow people to make predictions about what will happen in a new situation and also provide causal information that is useful for reasoning about deviations from the typical course of events.

CONCLUSION

Three issues need to be considered when positing a representation in a theory of cognitive processing. First, a theorist must decide whether there is a representational system with a structure analogous to that of the represented world that should be used. Second, the theorist must determine whether it would be advantageous to use a distributed representation of the information. Finally, the theorist must determine whether constructing a representation in a domain will involve going beyond the information that is available in the environment. If so, then the theory must incorporate knowledge structures that allow the system to construct plausible inferences.

Representations, Abstract and Concrete

Intermediate article

Joan Gay Snodgrass, New York University, New York, USA

CONTENTS

Abstract and concrete representations are symbols that refer to an object, event or idea that has existed, does exist or might exist in the real world. Concrete representations bear a physical resemblance to their referents, whereas abstract representations do not. Both come to be learned through the process of categorization.

CONCRETE VERSUS ABSTRACT REPRESENTATIONS

A representation is a symbol that stands for something else. Usually the 'something else' is an object, event or idea that has existed, does exist or might exist in the real world. A concrete representation is one that bears a physical resemblance to the real-world object it represents. This representation could be visual, as in a picture of an object; auditory, as in the sound the object makes; tactual, as in the shape of an object felt through the skin; or olfactory or gustatory, as in the smell or taste of an object. In contrast, an abstract representation is one that bears no resemblance to the object being represented. The abstract representation *par excellence* is a word or combination of words in a language. Almost everything that can be experienced or thought about can be captured in a word or series of words in a speaker's language.

This article is confined to concrete representations that are pictorial symbols. These are most useful for representing objects: for example, line drawings of common objects and animals, such as those shown in Figure 1, are easily recognized as representing objects in the real world, as evidenced by the fact that they can be easily named by both children and adults, and are given comparable names across languages (e.g. the chair is consistently named 'chair' in English, 'chaise' in French and 'sedia' in Italian). Line drawings are easily recognized as representing objects even by children who have not been previously exposed to drawings.

Other pictorial symbols have been used to represent more abstract ideas. A good example is the international system of road signs, which uses a set of easily understandable symbols for road commands (although such symbols are not universally understandable without some training – for example, does the picture of an upright palm of a hand mean 'stop' or 'no entrance'?) Another example is the icons introduced by Apple Computer and incorporated into the Microsoft Windows operating system and software for lessening the memory load on users.

In terms of concrete versus abstract representations, we can imagine a continuum in which pictures in all their manifestations, including photographs, paintings and line drawings, can best represent the surface appearance of the world; while words in all their manifestations, including single words representing a common object, words representing abstract ideas, sentences expressing a complex idea, and poems representing inexpressible thoughts and feelings, can best express the abstract nature of the world. These different types of representations lie along a continuum, as shown in Figure 2. However, as we shall see, we could also consider a drawing of a generic object, such as the chair in Figure 1, to be abstract in some sense.

COMMON OR SEPARATE CODES?

A great deal of research has centered on the middle section of the abstract/concrete continuum of Figure 2, in which concepts can be represented both by pictures and by the words that name them. Two competing theoretical positions have been a focus of controversy in this research area. One, the common code model, argues that there is an underlying conceptual representation of an idea which can be accessed equally well by either of the two surface forms – the picture of an object or its

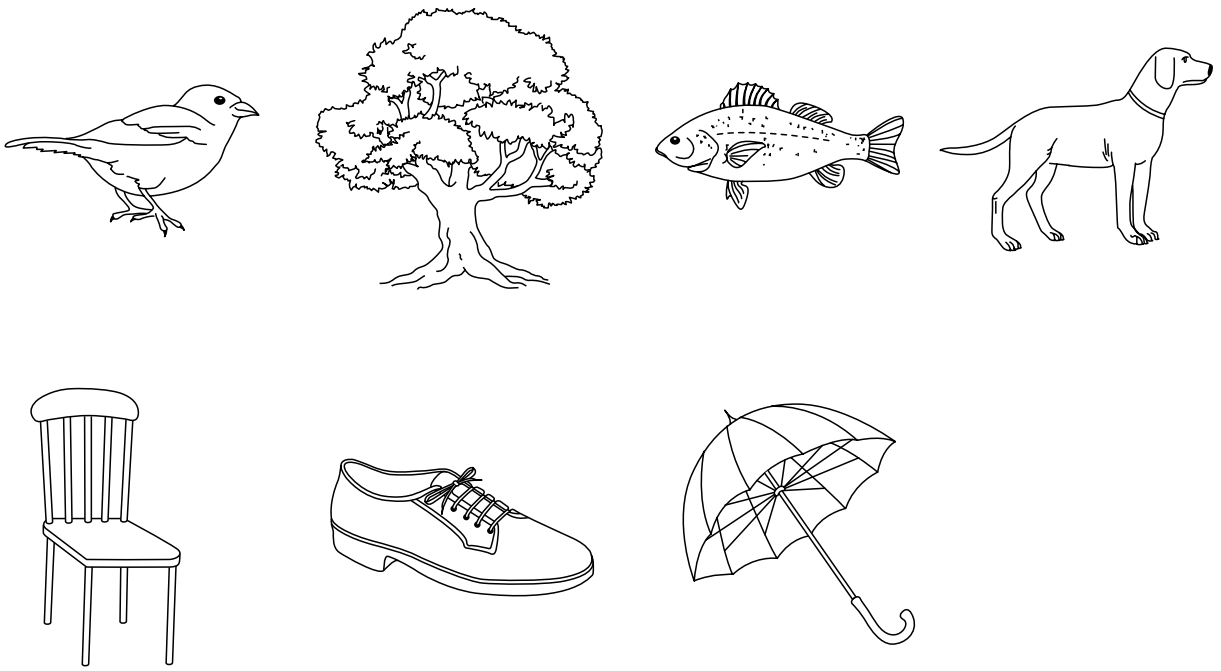

Figure 1. Examples of line drawings of common objects and animals (from Snodgrass and Vanderwart, 1980).

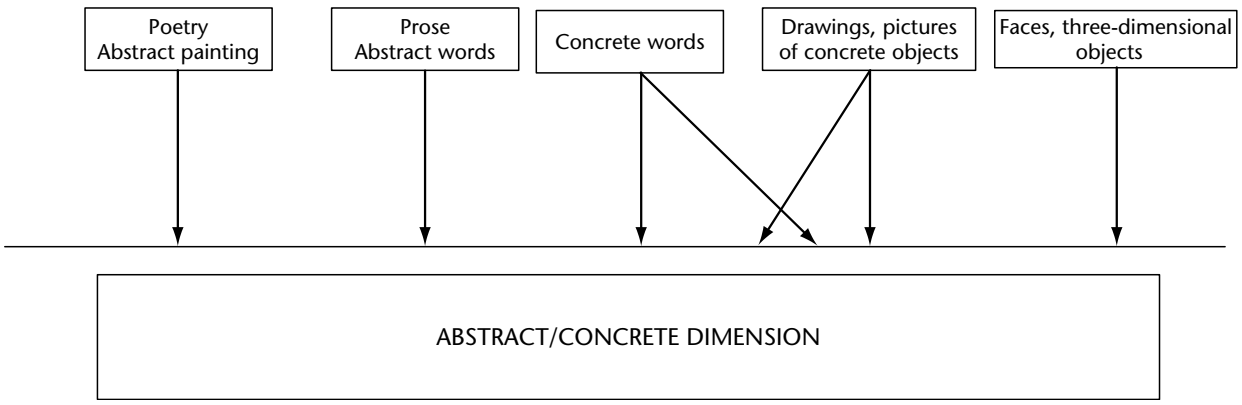

Figure 2. Abstract/concrete continuum illustrating the forms of representation best suited to abstract concepts (to the left) and those best suited to concrete concepts (to the right). The intermediate section, including both concrete words and pictures of common objects, is the representational domain most studied in cognitive science.

name. The second, the separate or dual-code hypothesis, argues that knowledge about the world is organized according to the way in which that knowledge was acquired, and thus different underlying representations or systems of meaning will be accessed by the two surface forms.

This dual-code hypothesis was first formulated by Paivio (1971), who proposed that images corresponding to objects or pictures of objects are kept in an image store, while verbal codes corresponding to the names of objects are kept in a verbal store. The two stores are associatively linked, so that pictures may be named and referents of words may be imaged, but the stores are separate and the two types of code are specialized for different functions. Both pictures and names of concrete objects may be dually encoded (Figure 2).

A picture is virtually certain to produce an image code, and may also produce a verbal code if the picture is named by the observer. Similarly, a word is virtually certain to produce a verbal code and may also produce an image code if the observer forms a mental visual image of the referent of the word. However, Paivio assumed that pictures are

more likely to be spontaneously dually encoded than words are. In addition, Paivio argued that the image code produces a stronger memory trace than the verbal code. These two assumptions – that pictures are more likely to be dually encoded than are words, and that the image code is a better memory trace than the verbal code – were used by him to account for the picture 'superiority effect' in memory: pictures are generally remembered better than words, regardless of whether the memory test is recall or recognition (Figure 3).

Paivio also proposed that image and verbal codes differ in the processes for which they are specialized. Image codes are specialized for representing spatial properties such as size and location, while verbal codes are specialized for representing temporal properties such as order. As support for this, he showed that size differences between objects in the real world were more quickly discriminated when the objects were represented by pictures than by words (Paivio, 1975).

Although Paivio's assumptions about differences between image and verbal codes have generally been accepted on the basis of experimental evidence, his assumption that the core concepts or meaning underlying image and verbal codes reside in separate stores has not. Instead, a hybrid model conceptualizing separate stores for image and verbal codes and a common store for their underlying representations has evolved (Figure 4).

This hybrid model contains an intermediate level which corresponds to Paivio's dual-coding model. The verbal code is assumed to be an acoustic image of the word in question (the phonological code), and the visual code is assumed to be a visual image of the picture which preserves the spatial

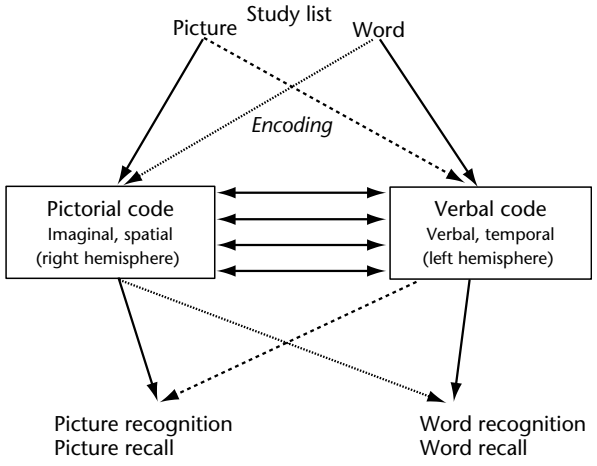

Figure 3. Paivio's dual-code model.

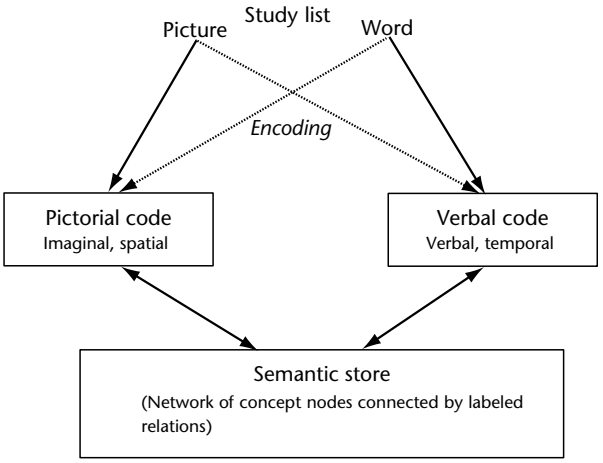

Figure 4. The common store model.

relationships among the elements of the picture but may not preserve every detail. This intermediate level corresponds to the contents of conscious thought, which consists of a series of acoustic images (we hear ourselves think) and a series of visual images (we visualize past, present and future events). Although not pictured in Figure 4, this model – described more fully by Snodgrass (1980) – assumes that the acoustic and visual image stores contain information about how the typical object looks and the typical word sounds. Because most of the words and pictures we experience are familiar, we assume that each has a corresponding acoustic and visual code that can be accessed and used to generate acoustic and visual images. So we can hear the word 'apple' spoken in our mind's ear, and see the visual image of an apple in our mind's eye by generating the corresponding image from the image store.

A presented word or picture may not always correspond to the stored prototypical image. For example, a word printed in mixed-case letters (ApPlE) or spoken with a foreign accent will produce a mismatch between its physical code and the prototypical store and accumulate in a mismatch accumulator, which detects discrepancies between the heard or seen word or picture and its prototype. It is much more common, however, for a picture to produce a mismatch (because pictures of objects can be drawn in so many different ways), so pictures are more likely than words to accumulate mismatch information. This accumulation of mismatching information for pictures is assumed to provide another way in which pictures may be remembered better than their names, by making them more distinctive. This 'distinctiveness hypothesis' for the picture superiority effect in

memory was first proposed by Nelson and his colleagues (Nelson *et al*., 1977; Nelson, 1979).

The common store accessed by both pictures and their names is the semantic store (Figure 4). This is an abstract set of nodes and interconnections among nodes, which differ qualitatively and could be labeled by such relationships as 'is a member of the category', 'has the property', and so on. Although we use language to talk about the properties of the semantic store, semantic memory has no language or visual images and its operations are not accessible to consciousness. Both words and pictures have access to the semantic store, but words referring to abstract concepts will access parts of the semantic store inaccessible to pictures, and pictures referring to indescribable concepts will access parts of the semantic store inaccessible to words.

The reality of visual imagery, whether produced as mental representations of a visual object or scene, or generated by an observer to a verbal description, has been well documented in both behavioral and cognitive neuroscience. Attention has increasingly focused on similarities and differences in processing of pictures and words in particular, and in concrete and abstract representations more generally.

GROUNDING OF ABSTRACTIONS

An abstract representation is one that bears no resemblance to what it represents. However, there are degrees of abstraction, from the most abstract (such as a word describing an idea, e.g. 'truth', which has no material referent in the world) to the most concrete (such as an object in your home). The chair pictured in Figure 1 is meant to represent a typical chair, and is easily understood as a chair even though it may not represent the exact form of any chair in a person's home. The name 'chair' is even more abstract in the sense that it includes properties that are not visible in a picture, such as the fact that a chair is constructed of rigid material, or that a chair is a member of the superordinate category furniture, or that a chair may be bought in a furniture store. Even more abstract concepts such as truth and beauty are not represented directly in objects we encounter in the world, but rather come to be inferred from our experience with the world.

To return to the concept of chair, we can think of this concept as a category of things representing an intermediate level of abstractness, ranging from a thing in the world, to artefact, to furniture, to chair, to dining-room chair, to the chair in my dining room with the nick on its right leg. How do we decide on the level of abstractness with which to describe our world? Of course, it depends upon the purpose; if I want the nick on my dining-room chair repaired, then I will speak of a specific chair. However, in common discourse we generally choose an intermediate level of abstractness which Rosch *et al*. (1976) have termed the 'basic level'. The basic level of categorization is a unique level of abstraction which provides an optimum level of specificity so that human information-processing abilities are not overtaxed, yet with sufficient specificity so that accurate communication can occur. Rosch and her colleagues used a variety of techniques to show that the basic level was optimum for communication. These included asking observer participants to list features for various levels in a hierarchy, determining which level showed the most commonality of motor movements, and determining which level showed the greatest commonality of shape. They showed that the basic level had the greatest number of features that distinguished one basic level object from another (known as cue validity), provided the greatest commonality of motor movements (the motor movements for sitting on a chair are the same regardless what the chair looks like), and provided the greatest commonality of shape.

Priority of Specific or Concrete Information

Many investigators have concluded that concrete representations such as pictures of objects are processed more efficiently than abstract representations such as the names of objects. These two surface forms have usually been compared in tasks in which existing knowledge (semantic memory) is required, so they are known as semantic memory tasks. In semantic memory tasks, participants are assumed to enter the laboratory in possession of this general cultural knowledge, such as the names of pictures, the pronunciation of words, or the categories to which objects belong. Because participants do not need to learn anything new to perform these tasks, they have also been called 'online processing tasks'.

Two types of tasks have been used to compare online processing differences between pictures and words: naming or reading tasks, and categorization tasks. In the naming task, participants are shown either pictures or words and asked to vocally name them. The experimenter measures both naming time (time from the presentation of the stimulus to voice onset) and, particularly for brain-damaged individuals, naming errors. More than a century

ago, Cattell (1886) noted that naming pictures took longer than naming words. He attributed this word advantage to habit – to the closer association between concept and expression built up through experience. Theios and Amrhein (1989) reviewed a number of theories for the word naming advantage and showed that habit could not completely account for the superiority, rather that one needed to include the possibility that words can be named phonologically. Thus, the fact that word reading is faster than picture naming does not mean that pictures are less readily understood than words, but rather that word naming benefits from overlearning and from correspondence between the graphemes in a printed word and rules for their pronunciation.

A task that is more generally agreed to index the speed with which a representation is understood is the categorization task. Here, participants are asked to determine the superordinate category of an object, represented as either a picture or a word, and their categorization speed is determined. There are a number of ways in which categorization may be performed: participants may be asked to name the superordinate category (superordinate naming), to decide whether two exemplars are from the same or different categories (same/different tasks), or to make a binary decision about whether an exemplar is from one or the other of two categories (binary decision task). Across tasks, the general finding is that pictures are categorized faster than their names, and this has been taken to mean that pictures are understood faster than words (Potter and Faulconer, 1975; Pelligrino *et al*., 1977).

There are a number of reasons why pictures might be understood more quickly than words. First, 'form follows function' – the shape of objects often represents their function. For example, animals locomote, and their manner of locomotion, legs, are often a prominent feature of their pictorial representation; whereas tools are manipulated by hand, so a handle is often a prominent feature of *their* pictorial representation (Snodgrass and McCullough, 1986). Indeed, a basic dichotomy between living things and artefacts has been proposed on the basis of a number of studies of people with brain damage. Several patients have been reported to show category-specific naming deficits which differentially affect living things as opposed to artefacts; see Saffran and Schwartz (1994) for a review. This has been taken as evidence that different brain regions subserve understanding of living things versus artefacts. The next section considers how categories develop, and what models of categorization have been proposed.

THEORIES OF CATEGORIZATION

Categorization is a basic human cognitive process which is indispensable in structuring both experience and thought. Although some categories are arbitrary and must be learned by rote (e.g. letters of the alphabet) and still others are physiologically based and appear to be universal across cultures (e.g. color and form), many categories of natural objects and artefacts, such as those representable by both pictures and words, appear to be mediated by physical and functional similarity in which some members of the category are more central or typical than other members of the category.

The basis of virtually all theories of categorization is similarity. In the classical theory, which goes back to Aristotle, each member of a category is held to possess a set of features or properties which taken together are singly necessary and jointly sufficient to define the category. There are certain categories, such as geometric figures and members of the two gender classes male and female, which are classical in that sense. However, most other categories such as natural things and manufactured objects have graded representations. Consider, for example, the category of 'bird'. All birds have feathers and wings; most 'typical' birds are small, can fly, build nests, lay eggs and eat insects. However, ostriches are large and cannot fly, hawks eat meat, and bats, although not birds, have many of the visible features of birds. In fact, people make distinctions among exemplars of categories which reflect how closely they resemble the typical member of a category. The most typical member of a category is called a 'prototype'. The prototype of a category may not exist, but simply possess most of the important diagnostic features characteristic of the set of exemplars.

The importance of prototypes in structuring naturally occurring categories has been demonstrated in many ways. First, people agree on their ratings of prototypicality – 'robin' is rated as a more typical bird than 'ostrich'. Second, a more prototypical member of the category is categorized more quickly than a less prototypical member. Finally, in experiments in which artificial categories are constructed and taught to participants, the prototype of the constructed category, which may never be shown during the learning process, is usually classified as a member of the category quickly and with relatively little error in a transfer test.

How do people come to form abstractions or categories based upon experience with the world? How does a child, having experienced several furry objects that have been called 'dog', come to

recognize a new object as a dog? This question has been asked, for adults, by giving them experience with artificial categories. This permits the investigator to control a participant's experience with the category. For a variety of reasons, a relatively sparse representation has been commonly used, in which objects can belong to only one of two categories (A or B), the exemplars of the two categories differ in only a few features, and there is no single feature that can be used to distinguish members of category A from those of B. A particularly influential category structure was first introduced by Medin and his colleagues (Medin and Schaffer, 1978), and has been used by many investigators since. This structure is shown in Table 1. The ones and zeros represent the presence and absence, respectively, of a particular feature. Note that Table 1 represents the entire population of the 16 exemplars which can be constructed from four dimensions varying on only two values (i.e. $2^4 = 16$).

The categories are linearly separable, which means they can be separated by a hyperplane so that it is possible to learn to classify the objects into each category without error, although participants do not always learn to do so. In general, category A exemplars have more positive values on dimensions, and in particular more positive values on dimensions 1 and 3, whereas the opposite is true for category B. Note, too, that the prototype for category A is transfer stimulus 11 (T11) and the prototype for category B is training stimulus 9 (B9).

Table 1. The 5–4 category structure introduced by Medin and Schaffer (1978) (adapted from Smith and Minda, 2000)

Stimulus	*Dimension 1*	*Dimension 2*	*Dimension 3*	*Dimension 4*
Training stimulus				
Category A				
A1	1	1	1	0
A2	1	0	1	0
A3	1	0	1	1
A4	1	1	0	1
A5	0	1	1	1
Category B				
B6	1	1	0	0
B7	0	1	1	0
B8	0	0	0	1
B9	0	0	0	0
Transfer stimulus				
T10	1	0	0	1
T11	1	0	0	0
T12	1	1	1	1
T13	0	0	1	0
T14	0	1	0	1
T15	0	0	1	1
T16	0	1	0	0

The experimental procedure is to have participants go through several runs of the nine training stimuli, with feedback, and then test them on the transfer stimuli. The dependent variable that categorization models attempt to predict is the proportion of errors made on the training and transfer stimuli, usually after several epochs of training.

Medin and Schaffer (1978) showed that prototype theory failed to predict the pattern of errors in this task, and instead they presented a new theory – context theory – which proposed that participants used the similarity between the transfer stimulus and stored exemplars in order to make their categorization responses. This exemplar model of categorization has been very influential and has led to many refinements and a virtual explosion of research. Exemplar theory states that people store memories of exemplars of each member of a category, and then classify a new exemplar according to its similarity to the set of stored exemplars. This provides a natural way for children to learn new concepts. After seeing several furry objects that adults in their environment have named 'dog', the child is able to call a new object 'dog' if that object shares enough similar features with enough stored exemplars.

One problem with exemplar theory is that it would appear to require massive amounts of memory, as specific exemplars of each of the many categories of knowledge we possess would seem to be required in order to categorize each new object. This theory would also seem to make the existence of semantic memory unnecessary and redundant, as what we have been calling semantic memory would simply be based upon episodes of experience in episodic memory.

Smith and Minda (2000) analyzed the bases on which exemplar models have succeeded, and prototype models have failed, in accounting for data from the category structure in Table 1. They concluded that the successes of exemplar models rest on their ability to account for superior categorization of the trained exemplars, and that when prototype models are given that same facility, they are able to fit the data as well as the context (exemplar) model. They also suggested that because of the sparseness of the category structure, participants may have been motivated to memorize the training examples rather than to search for a classification rule, thus producing better performance on the training exemplars than would be

predicted by their performance on the transfer exemplars. If nothing else, this analysis suggests that, in category formation, the roles of familiarity and experience are important.

CONCLUSION

This article has compared two types of representations – concrete representations of pictures and abstract representations of the words that name them – and has argued for a common code model which relates the two surface forms. Consideration has been given to ways in which abstract representations are built up out of the overpowering specificity of the world.

Rule-based Thought

Introductory article

Ulrike Hahn, University of Wales, Cardiff, UK

CONTENTS

Rule-based thought involves cognitive processes based on the applications of general statements which have been derived from past experiences.

INTRODUCTION

The principle that cognition is based on the application of mental rules was once virtually axiomatic. However, difficulties with rule-based approaches subsequently gave rise to a wide range of alternative models of thought, the chief ones drawing on similarity-based processes. This prompted a large experimental literature seeking to determine empirically whether or not particular cognitive processes are rule based.

RULE- VERSUS SIMILARITY-BASED THOUGHT

The extent to which human cognition is based on rules is an issue of longstanding interest. In the early days of artificial intelligence it was axiomatic that human thought is rule based. Rules no longer have this general dominant role, but there are still rule-based accounts of many tasks, whether these be language, problem solving or classification. However, the notion of rule is one of the most confused within cognitive science, and conceptual clarification is necessary if claims that a particular behavior is rule based are to have substance. The crucial distinction that must be made is between behavior which is *guided* by rules and behavior that is merely *described* by rules. Corresponding to this distinction, there are two different types of appeals to 'rules' in the literature, regarded as 'weak' and 'strong', respectively. An example of weak usage of the term 'rule' in explaining behavior is a general behavioral claim that a language learner has succeeded in 'mastering the rules of English', or the assumption that infants are born with 'rules for looking' which guide their exploration of the visual environment. Statements such as these use the term 'rule' to refer to an external regularity (of English) or an internal constraint without making a claim about mental architecture (i.e. without wishing to endorse a particular view about how the external regularity or the innate constraint are internally represented by the agent). Such a weak usage of the term 'rule' in a cognitive context is *not* the focus of the debate about mental rules, which revolves around the 'strong' use of 'rule'. According to the strong reading, speaking of an agent as possessing a rule is a statement about cognitive architecture. It is the claim that an agent is making use of mental representations of a particular representational format, namely 'rules', which can be distinguished from other types of mental representations. This stronger, more specific claim lies at the heart of debates in which rule-based models are contrasted with similarity-based accounts such as exemplar models. Crucially, the strong use claims an agent-internal role for the rule. Stating that an agent possesses a particular rule is not merely saying that this agent's behavior displays a particular regularity, but rather it is saying that this 'rule' has a causal role in producing this behavior – that is, the behavior has the regularity that it does *because* the agent possesses the rule in question.

This is commonly phrased in terms of the distinction between rule-guided or 'rule-following' behavior and behavior which is merely conveniently described by rule. Rule following is exemplified by legal systems and their effect, where documents that encode the law cause particular behaviors, such as paying certain amounts of tax. Merely rule-describable but not rule-guided behavior is exemplified by planetary motion – planets' orbits are well described by physical laws, but planets do not themselves consult these laws in order to guide their behavior. In the latter example, the statement of the rules of planetary motion does not function causally in the generation of the planets' behavior, as do legal rules. This is readily apparent from the fact that planetary motion is unaffected by the presence or lack of knowledge of the appropriate physical laws, whereas legal

rules must be known for them to produce the behaviors in question.

Confusion readily arises because cognitive theories speak of rule-guided behavior even when the rules are entirely agent internal and not consciously accessible. Terminologically, it helps to avoid confusion if 'rules' are distinguished from mere 'regularities.' A 'rule', as invoked by the strong usage of rules, is not the regularity itself but rather a *statement* of this regularity. In other words, a rule is a representation of the regularity which follows a particular representational format. Any strong claim about the rule-based nature of a particular behavior is claiming that an appropriate *statement of a regularity in a rule-based format has a causal role in the production of the behavior* in question, whether or not the cognitive agent is aware of this.

This can be illustrated by a classic example. In English, the vast majority of past tenses of verbs are formed by adding /ed/ to the stem of the word (e.g. walk → walked, talk → talked, kiss → kissed). This constitutes a regularity governing the English past tense. One way in which this regularity might be exploited by the cognitive system is through the acquisition, on the part of the language learner, of an internal mental rule, the content of which would be 'stem + /ed/ → past tense', and which is applied (albeit unconsciously) whenever a past tense is to be formed. This would constitute an instance of rule-guided behavior. However, an internal mental rule of this kind need not be the only way in which this regularity might be exploited. A statistical device such as a standard connectionist network, or a similarity-based approach in which past tenses are formed analogously to those of the most similar-sounding known words, might give rise to the same behavior. These would not constitute examples of rule-based cognition.

In many if not all areas in which rule-based explanations of cognitive performance have been advanced, they have been contrasted by explanations based on similarity or analogy. Another example of this type concerns the way in which we classify objects in day-to-day life. For example, when learning about dogs we might have abstracted a general rule, say 'If a creature is furry, has four legs and barks, then it is a dog', which we apply in order to determine whether or not something is a dog. Alternatively, we might simply store in memory lots of individual dogs that we have encountered (Lassie, the neighbor's dog Rex, etc.), and classify as a dog anything which we find to be sufficiently similar to those dogs we have in memory. The key difference between these two approaches is that the application of the rule requires that all of its criteria are met. In other words, matching of the rule to the instance to which it is to be applied is *strict*, whereas similarity-based classification is a matter of *partial* matching – that is, the instance one is seeking to classify need not match a stored instance in all respects, but may only match it more or less. A direct consequence of the fact that rule application is strict is that rules must be more *abstract* than the instances to which they are applied, if they are to match more than one instance. By contrast, the partial matching involved in similarity comparisons means that abstraction is not required.

Strict application versus partial matching, and the need for abstraction versus independence from abstraction for generalization, constitute the core criteria of rule-based and similarity-based thought, respectively. In addition, further criteria might be specified before one would be willing to regard an internal representation as a 'rule', or a partial matching process as a 'similarity comparison', but these general criteria and their implications are all that need be assumed for most empirical efforts to distinguish rules from similarity.

HALLMARKS OF RULE USE

The fact that rule application involves the strict application of an abstraction gives rise to the critical prediction that performance on items to which the rule is applied should be *uniform*.

In other words, idiosyncratic individual properties of instances which are not referenced by the rule should not affect behavior. Typically, the idiosyncratic properties of items which are experimentally manipulated in empirical tests for rule-based thought are the items' similarity to each other. Similarity between items is expected to affect performance on similarity-based accounts but not on rule-based accounts. For example, in classification, only similarity-based accounts suggest that one might expect items with high similarity to others of the class to be classified more confidently (as indeed is typically the case), whereas to the rule, 'all items are created equal'. The general logic present here can be exploited experimentally in numerous ways – for example, by examining behavioral responses (confidence, response times, etc.) in familiar instances, or through the examination of generalization performance on previously unseen items which vary in their similarity to known items. Although most of the empirical studies that seek to provide evidence for or against rule-based thought are instances of this general approach, other strategies have also been used. Because rule- and similarity-based models require

different learning strategies (rule induction versus instance storage), they might produce quite different learning profiles – the time course of learning can differ, as may what is easy and what is hard. One might be more tolerant of 'noise' in the data, and so on. *Any* such attributes could be called upon. However, the one that has probably received most attention is the presence of discontinuities in performance as learning progresses. The classic example here is the so-called 'U-shaped learning' found in (among other areas) language learning, whereby a period of correct performance on exceptions to the general regularity (e.g. the past tense forms come → came, or sing → sang) is followed by sudden over-regularization of these exceptions ('comed', 'singed'), which only gradually subsides. The onset of regularization has been explained as reflecting a transition from instance storage to rule use on the part of the learner, although non-rule-based explanations for such discontinuities have also been found.

ADVANTAGES AND DISADVANTAGES OF RULE USE

A prime advantage of rule-based models is that they are conceptually straightforward to generate, a fact which has presumably greatly contributed to their popularity. Specifically, once a regularity has been observed, we need only posit a representation or statement of that regularity which is agent internal and we have the core of a cognitive account. Given the observation that the vast majority of English words form a past tense by adding the suffix /ed/ (the regularity), one can immediately derive a cognitive account by positing a mental representation of this regularity (roughly 'for past tense add /ed/') as an internal rule which speakers are using to generate the appropriate forms, and one has a cognitive theory of past tense production.

However, rule-based theories have other advantages. A single rule can cover many, often disparate instances, thus enabling generalization across a wide range of circumstances. This power becomes extremely valuable where the rule can be communicated, thereby allowing the solution to many different examples to be acquired in one fell swoop. Practical examples of this are found in educational and legal settings. For example, the single simple rule 'No vehicles allowed in park' suffices to convey that cars, lorries, buses, bicycles, tricycles and motor scooters are all banned. However, this same generality can pose problems if the rule has to be induced (i.e. learned from experience). This is because there are typically many alternative rules which fit an existing set of data. For example, faced with three brown dogs which bark, we could infer the rules that 'all dogs bark', 'all brown dogs bark', 'all brown creatures bark', 'all four-legged creatures bark', and so on. A similar indeterminacy arises if a rule has to interact productively with already existing rules. When the predictions of a body of rules turn out to be false, there are typically many potential solutions to the question of which rule(s) to adjust. For example, if while in possession of two rules, first that 'all spiders make webs' and second that 'all eight-legged land creatures are spiders,' one discovers an eight-legged land creature which does not make webs, one could adjust either the first rule or the second one in order to eliminate the conflict with one's observation. The observation data itself does not pinpoint any unique solution.

By contrast, learning and revision in instance-based models are trivial – items are simply stored in memory. New conflicting experiences are dealt with in exactly the same manner, which means that adjustments are always local, and consequently problems like that of deciding which of many interacting rules to adjust simply do not arise. However, in order to achieve adequate performance on complex problems, large numbers of instances are typically required, or alternatively the type of analogizing performed must be of considerable sophistication and complexity, which typically requires a background knowledge of some sort. Consequently, rule- and similarity-based reasoning might be seen as complementary in their strengths and weaknesses, which suggests that cognition might do worse than resort to both.

Schemas in Psychology

Introductory article

Evan Heit, University of Warwick, Coventry, UK

CONTENTS

A schema is a source of general knowledge that tells us what to expect from observations, as well as providing a structure for understanding them.

INTRODUCTION

One of the most important contributions of cognitive psychology is the idea that people do not just passively collect information. Instead they bring their prior knowledge to bear to help them to learn about new things. For example, someone learning a new computer game would rely on previous knowledge of other computer games. By this account, a new computer game that is very similar to known games should be especially easy to learn, and indeed, the prior knowledge might help to highlight what is especially new about this new game.

BARTLETT'S STUDIES

The idea that prior knowledge or schemas guide our learning from observations has a distinguished history in psychology. Frederic Bartlett's work early in the twentieth century was a response to the Ebbinghausian tradition of studying memory through supposedly meaningless stimuli such as nonsense syllables. Bartlett argued that it is impossible to separate any stimulus from its subjective meaning, and crucially, the influences of people's knowledge are central to the nature of memory. Bartlett conducted an extensive series of studies documenting the influences of schemas on memory. (*See* **Ebbinghaus, Hermann**)

These studies showed that remembering pictures as well as written material such as stories depended highly on reconstruction, and that veridical or perfectly accurate memory was rare. For example, some participants were shown drawings of scenes such as a closed gate in a field, with a sign next to it. They later recalled that the sign said 'Trespassers will be prosecuted' even though the sign was not legible in the original picture.

Using his method of repeated reproduction, Bartlett showed the pervasive influence of schemas on memory for stories. Bartlett had British people read a story from another culture, such as an American Indian folk tale known as 'The War of the Ghosts'. These participants were required to recall the story repeatedly over a period of days or weeks. Many details such as proper names were omitted from the recalled stories. Participants tended to recall the gist of the story rather than the exact words, but even the gist of the story was distorted or 'rationalized' in light of the participants' own cultural conventions. For example, this supernatural story about a battle with ghosts was sometimes recalled as a battle with a clan of men known as the Ghosts.

SLOTS, FILLERS, AND DEFAULTS

Central to the idea of schemas is that they do not simply express people's beliefs, or tell them what to expect, but represent this information in a highly structured fashion. According to schema theory, schemas can be thought of as having a hierarchical structure, with more general schemas including more specific variants. For example, within the building schema there is a house schema, an office building schema, a church schema, and so on. When a person approaches some building for the first time, this person would need to observe the building directly, but would also need to retrieve a specific schema for understanding this building, depending on whether it is a house or an office or another kind of building. Merely retrieving a general building schema would not be informative enough. However, retrieving the wrong schema would also lead to difficulties. For example, an incorrect assumption that someone's private house is actually a place of worship would lead to

further incorrect assumptions about whether it is all right to enter without knocking.

Another way that schemas have structure is that they are used to organize knowledge into compartments or slots. For example, a house schema would have slots for the house's address, the name of its owner, what color it is painted, how many floors it has, and so on. Learning about some particular house can be thought of as obtaining fillers for these slots, such as filling in the address and the owner's name. (This process is also known as instantiating the schema.) In this way, schemas guide us to look for certain information that is relevant. Information that does not correspond to an existing slot can easily be lost. For example, if the house has its own roller skating rink then details about this (such as its color and size) could be forgotten because there are no slots for roller skating rink details in the house schema.

Perhaps the greatest value of schemas is that they provide defaults, that can fill slots with expected values, even before direct observations are made. For example, it can be assumed by default that rooms have ceilings, kitchens have ovens, and bathrooms have baths even without checking all these details. In this way, schemas can potentially save a lot of time. Imagine the inconvenience if each time someone entered a room, it could not be assumed that the room had a ceiling and a floor. However, these default values can be overridden, so that for example it is easy to note that a bathroom does not actually have a bath but has a shower instead.

SCHANK'S SCRIPTS

When schemas refer to events they are usually known as scripts. For example, according to script theory people have scripts for going to the doctor, buying groceries, going to a restaurant, and so on, that represent their general knowledge about these everyday events. Roger Schank was interested in how people apply these scripts to understanding events. He was also interested in characterizing this human activity in a formal manner that could be expressed as a grammar or a computer program. If people's use of schemas can be formalized, then this characterization could be used to help build more intelligent computer programs that can understand stories or draw common-sense inferences.

For example, consider the following story:

> John went to a restaurant. He ordered chicken. He left a large tip.

Crucial to understanding this story is filling in the blanks, for example that John also sat down, he read the menu, the waiter brought the chicken, John ate the chicken, and he paid the bill. These inferences depend on the causal knowledge that would be contained in scripts, for example that ordering food causes the waiter to bring the food.

Script theory also provides a means for embedding scripts within each other. For example, eating chicken can be thought of as filling a slot within the restaurant script, but eating chicken can also be thought of as a script-based activity in itself, which indeed is a specialized version of a more general eating script.

EVIDENCE FOR THE USE OF SCHEMAS

The influence of Bartlett's studies can be seen in later psychological experiments in the 1970s and 1980s, that provided further evidence for schema theory and script theory. Brewer and Treyens looked at how people remembered directly observed scenes, such as what they recalled after waiting in a graduate student's office in a university laboratory. It appeared that people have an office schema that is applied to observations of real offices. This schema had a number of effects on what was later remembered about the office. One effect was that the schema seemed to support memory for details that were part of the schema: for example, people accurately recalled that the office had a desk and chairs. However, the schema also acted as a filter: participants left out certain details, such as a skull sitting on a shelf, that did not fit with the office schema. Another effect was that people used their schemas to draw (incorrect) inferences: people recalled having seen books on the shelves although there were actually no books in the office. It is quite natural to think of these results in terms of slots, fillers, and defaults for the office schema.

There is also good experimental evidence supporting the basic elements of script theory. For example, Bower, Black, and Turner asked people about their knowledge about going to a restaurant. It was found that people generally agreed about the key elements of this script, with a stereotypical sequence of being seated, looking at the menu, ordering the meal, eating, paying the bill, and leaving. This general knowledge about restaurants affected what participants remembered after they read stories about people in restaurants. As in the other studies, participants' previous knowledge seemed to affect what they remembered as much

as what they actually saw in the story. The use of inference was common; for example, participants would recall that the people in the story ate their food, even if this was not stated in the story. A more dramatic effect was that script knowledge led to changes in the order of remembered events. For example, when people in the story paid the bill before reading the menu, the story was often recalled with these events in the more conventional order.

PDP APPROACH

Some of the more recent work in schema theory has involved further efforts to implement schemas in a form that can be run by a computer program. Rumelhart and colleagues took a different approach than Schank, implementing schema theory with connectionist or PDP (parallel distributed processing) networks. These networks represent knowledge in terms of a pattern of associations between various units, which could correspond to default values for various schema. For example, the schema for a kitchen may be represented as associations between units for oven, cupboard, coffeepot, fridge, and so on.

PDP networks can represent positive as well as negative associations. So the same network could represent positive associations between sofas, easy chairs, and televisions, as well as a negative association between sofa and fridge. In this way, the network could embody multiple schemas such as the kitchen schema and the living room schema. Furthermore, the network could be used to draw inferences, such as that when a sofa is present a chair is also likely to be present, but a fridge and oven are unlikely to be present. Implicitly, the network would draw on its knowledge of the living room schema to make this inference. Although not capturing all the causal knowledge assumed by Schank's script theory, the PDP approach still provides an elegant way of implementing mathematical models that can be used to recognize schemas and apply them to observations. In particular, the PDP approach gives a successful account of constraints between fillers of different slots.

CONCLUSION

In the present day, schema theory in itself is not as much a direct object of research as it was during earlier periods in the history of psychology. Indeed, modern researchers do not necessarily assume that schemas exist in the exact forms that have been proposed. However, the influence of schema theory on current psychological research is thorough and pervasive. It is now taken for granted that modern theories within cognitive psychology, addressing memory, reasoning, comprehension, and so on, must take into account people's use of previous knowledge. Furthermore, it is accepted that schematic knowledge is richly structured, for example, with different levels of generality and with interrelations between different features of what we may observe.

Scientific Thought

Introductory article

Kevin Dunbar, Dartmouth College, New Hampshire, USA

CONTENTS

'Scientific thought' refers to the thought processes involved in the wide field of scientific activity, and in the process of radical or mundane revision of scientific concepts through a variety of reasoning techniques and problem-solving heuristics.

INTRODUCTION

Scientific thought refers to the thought processes involved in scientific activities, ranging from theory building and experimental design to data interpretation and scientific argumentation. More deeply considered, scientific thought involves a process of conceptual change whereby individuals and entire scientific fields both add to and radically change scientific concepts using conceptual and empirical processes. This process of conceptual change is accomplished using categorical, analogical, distributed, and causal reasoning as well as specific problem-solving heuristics.

Scientific thought is obviously a product of the human mind and uses the same cognitive processes that all human beings use in other domains such as football, art, and business. What differentiates science from these other human activities are the particular ways that the cognitive processes are combined; rather than merely using a particular cognitive process, such as induction, many cognitive processes are used and combined in scientific thought. For example, where one inductive reasoning process, analogy, might be used on its own in art, business, war, or football, scientists frequently use analogy along with causal reasoning and induction by generalization when they encounter unexpected findings, or analogy along with causal reasoning and deduction when designing experiments. Thus, while scientific thought is composed of the whole range of human thought processes, these processes are used in very specific ways in science; further, the ways that these cognitive processes are combined can vary even within disciplines, such as in physics when the thinking of experimental and theoretical physicists are compared.

Five main approaches have been used to investigate scientific thought: (1) focusing on the reasoning strategies of important scientists such as Faraday and Einstein; (2) conducting detailed investigations of the evolution of concepts in particular fields, such as the concept of disease; (3) investigating the acquisition of particular scientific concepts in adults and children by conducting experiments in the cognitive laboratory ('*in vitro*' cognition); (4) analyzing scientists *in vivo* as they think and reason at work in their laboratories; and (5) building computational models of key scientific reasoning heuristics and discoveries. Taken together, these different approaches to investigating scientific thought have converged upon a set of key mechanisms that are at the core of the scientific mind. This article will thus focus on the underlying mechanisms rather than the different types of approaches.

SCIENTIFIC CONCEPTUAL CHANGE

With the shift in philosophy of science from purely analytic methods to an understanding of the conceptual structures in science and the origins of scientific revolutions, there has been a shift to understanding the changes in the ways that scientific knowledge is represented in entire scientific fields, in particular scientists, and in children. These analyses have revealed that often conceptual change is little more than an addition or deletion of a certain fact to a theory or model. More rarely, an entire conceptual structure has to be reorganized. This latter type of change is what is most commonly referred to as radical conceptual change.

Radical conceptual change is evident in entire fields, in the work of particular scientists such as Faraday, and in children acquiring new scientific knowledge such as that involved in physics and biology. Computationally, this type of far-reaching

conceptual reorganization has been captured in models such as 'Explanatory Coherence by Harmany Optimization' (ECHO) and 'Scientific Discovery as Dual Search' (SDDS). In ECHO, explanatory coherence is the driving force behind theory change in science. In SDDS theory, change is proposed to involve shifts in frames or schemas as a function of obtaining findings inconsistent with a particular hypothesis. These models also capture the more mundane conceptual changes that are most common in science. The mechanisms underlying scientific conceptual change range from inductive processes, such as generalization and abductive reasoning, to the use of deductive reasoning heuristics.

One important question for research on scientific thought is whether the types of mental processes underlying radical conceptual change are the same as or different from those underlying more mundane conceptual changes. Some authors have argued that the processes involved in these different kinds of change are fundamentally different. Others have argued that they are the same. Answers to this question are important as they have many implications for models of scientific thinking. Thus, this is not merely an academic question, as the goal of much work in science education, and science itself, is to foster conceptual change in scientific concepts. Currently, detailed analyses of children's and scientists' subtle changes in concepts over time are being conducted and should make it possible to both understand and harness conceptual change in development, to aid practising scientists, and to build computational tools that foster both radical and mundane conceptual change in areas such as bioinformatics and cosmology.

ANALOGICAL REASONING IN SCIENCE

Scientists frequently refer to the important roles that analogy has had on their research. There are numerous anecdotes of particular analogies being the impetus for a conceptual change. Kekulé's analogy to snakes being the origin of the benzene ring is a frequently given example of the role of analogy in science. As with Kekulé's snake analogy, many scientists have talked about analogies where the source and the target are from radically different domains, such as Francois Jacob saying that by drawing an analogy between the genes he was working on and his son's toy he was able to propose the first theory of genetic regulation. Many theories of creativity in science have argued for the importance of these distant analogies.

However, recent analyses of the historical uses of analogy in science and detailed analyses of scientists' reasoning live in their laboratories reveals that the use of distant analogies in science is usually, though not always, limited to explanations. Instead, these analyses reveal that analogies to concepts and methods from the *same* domain are frequently the source of new hypotheses and are important in conceptual change. When scientists have been examined live, or *in vivo*, it has been found that a whole sequence of different analogies from the same domain can produce conceptual change. Rather than one distant analogy being the source of a conceptual change, many analogies can be the source of different aspects of the conceptual change.

Analogies in science are often used in the service of particular goals such as discovering why a certain unexpected finding was obtained. The ways that analogy is used in science are thus highly related to the goals of the scientist. If the goal is to fix an experimental problem, the analogy will be to similar experiments. If the goal is to formulate hypotheses, the analogy is to something in a related domain that shares underlying sets of relations. However, if the goal is to explain a concept to the general public or to nonspecialists in an area, then analogies are often made to very different domains.

SCIENTIFIC CAUSAL REASONING

One important component of scientific thought is the construction of causal models. These models frequently provide a particular mechanism for going from a cause to an effect, such as a mechanism for how HIV causes AIDS, and also captures statistical information about the co-occurrence of cause and effect. Causal reasoning is ubiquitous in science and is involved in experimental design, theory building, and accounting for unexpected findings. While the causal reasoning literature has tended to focus on either mechanistic or statistical information as the main source of information on causal reasoning, scientists use both statistical and mechanistic information to constrain their causal models.

Research on experimental design and hypothesis testing has frequently shown that people use underlying knowledge of causal mechanisms to interpret patterns of data. In certain circumstances scientists use their causal models to override the statistical information that they receive. This has been referred to as 'confirmation bias', and has been frequently documented *in vitro* (standard

psychological experiments) in the cognitive laboratory. However, expert scientists appear sensitive to both the scope of their statistical information (the number of samples that it comes from) and the underlying base rates when interpreting their data. Thus, while some spectacular examples of confirmation bias exist, such as the discovery of cold fusion, the actual causes and frequency of this phenomenon have been difficult to determine.

One important place where causal reasoning is used is in the design of experiments. Both *in vitro* and *in vivo* research on experimental design has shown that the possibility of error in an experimental result is a key factor that dictates the types of experiments conducted and the interpretation of results. When scientists reason at their lab meetings, they spend a considerable amount of time planning controls into their experiments that specifically control for the possibility of error. However, some research has shown that when people are told that there is the possibility of error in experimental results, this allows them to insulate their hypotheses against disconfirmation and allows them to maintain disproven hypotheses. One way that scientists deal with the issue of error is to build various different types of controls into their experiments that allow them to isolate a particular cause of the error.

DISTRIBUTED SCIENTIFIC THOUGHT

The image of a lone scientist toiling away under a naked light bulb is one that has implicitly dominated cognitive science since the 1960s. However, recent historical and *in vivo* analyses of science, as well as situated models of cognition, have highlighted the fact that much of scientific thinking and reasoning takes place in groups. Often scientists build models and theories, design experiments, and explore entire conceptual spaces in groups, and the reasoning is distributed over many people rather than being inside the head of one person. This distributed reasoning in science is usually collaborative, with members of a group changing parts of the representation of a concept by adding, deleting, and replacing components of a conceptual structure. Occasionally, groups of scientists can converge on completely new conceptual structures that can change an entire field. The exploration of the interaction of situational, cognitive, and social factors in distributed scientific thought is a new emerging direction for the field of scientific thinking.

CONCLUSION

Scientific thought involves the entire gamut of thinking and reasoning processes that human beings use. It makes use of a combination of various cognitive processes such as problem-solving, concept change, and categorization, as well as analogy and causal and visual reasoning. Accounts of scientific thought focus on the way these different aspects of thought are combined and are used in the service of scientific goals such as theory building, experimental design, and scientific explanation. The ultimate goal of research on scientific thought is to understand the mechanics and development of the scientific mind and the relationship between cognition of science and its social context, to aid scientists in their work, and to help educate new generations of scientists on strategies that can be used to make discoveries.

Selective Attention

Introductory article

Asher Cohen, The Hebrew University, Jerusalem, Israel

CONTENTS

A fundamental aspect of our cognitive activity is selection, by attentional mechanisms, of a portion of the vast amount of information we are confronting at any moment.

INTRODUCTION

A fundamental empirical phenomenon in human cognition is its limitation. At any moment in time, a vast amount of information impinges upon our senses. Many studies show that we cannot fully process all this information, and that some of it appears to be lost. One trademark of a limited system is its need for selection. Given that not all the impinged information can be processed, it is mandatory to select which portion of it will be preferred. In theory, the selection can be random. However, people are able to perform a nonrandom selection. For example, drivers at a junction with traffic lights are able to focus on the lights rather than on other stimuli present in the scene. The mechanism in charge of the selection is termed 'selective attention'.

Any type of selection presupposes the availability of some information in order to perform the very selection. Thus, some 'pre-attentive' processing must be performed prior to the operation of selective attention, and its output is used for the selection. The distinction between pre-attentive and attentive processing is essential in the study of selective attention.

Extensive research over the last 50 years has explored the basic properties of selective attention. Many issues related to attention have been clarified, but questions concerning its operation are still debated among researchers. Perhaps the most basic question concerns the point in the processing stream of information where attention begins to operate. This issue, developed into a controversy known as 'early versus late selection', is reviewed first. We then review studies suggesting that there may be multiple levels in which selective attention operates.

EARLY VERSUS LATE SELECTION

It is useful to consider task performance as a stream of information processing starting with input (usually via our senses) and ending with output (usually, some behavioral action). A major question concerns the locus of processing at which selection is performed. As mentioned before, there is some initial pre-attentive processing at the input side, but up to what point? At what stage of processing does selection (and selective attention) begin? Because pre-attentive processing is by definition unlimited, whereas post-attentive processing is limited, one may answer this question by uncovering the point where limitation is first evident. This point is often called 'the bottleneck'. Two classes of studies, focal attention and divided attention, were used to explore this question.

Focal Attention Studies

In focal attention studies, subjects are required to focus on a subset of the stimuli presented to them and ignore all other stimuli in the scene. We focus on one such paradigm, the dichotic listening paradigm, but findings from other paradigms are similar. In a typical dichotic listening experiment, two auditory messages (e.g. two stories) are played simultaneously. Subjects are asked to monitor one message, usually by shadowing it (i.e. repeating verbatim), and ignore the other. Studies with this paradigm revealed an important difference between two types of task. In one type, the two messages differ by a physical property. For example, the messages may differ in their intensity or by their pitch (male versus female). In the second type, the messages differ by semantic content. For example, words denoting animate and inanimate objects are played simultaneously, and subjects are required to shadow the animate words.

Early studies showed a dramatic difference between these two types of studies. When the messages differed in semantic content, subjects simply

failed to perform the shadowing task. When the messages differed in a physical property, subjects could perform the shadowing task. This shadowing ability, however, was coupled with a profound inability to report the content of the ignored message. In one study the ignored message was repeated 35 times. In another study, the language of the ignored message was changed from English to German. Both changes were not noticed by the subjects. In contrast, subjects did notice a change of a physical property in the ignored message. For example, subjects immediately notice when the gender of the speaker of the ignored message changes. There is then a fundamental difference between processing of physical and semantic properties of stimuli. Moreover, processing of semantic information in a rejected/ignored message is dramatically limited.

To capture these findings, Donald Broadbent proposed his influential early selection model of selective attention. According to this model, physical properties in the scene are processed in parallel and without any limitation. To process any semantic content, attention selects a physical property and acts like a filter: the semantic content carried by the selected physical property is recovered by higher level processes. Semantic information not carried by this physical property is lost. For example, attention may select a range of pitches corresponding to a female voice. Consequently, the semantic content carried by the female voice is processed, but other kinds of semantic information in the scene is lost. It is an 'early selection' model because selection is done early in the stream of information processing, at a point where only physical properties are available.

Subsequent studies, however, indicated that pre-attentive processing is not as limited. Although subjects do not generally notice the content of ignored messages, they sometimes detect in them important information (e.g. their own name). Anne Treisman proposed her attenuation model to accommodate these findings. This model resembles that of Broadbent, with an important modification: the attention filter attenuates rather than blocks other stimuli. The implications of this modification are best understood with another important general assumption of standard cognitive models concerning the way we represent stimuli in our brain and how such representations reach consciousness. Namely, each representation has a variable level of activation. To reach consciousness, a representation has to accumulate a high level of activation. The resting level of activation of most representations is low and thus outside consciousness. Through perceptual processes, a stimulus impinging on our senses causes an increase at the level of activation of its representation that eventually leads to its conscious recognition. The resting level of different representations differs. Important representations or representations relevant to the current cognitive context have a higher resting level of activation and consequently need a smaller additional activation to be consciously recognized. We can now appreciate the difference between Treisman's and Broadbent's models. According to the attenuation model, non-selected stimuli can be processed as well, albeit to a lesser extent. However, if the resting level of activation of their representations is sufficiently high, the attenuated processing may still cause the representation to reach consciousness. This explains how subjects sometimes notice their name, a representation with a presumably high resting level of activation, in the ignored message.

The models of Broadbent and Treisman were based on studies using subjects' conscious report of ignored messages. Other methods, however, revealed that stimuli may be processed and affect behavior indirectly even when subjects cannot report them consciously. For example, some studies showed that words presented in the ignored message and not reported by the subjects may nonetheless affect the interpretation of the attended message. Late selection models were proposed to capture these findings. According to these models, semantic information is also processed pre-attentively. The bottleneck is between extensive pre-attentive (physical and semantic) processing and conscious report rather than between physical and semantic information.

The early versus late selection debate has not been settled with focal attention studies, partly because most such studies have an inherent problem: we cannot be certain that subjects indeed focus their attention on 'attended' messages. The ability of subjects to process portions of ignored messages may be explained as occasional shifts of attention to them. Studies based on direct report of subjects are problematic for another reason: ample evidence suggests that stimuli are often processed without being consciously reported. Late selection models can dismiss poor direct report of ignored messages as a reflection of interfering processes that mask the pre-attentive processing of these messages.

Divided Attention Studies

Focal attention studies led to 'bottleneck' theories. Another class of explanations emerged from

divided attention studies in which subjects are typically asked to perform two tasks simultaneously. The performance in this dual task situation is compared to that of each of the individual tasks. Limitation is revealed by a decrement in the dual task performance relative to that of the individual tasks.

Initial findings with this paradigm have led to two generalizations. First, performance in the dual task is generally poorer, indicating that the cognitive system is limited. Second, subjects can, upon instructions, prefer one task over another in a semicontinuous fashion. Subjects instructed to invest 50 percent, or 60 percent, or 70 percent, and so on in one of the tasks, perform progressively better in this task relative to the other. These generalizations are readily captured by a 'limited resources' theory, stating that people have a limited but flexible amount of cognitive resources (or energy). Dual task performance is limited because of limited resources: two tasks cannot receive simultaneously the same amount of resources as individual tasks. Because the resources are flexible, their division among the tasks can vary, leading to a better performance in the task with the added resources.

Later studies, however, revealed that a simple resources theory is not adequate. The main problem is that dual task performance is better when the two tasks are dissimilar to each other. For example, when the input to the two tasks is both auditory or both visual, performance is worse than when the inputs to the two tasks are visual and auditory respectively. To account for these and similar findings, the resource theory had to assume that there are several independent pools of resources, each of which is limited. When two tasks draw on the same pool of resources, performance is limited. The more the two tasks draw on different pools of resources, the less limited is the dual task performance. There are few studies in which no decrement in dual task performance was observed. The multiple resource theory explains these findings by stating that the tasks in these studies draw upon entirely different pools of resources. One persistent problem with this theory, however, is that it has proven impossible to identify the nature of the independent pools of resources.

Summary

Although bottleneck and resource theories were primarily designed for focal and divided attention studies respectively, both were proposed as general accounts, and each theory was used as an explanation for both paradigms. Resources theories claim that the reduced processing of unattended messages is caused by allocation of fewer resources for this purpose. Bottleneck theories claim that decrements in dual task performance arise when both require a processing unit that can only be used for one task at a time.

The debate among the theories has not yet been settled. One difficulty is methodological: it turned out to be exceedingly difficult to control tightly the subjects' attention, a prerequisite for an unambiguous interpretation of the findings. Another possible reason is that there may be more than one source of limitation (or selection) in the stream of processing. The next section addresses this latter possibility.

MULTIPLE LEVELS OF SELECTION

The models described so far assume a single selective attention mechanism. The early versus late selection debate concerns the locus of that single mechanism. The literature, however, suggests that there may be at least two distinct levels in which selection may take place, with distinct mechanisms operating in each of these levels. There is a high-level selection used for strategic choices such as a preference of one task over another, or a shift from one task to another. It is often stated that strategic selection is performed by a set of processes called 'executive functions'. There is also a second, lower-level selection mechanism that may even be modality-specific.

Selection by Executive Functions

We are constantly facing strategic cognitive choices in our everyday life. At a larger scale we decide on the activities in which we want to be involved. At a smaller scale we are often faced with several possible tasks and need to decide which has a higher priority or when to shift from one task to another. For example, we can be engaged in driving, listening to the radio, and talking to a friend. We may decide to carry out all these activities simultaneously, but we often assign different priorities to the tasks, and can shift these priorities with changing conditions. The executive functions perform these control activities.

We focus on one paradigm, known as the psychological refractory period (PRP) paradigm, because it is relevant for the question concerning the locus of selection. In this paradigm subjects are required to perform two different tasks in succession. The input to the two tasks is presented in succession as well. Subjects respond to the two tasks as fast as possible with the constraint that the

response to one task (T1) is performed before the response to the second task (T2). The main manipulation is the temporal gap, called stimulus onset asynchrony (SOA), between the presentation of the inputs to T1 and T2. Subjects are usually able to conform to the instructions, presumably by the use of executive functions: the response to T1 is committed first, and is not affected by the SOA. The response to T2, however, is typically dramatically affected by the SOA. At very short SOAs (e.g. 50 milliseconds), response to T2 is very slow. With longer SOAs, response to T2 improves progressively. Around SOA of 300–400 milliseconds, the response becomes similar to that of T2 by itself.

Why is the response to T2 affected by its temporal proximity to T1? Much evidence suggest that subjects do not assign stimuli to responses for two tasks simultaneously, a process called response selection. That is, while response selection is performed for T1, it cannot be done for T2. Instead, subjects 'wait' until response selection for T1 is complete and only then proceed to the response selection of T2.

These findings led some researchers to suggest that a 'bottleneck' in the stream of processing occurs at the response selection stage. Others claim that this apparent bottleneck at the response selection stage is only a reflection of decisions by the executive functions to allocate all the resources to response selection of T1. In other words, both 'bottleneck' and 'resources' theories can explain these findings. Regardless, we see how selection of T1 in the expense of T2 is presumably done by selective attention mechanisms related to the executive functions.

Selection within Modalities

The preceding section showed how attention selects between tasks. Attention also selects within a single task, even when the task is exceedingly simple. We focus on the visual modality because most of the research in this domain used visual tasks. Selections also take place in other modalities.

Imagine a task where you are required to make a single response to a stimulus when it appears inside one of two boxes located to your right and left. The location of the stimulus is not relevant to your response because the same response is required for the two locations. Much research suggests that if you are cued in advance that the target is likely to appear in one side, your response is faster when the target indeed appears in the cued location and is slower when the target appears in the other side, relative to situations with no cueing. The costs and benefits from the cueing are ascribed to the operation of visual attention. Attention operates by selecting the location (or the box) of the cued area, leading to facilitation in the response to targets within the selected area.

As in other phenomena of selection, there are disagreements concerning the locus in which attention affects processing. It could affect perception of the target, or it could affect response decisions for the target, or more resources are assigned to the selected area. Note that this selection is observed even for exceedingly simple tasks. There may be additional types of selection required for more complex task. These, however, are more controversial and will not be reviewed here.

Relation between the Two Types of Selection

The selection between two tasks, and the selection within a single task appear quite different. Indeed, there are behavioral and neuropsychological studies that support the separation of these two types of selection. Behaviorally, there is evidence that, although (as noted above) subjects in the PRP paradigm do not select responses to task 2 when performing task 1, they are able to shift their visual attention for task 2 during the performance of task 1. This suggests that response selection, done by the executive functions, and visual attention are distinct. Data from neurologically impaired patients and from imaging techniques suggest the existence of a posterior system of attention, presumably dedicated to lower-level selections (e.g. visual attention), and an anterior system dealing with executive functions.

Self, Psychology of

Introductory article

Roy F Baumeister, Case Western Reserve University, Cleveland, Ohio, USA

CONTENTS

Social psychology of self is the study of structures and processes through which people know and evaluate themselves, present themselves to others, and exert control.

Psychology's efforts to understand the self date to its earliest thinkers, including William James, Sigmund Freud, and Carl Jung, and in recent decades it has been a pervasive theme among researchers. Under the broad umbrella of studying the self, many different subtopics have flourished. Interest has been sustained by the importance of many findings and questions, by lively debates among researchers with different theories, and by the fundamental fascination with the topic, as captured in the ancient Greek philosopher's injunction to 'Know thyself!'

The vast quantity of research on the self can be conveniently grouped into three broad categories. First, the cognitive processes include self-concepts and other representations of self, self-awareness, self-esteem, and other links between the self and the processing of social information. Second, interpersonal processes include managing how the self is perceived by others, identification of self as part of social groups, and altering the self to fit the communications and expectations of others. Third, the executive function involves how the self acts and decides, as well as how the self regulates and controls itself. These three categories roughly cover the entire field and can be used to organize the available information, even though inevitably there is some overlap between them.

SELF-CONCEPT AND COGNITIVE PROCESSES

Although experts believe that rudimentary signs of self-awareness can be observed in other species (especially primates), the capacity for being aware of self is much greater and more developed in human beings. Awareness of self makes it possible for people to form mental representations and concepts of themselves and to regulate their own behavior. In particular, self-awareness typically involves comparing oneself to goals, ideals, norms, other people, and various other standards.

The self-concept refers to a mental representation of a person by that same person. Typically this encompasses one's social identity in the sense of one's roles, as well as one's personality traits and to some extent one's major values and beliefs. The term is used loosely by researchers such that any knowledge or beliefs about the self can be considered to be part of that person's self-concept.

The simple term 'self-concept' is misleading in some ways, because it implies a single, unified, consistent representation of the self. Contrary to that view, people seem to have multiple beliefs about themselves, and these are not necessarily integrated or consistent with each other. To be sure, people do make efforts to resolve obvious contradictions, but many inconsistencies can survive without being recognized as such. Different versions of the self-concept may dominate at different times and in different contexts, such as when a young person thinks and feels differently when attending church with his parents as opposed to partying with fraternity brothers. Some theorists have taken this inner diversity as a reason to speak of having 'multiple selves', but it is better understood as a multiplicity of conceptions or of versions of the same self.

In any case, it is clear that different conceptions of the self may dominate at different times. People have a great stock of self-knowledge, and at any given time they use only a small part of it. That is why they can have inconsistent and even contradictory views of self.

Three main motives dominate the acquisition, memory, and use of information about the self. First, the positivity motive involves the desire to think well of oneself and hence exerts an ongoing preference to learn favorable things that reflect well on the self. This motive is reflected in people's

desire to obtain positive feedback and in their tendency to distort memory so as to portray the self in a more flattering light. Second, the consistency motive refers to a wish to maintain a stable, unchanging view of self, and so it exerts a preference for information that confirms what the person already believes about the self. People report skepticism and even rejection of information that disconfirms what they believe about themselves. Last, the diagnosticity motive signifies a desire to learn accurate, correct information about the self. Sometimes people show an interest in performing tasks (such as those of intermediate difficulty) that will provide the clearest and most unambiguous information about the self and what it can do.

Because accurate knowledge would seemingly be the most useful of the three types of information, there is reason to regard the diagnosticity motive as the most adaptive and important of these motives. However, research consistently finds that the positivity motive is the strongest, with consistency second and diagnosticity the weakest. All three motives are genuine and exert some influence, however.

Partly because of conflicting motives, people end up with self-concepts that are not strictly accurate. In particular, there is ample evidence that people hold favorable, flattering, and comforting assessments of themselves. More precisely, self-knowledge shows three persistent patterns of distortion. First, people overestimate their good qualities, achievements, and strengths while underestimating or downplaying their faults and misdeeds. Second, people overestimate their degree of control over the events that affect their lives. Third, people are unrealistically optimistic and hence prone to expect that good things are more likely (and bad things more unlikely) to happen to them than to the average person. These distortions may sound like narcissistic delusions of grandeur, but in fact they are common and pervasive among normal, psychologically healthy individuals. They are less common among people with low self-esteem and among depressed people, whose self-assessments tend to be more even-handed and accurate.

Self-esteem refers to the favorability of the self-concept. People with high self-esteem think well of themselves. Low self-esteem does not however usually indicate a strongly negative view of self, but more commonly low self-esteem refers simply to the absence of favorable views (thus indicating a neutral, intermediate view of self). People with low self-esteem also tend to exhibit 'self-concept confusion' in the sense that their beliefs about themselves are likely to be inconsistent, contradictory, tentative, and uncertain. A difference in broad approach to life is also apparent: people with high self-esteem seek to enhance themselves by accomplishing great things and winning new friends and admirers, whereas people with low self-esteem seek first to protect themselves against failure, rejection, and embarrassment. People high in self-esteem seek to identify their strengths and capitalize on them, whereas people low in self-esteem try to identify their weaknesses and remedy them.

The benefits of high self-esteem have been debated. High self-esteem appears to confer confidence, which can help performance, although in most studies people with high self-esteem do not perform any better (or much better) than people with low self-esteem – they merely regard their performance as better. It confers a stock of good feelings that can be useful to help people recover from setbacks and traumas and to help them persist in the face of discouraging failure. People with low self-esteem are more prone to give up easily. Thinking well of oneself does not appear to produce much else in the way of benefits, such as being better citizens, avoiding self-destructive or interpersonally harmful acts, or accomplishing more in life. Some forms of high self-esteem, such as a narcissistic belief that one is superior to others and entitled to special, preferential treatment, have been associated with aggressive and destructive tendencies. By and large, self-esteem has at best weak correlations with success in life, and even when such links have been found, there is reason to think that self-esteem is the outcome rather than the cause of success.

INTERPERSONAL PROCESSES

The self is not just a stock of information but rather also comprises a tool for interacting with others. Hence the self is strongly shaped by interpersonal processes and will be modified by social interactions.

Social identity is formed by recognizing oneself as a member of various groups and categories. From early in life, self-knowledge involves being a member of a particular family and having a particular gender. Identification with various ethnic groups, nationalities, organizations, and other categories continues to be important throughout life. For some (but not all) people, self-esteem and self-knowledge are heavily intertwined with these collective aspects of the self (such as racial pride). Immersion of self in a group sets up a

conflict between the motive to be distinctive in some way versus the motive to fit in to the group, and there is some evidence that cultures differ in the relative emphasis they put on them. Specifically, Asian cultures appear to emphasize the collective aspects of the self and people try to fit in with others, whereas Western cultures foster more individuality and people expend more effort cultivating independence and distinctiveness. Indeed, this idea was proposed in a highly influential article by Hazel Markus and Shinobu Kitayama (1991) and has become one of the most heavily studied theories in cross-cultural work on the psychology of self. In support of it, Westerners tend to emphasize aspects of self-concept that distinguish them from others, whereas Asians may focus on aspects of self that involve relationships to others and common traits that link one to one's social groups.

Undoubtedly much self-knowledge is distilled from social interactions. In fact, symbolic interactionist theories emphasized that the inner self is essentially derived from interpersonal, social events. The simplest version of this view is that people learn about themselves from others, but the evidence has not supported this simple version. That is, people's self-concepts do not closely match the way they are perceived by their friends and family. Two significant processes prevent people from coming to see themselves as others see them. First, people do not communicate all their impressions accurately, especially when it comes to telling someone his or her faults. Therefore people do not learn the full story about what others think of them. Second, individual self-knowledge is subject to motivated biases, and so people discount what others may tell them if they do not want to hear it.

People also seek to mold how others perceive them (impression management, also known as self-presentation). Often they try to portray themselves in a very positive manner, such as by concealing their faults and emphasizing or exaggerating their good qualities. Sometimes this is a simple matter of trying to conform to the expectations of others, such as when a person might conceal habits of laziness or drunkenness during a job interview. More broadly, people try to present themselves to others as a way of claiming desired identities for themselves. Theorists dating back at least to the symbolic interactionist school have emphasized that identity requires social validation, and so before someone can claim to own a specific identity it is necessary to persuade or induce some other people to perceive oneself as having that identity.

EXECUTIVE FUNCTION

The executive function refers to how the self exerts volition, such as by making choices and decisions, initiating action (as opposed to being passive), and regulating the self. This operates primarily by means of deliberate, conscious control. It is obvious that in most other species behavior can occur steadily and automatically without the involvement of anything resembling a human self. Even among human beings, most behavior may well occur as a result of automatic processes, habit and routine, natural impulses, and situational pressures. The operation of the executive function is akin to the traditional concept of 'free will' (in which the person defies impulses and external pressures in order to act in a carefully chosen manner) and encompasses only a small proportion of all behavior – but nonetheless a very powerful and influential one. People are motivated to seek and maintain control over what happens to them, even though they do not use this control all the time.

The regulation of self (akin to the popular notion of self-control) is an important manifestation of the executive function. The regulation of self is accomplished by means of a feedback loop. This conscious process compares the self to a given standard, and if there is an unwanted discrepancy, it initiates some action to remedy this. Once the discrepancy is resolved (as indicated by comparing the perceived self to the goal or standard once again), it terminates the process.

The process by which the self changes itself appears to involve some form of energy, not unlike the traditional notion of 'willpower'. This force is used to override the self's initial response (such as in resisting temptation) and instead perform some alternative, more acceptable act. It appears further that other acts by the executive function, such as making choices and decisions, also draw on this same resource. These acts of self-control and choice can deplete the self's energy, leaving it less able function effectively until it is replenished. In that depleted state, people are reluctant to make decisions, assert themselves, or resist temptation. The expenditure of energy is one reason that the executive function can only be used sparingly, and so most of life has to be lived according to routine, habit, and automatic responses.

Although the executive function is undoubtedly a powerful tool for fostering the rational pursuit of enlightened self-interest, people do sometimes perform self-defeating acts (defined as acts that thwart the self's best interests) as well. Typically, these

self-defeating acts involve seeking short-term gain despite long-term risks and costs, such as in smoking cigarettes or abusing drugs. Indeed, resisting the temptation of short-term benefits in order to pursue long-term ones may be a crucial reason that the executive function (with its capacity for self-control and future orientation) may have evolved in the first place.

Self-organizing Systems

Introductory article

Scott Camazine, Boalsburg, Pennsylvania, USA

CONTENTS

Self-organizing systems are physical and biological systems in which pattern and structure at the global level arises solely from interactions among the lower-level components of the system. The rules specifying interactions among the system's components are executed using only local information, without reference to the global pattern.

WHAT IS SELF-ORGANIZATION?

Self-organization is a process whereby pattern at the global level of a system emerges solely from interactions among the lower-level components of the system. The rules specifying the interactions among the system's components are executed using only local information, without reference to the global pattern. Examples of self-organization include a wide range of pattern formation processes in both physical and biological systems: sand grains assembling into rippled dunes, chemical reactants forming swirling spiral patterns, the patterns on sea shells, or fish swimming in coordinated schools (Figure 1). 'Pattern' is used here in a broad sense to refer not only to a particular arrangement of objects in space, but also to structure and organization in time. An example is the remarkable synchronous flashing that sometimes develops among aggregations of thousands of fireflies in southeast Asia. In neurobiology, self-organization contributes to temporal structure and anatomical organization in systems ranging from central pattern generators in simple invertebrates to cognition in humans.

In self-organizing systems, pattern and organization develop through interactions internal to the system, that is, without the intervention of external influences, such as a 'leader' who directs or oversees the process. The pattern is an emergent property of the system itself, rather than a property imposed upon the system by an external supervisory influence.

EMERGENT PROPERTIES IN A SELF-ORGANIZING SYSTEM

The term 'emergence' refers to a process by which a system of interacting elements acquires qualitatively new pattern and structure that cannot be understood simply as the superposition of the individual contributions. Although the term may suggest that something mysteriously or magically materializes within the system, this is not the case. The human mind is generally poor at predicting the properties of systems that consist of multiple components with complex, dynamic interactions. Thus, even if one has a full knowledge of the system's elements and their mode of interaction, the collective properties of a self-organizing system often seem to arise unexpectedly.

HOW DOES A SELF-ORGANIZING SYSTEM WORK?

An example may make this abstract description of self-organization and emergent properties clearer. Striped and mottled patterns are found throughout nature – on a zebra's coat, on a fish's skin, and in the ocular dominance columns of the brain (Figure 2). Experimental and theoretical work suggests that these patterns develop from a few simple rules that are continually iterated among the components of the system. Suppose, for example, that each pigment cell on a zebra's coat could either produce a dark pigment or not, depending on a certain chemical activation above or below a certain threshold level. Further suppose that the cells in the skin produced both a chemical activator and an antagonistic inhibitor (called 'morphogens'), which both diffused through the skin. The rules regulating the state of each cell – either 'on' (producing pigment) or 'off' (not producing pigment) – depend on the relative strengths of the activation and inhibition,

their diffusion rates, the initial distribution of the cells, and their thresholds for pigment production.

In 1952, Alan Turing first suggested the general scheme for this mechanism of self-organized pattern formation. In 1972, A. Gierer and H. Meinhardt developed a model as shown in Figure 3. Their system has a series of sites that are the source of a short-range activator, which has two functions: to promote its own productions (autocatalysis), and to cause an increase in the production of an antagonist, the inhibitor. Since the inhibitor diffuses rapidly into the surroundings, the result is a local increase in the activation and a long-range antagonistic effect that restricts the self-enhancing reaction and keeps it localized.

SIMULATION OF SELF-ORGANIZING SYSTEMS

Because of the difficulty of predicting the behavior of these systems, computer simulations are a useful means of performing 'thought experiments' and for better understanding how these systems work. One method of modeling these systems is by the use of nonlinear differential equations. Another method is to simulate the system by means of cellular automata.

A cellular automaton is a simulation that is discrete in time, space, and state. Typically, the components (cells) of the system are arranged on a two-dimensional grid or lattice. Each cell is characterized by its location on the grid and its condition (state). Cells interact with each other according to a set of simple rules which take into account their proximity to neighboring cells, their own state, and the states of their neighbors. The rules specify the transition of the cell from one state to another as the system evolves over time.

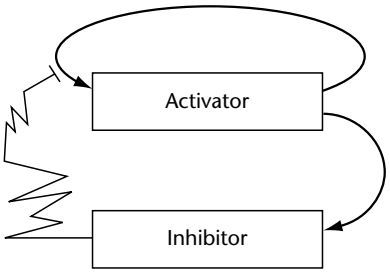

Figure 3. Reaction scheme for pattern formation by autocatalysis and long-range inhibition. The two arrows denote activation, with the activator stimulating both its own production (autocatalysis) and that of the inhibitor. The jagged line shows the effect of the inhibitor which provides negative feedback by inhibiting the effect of the activator. Adapted from: Meinhardt H (1995) *The Algorithmic Beauty of Sea Shells*. Berlin, Germany: Springer.

Consider the example of animal coat patterns presented above. This can be implemented as a cellular automaton model that consists of a set of cells laid out on a grid. Each cell is initially assigned a state randomly, 'on' or 'off'. Each 'on' cell is assumed to produce a specified amount of activator and a specified amount of inhibitor that diffuse at different rates across the grid. In the simulation, each 'on' cell is represented as black and each 'off' cell is represented as white. At each timestep, the program calculated the net amount of activation at each site on the grid. This is determined as the difference between the sum of all the activation from the cells in the neighborhood and the sum of all the inhibition from those cells in the neighborhood. If this total is above a prespecified threshold level, then the cell at that site is assigned the 'on' state; otherwise, it is assigned the 'off' state. In this manner, cells switch from one state to another according to a single rule. The program continually iterates the rule, causing a pattern to emerge from the initial random array of 'on' and 'off' cells, as shown in Figure 4. For one set of diffusion rules, an irregular mottled pattern develops. When the

conditions are changed slightly, a zebra-stripe pattern develops. The only differences between the two examples shown are that in the zebra-stripe pattern the diffusion of the activator and inhibitor is greater in one direction than the other, and that the relative strengths of the activator and inhibitor are different in the two cases.

SELF-ORGANIZATION IN THE NEURAL AND COGNITIVE SCIENCES

To understand the brain is one of the greatest challenges in biology. The brain of an insect such as a honey-bee contains relatively few neurons – approximately one million. In isolation, each neuron is essentially a simple switch. When stimulated sufficiently, an impulse is fired, and a brief electrical event called the *action potential* moves through the cell from one end to the other. Although the insect brain is miniscule, with relatively few neurons, compared with that of birds or mammals, it nonetheless coordinates very sophisticated behaviors. The honey-bee is arguably more complex than any computer. This tiny insect can navigate by the sun, fly to a food source, make decisions, communicate with other honey-bees, and perform many other complex activities.

The brain achieves this complexity largely through the connectivity of its elements and their interactions. Each neuron is connected to others through synapses, which form a vast network of dense interconnections. In ways that we are just beginning to understand, this connectivity is the basis of the brain's enormous complexity.

Neuroscientists are beginning to understand both how these connections among the neurons develop and how their interactions make cognition possible. Both of these processes rely, in large part, on self-organization. One of the great mysteries of biology is how the enormous morphogenic, physiological, behavioral, and cognitive complexity of an organism can be achieved with the limited amount of genetic information contained within the genome. It is inconceivable that the pattern of connections for each neuron in the brain could be genetically coded. Rather, there must exist special mechanisms for economizing on the amount of information that must be coded within the genes. Self-organization is such a mechanism. For example, the pattern of ocular dominance stripes in the visual cortex of the brain (Figure 2(c)) is a characteristic morphogenic feature of neuroanatomical organization. The neural inputs from each eye to the visual cortex in the back of the brain consist of a series of alternating stripes. This architecture is believed to play an important role in how the brain organizes and interprets visual information received by the retina. This functional architecture can be seen by injecting radioactive proline into one eye, and making autoradiographs of sections of the cortex. The resulting pattern is reminiscent of the stripes seen on a zebra's coat or the ridges of a sand dune. These patterns are believed to arise through a self-organizing activation–inhibition mechanism similar to that described above.

Studies such as these suggest that through natural selection, organisms can evolve mechanims that rely on relatively simple sets of rules – algorithms economically encoded in the genome. Through self-organizing processes these algorithms can generate the enormous complexity seen in biological systems. The result has been the evolution of complex morphological and physiological adaptations and behavioral and cognitive abilities.

Semantic Memory: Computational Models

Intermediate article

Timothy T Rogers, Medical Research Council, Cambridge, UK

CONTENTS

Semantic memory encompasses knowledge about the meanings of words, objects, and events. Computational models of semantic memory describe explicit mechanisms for the storage, representation, and retrieval of semantic information. Three modeling approaches are discussed in this entry: hierarchical processing models, similarity-based categorisation models, and connectionist models.

INTRODUCTION

Semantic memory is typically defined as memory for the meaning of words and objects. It can encompass knowledge about object properties (e.g. dogs have fur, hearts, and bones) and arbitrary facts (e.g. Napoleon was defeated at Waterloo), as well as the meanings of verbs, abstract nouns, and events, though most research in the domain has focused on understanding human knowledge about concrete objects and their properties. Semantic memory is *explicit*, in that its contents are accessible to conscious awareness, and *declarative*, in that these contents may be described verbally. In contrast to episodic long-term memory, semantic memory is not typically associated with a particular place and time – for example, although most everyone knows the meaning of the word 'dog', they do not tend to remember specifically where and when they first learned this information.

The basic research question posed by most theories of semantic memory is: how do human beings know which objects in the world have which properties? For example, upon encountering an unfamiliar dog for the first time, we are able to make a broad range of inferences about it: we know that it is called a 'dog', that it barks, it likes to chase sticks, it may bite, it has internal organs, it can grow, etc. We know these things despite having never previously encountered this particular dog. What accounts for this remarkable human capacity?

One view with a long provenance in philosophy and cognitive science posits that semantic memory is subserved by a process of categorization. We can make appropriate inferences about the properties of an unfamiliar object when we know what class it belongs to, because we have stored information about these classes generally. On this view, semantic task performance is a process of logical inference: in the classical syllogism, Aristotle infers that Socrates is mortal by categorizing him as a *man*, and consulting his knowledge about the class (Socrates is a man; all men are mortal; therefore, Socrates is mortal). For much of the history of the study of cognition, the dominant view has been that semantic knowledge is stored in memory as a system of concepts and propositions of this sort. In the twentieth century this view has begun to change, thanks in part to rapid advances in computational modeling of cognitive and neural processes during the past thirty years.

Computational approaches to semantic memory fall into three broad classes, which will be reviewed in this entry: *hierarchical processing models*, such as the spreading activation model proposed by Collins and Quillian (1969); *similarity-based categorisation models*, which include category prototype theories as well as exemplar or instance-trace theories; and *connectionist* or *parallel distributed processing* (PDP) models.

HIERARCHICAL PROCESSING MODELS

One of the earliest and most influential computational theories comprised an effort to directly implement semantic memory as a system of logical inference involving stored concepts and propositions (Collins and Quillian, 1969). In this model, shown in Figure 1, different concepts are represented as discrete nodes, whereas different

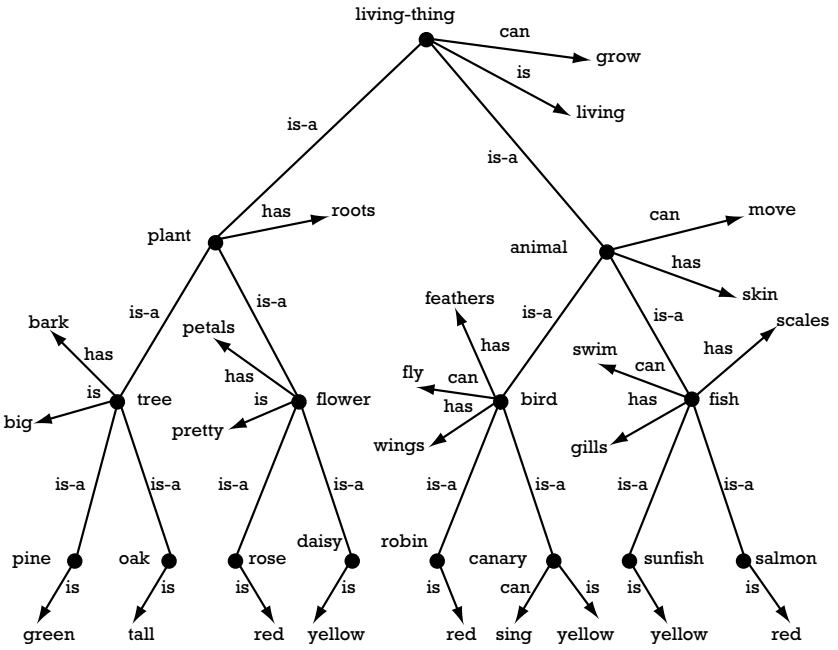

Figure 1. Collins and Quillian's (1969) hierarchical spreading-activation model. Individual concepts are represented as nodes, and propositions describing the relations between concepts are represented as links between nodes. Reprinted from Figure 4 of McClelland et al. (1995).

propositions are represented as labeled links. Semantic knowledge is represented in the model by the particular set of nodes and configuration of links that constitute the 'semantic network'. For example, the nodes labeled *robin* and *bird* in the illustration indicate that the system has stored knowledge about the class of birds and robins separately. The link between the *robin* and *bird* nodes (labelled *isa*) indicates knowledge that robins are a subset of the class *bird*. The link between *robin* and the concept *red* (labelled *is*) indicates that items in the class *robin* are likely to be red.

The diagram provides a concise description of the contents of semantic memory, but it was also intended to illustrate a processing model of semantic storage and retrieval. Information could be stored simply by adding new nodes and links to the network, or by altering the configuration of links between nodes. To store a new fact such as 'a wren is a kind of bird', one would create a new node corresponding to the concept *wren*, and attach it to the *bird* node with an *isa* link. To search memory, the authors proposed a *spreading activation* mechanism, by which the activation of a concept in memory would spread outward along stored propositional links, resulting in the activation of related concepts (and hence retrieval of semantic information stored with these nodes).

One appeal of the Collins and Quillian model stems from the observation that category membership for more inclusive categories (such as *animal*) entails properties true of more specific categories (such as *dog* or *german shepard*). These properties need only be stored with the more general category node, and will be inherited by more specific concepts as a consequence of the spreading-activation mechanism. For example, a property such as *has blood* need not be stored separately with each different animal concept (e.g. *goat*, *pig*, *dog*, *bird*) but can be stored once with the more inclusive concept *animal* and will extend to these more specific concepts by virtue of stored class inclusion links in the semantic network.

Quillian wrote a computer program that implemented the proposed architecture and memory-search procedure for semantic networks similar to the one shown in Figure 1. The implemented model allowed the authors to make empirical predictions about the processing time that would be needed to perform different kinds of semantic tasks. For example, they devised a sentence verification task in which participants listened to simple propositions such as 'all birds have wings', and had to decide as quickly as possible whether the proposition was true or not. On the basis of the model, Collins and Quillian predicted that sentences would take longer to verify when their terms were distal (i.e. separated by many links) in the semantic network than when they were proximal. Early work seemed to confirm this prediction – participants

were faster and more accurate to verify propositions separated by a single link (e.g. 'all robins are birds') than those separated by many links (e.g. 'all robins are animals'), just as was the computer program. Collins and Quillian and others used the theory to explain further data from a broad range of semantic tasks, including priming experiments, category fluency studies, and several different permutations of the sentence verification paradigm.

However, some results from the sentence-verification procedure were not explained by the original spreading-activation theory, and others directly contradicted the model's predictions. For instance, subjects are faster and more accurate at verifying the properties of typical category members (e.g. a robin is a bird) than those of atypical members (e.g. a penguin is a bird). Since both penguin and robin concepts are attached directly to the bird node in the semantic network, there is no reason why propositions about one should take longer to verify than propositions about the other. Moreover, subjects are sometimes faster to categorise atypical items at a superordinate rather than an intermediate level – verifying the sentence 'a chicken is an animal' more quickly than the sentence 'a chicken is a bird'. This result was not compatible with Quillian's implemented model, because there was no way for activation to spread in the hierarchy from *chicken* to *animal* without passing through *bird*. Finally, the empirical phenomena that were accounted for by the theory turned out to be susceptible to confounding factors other than the distance between terms in a semantic network, such as concept familiarity and typicality. Once these factors are taken into account, it is not clear that distance in the semantic network adds any explanatory power. Responding to these challenges, Collins and Loftus (1975) adapted the original framework by adding link strengths, activation thresholds for concept nodes, and various other constructs. Though they did not implement these in a computational model, these ideas have been incorporated into subsequent implemented spreading-activation-style models. (*See* **ACT**; **Semantic Networks**)

The strong influence of Collins and Quillian's (1969) theory is due in part to the specific and testable empirical predictions derived from Quillian's implemented model. Challenges to these predictions set the stage for further study. For example, where the spreading-activation theory concerned itself with how inferences were made once a given category representation had been activated in memory, it neglected the important question of how objects in the world were categorized in the first place. With the data mined from the property-verification task, several interesting theoretical questions presented themselves. Why were typical category exemplars easier to categorize than atypical exemplars? How did familiarity and frequency exert their influence on storage and retrieval processes? How was information about different classes extracted from the environment in the first place? These questions lead to an increasing focus on understanding mechanisms of categorization.

SIMILARITY-BASED CATEGORIZATION MODELS

Categorization-based theories of semantic memory come in two varieties. *Prototype theories* propose that knowledge about classes is stored in summary representations that describe the properties typical of category members (Rosch and Mervis, 1975). Usually prototypes take the form of a vector of attributes. For example, the prototype for the category *dog* might include features such as *is furry*, *isa pet*, *has four legs*, *can bark*, etc. To make appropriate inferences about a novel object, prototype models compare the object's observed properties to the known properties of stored prototypes, and assign the item to the category with the best fit according to some measure of similarity. Other properties stored with the prototype are then retrieved and attributed to the object. One appeal of prototype theories is that they offer an intuitive means of explaining the influence of typicality on semantic task performance. By definition, typical exemplars of a category have many properties in common with other members of the class and few distinguishing characteristics. Hence, typical members will more closely match the category prototype than will atypical members, and are faster and easier to categorize.

Like category prototype theories, *exemplar* or *instance-trace* (e.g. Nosofsky, 1988) theories propose that information about objects and categories is stored in discrete feature-vector representations, and is accessed by measuring the similarity between a probe stimulus and stored representations. Rather than storing summary representations of different categories, however, instance-trace theories propose that a separate representation (or memory-trace) is stored for each individual object or event experienced in the environment. During retrieval, a probe stimulus activates each trace in parallel in proportion to its similarity to the probe; for example, upon encountering a novel dog in the world, the system will activate stored traces of

other encounters with particular dogs. Properties common to these traces (e.g. *has fur*, *has four legs*, etc.) are stored with every individual trace and hence are likely to be retrieved successfully. The idiosyncratic properties of each particular dog are supported by only a small number of traces, and hence are not likely to be attributed to the unfamiliar dog.

Like prototype theories, instance-trace theories can explain typicality effects in categorization and property-verification tasks: because typical exemplars share many properties with other category exemplars, they will be similar to many stored instance traces and will activate all of these in parallel, resulting in rapid retrieval of properties shared by the class. However, instance-trace theories can also explain experimental data showing that knowledge about individual familiar instances can influence information processing speed and accuracy in certain experimental paradigms (see Whittlesea, 1987). Category prototype theories have difficulty with such findings, because they assume that information about individual items is subsumed in the prototype representation and is not retained in memory – thus processing speed and accuracy should not be influenced by similarity to the particular training instances. Prototype theories and instance-trace theories represent a trade-off between explanatory power on the one hand and representational capacity on the other: though instance-trace theories may explain a broader range of data, category prototype theories offer a more economical means of storing information in memory.

Both kinds of similarity-based models encounter computational difficulties that neither has yet resolved. In both cases, the attributes of an object are usually assumed to contribute independently to the similarity metric that determines their match to representations in memory. However, the weight that should be given to a particular attribute can depend upon the category of the object, or on the other attributes that constitute the stimulus description. For example, color is an important attribute when considering whether a particular fruit is an orange or a grapefruit, but it is irrelevant when considering whether a particular car is a Ford or a Chrysler. Whether or not color should be considered when categorizing a particular object, then, depends upon whether the object is a car or a fruit – but the category cannot be determined until the similarity between the probe and the representation has been computed.

This difficulty can be overcome in a model with hierarchical processing structure. For example, suppose that a particular object can be classified as a kind of fruit on the basis of its shape and texture. In a hierarchical model, knowledge about how other properties (such as color) should be weighted can be stored with the *fruit* representation, and used to constrain more specific category assignments (e.g. *orange* or *grapefruit*). However, the apparent simplicity of this idea is belied by the difficulty of implementing such a theory in a computational model.

CONNECTIONIST NETWORKS

The third computational approach offers a quite different means of understanding semantic memory storage and retrieval processes. *Connectionist models* propose that semantic knowledge is stored in the configuration of weights in a neural network which performs mappings between perceptual representations of words and objects, and internal semantic representations. In the connectionist paradigm, representations take the form of patterns of activity across a set of simple, neuron-like processing units. Different pools of units encode different kinds of representations. For example, the phonological structure of a spoken word might be encoded by a pattern of activity across one pool of units; the visual appearance of an object might be coded by a pattern of activity across another; and an object's semantic representation might be coded by patterns of activity across a third pool. Just as neurons in the brain communicate with one another by sending chemical signals across synapses, the units in connectionist networks communicate their activation states by means of weighted connections with other units in the system. Information processing proceeds by the successive updating of unit states in response to inputs. The way that downstream units respond to a given input depends upon the particular configuration of interconnecting weights: when the weights are set so that the system can produce correct outputs in response to probes, the system can be said to 'know' the domain. (*See* **Connectionism**)

Hinton's Distributed Semantic Network

One of the seminal connectionist models of semantic memory was proposed by Hinton (1981). Hinton's model, shown in Figure 2, consists of several banks of simple neuron-like processing units, grouped into layers and connected as indicated in the illustration. The architecture of the model reflects the structure of a simple proposition, with one bank of units (labeled *Object*) representing the

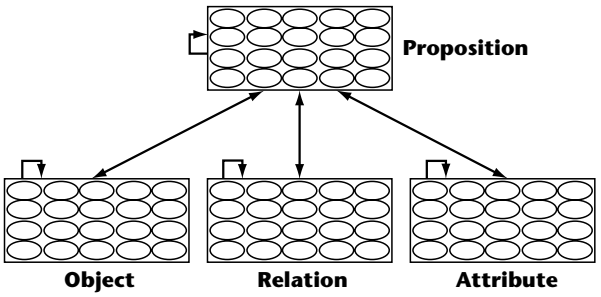

Figure 2. Hinton's (1981) PDP model of semantic memory. Each term in a simple proposition (e.g. 'Clyde isa elephant') is represented by a pattern of activity across the corresponding pool of units. Units in different pools interact with one another by means of weighted connections with units in the pool labeled *Proposition*. Individual propositions can be stored by adjusting the weights within and between pools, so that the patterns of activity corresponding to the terms of the proposition are stable. Redrawn with alterations from Hinton (1981). Permission pending.

first term, one bank (labeled *Relation*) representing the proposition, and one bank (labelled *Attribute*) representing the second term. Different fillers for these three slots are coded by different patterns of activity across the corresponding units.

All three banks of units send projections to (and receive projections from) a fourth layer, labeled *Proposition* in the figure. The sign and magnitude of each weight determines how the activity of the sending unit will influence the state of the receiving unit. When an input is presented to the network, each unit updates its state by taking a weighted sum across all units from which it receives projections (with the contribution of each sending unit weighted by the strength of the intervening connection). Thus when a proposition is given to the network as input, activity in the *Object*, *Relation*, and *Attribute* layers gives rise to a pattern of activation across the *Proposition* units. These units in turn send new signals to the *Object*, *Relation*, and *Attribute* units, which update their states accordingly. The process iterates until the unit states stop changing, at which point the network is said to have *settled* into a steady state. Hinton demonstrated that individual propositions could be stored in the network, by adjusting the weights to make the patterns representing the proposition stable. Each stored proposition would then be represented in the network by a unique pattern of activity across the *Proposition* units, which simultaneously activated and received support from the input patterns.

Like the spreading-activation model, the network was capable of completing stored propositions when given an appropriate cue as input. For example, if the model was taught the proposition *Clyde isa elephant*, and was then given the incomplete input *Clyde isa*, it would settle into a steady state in which the pattern representing the correct completion of the proposition (*elephant*) was observed across the *Attribute* units. This retrieval mechanism also provided an account of knowledge generalization quite different from that embodied in the Collins and Quillian model. If related objects (such as various individual elephants) were represented by overlapping patterns of activity across the *Object* units, they would contribute similar inputs to the *Proposition* units. Thus, the entire network would tend to settle into an appropriate steady state (corresponding to the most similar stored proposition) when given a novel input that overlapped with familiar, stored patterns. For example, if the network had stored the proposition *Clyde is gray*, and was then given the inputs *Elmer is* in the *Object* and *Relation* units, it would settle to a state in which the pattern corresponding to *gray* was observed across *Attribute* units – provided that the representations of *Clyde* and *Elmer* were sufficiently similar.

Extensions of Hinton's Approach

Where the architecture of Hinton's model reflected the structure of simple propositions, subsequent approaches have employed architectures that more closely capture the functional organisation of the cortex. One common architecture is shown in Figure 3. Visual representations of objects are represented by patterns of activity across *Visual* units; the perceptual structure of spoken words or statements is represented by activity in the *Verbal* layer; and semantic representations are encoded in the activity of the *Semantic* units. Words with similar sounds (such as 'cat' and 'bat') give rise to similar patterns of activity across *Verbal* units, whereas objects with similar appearances (e.g. a bat and a bird) give rise to similar patterns of activity across *Visual* units. Units in the *Semantic* layer perform the mappings between phonological and visual layers, just as did the *Proposition* layer in Hinton's model. When semantically related objects are represented with similar patterns of activity in this layer, the architecture provides a mechanism for the generalization of stored knowledge to novel items on the basis of semantic relatedness.

In this framework, storage of semantic knowledge involves the gradual adjustment of the weights that connect units within and between pools in the system, so that activation of a given

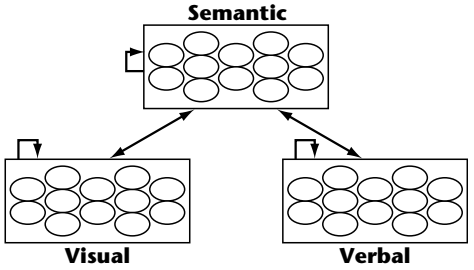

Figure 3. A common connectionist architecture for semantic memory which is more consistent with the gross functional anatomy of cortex. Verbal units code the perceptual structure of speech sounds; Visual units code the visual structure of a perceived object; and Semantic units code the semantic similarity relations existing among objects in the world.

Visual or *Verbal* representation will give rise to the appropriate pattern of activity across other pools. Several powerful learning algorithms have been proposed for finding weights that will allow models like the one in Figure 3 to perform the correct mappings.

Acquisition of Semantic Representations

Whereas the models described above assign prespecified semantic representations to objects, other approaches have explored how such representations might be acquired through learning in a connectionist network. For example, Rumelhart and Todd (1993) demonstrated that the propositional content contained in Collins and Quillian's hierarchical model could also be coded in the distributed representations acquired by a connectionist network trained with backpropagation. Their model is shown in Figure 4: entities in the environment are represented by individual input units in the layer labeled *Item*; different propositional relations are represented by individual units in the layer labeled *Relation*; and the various completions of different propositions are represented by units in the layer labeled *Attribute*. In order to answer queries about various items, the network must find a configuration of weights that will produce the correct states across output units when a single *Item* and *Relation* are provided as inputs. However in this case, the mediating representations are unspecified. Instead, weights throughout the model are initially set to small, random values, and the network is trained with backpropagation. (*See* **Backpropagation**).

The activation of a single input unit generates a distributed pattern of activity across *Representation* units; and when the model's weights are small and random, every input produces a similar pattern of activity throughout the network. Because semantically related items share many attributes in the output, they give rise to similar error signals early in learning, and produce similar weight changes throughout the network. Consequently the network continues to generate similar patterns of activity across the *Representation* units for related items as it learns, but gradually differentiates its representations of unrelated items. Ultimately, the internal representations acquired by the network capture the semantic similarity relations that exist among the objects in its environment; and this learned similarity structure can provide the basis for knowledge generalization.

Neuropsychological Models

A further advantage of the connectionist framework is that, because the learning and information processing principles it adopts are grossly consistent with those known to operate in the brain, models developed in this tradition offer a means of understanding how the functional anatomy of cortex supports semantic cognition. Consequently, connectionist models of semantic memory have probably had their strongest impact in the domain of neuropsychology.

To understand neuropsychological impairment in a connectionist framework, theorists begin with a working model of the phenomenon in question, and investigate how the model's behavior changes when the knowledge stored in its weights is disrupted by simulated lesions. For example, several studies have shown that semantic knowledge about living and nonliving things can be doubly-dissociated as a consequence of neural trauma. Warrington and Shallice (1984) suggested that this pattern might arise as a consequence of the sensory-motor organisation of the cortex, assuming first that knowledge about the sensory and functional properties of objects are stored in separate areas of cortex that may be damaged independently; and second, that functional information is more important for the representation of nonliving things, whereas the reverse is true living things. Under these conditions, damage to areas of cortex subserving functional versus perceptual knowledge would differentially affect knowledge of nonliving and living domains.

Farah and McClelland (1991) proved the feasibility of this hypothesis in a computational model

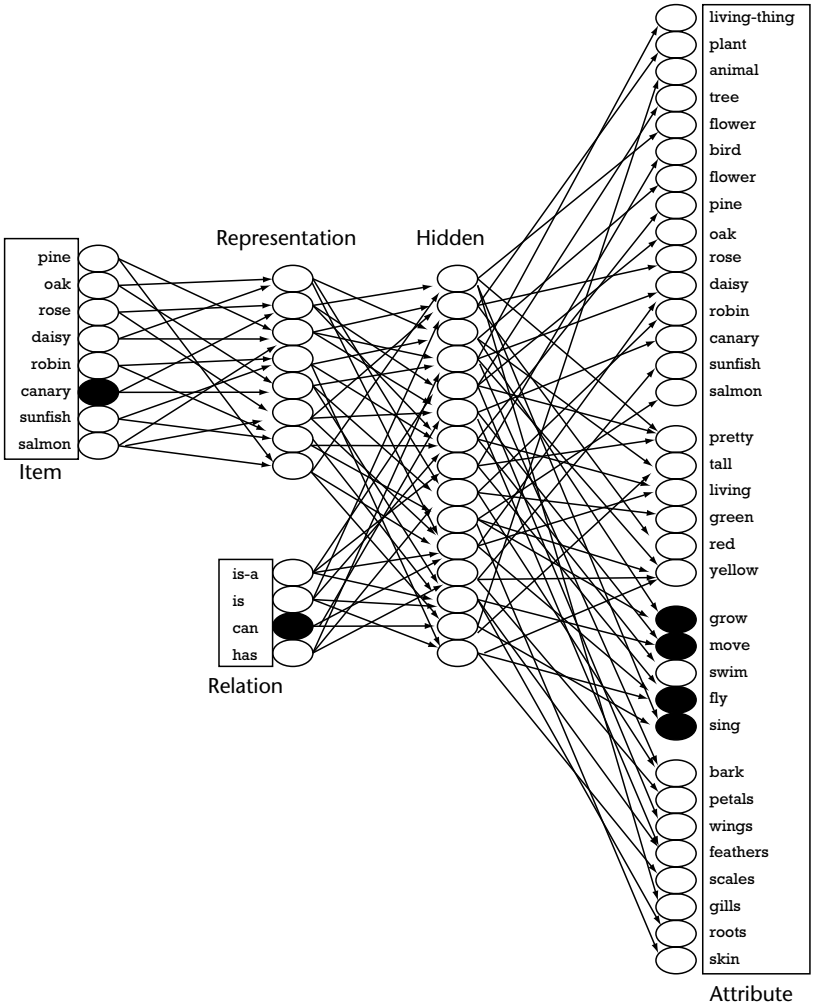

Figure 4. A feed-forward model of semantic memory described by Rumelhart and Todd (1993). As it learns to complete various propositions, the network constructs distributed internal representations for the objects in its environment that capture their semantic relations. Based on the network depicted in Rumelhart and Todd (1993).

with an architecture similar to that shown in Figure 3. They created *Verbal, Visual*, and *Semantic* representations of objects by generating patterns of activity across each of these pools. However, they also assumed that some of the units in the *Semantic* layer would be responsible for encoding primarily functional information (*functional-semantic* features) whereas others would encode primarily perceptual information (*perceptual-semantic* features). To capture the intuition that living things rely to a greater extent on perceptual information than do nonliving things, they created semantic representations of living things that had many perceptual-semantic features, and representations of nonliving things that had relatively few. The model was then trained to associate visual, verbal, and semantic representations, using an error-correcting learning algorithm.

Once the model had learned to perform the correct mappings, the authors investigated its behavior under simulated lesions to either the functional-semantic units or the perceptual-semantic units. They found that, when perceptual-semantic units were lesioned, the model was frequently unable to produce the correct name in response to a visual input – but that this deficit was much more apparent for living things than nonliving things. When functional-semantic units were lesioned, the reverse was true: the model had a more difficult time retrieving the correct name for nonliving things.

The Farah-McClelland model challenged the conclusion often drawn from double-dissociations in the case literature, that the pattern of data reflects the existence of independent subsystems that are specialized to each dissociated function. In this

case, the model showed that knowledge of living and nonliving things might be doubly dissociated, without there being independent systems for representing each domain. It also demonstrated that the sensory-functional hypothesis had some appealing and counter-intuitive implications. For example, although the model showed worse performance for living things relative to nonliving things when its perceptual-semantic units were damaged, its performance with nonliving things was not perfect. The same is also true of patients: so-called category-specific deficits are almost invariably accompanied by milder impairment of knowledge for objects in the relatively spared domain.

FUTURE DIRECTIONS

The models reviewed in this entry mark a progression from formal logical approaches to semantic cognition, involving the storage of discrete concepts and propositions, toward somewhat more graded and distributed schemes in which the similarity structure of internal representations guides semantic knowledge generalization. Connectionist models provide a means of linking intuitions about similarity-based representation to principles of information processing known to operate in the brain, and to the functional neuroanatomy of cortex at a gross scale. Such models offer great promise for a detailed and mechanistic account of semantic knowledge about concrete objects. However, the scope of semantic knowledge extends far beyond concrete object knowledge. Very little computational work has been done to understand knowledge about the meanings of verbs and abstract words, relations between objects, events, actions, or complex scenes. One appeal of propositional approaches to conceptual knowledge is that they may extend well to these domains: under such theories, knowledge about abstract words and verbs may be stored as sets of concepts and propositions, just as is knowledge about concrete objects. A challenge for similarity-based and connectionist models in future will be to account for such knowledge using the same principles of knowledge acquisition and processing that explain concrete object knowledge.

Sentence Processing

Introductory article

Michael K Tanenhaus, University of Rochester, Rochester, New York, USA

CONTENTS

Sentence processing is the study of the representations people form as they understand a sentence or utterance and the mechanisms underlying the component processes. These include recognizing the words in a sentence, determining the syntactic and semantic relationships among these words, and interpreting the sentence with respect to the relevant linguistic and non-linguistic context.

INTRODUCTION

The goal of research in sentence processing is to understand the representations people form as they understand a sentence and the processes involved in developing these representations. Sentence processing involves recognizing the words in a sentence, determining the syntactic and semantic relationships among these words, and interpreting the sentence with respect to the relevant linguistic and nonlinguistic context. These processes draw upon specifically linguistic knowledge as well as knowledge about the world and how people use language for purposes of communicating their ideas, goals, and intentions. The interdisciplinary community that addresses issues in sentence processing includes linguists, computer scientists, and psychologists, and it draws upon theoretical ideas and methodological tools from each of these disciplines.

During comprehension, readers and listeners construct a mental model or discourse model. In order to build the model, the comprehender must recognize each of the words in the sentence and determine the syntactic (and semantic) relationship among them, as defined by the grammar of the language. The process of assigning syntactic relationships is generally referred to as 'parsing', though this term is sometimes used to include both the assignment of syntactic relationships and interpretation. As a result of parsing the sentence, the comprehender can determine the 'message' expressed by the sentence, i.e. who did what to whom.

As the propositional content of the sentence is extracted, new events and entities are introduced into the model and reference is made to those that have already been introduced. Referring expressions known as 'anaphors' and other contextually dependent expressions play a primary role in this process. In addition, readers and listeners may routinely incorporate some inferences that are triggered by information in the sentence, the context of the sentence or utterance, and general world knowledge.

As an example, consider the sentence, *The student spotted by the proctor was expelled*. Syntactically, *student* is the head noun in the definite noun phrase *the student spotted by the proctor*, which is the subject noun phrase for the verb phrase *was expelled*. *The student* is modified by a relative clause (*spotted by the proctor*). Both the main clause and the embedded clause are in the passive voice and both are in the past tense.

Semantically, the sentence describes two events: a spotting event and an expelling event, each of which takes place in the past. The proctor and the student are discourse entities who each participate in the spotting event in different ways or modes, commonly referred to as 'thematic roles'. The proctor is the agent of the spotting event – the one doing the spotting – and the student is the theme or patient – what is being spotted. The student is also the theme or patient of the expelling event. Thematic roles are closely linked to the syntactic relationships among verbs (and other relational words) and their syntactic complements or arguments.

The syntactic and semantic relationships in a sentence are in large part determined by

constraints defined by the structure of the language. However, the way that they are recovered in sentence processing is strongly influenced by the sequential nature of the input. The input is sequential in spoken language because auditory stimuli are composed of transient acoustic events. The input is sequential in written language because readers typically fixate successively on each word in a sentence, processing only a limited amount of information from the periphery.

IMMEDIACY OF COMPREHENSION

Many aspects of sentence processing are remarkably time-locked to the unfolding linguistic input. Access to the semantic representations of spoken words begins as soon as phonetic input is encountered. By the middle of the first vowel in *student*, potential lexical candidates, such as student, stool, and stoop are becoming active in memory, along with their associated syntactic and semantic representations. In the absence of strongly constraining context, convergence on the most likely lexical candidate occurs shortly after enough phonetic input is received to distinguish the input from other likely alternatives – often well before the word ends. Constraints based on prior syntactic, semantic, and discourse constraints further increase the speed with which a word is identified, suggesting that semantic integration takes place in parallel with lexical access. Syntactic processing occurs equally quickly. When a sentence becomes syntactically anomalous, processing effects are observed immediately after the word where the anomaly occurs. Moreover, when a sentence that is briefly ambiguous between two or more syntactic alternatives is disambiguated in favor of its less preferred alternative, processing consequences are observed as soon as the disambiguating information is encountered. Similar effects are observed for semantic and pragmatic anomalies.

Methodological Consequences

The speed with which sentences are comprehended has led researchers to focus on 'on-line' experimental measures that are closely time-locked to the input. The most widely used methodologies include:

1. monitoring tasks in which a participant subject is timed while monitoring the incoming linguistic input for various linguistic units, e.g. a target phoneme, word, member of a category or a rhyme;
2. probing and priming tasks in which the developing representation is probed by examining response times to targets that occurred in the sentence or are related to a word or a phrase in the sentence;
3. participant-controlled or self-paced reading in which reading times are measured while subjects read text in presentation 'windows' of various sizes;
4. monitoring event-related potentials (ERPs) as subjects read or listen to sentences; and
5. monitoring eye fixations as participants read text or listen to spoken utterances in the context of visual displays containing potential referents.

AMBIGUITY

Nearly all sentences contain numerous temporary ambiguities as they unfold over time. While ambiguity exists at all levels of language comprehension, from categorizing a phoneme to recognizing a speaker's intentions, researchers in sentence processing have been primarily concerned with how readers and listeners resolve the structural ambiguity that arises in assigning grammatical relationships to words and phrases as a sentence unfolds.

Structural ambiguity arises because of several characteristics of natural language. Linguistic forms such as words and morphemes are frequently ambiguous with respect to their syntactic category, and tense and voice (e.g. *spotted* could be either an adjective or a verb, and as a verb it could be a past tense form of a passive participle). Syntactic structure is hierarchical and, at least partially, recursive, resulting in frequent dependencies between non-adjacent words and phrases. Returning to the example, *The student spotted by the proctor was expelled*, the noun phrase *the student spotted by the proctor* contains a sentence embedded within a noun phrase. Consequently, *the student* is the subject of the verb *expelled* even though several words intervene, including another noun phrase, *the proctor*. Similarly the verb *was* agrees in number with the noun *student*, and not the most local noun *proctor*.

Ambiguous forms and non-adjacent grammatical dependencies often combine to result in fragments that are temporarily ambiguous among multiple syntactic structures. For example, *the student spotted …* is ambiguous between a past tense main clause in the active voice (e.g. *The student spotted the proctor*) and a relative clause (e.g. *the student spotted by the proctor …*).

The alternative syntactic structures for a temporarily ambiguous fragment typically have different semantic and discourse consequences. As a result, information at these higher levels could provide constraints that are relevant to resolving ambiguities at lower levels. For example, in a main clause, *the student* would be assigned the agent thematic

role (i.e. the agent of the spotting event, whereas it would be assigned the theme role in a relative clause. Therefore, the thematic fit of the noun phrase to each of these potential roles could be useful in resolving the syntactic ambiguity. *Student* is both a good agent and a good theme for a spotting event; however, another noun such as *crib sheet* is a good theme but a poor agent. Thus, thematic fit might be used to help disambiguate a fragment such as *the crib sheet spotted …* in favor of a relative clause at the verb.

A past tense main clause and a (restrictive) relative clause also differ with respect to how they would be integrated into the discourse model. A main clause is used to introduce a new event into the model, whereas a restrictive relative clause can be used to refer to an already established event. Thus the felicity with which each type of event could be incorporated into the model in specific discourse contexts is another potential source of constraint.

Beginning with the classic work by Bever in 1970, sentences with local syntactic ambiguities have served as a primary empirical base for developing and testing models of syntactic processing.

Processing modularity

The question of how and when the processing system exploits correlated constraints has played a central role in research on sentence processing. Two broad classes of approaches to these questions have been explored, each of which explaining the speed and efficiency of sentence processing differently. One approach, which has its roots in Marslen-Wilson's early work, assumes that the processing system is able to rapidly and optimally integrate different types of information by taking advantage of correlated constraints to evaluate the evidence for multiple alternatives. In these constraint-based or interactive approaches, use of correlated constraints is what underlies the speed and efficiency of on-line comprehension. As a consequence, processing at different levels is closely intertwined. For example, lexical and syntactic processing are interleaved with the interpretation and construction of a discourse model. Constraint-based approaches are increasingly drawing upon constructs drawn from neural network models.

A second approach posits informationally encapsulated subsystems or modules, each of which is responsible for processing distinct types of representations. In modular models, the speed and efficiency of on-line comprehension arises, in part, because certain processes are insulated from others. Thus correlated constraints are ignored in initial processing. Fast mandatory processes are often viewed as restricted to recovering the syntactic and perhaps semantic relationships defined by the grammatical structure of the sentence. These processes are insulated from higher-level interpretative and inferential processes that relate a sentence to its context.

These contrasting perspectives lie at the center of the modularity debate that played a prominent theoretical role in sentence processing research, especially research on lexical and syntactic processing during the 1980s and early 1990s. The modularity issue is closely intertwined with questions about the nature of linguistic representation and how grammatical knowledge is accessed and used in processing. Together these issues have played a central role in sentence comprehension research, especially research examining syntactic ambiguity resolution.

PSYCHOLOGICAL REALITY OF LINGUISTIC STRUCTURE

Some of the most influential early research in sentence processing was aimed at establishing the plausibility of controversial ideas drawn from theoretical linguistics. These ideas included the importance of abstract syntactic structure. Nearly all current research in sentence processing incorporates constructs drawn from linguistic theory. However, a subset of research is primarily focused on using experimental data to evaluate competing linguistic hypotheses. This approach typically contrasts predictions generated by different grammatical frameworks. In recent years, work in this tradition has focused on structures in which there are syntactic and semantic dependencies between non-adjacent constituents – structures that some, but not all, syntactic frameworks analyze by postulating phonologically unrealized (empty) categories that result when a constituent has been moved at some level of syntactic representation.

MODELS OF SENTENCE PROCESSING AND AMBIGUITY RESOLUTION

When a sentence containing a temporary ambiguity is resolved in favor of the less preferred alternative, people often experience a feeling of having been led down the 'garden path'. Preferences for particular interpretations of locally ambiguous

sentences are systematic; there is a strong tendency for sentences with similar structures to exhibit similar preferences.

Although the presence of systematic preferences for temporarily ambiguous sentences is well documented, models of sentence processing differ in how they account for these preferences. Models of ambiguity resolution can be divided into classes along two interrelated dimensions. First, models differ in whether they assume that a single syntactic alternative is initially considered (serial models) or whether multiple alternatives are evaluated in parallel. Second, models differ in what information is used when – in the case of serial models to determine the initial analysis, in the case of parallel models to determine the relative viability of the alternatives.

At one end of the continuum are models in which a restricted domain of information, typically syntactic constraints or a subset of syntactic constraints, plays a privileged role in initially structuring the input or ranking the alternatives. For example, in the garden-path model, an encapsulated syntactic processor initially structures the linguistic input, making a provisional commitment to a single structure using decision principles based primarily on structural complexity. Other encapsulated subsystems or modules are assumed to be responsible for other aspects of sentence processing, including lexical access, reference resolution, and assignment of thematic roles. Information from these modules does not inform initial syntactic decisions but is used to evaluate and, if necessary, revise initial syntactic commitments.

At the other end of the continuum are constraint-based models in which rich lexical representations make available multiple syntactic alternatives that are weighted by the frequency of lexical forms and their argument structures in specific syntactic environments. The alternatives are continuously evaluated, using relevant linguistic and nonlinguistic constraints such as the semantic/thematic fit between a phrase and a potential argument position, and the effects of information from the discourse context. A central claim of these models is that the complex patterns of structural preferences and interactions with discourse and local semantic context arise from simple, domain-independent integration mechanisms, without appeal to syntactic complexity as an explanatory primitive. Other models fall somewhere in between these two classes in the degree to which they rely on structural complexity, parallel analysis, and use of multiple constraints.

COMPUTATIONAL MODELS

In contrast to many other areas of cognitive science, including some domains within psycholinguistics, implemented computational models have played a surprisingly limited role in guiding theoretical and empirical research in sentence processing. For example, there are no computationally explicit realizations of the influential class of models that combine explicit assumptions about linguistic structure with decision principles designed to predict the processing environments that will result in explicit syntactic misanalysis and the nature of the recovery process when an initial analysis is incorrect. One reason is that the complexity of the component processes in sentence processing does not lend itself well to developing models that make close contact with empirical data without making numerous ancillary assumptions.

Gibson has developed an explicit model that accounts for word-by-word processing difficulty across a wide range of sentence types using two factors: (1) the number of syntactic predictions that are resolved at a word or phrase and (2) the number of intervening discourse entities over which the predictions must be maintained. These two factors increase difficulty because they require processing resources.

Most constraint-based models assume that probabilistic constraints across multiple levels of representation are continuously combined to weight alternative lexical and structural alternatives according to Bayesian principles. Models incorporating constraint-based ideas are increasingly realized within connectionist architectures. In hybrid models symbolic representations are computed using competition-based connectionist algorithms. For example, Stevenson has developed such a parser that accounts for many behaviorally observed patterns of processing complexity, while Vosse and Kempen adopt a related approach using competition with a lexicalized grammer.

One promising class of learning-based models combines lexicalized grammars with connectionist-based learning principles to predict preferences for locally ambiguous sentences. Another approach uses simple recurrent networks (SRNs) in which the task of the network is to predict the next upcoming word. The input to the network is a sequence of sentences presented one word at a time that is generated from a probabilistic-finite state grammar that mimics the frequency of occurrence of particular words and structures, as determined by prior corpus analyses. SRN models have simulated the relative difficulty of different types of

embedded sentences, including effects traditionally attributed to individual differences in working memory capacity as well as complex patterns of interactions between lexical, structural, and contingent frequency effects.

SOURCE OF CONSTRAINTS

There is an emerging consensus that at least four classes of constraints influence ambiguity resolution and the difficulty of processing unambiguous sentences in reading and listening:

- structural complexity that draws upon limited computational resources
- lexical constraints
- frequency-based constraints
- discourse and pragmatic context.

Computational Resources

The idea that limited capacity working memory resources place important constraints on sentence processing has played a central role in most models of sentence processing since the seminal work of Miller and Chomsky. Most generally, the assumption of limited capacity resources motivates a link between structural complexity and processing complexity. Although the precise nature of these capacity limits has been relatively unexplored, there is an ongoing debate about whether resource capacity limits reflect general or language-specific resource limits.

Miller and Chomsky hypothesized that sentences with multiple center embeddings such as *The student the proctor spotted cheated* are difficult because the *the student* has to be held in working memory while the embedded constituent *the proctor spotted* is processed. *The student* must then simultaneously be assigned the grammatical roles of object of *spotted* and subject of *cheated*. Working memory constraints motivated the need for recoding at clause boundaries in the clausal model proposed by Fodor *et al*. and they provide the rationale for why parsing is serial in the garden-path model. Memory constraints also motivate the two influential parsing principles that guide its syntactic decisions: minimal attachment (choose the syntactically simplest analysis) and late closure (adopt the analysis that incorporates a word or phrase into the most recent constituent). Memory and capacity constraints provide the motivation for differences in processing difficulty in Gibson's and Lewis's models. Similar patterns emerge from simple SRNs trained on representative corpora. These models have capacity limits, and a recency bias, but they do not have a dedicated working memory system.

Lexical Constraints

An ongoing issue in sentence processing is how and when syntactic processing makes use of constraints defined over grammatical categories (e.g. noun verb, preposition) or draws upon constraints that are tied to specific lexical items, such as the difference between the verb *put*, which requires three arguments (e.g. *John put the car in the garage*), an agent, a theme and a location, and the verb *died*, which allows only a single argument (e.g. *John died*). Syntactic and semantic aspects of verb-argument structure are accessed as soon as a verb is recognized and verb-specific constraints are rapidly used in resolving local ambiguities and in projecting upcoming structure, including potential arguments. However, the extent to which lexically based representations are used in parallel with and/or supercede structural constraints defined over syntactic categories (e.g. minimal attachment) remains controversial. The importance of lexically specific constraints can be illustrated by comparing the following two sentences, each of which has the same syntactic structure and sequence of syntactic categories:

The raft floated down the river sank. (1)

The salmon released in the stream spawned. (2)

Most readers find the first sentence confusing because it is difficult to identify *the raft floated down the river* as a relative clause (compare *the raft that floated down the river sank*). However, the second sentence is much easier to understand.

Frequency

The difference in processing difficulty between the example sentences in (1) and (2) is largely due to the frequencies with which the component are used in the syntactic structures in these sentences. Sentences are easier to process when words and structures are used in familiar ways. There is a strong correlation between frequency of use as a transitive verb and the frequency with which a verb is used as a past participle in a relative clause. *Floated* is frequently used intransitively, whereas *released* is nearly always used transitively.

Frequency effects are diagnostic of exposure-based influences, i.e. learning effects. As a consequence, they play an important role in motivating

constraint-based approaches, especially those approaches in which structural constraints are emergent properties of learning-based systems. Other approaches treat frequencies as biases that affect the probabilities with which different structures are chosen. An important issue for such approaches is how to define and constrain the 'grain' at which frequencies are stored by the processing system.

Discourse and Pragmatic Context

Research in language processing has been divided into two very different traditions. The dominant tradition in sentence processing, the 'language-as-product tradition', emphasizes the individual cognitive processes by which speakers create, and listeners recover, linguistic representations – the 'products' of language production and comprehension.

Within the product tradition, studies of context have focused primarily on how discourse referents affect the difficulty of sentence processing, typically focusing on temporally ambiguous sentences. Definite noun phrases presuppose a uniquely identifiable referent (e.g. *the raft*). Many garden-path sentences are temporarily ambiguous between a structure in which a new phrase is introducing an argument and a structure in which that phrase is modifying an existing argument. The typical preference for an argument interpretation is reduced or eliminated when the context provides several possible referents for the definite noun phrase, and the new phrase refers to salient context that disambiguates the referent.

The second tradition, the 'language-as-action' tradition, emphasizes interactive conversation as the most basic form of language use. A central tenet in work within this tradition is that utterances can only be understood within a particular context, which includes the time, the place, and the participant's conversation goals, as well as the collaborative processes that are intrinsic to conversation.

The advent of lightweight head-mounted eye-tracking methodologies has enabled researchers to investigate moment-by-moment comprehension processes in contexts with real-world referents, using tasks in which the language is grounded in well-defined behavioral goals for the speaker and the listener.

When listeners listen to spoken utterances in task-relevant visual contexts, saccades to potentially relevant objects are closely time-locked to the referring expressions in the utterance. Listeners dynamically update mental representations combining the unfolding linguistic input with task-relevant properties of real-world referents that affect the earliest moments of reference resolution and syntactic ambiguity resolution. Whether lexical access, parsing, and reference resolution also require the listener to take into account the common ground between the speaker and the listener is more controversial.

CURRENT TRENDS AND FUTURE DIRECTIONS

For most of the last two decades, research in sentence processing has been (productively) focused on accounting for a somewhat limited set of phenomena involving temporarily ambiguous sentences, with English as the primary target language, and reading as the preferred mode. Important work on these topics continues. However, the field is rapidly expanding to include a wider range of phenomena, including cross-linguistic investigations and investigations of sentence processing in preliterate children, and its development. As investigations of spoken language increase, there is more focus on the role of prosody in comprehension. Work at the interface between syntax, semantics, and pragmatics is increasingly seeking to bridge the language-as-product and language-as-action traditions, often making reference to ideas developed in studies of dialogue systems. Finally, researchers are beginning to examine how people process the types of natural, often disfluent, utterances that occur in spontaneous face-to-face conversational settings.

Sex Differences in Cognition

Intermediate article

Doreen Kimura, Simon Fraser University, Burnaby, British Columbia, Canada

CONTENTS

Men and women are known to differ reliably on a number of cognitive and motor abilities. Some biological influences on such abilities are reviewed.

INTRODUCTION

Men and women have, for several decades now, consistently shown average differences in their cognitive strengths. For example, men excel on some types of spatial abilities, and on mathematical reasoning. Women excel on memory for verbal material (words), and on a function called 'perceptual speed', where rapid identity comparisons must be made, as well as on some measures of verbal fluency. In the motor sphere, men are superior in targeting ability as manifested in throwing accuracy, and women in fine motor skills emphasizing finger dexterity.

Until fairly recently these sex differences were usually attributed to the differing environments that men and women experienced. The claim that the differences were not seen until after puberty was interpreted as supporting that position, though it is equally consistent with a hormonal influence. Since the 1980s, however, research on sex differences has intensified, and it has become clear that exposure to sex hormones early in life has an important influence on adult cognitive patterns. Moreover, some of these differences are present as early as ages three and four (and possibly earlier, could they be appropriately tested), and some of them appear in widely differing cultures. The former overriding salience of socialization as an explanation has thus been significantly diminished.

In fact, most current researchers on sex differences in behavior view them in terms of the long-standing division of labor between males and females during our evolutionary history. Men were responsible for both short- and long-distance hunting and scavenging, and for manufacture and use of weapons. Women foraged near home and cared for the home and for infant children. According to this schema, men were selected for spatial navigational ability and targeting skills, and women for perceptual abilities sensitive to small changes in children or in the home base. Though such theories are difficult to test, they provide a useful interim heuristic for understanding how sex differences might have come about.

WHAT ARE THE DIFFERENCES?

The review below is not exhaustive of all the sex differences in cognition that have been reported. Moreover, although this article outlines several tests on which either men or women are superior, it must be kept in mind that there is a great deal of overlap between the sexes on most tests. Abilities on which there is less overlap – that is, where the differences are quite large – are mental rotation, throwing accuracy, and verbal memory, described below.

Male-favoring Abilities

Spatial abilities

The kinds of spatial tasks on which men excel include both simple and complex abilities. One relatively simple task requires only that the slope of a line be correctly matched to its counterpart in an array of lines. More complex tasks include the ability to make a correction for a change in the orientation of an object, referred to as 'mental rotation' (Figure 1). A somewhat different kind of spatial ability favoring males requires that one imagine what a depicted object will look like when manipulated – for example, a flat surface when folded and then unfolded in various ways, a function often called 'spatial visualization'. Performance on a mental rotation test has been found to

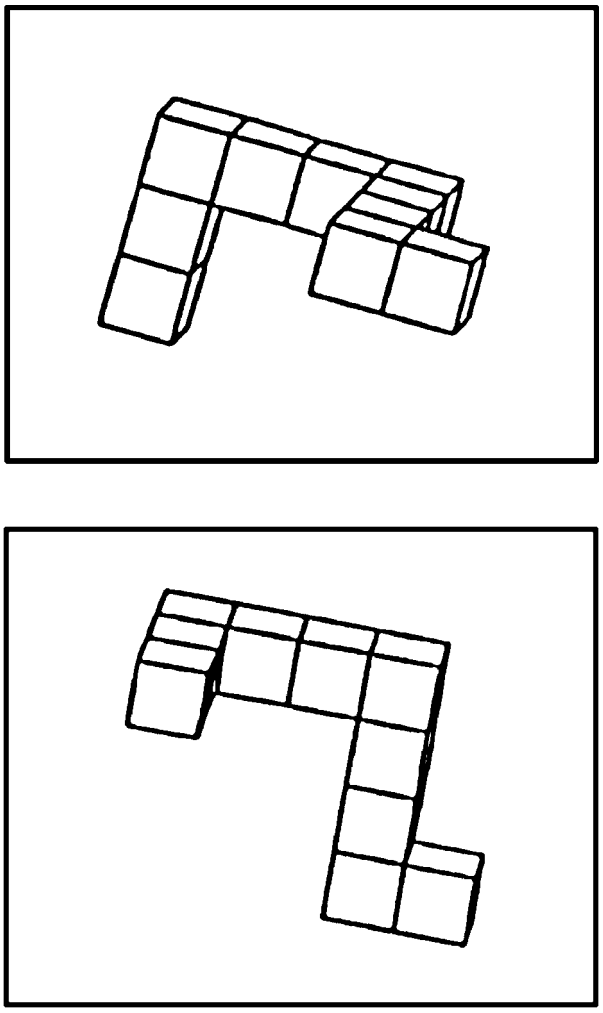

Figure 1. An example of a difficult 'mental rotation' task. The subject must decide whether the two figures are different, or are simply the same figure, rotated.

be closely related to that on a computerized labyrinth, suggesting that mental rotation ability contributes substantially to navigation (Moffat *et al*., 1998).

Mathematical reasoning

Ever since the invention of mathematical aptitude tests, boys have outperformed girls. In contrast, on school marks, which reflect learned solutions or achievement, girls do at least as well as boys in maths. It appears that boys are better able to use their maths experience to solve new problems. Although some have claimed that such sex differences are disappearing, the sex difference on the Scholastic Aptitude Test – Mathematics remained fairly steady from 1964 to 1981, with an effect size (a measure of the difference in standard deviation scores) of approximately 0.40 (Donlon, 1984).

The superiority of males becomes more marked as the tests become more demanding. So even in adolescents chosen for maths talent, the scores of males on the SAT–Math is higher than that of females, and at the highest end of the scores, males outnumber females by more than 10 to one (Benbow, 1988). On an even more demanding maths test, the Putnam competition in North America, less than 5 percent of the top scorers in a recent year were women. These findings may help explain why fewer women choose maths-intensive fields of study, such as physics, engineering, and maths itself (Lubinski and Benbow, 1992), whereas their entry into biological sciences approaches that of men.

Targeting accuracy

Men are much more accurate on average in hitting a target with a missile than women are. This difference appears early in life, before there is a wide divergence of sports activities, and in any case has been shown not to be accounted for by sports history (Watson and Kimura, 1991). Men are also more accurate in intercepting a launched missile, even if they merely have to touch it in flight. It appears that they are better able to process the spatiomotor requirements of such tasks.

Female-favoring Abilities

Verbal memory and verbal fluency

Women are better at recalling words, whether in a spoken list or a meaningful paragraph. This difference is present in children and lasts into old age. It is possible that verbal memory contributes to another task on which women outperform men – object location memory (Figure 2) (Eals and Silverman, 1994). Although men may be better at recalling locations *per se*, women appear to excel in recall of locations of specific objects when presented in an array. To the extent that the labeling of objects assists in recall of their locations, better verbal memory might provide an advantage on the task.

Women are also somewhat better at verbal fluency, by which is meant an ability to generate words with some constraint on the letters they contain, such as generating words beginning with a specified letter. It is well established that females are also faster at naming a series of patches of common colors, though it is still unclear whether this rapid naming advantage is restricted to colors or holds for forms as well.

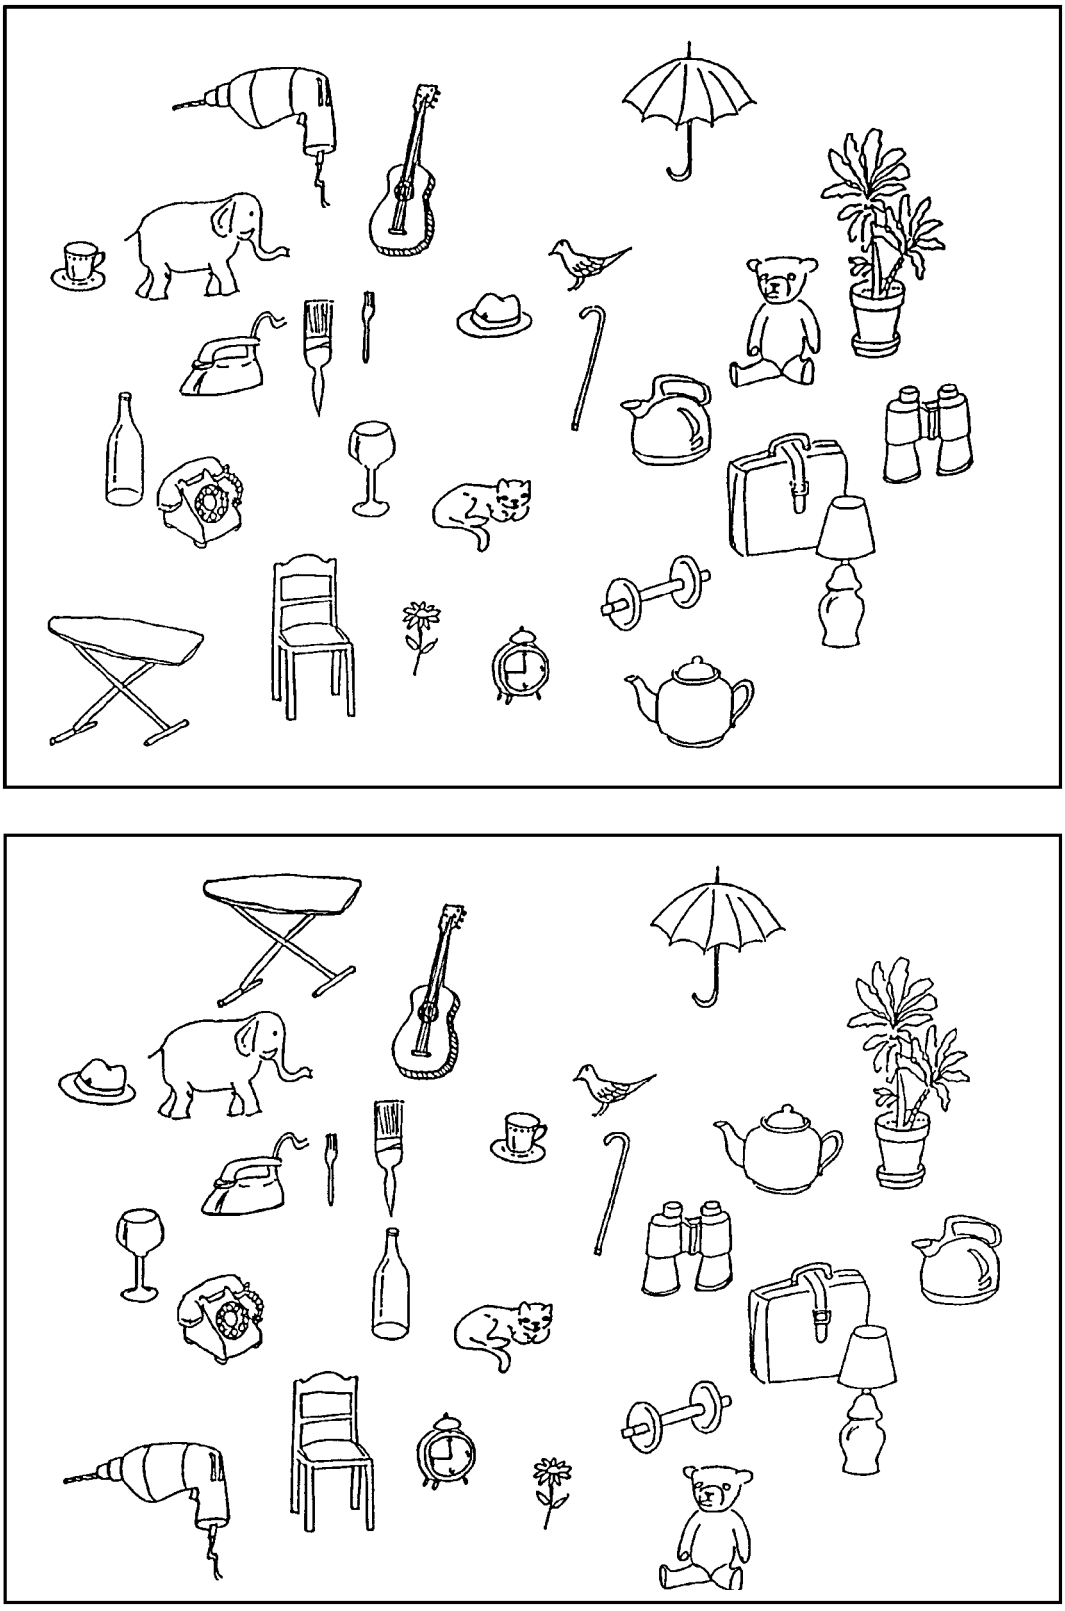

Figure 2. An object location memory task. The subject must decide which of the articles in the top array have shifted position in the bottom array. Reproduced by permission of the authors (Silverman and Eals, 1992).

Perceptual abilities

Women are faster at matching identical forms. For example, in a series of items like that in Figure 3, women complete more items in a specified time period. They also show better fusion of the images to the two eyes to yield the perception of depth, at least within personal body space. This enhanced depth perception may be related to the kind of fine motor skills women also enjoy.

Motor skills

Women excel at certain motor tasks requiring precise finger movements. For example, they can place pegs into a series of holes in a board more quickly than men. It has been suggested that this is due to their smaller fingers, but that does not appear to account for all instances of their greater fine motor skill.

HORMONAL MECHANISMS

General Effects

The effects of sex hormones on behavior are usually classified as *organizational* or *activational* (Goy and McEwen, 1980), concepts derived primarily from animal research. 'Organizational' refers to a demonstrated effect of early exposure to hormones (prenatal or immediate postnatal) on adult behavior, and has been seen chiefly in the influence of androgens in masculinizing the brain and behavior. 'Activational' refers to an effect of current hormone levels. The two are not entirely independent. The influence of hormones is seen not only in reproductive behavior but so far has appeared in almost all behaviors that differentiate males and females.

Cognitive Effects

Early exposure to androgens

In rats it has been shown that the male 'strategy' of using geometric cues to solve mazes, in contrast to the female strategy of using landmark cues, is due to the early exposure of males to androgen derivatives (Williams *et al*., 1990). Several studies suggest that the greater ability of human males to solve spatial problems of the kind shown in Figure 1 is due to a similar mechanism. The most convincing of such studies has shown that girls with congenital adrenal hyperplasia (CAH), who experience hyperexposure to adrenal androgens prenatally but not after birth due to corrective therapy, are superior to unaffected girls on such spatial tasks (Berenbaum *et al*., 1995; Hampson *et al*., 1998).

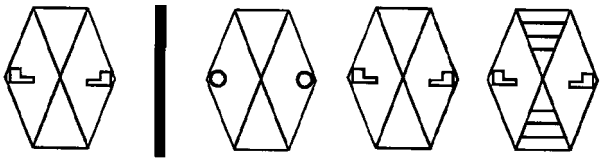

Figure 3. An example of a perceptual matching test. The subject must decide which of the three figures on the right is identical to the one on the left. A large series of such problems is presented, with a time limit.

Relation to current hormone levels

The current adult level of testosterone, the chief androgen, has been shown to relate systematically to scores on spatial tests similar to those enhanced in CAH girls. In young men with lower normal levels, spatial scores are higher than in young men with higher testosterone levels. In women, just the reverse occurs. This finding has been interpreted to mean that there is an optimal level of testosterone for spatial ability, and it is in the low normal male range. Below or above this, the spatial ability is poorer.

Cognitive patterns also vary within individuals with changing hormone levels. In men, testosterone levels change across the year and throughout the day, and spatial ability changes concomitantly. In women, estrogen, considered a female hormone, varies across the menstrual cycle, and women's cognitive pattern fluctuates with it. When estrogen levels are high, women are relatively better on tasks at which females typically excel, such as verbal fluency and fine motor skill; whereas on male-favoring spatial tasks, scores are relatively worse (Hampson, 1990). When estrogen levels are low, the reverse pattern appears.

These, as well as studies on hormone treatment in older men, and in the course of sex-change hormone therapy, combine to suggest that, although our cognitive strengths and weaknesses are strongly influenced by hormones early in life, they continue to be affected by current hormone levels in adulthood.

BRAIN SEX DIFFERENCES

Since the brain mediates all behavior, it must follow that consistent group differences in cognitive pattern, of the kind we see between men and women, will be reflected in brain differences of some kind. However, the search for brain correlates of cognitive sex differences has so far met with limited success. Nevertheless, we can confidently expect advances in this field in the coming years. This section will review two main features of brain or-

ganization that have been investigated as bases for such differences: functional brain asymmetry, and interhemispheric connections.

Brain Asymmetry

It is well established that the left and right cerebral hemispheres of the human brain have different functions, with the left hemisphere more concerned with communicative and complex motor ability, and the right with perceptual and spatial ability. This fact has been determined initially and most convincingly by studying the effects of damage to the left or right hemisphere, and later by perceptual techniques that can sample the function of one or other hemisphere, as well as by brain imaging techniques.

It has frequently been postulated that such functional brain asymmetry is more marked in men than in women, and that this is one basis for their differing cognitive patterns. When one examines the brain-damage evidence for sex differences in brain asymmetry, however, it seems that the left hemisphere is no less critical for basic speech functions in women than in men. That is, speech disturbances (aphasias) are no more frequent after right-hemisphere pathology in women, as would be predicted by the bilaterality hypothesis. However, the pattern of organization for speech *within* the left hemisphere is different, with speech more anterior-based in women, and more posterior-based in men (Kimura, 1999). In contrast to these more basic speech abilities, verbal functions such as vocabulary or defining words, and verbal fluency, do appear to be more bilaterally organized in women.

It has similarly been claimed that the right hemisphere develops earlier and is more specialized for spatial functions in men than in women. One would then expect that right-hemisphere pathology would be more disruptive of functions such as spatial rotation in men than in women, compared to left-hemisphere pathology, but this has not proved to be the case. Women's spatial ability is at least as affected by right-hemisphere strokes as is men's (Kimura, 1999).

Interhemispheric Connections

The largest commissural connection between the hemispheres is the corpus callosum, with a lesser role played by the anterior commissure, among others. The anterior commissure has been shown to have a larger cross-sectional area in women than in men, and the corpus callosum has been variously claimed to be larger in women in its posterior portion, called the splenium. A greater number of commissural fibers might be expected to result in better connections between the hemispheres, but so far no cognitive feature has been related to sex differences in the commissural area.

CONCLUSION

The differing cognitive patterns of men and women are known to be influenced by both early (pre- and possibly perinatal) and current levels of sex hormones. While such differences must obviously be based in the nervous system, the precise brain mechanisms are still to be determined.

Sexual Arousal

Intermediate article

John Bancroft, Kinsey Institute, Indiana University, Bloomington, Indiana, USA

CONTENTS

Sexual arousal is described as an emotional and motivational state involving complex interaction between information processing of sexual stimuli, central arousal, genital response, and behavior. The state motivates the individual to increase sexual stimulation and pleasure.

INTRODUCTION

The term 'sexual arousal', though used in a variety of ways, generally refers to a state motivated towards the experience of sexual pleasure and possibly orgasm, and characterized by genital response and other manifestations of general arousal. It shares some features with emotional states, and others with more clearly motivated states such as hunger. Although this emotional/motivational system is biologically organized to serve reproduction, in the human and a number of other primates nonreproductive exploitation of sexual pleasure is widespread, though susceptible to a variety of social constraints.

As with other emotional/motivational states, it is not yet possible to do more than infer the central state or 'drive' underlying sexual arousal. In such circumstances it is helpful to work back from the assumed behavioral objective. In the male, the fundamental reproductive goal of sexual arousal is coitus with male ejaculation into the female's reproductive tract. The motivational state driving this behavior is not dependent on any physiological deprivation, as with motivational states such as hunger or thirst, but relies in some way on the anticipation of and desire for sexual pleasure. In the male, an important aspect is that orgasm and ejaculation, once it occurs, is followed by an active inhibition of the capacity for further sexual arousal, producing a transient phase of refractoriness. This may show some parallels with satiation following excessive food intake, but there may also be important differences.

The situation in the female is less straightforward. In rodents, for example, coitus requires the female to express a reflexive lordosis response which involves active inhibition of other motor responses. It is far from clear to what extent this response pattern results from a motivation for sexual pleasure. In humans, the female may be more similar to the male, but orgasm in the female does not have the fundamental reproductive significance of male orgasm and ejaculation, and the capacity for female orgasm probably exists because there is no evolutionary need for it to be suppressed during development (Beach, 1976). Possibly because of the lesser reproductive significance of female sexual response, and a greater tendency for it to be inhibited in the female than in the male, the sexuality of women has been much more subject to social repression and constraint, particularly during certain historical periods. Whereas orgasm may be a motivational goal in women, it is clearly less crucial as an organizing factor in women's sexuality than it is in men.

Much of the confusion and inconsistency in the use of the term 'sexual arousal' stems from issues in operationalizing the definition for research purposes; and the particular and varied challenges involved have depended on the species being studied (Sachs, 2000). The underlying mechanisms are highly complex and our scientific observations are restricted to certain 'windows' into this complexity. The 'cognitive' window is both more accessible and relevant to the human. Invasive manipulations allow windows into brain mechanisms in animals, which are not available to human research. The types of physiological monitoring of sexual arousal used for human and animal research again involve very different 'windows'. This article focuses principally on the human, though its reference to underlying brain mechanisms depends to a large extent on evidence from animal studies.

We can thus view sexual arousal through four principal 'windows': (1) information processing of sexual stimuli, (2) central arousal or activation, (3) the elicitation of genital response such as penile erection in the male or clitoral tumescence and vaginal lubrication in the female, and (4) behavior, which is under voluntary control, aimed at intensifying sexual stimulation and likely, at least in the male, to result in orgasm. We can reasonably infer that these four aspects are both integrated and interactive with each other.

INFORMATION PROCESSING

The appraisal of a stimulus as sexual is usually the first step in initiating the interactive process leading to sexual arousal. Learning plays a major part in determining what stimuli are identified as sexual, though to some extent the 'sexual significance' of a stimulus may be innately determined and independent of previous experience. Processing of sexual stimuli operates at two levels: (1) 'automatic', fast, unconscious processing requiring little attention, and (2) 'controlled' (or attentional) cognitive processing (Janssen *et al*., 2000). 'Automatic' processing is regarded as fundamental in the appraisal of emotional events in general, leading to appropriately rapid 'response sets'. The 'controlled' processing allows an additional level of appraisal which may either augment or reduce the initial automatic response, and which may be activated and focused by the emotional arousal accompanying it.

Sexual stimuli are not only external; internal imagery can initiate the process. Automatic processing of spontaneous genital response or tactile stimulation is a further source. It is noteworthy that such 'positive feedback' of genital response is more predictable in men than in women.

AROUSAL

The brain responds to novel stimuli with an increase in alertness and attention. Such activation is a key component of emotional states, affecting both cortical activity and peripheral mechanisms such as blood pressure and heart rate. In general there is a pattern of generalized arousal, including peripheral autonomic responsiveness needed for motor response, which is relatively nonspecific, occurring in a variety of emotional states including fear, anger, and sexual arousal. What is more specific and also less well understood is the focusing of attention on to stimuli relevant to the specific type of arousal, and in the case of sexual arousal, the activation of genital response.

GENITAL RESPONSE

This is the most specifically sexual component of 'sexual arousal', which is essential for the completion of the reproductive sequence. In the male, penile erection is crucial, and controlled by a balance between excitatory and inhibitory signals originating from higher in the central nervous system (Steers, 2000). Specialized mechanisms in the penis involve arterial vasodilation, increasing blood flow into the erectile tissues, relaxation of smooth muscle in the sinusoidal spaces, allowing distension by inflowing blood, and venous constriction which prevents escape of blood from the erectile spaces. Vasodilation and smooth muscle relaxation depend mainly on cholinergic and nitrergic (nitric oxide) mediation, and are counterbalanced by the constricting effects of norepinephric mediation (Rehman and Melman, 2001).

Genital responses in the female are less well understood. Transudation of fluid through the vaginal wall and tumescence of the vulva and vaginal introitus serve to facilitate entry of the erect penis during coitus. Tumescence of the clitoral bodies is in many respects homologous to penile erection and may be an important source of sexual pleasure for some women. Apart from its motivating potential, clitoral response has no obvious reproductive function.

MOTOR RESPONSE

In animals, sexually relevant motor responses are typically divided into 'appetitive' (e.g. gaining access to receptive partner) and 'consummatory' (e.g. mounting and intromission) responses. In humans, while motor responses are a central part of sexual activity they do not fall easily into these two categories, though clearly certain types of human sexual activity are 'consummatory' (e.g. masturbation or coitus). In general, when experiencing sexual arousal there will be a motivation to 'do something about it' which can be seen as reflecting the motor component.

INTEGRATING THE SYSTEM

To what extent can we infer central mechanisms that integrate the various phenomena observed through our 'scientific windows'? The three monoaminergic systems originating in the brain stem are obviously crucial, although in each case their role is

relevant to aroused and motivated states in general, not just sexual arousal (Role and Kelly, 1991).

The norepinephric (NE) system is central to the arousal component. This has two parts which originate in two brainstem nuclei. One, the locus ceruleus (l.c.), has widespread ascending projections to the basal forebrain, hypothalamus, and cortex among other parts of the brain, and descending projections to sensory nuclei in the brainstem and to the spinal cord. The other, the lateral tegmental nucleus (l.t.n.), has even more diffusely projecting neurons which also include brainstem, spinal cord, and cortex. However, whereas the l.c. is activated by novel sensory input, the l.t.n. is involved in integration of autonomic function in brainstem and spinal cord nuclei. We can therefore reasonably assume that together they are a key part of the interface between emotionally relevant external stimuli and a generalized arousal response.

The dopaminergic (DA) system is more discretely organized into several subsystems, three of which are relevant to sexual arousal, one of them specifically and the other two nonspecifically. The nigro-striatal tract, degeneration of which causes Parkinson disease, is involved in the organization of motor behavior, particularly initiation of motor responses and 'readiness to respond'. This includes copulatory but also many other integrated motor patterns. The meso-limbic tract promotes 'appetite' for a variety of appetitive behaviors including sexual. More specifically, the dopaminergic input to the medial pre-optic area (MPOA) from the A14 periventricular system is involved in the orchestration of genital responses and associated motor patterns such as mounting or thrusting.

The serotonergic system, the most extensive of the three monoaminergic systems, has wide-ranging and predominantly inhibitory effects.

There is as yet no clearly identified center or system for producing genital response; the closest is the nucleus paragigantocellularis in the brain stem which is involved in the inhibition of erection (McKenna, 2000).

What is particularly unclear is how these various nonspecific systems in the brain become recruited to serve the specific state of sexual arousal. Testosterone (T) may have a role in this respect. T receptors are found in the NE system and may be involved in the sexual focusing of central arousal. T receptors are also found in the MPOA and in other sites and are likely to be involved in sexual focusing of the DA system. But at present we can only speculate on such interactions. Other neurotransmitters and neuromodulators, such as excitatory amino acids and neuropeptides, are also involved at some level in the development and integration of sexual arousal. This is well illustrated in the case of post-ejaculatory refractoriness and 'sexual satiation', a state induced in male rodents by allowing repeated access to receptive females in a short period of time. After seven or eight such copulations a state of sexual exhaustion (but not general exhaustion) becomes evident which may remain for several days. This state has been shown to be dependent on the integrity of the NE arousal system but also involves peptidergic, serotonergic, and dopaminergic mechanisms (Rodriguez-Manzo and Fernandez-Guasti, 1995).

Given the difficulties in explaining specific response patterns in this complex system, it is useful to think in terms of 'conceptual systems', which infer organizing mechanisms of functional relevance and which lend themselves to empirical testing.

One such conceptual system is the 'dual control' of sexual response, which postulates that there are both excitatory and inhibitory systems operating to determine whether sexual arousal and response occurs in any specific situation (Bancroft, 1999). Appraising stimuli as sexual and nonthreatening activates the excitatory system; appraisal of threat associated with a sexual stimulus activates the inhibitory system, reducing the likelihood that a sexual response will occur. Such a balanced mechanism can be seen as adaptive; while sexual behavior is biologically important and inherently rewarding it is also potentially dangerous, exposing the sexually aroused individual to a variety of hazards. Similarly, when faced with a nonsexual threat it is important to inhibit other response patterns, such as sexual or eating, which might distract from the avoidance of threat. Such a system may explain how central arousal may be channeled to sexual arousal in some situations and to fearful arousal in others. It is also inherently likely that individuals will vary in their propensity for both excitation and inhibition. Thus a person with low propensity for inhibition may become sexually aroused in the presence of a sexual stimulus even when threat is involved. Conversely, an individual with high propensity for inhibition may be unable to respond in relatively unthreatening situations, leading to sexual dysfunction.

This conceptual system also offers an explanation for the process described as 'excitation transfer', where arousal induced by one type of stimulus becomes recruited to activate the 'arousal response' to another type of stimulus (Zillmann, 1983). It has been shown experimentally that an individual experiencing anger may have an augmented response

to a subsequent sexual stimulus; or conversely, someone in a sexually aroused state may respond with greater anger to a subsequent provocation. It is unlikely that such patterns are found in everyone and this may be an important type of individual variability. The 'dual control' model postulates that such transfer of arousal, from say a frightening or threatening situation, may augment the response to a coexisting sexual stimulus in those individuals who have a low propensity for inhibition of sexual response. For the average or high-propensity individual, appraisal of threat would effectively ensure through inhibitor mechanisms that such excitation transfer did not take place, and in most situations that would be a more adaptive response pattern.

CONCLUSION

Sexual arousal involves the orchestration and integration of complex processes in the brain reactive to the presence of sexual stimuli and resulting in an emotional state which motivates the aroused individual towards obtaining increased sexual stimulation. The underlying mechanisms are only partially understood and individual differences in responsiveness of different aspects of this system are likely to contribute to the considerable variability of human sexual expression.

Signal Detection Theory

Introductory article

Justin A MacDonald, Purdue University, West Lafayette, Indiana, USA
JD Balakrishnan, Purdue University, West Lafayette, Indiana, USA

CONTENTS

Signal detection theory is one of the first attempts by psychologists to model the processes involved in elementary perceptual recognition tasks. The theory's main feature is a rigorous distinction between performance limits due to the quality of information provided by the senses (sensitivity), and limits arising from decision-making strategies (bias).

INTRODUCTION

Imagine the following situation: a pathologist has been given a tissue sample from a male child to check for the presence of cancer. If she incorrectly concludes that the sample is cancerous, the child will unnecessarily undergo a battery of costly and potentially risky interventions. On the other hand, if she incorrectly concludes that there is no cancer present, the disease may be allowed to develop beyond the ability of medical science to treat it. Because this disease is relatively rare in children, the pathologist knows that the probability that the cells are cancerous is small. Before looking at the tissue, therefore, she might be fairly confident that it is noncancerous. Unfortunately, the signs of cancer in a tissue sample are not clear-cut. Every sample is unique; sometimes there are obvious, strong indications that cancer is present, at other times the signs are moderate or weak. How does the pathologist combine the complex visual information from examining the tissue sample with her prior knowledge about the likelihood of a cancer being present? How do we evaluate the performance of these expert decision-makers to determine whether they are making the best possible use of their knowledge about the probability of the disease in this situation and the visual perceptual information they glean from examining the sample?

SIGNAL DETECTION THEORY

The pathologist's dilemma is one of many examples of what psychologists call the 'signal detection problem'. Are the cells in the tissue sample cancerous (a signal) or is it a false alarm (noise)? There are two possible events (signal and noise) and two possible decisions (detect and reject).

During the Second World War, engineers working on radar detection systems developed a model to describe the processes involved in this particular type of decision-making problem. They used this model to study the behavior of radar operators who were responsible for distinguishing random blips on the radar screen from blips caused by an actual ship or aircraft (the signal detection problem). This mathematical model was soon noticed by psychologists and developed into a set of more detailed models and procedures, which have come to be referred to collectively as 'signal detection theory' (SDT).

According to this general theory, there are two distinct stages in the detection process, assimilation of information from the environment (encoding) and selection of an appropriate response (decision-making). Detection errors occur either because the output of the encoding process is misleading (due to noise in the outside world or in the brain) or because the detector's decision-making strategy is flawed.

Although the basic principles of SDT are general enough to encompass more complex decision-making tasks, most applications have focused on the original problem, in which there are only two possible stimuli and two possible responses. In such situations (often called discrimination tasks), the four possible outcomes of a given trial during the experiment are 'hits' (correctly detect a signal),

'misses' (fail to detect a signal), 'correct rejections' (reject a non-signal event) and 'false alarms' (incorrectly identify a non-signal event as a signal event).

Since there are only two possible decisions, detect or reject, the proportion of hits on signal trials plus the proportion of misses on signal trials must equal 1. Similarly, the proportion of false alarms on noise trials plus the proportion of correct rejections on noise trials must equal 1. The performance of a subject can therefore be reduced to two values, one for each stimulus condition, and it is customary to report just the hit and false alarm rates.

SENSITIVITY AND BIAS

One of the basic assumptions of SDT is that all of the sensory information that could conceivably be used to come to a decision on a given trial can be represented as a single point on a one-dimensional continuum called the 'decision axis'. Points near the left extreme of the axis correspond to sensory information that constitutes compelling evidence that only background noise was present; and points near the right end are compelling evidence for a signal. Somewhere between these two extremes lies the point at which the sensory information is entirely inconclusive (the two stimuli or conditions are equally likely). In the pathologist's situation, the axis might be the number of what appear to her to be questionable cells in the tissue sample: many questionable cells might constitute very strong evidence that the sample is cancerous while very few questionable cells might indicate a noncancerous sample. The decision-maker must combine this sensory information with other information, such as the history of the patient.

Because of the random variability that is almost sure to exist either in the environment or in the brain (or both), the sensory effect of a stimulus should be expected to vary from trial to trial even if the stimulus stays constant (in the pathology example, different cancerous tissue samples would look different). However, some effects should be more common than others when they come from a single type of source. For technical reasons, the most popular version of SDT assumes that these relative frequencies for a given stimulus follow a standard probability distribution, the 'normal' or 'bell-shaped' curve, as illustrated in Figure 1.

Notice that each stimulus has its own distribution, because each stimulus should have its own set of effects that it will produce often (effects near the center, or mean, of the distribution) and its own set of effects that are possible but rare (effects in the tails of the distribution). The degree to which the distributions for two different stimuli overlap is a measure of the 'sensitivity' of the senses to the physical differences between the two stimuli. In general, sensitivity should decrease with increasing physical similarity of the stimuli being discriminated.

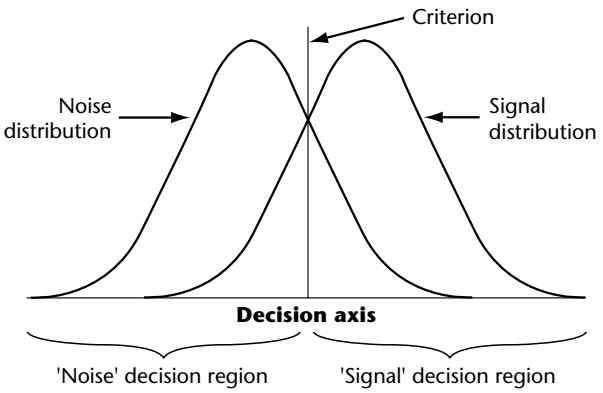

Figure 1. The distributions of effects on signal and noise trials in SDT. Notice that the two distributions have the same variance but different means. According to SDT, the observer changes his or her response strategy by shifting the criterion along the decision axis, thereby changing the boundary between the 'signal' and 'noise' response regions. In this example, the criterion is placed at the point of intersection between the two distributions and is therefore unbiased. Response biases affect the placement of the criterion (shifting it to the left or right), but not the distributions themselves.

Decision-making Strategies

The fact that the two distributions in Figure 1 overlap is a fundamental problem for the decision-maker: for any given sensory effect, the decision-maker cannot be sure which stimulus was presented. From the SDT point of view, this is the main reason why subjects make errors in discrimination tasks. On the other hand, the sensory effect does provide some information: some effects are more likely to have been caused by the signal stimulus and others are more likely to have been caused by the noise stimulus. The decision-maker's task is therefore to find a 'decision rule' that maps each effect to its most probable cause. SDT assumes that, to accomplish this, a 'criterion' is set somewhere on the decision axis.

Intuitively, the best place to put this criterion might seem to be the point at which the two distributions intersect; i.e. where the relative frequency of the sensory effect is identical on signal and noise trials. This is valid if the signal and noise trials

occur with equal frequency during the experiment (i.e., the 'base rates' of the stimuli are equal). However, if the base rates are unequal, the optimal placement (maximizing the percentage of correct responses) will be somewhere to the left or right of the point of intersection of the two distributions, depending on which stimulus is presented more often.

To see why the criterion should shift in accordance with the base rates, consider the case in which the signal stimulus will never be presented (when its base rate is zero): the optimal decision-maker would always respond 'noise', no matter what sensory effect is present. In terms of the model, the criterion in this case would be shifted to the extreme right of the decision axis so that all of the sensory effects are mapped to the noise response.

For each pair of base rates, there is one and only one position on the decision axis that would lead to optimal performance: all of the others are suboptimal to some degree. Any criterion placed at any point other than the point of intersection (which may or may not be suboptimal, depending on the base rates) is called a 'biased' decision rule.

CALCULATING SENSITIVITY

For any set of base rates, the SDT model illustrated in Figure 1 can be fitted to the data (i.e. to the hit and false alarm rates) to estimate the two parameters of the model, which are the distance d' between the means of the two distributions (in standard deviation units) and the position X_C of the criterion. Assuming a standard deviation of 1, the formulas for these two parameters are:

$$d' = \Phi^{-1}(p_{\text{hit}}) - \Phi^{-1}(p_{\text{fa}}) \quad (1)$$

$$X_C = -\Phi^{-1}(p_{\text{fa}}) \quad (2)$$

where p_{hit} and p_{fa} are the hit and false alarm rates, respectively, and Φ^{-1} is the inverse cumulative distribution function for the standard normal distribution. The values of these inverse functions can be obtained from tables or from statistical software packages.

ROC CURVES

In principle, there is no reason why the two distributions of effects should always be normal, or should differ only in their mean values. In fact, empirical studies often suggest that the signal distribution is more variable than the noise distribution. Partly for these reasons, detection theorists often estimate sensitivity using a different approach that incorporates the same basic principles of the detection model but does not assume anything about the particular shapes of the distributions. To do this, it is necessary to estimate the hit and false alarm rates for several different positions of the decision criterion. These pairs of estimates are then presented in a scatter diagram, with the false alarm rate on the abscissa and the hit rate on the ordinate. An example of such a 'receiver operating characteristic' (ROC) curve is shown in Figure 2. In addition to illustrating how different degrees of bias towards one of the two responses would affect a decision-maker's performance, such plots can also provide a convenient estimate of sensitivity, because the area underneath a plot will generally increase as the sensitivity of the subject increases.

Of course, in order to estimate the ROC curves at more than one point, the investigator needs more estimates of the hit and false alarm rates than are available from a standard discrimination task. One approach is to run several experiments using different base rates, presumably inducing the subjects to shift their decision criteria to the left or right depending on the relative frequency of the signal. However, since this approach is more costly in both time and effort, most investigators prefer an alternative method, which is to run a single condition with equal base rates but to ask the subjects to report both the stimulus that they think was presented and their degree of confidence in this. In effect, this is equivalent to asking the subjects to report the position of the sensory effect on the decision axis as well as the response they wish to

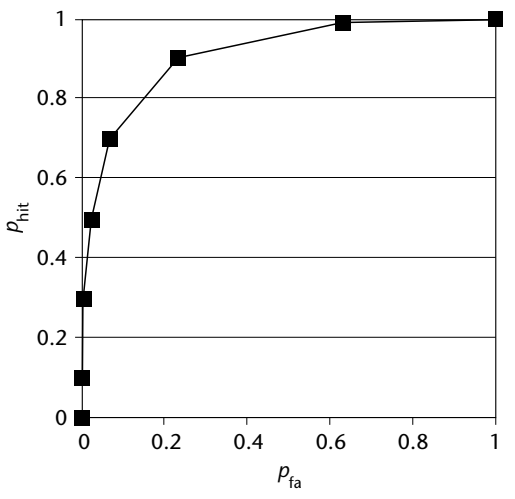

Figure 2. ROC curve from a hypothetical discrimination experiment. Points along the curve correspond to conditions with different signal base rates.

assign to this effect. From this extra information it is possible to estimate the ROC curve.

APPLICATIONS OF SDT

SDT has been adopted as a framework for studying human performance in many different areas of basic and applied research, including perception and memory, decision-making, radar monitoring, airport security, and personnel evaluation. Because the need to discriminate between two possible states of the physical world from imperfect (but not useless) information arises in so many situations in the laboratory and in the workplace, it is important to have a rigorous means of describing these kinds of activities and the effects that decision-making biases can have on them. When its underlying assumptions are known to be satisfied, SDT can be a useful tool to help assess decision-making styles and distinguish these styles from other aspects of the skills involved in a discrimination task. In these cases, it provides a legitimate method of identifying and helping to correct potentially harmful biases of decision-makers in critical decision situations. In addition, SDT is often used as a basis for testing theories that make predictions about factors that either should or should not affect the inherent difficulty of a task (rather than merely the strategies that subjects will choose to employ), and to summarize in an efficient way the effects of these factors on performance.

However, these applications of the model have little or no scientific merit if the model's representation of behavior is inaccurate. It is important, therefore, to test the model's assumptions in a rigorous way before accepting them. Some of the most convincing evidence in favor of the model comes from manipulations that according to SDT should be directly related to the decision-making process (the placement of the criterion) and unrelated to the sensory encoding process (and hence the sensitivity level). In particular, if the noise and signal trials are not presented with equal frequency (the base rates are unequal), or if a 'miss' is, say, more costly than a 'false alarm', the optimal decision-maker will shift the criterion away from the point of intersection. If the criterion is shifted to the right, the hit and false alarm rate should both decrease; and many studies have shown that this is precisely what occurs when the frequency of the noise stimulus (or the penalty for a false alarm) is increased. In other words, this fundamental prediction of the SDT model is confirmed by empirical data.

SDT also makes some other predictions, however, that have been shown to be violated. If the criterion is biased towards, say, the signal response, as in the example shown in Figure 3, the theory predicts that the relative frequency of low-confidence signal responses (effects immediately to the right of the criterion) should be lower on signal trials than on noise trials. This prediction is

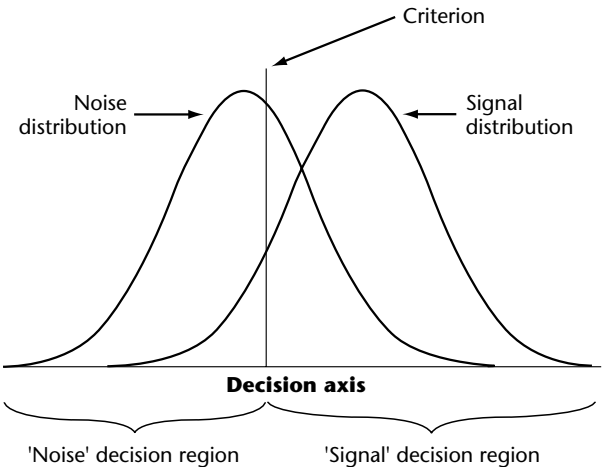

Figure 3. An SDT model with a biased decision rule. The criterion has been shifted to the left of the point of intersection between the two distributions, indicating a bias towards the signal response (compared to the unbiased rule, more of the effects on the decision axis are mapped to the signal response).

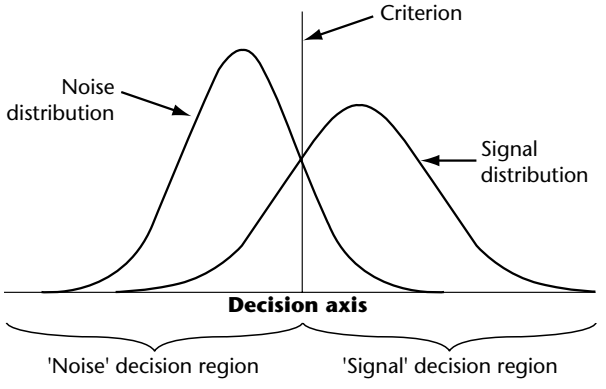

Figure 4. A modification of the SDT model that is consistent with empirical data. Instead of the decision criterion shifting, the relative variances of the two distributions change as the bias increases. Higher base rates of a stimulus lead to a distribution with smaller variance. In this example, increasing the base rate of the noise stimulus decreased the variance of the noise distribution and increased the variance of the signal distribution. The decision rule is unbiased, but the change in variance accounts for the relationship between hit and false alarm rates when base rates are manipulated.

consistently violated in discrimination experiments. These two relative frequencies convergence to the same value as the subjects' confidence decreases (the likelihood ratio at the criterion is 1).

In order to explain the covariance of the hit and false alarm rates under base rate manipulations, while also explaining this direct empirical evidence that the decision rule is always unbiased, the SDT model needs to be modified so that the shapes of the distributions change as the base rates are manipulated. An example is shown in Figure 4. Instead of the criterion shifting, the relative variances of the two distributions change, with a higher base rate for a given stimulus leading to lower variance in its associated distribution of sensory effects. Obviously, this is a very different kind of bias, and one which eliminates the 'shifting criterion' representation of decision-making processes in SDT. It is not yet clear exactly what causes the distributions to change shape in the manner shown in Figure 4, or what consequences this effect has for measurement of discrimination skills. More research is needed to answer this important question. Meanwhile, applications of the traditional SDT models should be regarded sceptically.

Similarity

Intermediate article

Ulrike Hahn, University of Wales, Cardiff, UK

CONTENTS

Similarity can be viewed as the degree of resemblance between two objects or events. This is thought to influence a wide variety of cognitive processes.

INTRODUCTION

Similarity is a ubiquitous concept within cognitive science. Though not without critics, it forms part of the explanation of cognitive processes as diverse as memory retrieval, categorization, visual search, problem-solving, learning, language processing, reasoning, and social processes. Several distinct approaches to similarity have emerged; each of these can be viewed both as a tool for the measurement of similarity and as a theoretical statement about its nature.

SPATIAL MODELS

Spatial models seek to represent similarity in terms of distance in a psychological space (see Shepard, 1980, for an overview). An item's position is determined through its coordinate values along the relevant dimensions; nearby points thus represent similar items, whereas distant items are psychologically very different (see Figure 1). Typically, the relevant space is derived from matrices of 'proximity' data such as pairwise confusability or similarity ratings between items through the application of multidimensional scaling (MDS) – a statistical procedure for dimensionality reduction. Spatial models have been used widely for data visualization. They have also formed the heart of very detailed cognitive process models, for example, of recognition and classification.

FEATURAL MODELS

In contrast to the continuous-valued dimensions of spatial models, featural models assume binary features as their representational basis. In other words, a continuous dimension such as 'size' might be reduced to a single psychological feature 'tall' or 'not-tall'. (Often cumbersome schemes for translating dimensions into features and vice versa have been proposed in Tversky (1977).) The most famous featural account of similarity is Tversky's *contrast model*. This account was developed to address perceived limitations of spatial models which seem to bring these into conflict with behavioral data (see below).

In the contrast model, similarity is a function both of the features common to the pair of items under comparison and of the features distinctive to each. In full, the model is specified as:

$$\mathrm{Sim}(\mathrm{D},\mathrm{E}) = \alpha f(\mathrm{D} \cap \mathrm{E}) - \beta f(\mathrm{D} - \mathrm{E}) - \gamma f(\mathrm{E} - \mathrm{D})$$

where D and E are both objects or events each of which is represented in terms of a set of characteristic features; $(\mathrm{D} \cap \mathrm{E})$ represents the set of features common to both D and E, whereas $(\mathrm{D}-\mathrm{E})$ and $(\mathrm{E}-\mathrm{D})$ represent the distinguishing features of D and E, respectively. Each of these three feature sets is goverened by two kinds of parameters (for full details see Tversky, 1977): f represents a scaling parameter reflecting the salience or prominence of different features; α, β, and γ are weighting parameters that allow the model to capture attentional differences present in so-called directional similarity comparisons (e.g. 'how similar is D to E', as opposed to 'how similar *are* D and E'). They enable the model to capture asymmetries in similarity judgments, to be discussed in more detail below, which have been put forth as important empirical evidence against spatial models.

ALIGNMENT AND TRANSFORMATION MODELS

More recently, it has been argued that spatial and featural models share a fundamental limitation in that they define similarity over very specific – and very simple – kinds of representations: points in

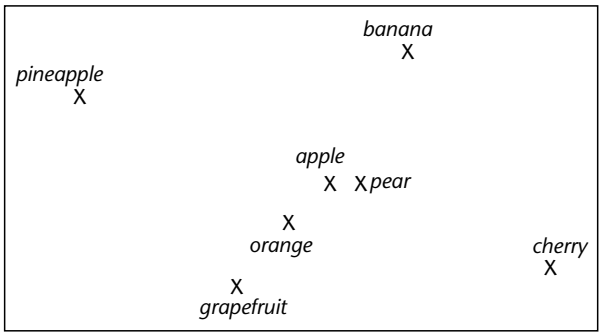

Figure 1. A sample MDS-derived spatial representation of the similarity relations between various kinds of fruit.

space or feature sets. Arguably, most theories of the representation of natural objects, whether they be faces, visual or auditory scenes, or sentences, assume that they cannot be represented in line with these restrictions. Instead, they seem to require *structured representations*: complex representations of objects, their parts and properties, and – crucially – the interrelationships between them. Such descriptions cannot be boiled down to either lists of features or points in space. This can be illustrated with a simple relation such as MOTHER-OF(,) and its arguments *Jane* and *Jim Jnr* which, as MOTHER-OF(*Jane, Jim Jnr*), provides a represention of the fact that Jane is the mother of Jim Jnr in a classic scheme for structured representations – the language of first-order predicate logic.

This representation scheme distinguishes relations and their arguments so both can be accessed and compared independently: the MOTHER-OF relation might be found to be semantically similar to the relation FATHER-OF(,), and the state of affairs represented by MOTHER-OF(*Jane, Sally*) would be classed as closely related as well. However, on a featural or spatial scheme, relations and their arguments are necessarily bound together into single atomic units which represent objects or states of affairs as a unitary whole. Such a single feature representing the composite fact that Jane is Jim Jnr's mother does not allow independent access of the relation and arguments in question because these are representationally bound together into a single unit. Consequently, the feature representing the fact that Jane is Jim Jnr's mother is completely distinct from a feature representing the fact that Jim is Jim Jnr's father or that Jane is also Sally's mother. None of the features representing these events will match exactly (otherwise they couldn't represent different events), and the fact that they represent events with overlapping components is inaccessible because featural schemes are by definition not componential.

The structural alignment account of similarity (e.g. Gentner and Markman, 1994), which has its roots in the literature on analogical reasoning, operates over structured representations. The structural alignment process begins with semantic similarities between two comparison objects or events and then seeks a structurally consistent mapping. The semantic comparison requires that at least some of the predicates (that is, relations such as ABOVE(x,y)) are identical across the comparison. These identical predicates are placed in correspondence and the alignment process then seeks to build maximal structurally consistent matches between the two representations. Structurally consistent matches are ones that respect the constraints of *parallel connectivity* and *one-to-one mapping*. Parallel connectivity implies that wherever relations are placed in correspondence, their arguments are placed in correspondence also. The one-to-one mapping constraint requires that each element in one representation must match at most one element in the other representation. (In Figure 2, parallel connectivity means that the two 'function' predicates will be placed in correspondence, as will their arguments 'sitting' and 'eating'.) Structural alignment has been implemented in a variety of computational models

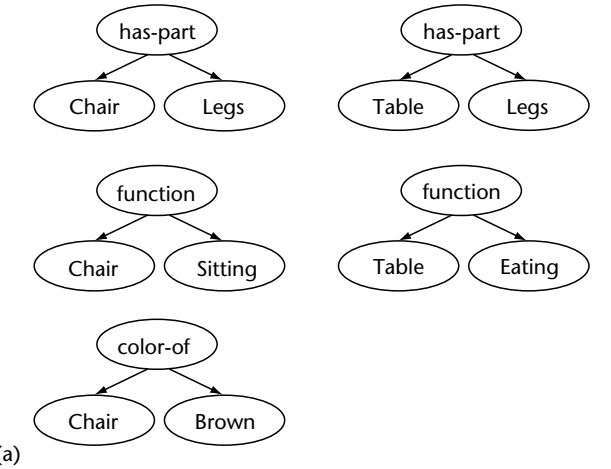

Figure 2. An example of structural alignment (after Markman, 2001).

(see Markman, 2001) which have been used to capture behavioral data.

The capacity to deal with structured representations is also central to recent transformational approaches to similarity (Hahn *et al.*, 2001). In the transformational framework, the similarity between two object representations is seen to be a function of the 'effort' required to transform one representation into the other. For example, an image of a robin could be more readily transformed into an image of a blackbird than into an image of a dog, reflecting the greater similarity between the two birds. The basic idea of a transformation-based measure of similarity is also present in the edit-distance measures popular in psycholinguistics. Here, the similarity between two sound sequences depends on the number of insertions, deletions, and substitutions required to turn one sequence into the other. The words 'bet' and 'bent', for instance, are separated by only a single insertion ('n') and sound far more similar than do 'bet' and 'mat' which require two substitutions in order to be made identical.

EMPIRICAL DISTINGUISHABILITY

Experimental attempts to reveal the psychological function governing similarity initially focused on the so-called metric axioms which underlie any spatial scheme (see Tversky, 1977). Several apparent violations of these axioms in behavioral data were discovered, and were taken as evidence against the psychological validity of spatial accounts. Because the contrast model is not subject to the metric axioms such violations were presented as evidence in its favor, but they equally support any other approach not subject to these assumptions.

The two most important metric axioms in this context are (1) the symmetry constraint, and (2) the so-called triangle inequality.

Distances in the psychological space posited by spatial models are necessarily symmetrical: the psychological distance of item D to item E necessarily equals that of E to D. However, there is considerable evidence for asymmetries in human similarity data, whether these data be explicit ratings or confusability data (Tversky, 1977). In particular, typical members of a category may be perceived as less similar to atypical members than vice versa; for example, the similarity of penguins to robins might be rated higher than that of robins to penguins.

The triangle inequality, by contrast, imposes a constraint on the possible relationships between more than two items. Specifically, for any three distances d between the items a, b, and c:

$$d_{ab} + d_{bc} \geq d_{ac}$$

An informal apparent counterexample is provided by Tversky's example of Jamaica, Cuba, and (then Soviet) Russia. Jamaica (a) seems very similar to Cuba (b), as does Cuba (b) to Russia (c), yet Russia and Jamaica seem very dissimilar indeed; in other words, the psychological distance (ac) between Russia and Cuba is likely to exceed the sum of the other two distances (ab) and (bc). Ingenious experiments showing violations of this metric axiom were presented by Tversky and Gati (1982).

Neverthless, the demonstration of these various violations of fundamental constraints of spatial models has been less damaging than might have been expected. This is largely due to the fact that the most successful applications of the spatial paradigm to cognitive modeling embed these in more encompassing models; Nosofsky's spatially based *generalized context model* of identification, recognition, and classification, for example, involves an exponential function which converts the basic distances of the underlying spatial model into a measure of psychological similarity. This allows apparent violations of the triangle inequality. Similarly, the model incorporates a bias term which allows it to capture asymmetries (see Nosofsky, 1991 for complete details).

Potentially more damaging to spatial models – and equally threatening to featural accounts – is the evidence for the importance of structural information in human similarity judgments. One prediction of the structural alignment account is of a cognitive difference between *alignable* and *unalignable differences*. Unalignable differences between two representations are representational elements of one object which have no correspondence in the other; alignable differences, by contrast, are representational elements which correspond across the two representations but which are nonidentical. (In Figure 2, 'color' for which no information is included in the representation of 'table' constitutes an unalignable difference between the two objects. The different functions 'eating' and 'sitting' constitute alignable differences.) This distinction has received a fair amount of empirical support, both in that participants typically list more alignable than nonalignable differences in free listing tasks, and in that alignable differences seem to affect perceived similarity more strongly than do unalignable differences. Relational structure does seem to matter in the context of similarity, and this would seem to count against both spatial and featural accounts.

At present, spatial and featural models survive, not only owing to their simplicity but because spatial models, in particular, have very successfully provided detailed models of cognitive performance in a variety of tasks. This might be because the particular stimulus materials used simply did not require relational information to be processed; in this case, models should be shown to falter with more naturalistic materials. It is also possible that the cognitive system makes use of both fairly 'cheap' computations well approximated by spatial models and computationally more 'expensive' processing which incorporates relational information for higher-level tasks. Only further research, not only into similarity but also into the nature of supposedly similarity-based cognitive processes, will be able to tell.

Skill Learning

Introductory article

Richard A Carlson, Pennsylvania State University, University Park, Pennsylvania, USA

CONTENTS

Skill learning is the acquisition and improvement of mental or physical abilities through practice.

INTRODUCTION

Skill refers to an acquired ability that has improved as a consequence of practice. Skills may be primarily physical or *motor* in nature (for example, riding a bicycle) or largely mental or *cognitive* (playing chess, solving mathematical problems). Skill learning obeys similar principles across motor and cognitive domains. It can be distinguished from other types of learning such as conditioning, acquiring knowledge of facts, or learning a first language, though skill learning and these other types of learning may share some underlying mechanisms. *Expertise* usually refers to a broad repertoire of knowledge and skills in some domain, and can thus also be distinguished from skill. Studies comparing experts and novices in particular domains have, however, been important in advancing understanding of skill learning. Finally, skill should be distinguished from *talent*, an innate capacity to acquire certain types of skill or knowledge.

PHENOMENA OF SKILL ACQUISITION

The most obvious feature of skill learning is improvement with *practice*, the repeated performance of the same activity. All modern theories of skill learning share the view that practice results in the acquisition and improvement of relatively specific knowledge, in contrast to historical views that practice could improve abstract, general mental abilities.

A key feature of practice is regularity or *consistency* – something must stay the same from trial to trial in order for performance to improve. Improvement in performance may be measured in a variety of ways: by a reduction in errors or increase in the likelihood of success, by more precise coordination of component actions with one another or with the environment, by reduction in the effort required for performance, or by more rapid performance.

Each of these approaches to assessing skill might be seen as one aspect of *fluency*, the ability to perform an activity readily, smoothly, and effectively. Of course, which aspect is most important depends on the particular skill being considered – it might be argued that faster is always better in solving mathematical problems, but it would be odd to argue that faster is always better in performing music (though the possibility of performing faster indicates a higher level of at least some components of musical skill). Research has established a number of empirical phenomena that indicate the ways in which fluency increases as a consequence of practice.

Increases in Speed

Research on skill learning has often emphasized speed of performance. Across a wide range of mental and physical skills, the effect of practice on speed of performance follows a similar function: large speed-ups are observed over the first few attempts, with additional trials resulting in progressively smaller increments in speed. Researchers have observed this pattern with skills as disparate as solving mathematical problems, typing, rolling cigars, and even writing novels.

This pattern of speed-up with practice is usually well described by a mathematical *power function*, which states that the time required to perform a task is a function of the number of trials raised to some power. This function is represented by the equation $T = a + bN^{-c}$, where T is the time needed to perform the task, a is the asymptotic (shortest possible) time, b is the total amount of speed-up possible, N is the number of practice trials, and the exponent c is the rate of learning. The power function implies that speed-up will continue indefinitely, though after extensive practice each additional trial will produce only very small speed-ups

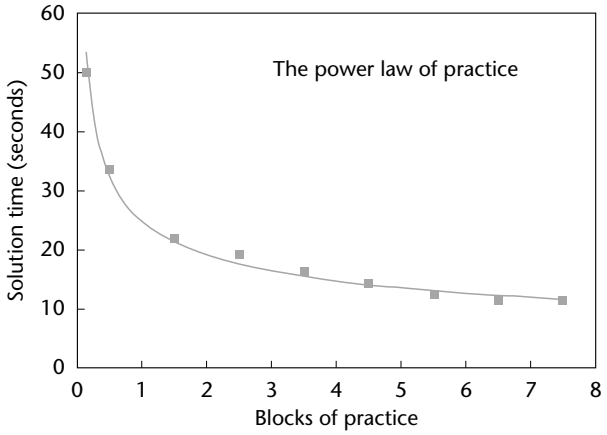

Figure 1. Time required to solve multiple-step arithmetic problems as a function of practice. A power function curve is fitted to the data.

(see Figure 1). This relation between practice and performance time has been described as the *power law of practice*, though some authors have argued that alternative functions (e.g. exponential functions) are better mathematical representations of the practice–speed relation.

Regardless of the exact mathematical representation, it is clear that learning curves typically show greater improvement early in practice than late in practice. Recent analyses suggest that smooth, continuous power-law speed-up will be observed only for particular strategies or component skills, and that much of the speed-up of complex skills depends on the combined effect of component skill speed-up and reorganization of component skills.

Restructuring and Chunking

Another consequence of practice is *restructuring*, the reorganization of activity to generate superior performance. A simple example is the acquisition of arithmetic skill: most theorists agree with the common observation that children learning addition shift from relatively laborious, inefficient counting procedures to direct, single-step retrieval of addition facts from memory. This kind of restructuring makes it possible to skip steps that may have been necessary in novice performance. Restructuring may depend in many cases on the acquisition of *perceptual chunks*, perceivable patterns that are meaningful in the context of a particular skill. For example, chess experts are superior to novices in identifying and remembering particular arrangements of chess pieces, if those arrangements are meaningful in the context of chess games.

Some researchers concerned primarily with complex physical skills have suggested that skill learning may involve the discovery of new *coordinative modes*, new ways of relating component actions to apply the system of components more effectively. Running and walking, for example, involve two coordinative modes for locomotion, organizing the movements of various parts of the body differently.

Another form of restructuring is *information reduction*. Skilled performers are more efficient in selecting information from the environment, reducing the amount of information that must be considered in order to perform an activity. For example, skilled pilots have efficient strategies for scanning cockpit instruments to guide their decision-making and control of flying.

Automaticity

A particularly interesting consequence of practice is *automaticity*, the ability to perform a task rapidly with minimal effort, little need for deliberate control, and sometimes little or no memory of having performed the task. Acquired automaticity has been documented by showing that, after extensive practice, individuals can perform tasks with little interference from other concurrent tasks, and with little effect of factors such as the number of alternative stimuli or responses. For example, anovice performing the laboratory task of searching a computer display for a particular target letter will be slower, the more items are displayed. Given sufficient practice with consistent search – that is, a letter that is a target is always a target – individuals in some circumstances can learn to search displays equally rapidly regardless of the number of letters displayed. Familiar examples of acquired automaticity include such skills as driving a car.

Such examples make clear that most real-life skills involve a combination of automatic and deliberate or controlled components. Automaticity is a matter of degree, and large amounts of practice are typically required for high levels of automaticity. Learning component skills to a high level of automaticity may be important for combining those skills in performing more complex tasks. For example, the ability to retrieve arithmetic facts automatically may be important for skilled solving of mathematical problems.

Retention and Transfer

The retention of skill over time, and the possibility of *transfer* from particular practice conditions to new situations or tasks, are important for both

practical and theoretical reasons. Retention of well-learned skills is often very good, with little decline in skill over months or years of disuse. Larger amounts of practice may increase retention, even when practice is continued to the point that improvements in performance are very small. Interestingly, retention often cannot be predicted effectively from practice performance. Conditions such as reduced feedback or interference among multiple skills may lead to poorer performance during practice but to superior retention.

Skill learning also typically exhibits *specificity of practice* – when the conditions for performing a skill are changed only slightly, the benefits of practice may be lost or dramatically reduced. For example, practice in generating lines of computer code may provide little benefit in evaluating what similar lines of code do. Another way to describe this phenomenon is to say that *transfer* – the application of knowledge or skill acquired in one context to a new situation – is typically quite narrow. Transfer can usually be improved by designing practice so that learners focus on aspects of a skill that are sufficiently abstract to apply to new situations, but specificity of practice is a major practical limit on skill training.

Dissociations of Declarative and Procedural Knowledge

Skill learning often demonstrates a dissociation between *declarative* and *procedural* knowledge of the skill. Declarative knowledge is knowledge that can be explicitly expressed ('declared') or consulted, whereas procedural knowledge ('knowing how') can only be performed. A commonplace observation is that knowing how to ride a bicycle does not imply an ability to describe how one rides a bicycle.

Researchers have documented this dissociation in various ways. For example, some patients with brain damage that produces near-total amnesia (and thus an inability to explicitly recall their experience of learning) can nevertheless acquire new skills. In some laboratory tasks, learners appear to acquire skills *implicitly* in the sense that their performance of tasks improves even when they cannot describe the regularities that allow them to learn the task. One consequence of this dissociation is that highly skilled performers are often unable to reflect on or talk about how they achieve their skilled performance.

Individual Differences

Individuals differ both in the ease with which they acquire skills and in the final level of skill they achieve. The existence of highly specific talents for learning particular skills is controversial, and many individual differences may result from differences in motivation and experience rather than innate talent. For many skills, though, individual differences in general ability, perceptual speed, and psychomotor ability do affect the course of skill acquisition. General ability is typically most important in the early stages of skill learning, whereas perceptual speed and psychomotor ability are more important in later stages of learning and the final level of skill achieved.

STAGES OF SKILL LEARNING

In many situations, skill learning appears to proceed through a series of characteristic stages. In acquiring a new skill, the first problem for the learner is to perform the skill for the first time, beginning the practice that will finally result in a fluent skill. This initial performance is often guided by verbal instruction (possibly self-instruction generated by the learner), by analogy to an existing skill, or by the use of an example or model to be imitated. A learner may continue to rely on such information for some time, perhaps refining his or her self-instruction or using examples or models in a more focused way. This initial stage of skill acquisition has been described as *cognitive, directed*, or *declarative*.

There has been some controversy over the best characterization of this initial stage, as some authors have argued that it necessarily involves declarative knowledge whereas others have pointed to such phenomena as *implicit learning* as evidence that skill can be acquired in the absence of relevant declarative knowledge. It seems clear, however, that initial performance of a new skill requires some kind of direction, usually external, that is not needed once the skill has been extensively practised. During the cognitive stage of skill learning, performance is limited both by lack of knowledge and by limits on working memory, the ability to temporarily hold information needed to support performance. Depending on the particular skill considered, this initial cognitive stage of learning may last for only a few trials, or may extend for some time.

Relatively modest amounts of practice are typically sufficient for a learner to move beyond the initial cognitive stage of skill learning. However, restructuring of the skill may continue for a long time, resulting in increasingly refined strategies and procedures. This intermediate stage of practice has been described as the *associative* or *knowledge*

compilation stage. During this stage, learners may begin to skip some steps that were required in the cognitive stage as they acquire more efficient procedures.

A third stage of skill acquisition involves gradual continuing improvement in the performance of a skill that is already stable and well-learned. This continuing improvement has been called the *autonomous, procedural*, or *routine* stage of skill learning. The routine stage of skill learning may extend for many thousands of trials, with performance continuing to show small improvements in fluency.

CONDITIONS OF PRACTICE

The success and efficiency of skill learning depends on the conditions of practice. Simple repetition may suffice to improve performance of some skills, but the effectiveness of practice depends on a variety of factors.

External Support

Skill acquisition, especially in the initial cognitive stage, often depends on external support for the initially unskilled performance. This external support may be provided by a teacher or coach who guides the learner and provides feedback. Increasingly, external support for skill learning is provided technologically by means such as videotape or computer software.

Some form of guided learning is necessary in at least the initial stage of learning most skills. However, research suggests that strict guidance, such as that provided by the keystroke templates in many computer tutorials, results in less effective learning than discovery learning, in which the learner must discover how to perform the task. External support that helps learners overcome the working memory difficulties typically encountered in complex mental skills may also be important in allowing multiple skill components to be held in mind together in order that links among them can be learned.

The initial performance of a skill is often guided by an example, model, or analogy. For cognitive skills such as solving mathematics or science problems, learners often make use of worked examples that illustrate the solution of similar problems. For perceptual-motor skills, learners often rely on observing a model, a skilled performer whose actions can be imitated. The issues involved in using examples or models are similar: learners must be able to correctly interpret and analyze the example or model, and must already possess component skills adequate to follow the example or model. Examples and models are most effective when they convey the hierarchical structure of a task domain. For example, students learn to solve mathematical problems most effectively when example problems highlight particular subgoals and their relations to the overall goal of solving a problem.

Many skills involve interacting with a mechanical apparatus (for example, piloting an airplane) or a symbolic medium (for example, solving a mathematical problem with pencil and paper or on a computer). These devices or media provide external support for memory and for monitoring performance. Of course, all skills are performed in some environment that provides external support for some of the psychological aspects of the skill. However, practice need not depend on external support. For many skills, *mental practice* can improve performance, though usually not as much as practice in the actual task environment.

Feedback

An important aspect of practice is the *feedback* available to the learner, information that specifies to what degree the skill is performed accurately and fluently. Feedback may result from the learner's own comparison of his or her performance to a mental standard, or may be provided explicitly by a teacher or by some mechanical means such as a software program. Research on the effects of feedback has focused for practical reasons on explicit feedback.

Feedback may vary in a number of ways. First, it may convey information primarily about the final outcome of a performance (*knowledge of results*) such as whether the answer to a problem is correct, or about the dynamic characteristics of the performance (*knowledge of performance*). Second, feedback may be available immediately on every attempt to perform a skill, or it may be delayed, intermittent, or summarized over multiple attempts. Finally, feedback may vary in its precision or in the aspects of outcome or performance about which it is informative.

Feedback is usually most effective when it is specific and immediate, allowing the learner to focus on those aspects of a particular performance that need improvement. However, learning may be better when feedback is not provided on every trial,

because learners given continual specific feedback may come to rely on that feedback to guide their performance and thus perform poorly when feedback is no longer available.

Practice Schedules

Another important aspect of practice is how that practice is distributed over time. *Distributed* or *spaced practice*, in which a skill is practised on multiple occasions spread over an extended period of time, generally results in better retention than does *massed practice* in which the skill is practised repeatedly in a relatively short period of time. The benefits of distributed practice have been demonstrated for a wide variety of skills, ranging from retrieval of arithmetic facts to complex perceptual-motor skills. A related phenomenon is the *contextual interference effect*, observed in verbal memory as well as in both motor and cognitive skills. When multiple skills are to be learned, practising the skills in a random schedule in which tasks are presented in a mixed fashion results in poorer performance during learning, but superior retention and transfer, relative to practising each skill in a separate block of trials.

Motivation

An important feature distinguishing effective from less effective practice is the learner's motivation. Motivation is of course necessary for practice to occur at all, a fact well known by teachers, parents, and coaches. Given that a learner does practise, however, the nature of the motivation with which they approach practising has a large effect on the level of skill attained. *Deliberate practice*, practice undertaken with the goal of improving performance, involves the selection of specific tasks and attention to particular cues that focus on aspects of performance to be improved. Research suggests that it is the amount of deliberate practice that largely determines the level of skill achieved in real-life domains such as music and sports.

Individuals who come to stand out as experts generally do so as a result of high motivation and large amounts of deliberate practice. However, individual differences in motivation may also explain differences in more modest levels of achievement. Some individuals seem to be characteristically motivated for immediate achievement, whereas others are characteristically motivated for learning. These differences in motivation result in differences in how learners approach tasks, in both laboratory and educational contexts. Individuals motivated for learning are likely to benefit more from practice, especially with difficult tasks.

THEORIES OF SKILL ACQUISITION

Behavioral Principles

Much theorizing about skill learning has involved primarily the accumulation of empirical principles, based on the generalizations described above, that provide guidance for effective practice. For example, it is safe to say that more practice is usually better, that appropriate consistencies make practice more effective, and that practice reduces the effort required to perform a task. A general principle governing the transfer of skill to new situations is known as *identical elements theory*, the idea that practice will transfer to the extent that the new skill shares identical elements – stimuli, rules, or responses – with the practised skill.

Cognitive–Symbolic Theories

Beginning in the 1970s, a number of researchers proposed and tested theories of skill acquisition based on the information-processing or computational approach to psychological theory. These theories explain skill learning by considering changes in the representation of knowledge as a function of practice. For example, one way to explain increasing skill in arithmetic is to describe the learning of 'number facts' as the acquisition of specific memories associating problems and answers. These memories can then be used in place of more laborious procedures (such as multiplying by repeated addition), resulting in faster solution of arithmetic problems.

The most highly developed cognitive–symbolic theories take the form of *production systems*, computational systems that represent knowledge in the form of productions, or if–then rules, that specify the conditions under which particular actions will be taken. Productions represent a fine-grained analysis of skill, such that between five and 100 production rules would be executed each second during skilled performance. In production-system theories, the effects of practice are represented by the acquisition of new production rules, by the combining of small sets of production rules into single, more efficient production rules, and by the speed-up in application of individual rules.

Cognitive–symbolic theories have been successful in explaining many phenomena of skill learning, especially in cognitive domains, and continue

to support active research programs. These theories have generally de-emphasized the perceptual-motor details of how skills are performed.

A related idea in the domain of motor skill is *motor program theory*, which suggests that the acquisition of skill involves learning and tuning a motor program that directs movement. According to this theory, the knowledge underlying a motor skill is analogous to a computer program. The effect of practice, according to this theory, is to adjust parameters of the program for optimal performance.

Dynamical Systems Theories

Dynamical systems theories of skill learning have recently become prominent among researchers concerned with motor skills. A starting point for these theories is the observation that motor skills involve coordinating the movements of multiple muscles and joints to accomplish movement goals, and that movement goals can generally be accomplished in more than one way. For example, grasping a glass requires coordinating movements of the fingers, wrists, and arm, and one may successfully reach for and grasp the glass in a variety of ways.

Dynamical systems theory treats skill learning as the process of discovering ways of coordinating activity, and focuses on the physics of movement as a source of constraints on coordination. From this point of view, an important characteristic of learners is that their musculo-skeletal systems, together with the environment in which they act, can be seen as *self-organizing* in the sense that the parts of these systems mutually constrain one another.

In contrast to cognitive–symbolic theories, dynamical systems theories de-emphasize mental representations but may provide substantial detail concerning how skills are actually performed. The control of skilled performance is thus viewed as a joint function of the performer and the environment.

Neurological Theories

Recent advances in methods for studying the brain are providing new insights into the neural substrates of skill learning. One important finding is that the brain appears to have multiple systems for learning, involving different neural circuits and different means of representing knowledge. Some neural systems may be involved in many kinds of skill; for example, the cerebellum appears to be involved in perceiving and producing sequential activity in both mental and perceptual-motor skills. Other neural systems may be involved primarily in specific kinds of skills; for example, portions of the temporal cortex seem to be active mostly in the performance of skills that have verbal or symbolic components.

COMPLEX SKILLS: MUSIC AND SPORTS

Most laboratory research on skill learning has focused on relatively simple skills, or on intellectual skills such as scientific problem-solving. The study of some complex real-world skills, such those involved in music and sports, raises additional issues. These skills typically combine cognitive, perceptual-motor, and emotional or esthetic aspects.

For example, skilled musical performance involves thought about musical structure, skills for manipulating an instrument, and judgments about performance details that convey expressive aspects of the music. Skilled performance in sports requires not just high levels of perceptual-motor skill, but skill in making strategic and tactical decisions in game settings. Issues such as anticipation, flexibility in recruiting component skills, and precise tuning to the environment (including the actions of fellow players or, in the case of sports, opponents) are thus more prominent in music and sports than in most laboratory research on skill.

It is widely believed that talent plays a greater role in acquiring music and sports skills than it does in other domains, and this belief dominates the literature on skill in other esthetic domains such as painting and drawing. However, research provides little support for this view. For example, a high degree of sensitivity to musical structure appears to be nearly universal, though acquiring substantial musical skill requires a large amount of deliberate practice. Motivation and deliberate practice appear to account for much of the difference between outstanding performers in sports and music and those who are less skilled.

Domains such as music and sports involve public performance. The best performers are highly valued by society, and thus represent a highly selected sample characterized by considerable levels of skill. Research suggests, however, that the principles of skill learning observed in laboratory research also apply to these complex and culturally situated skills. The scientific study of skill learning thus promises to explain even the highest levels of skill.

Sleep and Dreaming

Introductory article

J Allan Hobson, Harvard Medical School, Boston, Massachusetts, USA

CONTENTS

Sleep and dreaming have an important role in the regulation of cognition. New investigative techniques suggest that brain activity during sleep is fundamental to learning.

INTRODUCTION

The cognitive neuroscience of sleep and dreaming has recently enjoyed a welcome growth spurt owing to a confluence of new results from neuropsychology, experimental psychology and fundamental neuroscience. Neuropsychology has contributed new brain imaging data regarding selective activation and deactivation of brain regions during normal sleep and complementary findings regarding the effects of brain damage upon dreaming in neurological patients. Experimental psychology has shown that sleep is not only permissive but essential to certain kinds of learning. Fundamental neuroscience has provided new models for understanding how the various stages of sleep are controlled by the brainstem and linked to the circadian rest–activity cycle controlled by the hypothalamus. The result is a coherent picture that illustrates the dynamic and highly functional role of sleep and dreaming in the regulation of cognition as well as other adaptive responses. For a discussion of the implications of these findings for theories of consciousness. (*See* **Consciousness, Sleep, and Dreaming**)

STAGES OF SLEEP

The rich differentiation of sleep into its component phases has been revealed by laboratory studies of humans and other mammalian subjects using the electroencephalogram (EEG) for recording brain waves; the electromyogram (EMG) for recording postural muscle tone; and the electrooculogram (EOG) for recording eye movement (Table 1, Figure 1). In essence the sleeping brain fluctuates between epochs of relative inactivation (quiet or slow-wave sleep) and epochs of activation (active or fast-wave sleep). These epochs can be distinguished by the presence or absence of rapid eye movements (REM). Nonrapid eye movement (NREM) or slow-wave sleep is associated with a decline of cortical electrical activity and of postural muscle tone. The NREM phase occupies about 75% of total sleep time and can be further subdivided into four stages according to EEG characteristics (Table 2). The degree to which NREM sleep is dominated by stages III and IV declines over the night along with the depth of sleep and the level of associated mental activity, although the period and length of each cycle is constant (Figure 1b). Stages III and IV are associated with energetically restorative processes as evidenced by the release of growth hormone and the secondary sex hormones follicle stimulating hormone and luteinizing hormone, as well as by low levels of sympathetic autonomic activity: decreased blood pressure, respiratory rate, etc. (Figure 1c). People are difficult to rouse from stage III or IV and often experience confusion, disorientation and confabulation on arousal. Reports of dreaming are rare, although sleep-walking, sleep-talking and nightmares can occur. As the night progresses the NREM epochs become less sharply differentiated from the REM epochs and mental activity often indistinguishable from REM is increasingly reported.

At intervals of about 90 min throughout the night the NREM phase is interrupted by the spontaneous EEG activated eye movements and muscle tone suppression of REM. This REM phase is typically short early in the night but lengthens as sleep progresses so that it occupies about 25% of total sleep time. Rapid eye movement sleep is correlated with increases in sympathetic autonomic activity and with penile erection; and arousals yield long and detailed reports of dreaming.

This cyclical organization of sleep into NREM and REM phases is seen in all mammals at all

Table 1. Electrographic differentiation of waking and sleep

	Awake	*NREM*	*REM*
EEG	+	−	+
EMG	++	−	0
EOG	+	−	+

Table 2. Electroencephalographic characteristics of NREM sleep stages

NREM sleep stage	*EEG frequency range (Hz)*	*EEG rhythm*
I	4–8	Theta
II	12–15	Sigma (spindles)
III	1–4 + 12–15	Spindles plus slow waves
IV	1–4	Delta (slow waves)

EEG, electroencephalogram; NREM, nonrapid eye movement.

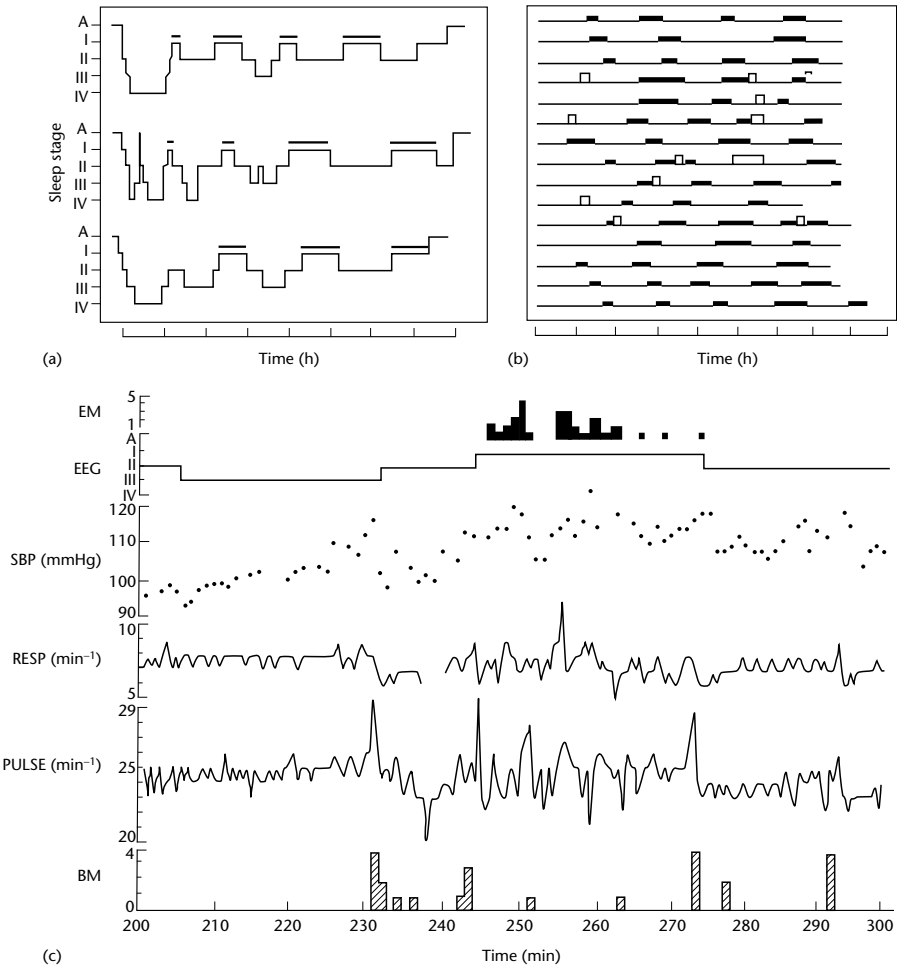

Figure 1. Sleep cycle with periodic activation. (a) Detailed sleep-stage graphs of three human subjects: note the preponderance of the deepest stages of NREM sleep in the first two or three cycles of the night; REM sleep is correspondingly brief (in subjects 1 and 2) or even aborted (subject 3). During the last two cycles, NREM is restricted to the lighter stage II, and REM periods occupy proportionally more time, with individual episodes often exceeding 60 min. (b) REM sleep periodograms of 15 human subjects show the same tendency to increase REM sleep duration. (c) Fluctuations in sympathetic autonomic activity. EEG, electroencephalogram; RESP, respiratory rate; SBP, systolic blood pressure.

stages of development but the period length of the cycle varies as a function of size and age (the larger and older, the longer), and the characteristics of the NREM and REM phases also change with development. Newborns have abundant REM sleep indicating its possible importance for early brain

development. Adolescents have abundant stages III and IV sleep, signaling its importance for psychosexual and intellectual maturation. With advancing age both sleep length and depth typically decline together with the gradual deterioration of the brain and cognitive function.

Normal Variations in Sleep Length and Depth

Like all other biological variables, the length and depth of sleep show large individual differences. Some people, 'larks', awake early and easily in the morning; others, 'owls', are able to stay up late at night without feeling tired. Whatever their times of sleep onset and offset, some are refreshed by as little as 4 h sleep while others need 8–10 h and may still feel listless by day. Short sleepers tend to be more energetic, ambitious, optimistic and productive, while long sleepers are more easily fatigued, accomplish less, and experience pessimistic and even depressed moods. Threshold to arousal also varies normally: some can sleep in daylight, with the windows uncovered and fire engines roaring by, while others have difficulty staying asleep in the depth of night, in the total silence and comfort of a well-insulated bedroom.

Whether or not the extremes of normal sleep variability should be considered pathological is an important clinical judgment, particularly in view of the risks of long-term sedative and stimulant use. Individuals who have too little or too much sleep for their social and physical comfort should know and follow certain simple rules before turning to medication. The first is that the timing of sleep is very sensitive to the time of waking; getting up early is the best way to promote falling asleep at the desired time of night. The second is that sleep is exquisitely carefully self-regulated by the brain; this means that debts are carefully accounted and paid back. The third is that sleep is impeded by stress, anxiety, and obsessive thinking, but enhanced by physical work and exercise.

The fact that cognition (depending on its content) can either benefit or impede sleep is a corollary of the functional principle that sleep, depending upon its content, can benefit or impede cognition. The worst thing that a poor sleeper can do is think about it, because obsessive reflection makes sleep worse. On top of that, poor sleepers tend to grossly overestimate the time spent awake, hence both exaggerating their insomnia and applying the resulting anxiety to their sleep loss worries. This vicious circle responds to its treatment of choice: cognitive behavioral therapy.

SLEEP DEPRIVATION

Following the discovery of REM sleep by Aserinsky and Kleitman in 1953 and its correlation with dreaming by Dement and Kleitman in 1957, researchers began to investigate the psychological consequences of selective deprivation of REM. While the hypothesis that REM deprivation ('dream deprivation') might have a specific deleterious effect on cognition was not confirmed, the experiments did reveal that both REM and NREM sleep were rigorously regulated. When either was prevented by instrumental awakenings, the participants' sleep intensified so as to restore the losses, and it became increasingly difficult to activate the deprivation as it was repeated. The quantitative relationship between the amount of sleep lost and that recovered later indicated that sleep was homeostatically controlled by highly reliable brain mechanisms and that sleep was not only functionally valuable but indispensable to adaptation and to life.

Humans who are subjected to REM, NREM or total sleep deprivation are not merely sleepy; they are also inattentive, emotionally labile, and unable to perform complex analytic tasks. These cognitive symptoms can be seen early in even modest sleep curtailment regimens if the individual is sensitive, middle-aged to aged, or is engaged in intellectually demanding work. Critical monitoring tasks, such as automobile, aircraft, ship or railroad train operation, also require remedial attention. Spectacular anecdotal examples like the *Exxon Valdez* oil spill catastrophe have prompted quantitative epidemiologic studies showing clearly that accident incidence is correlated with sleepiness and substantial loss of vigilance.

When carried to greater lengths, sleep deprivation can within days precipitate hallucinations, delusions, or frank psychosis in humans. In animals deprivation of sleep leads to death within 4 weeks. En route, experimenters observe a breakdown of the integrity of the skin, voracious appetite, and powerfully driven heat-seeking behavior in sleep-deprived rats. These signs of overdriving and exhaustion of the sympathetic nervous system ultimately result in an inability to maintain body weight or body temperature. However, if the deprived animal is then allowed to sleep, even for a few hours, these functions are immediately

restored. If not, they lead to death by sepsis when gastrointestinal bacteria invade the bloodstream and overwhelm weakened immune defenses.

REM SLEEP AND DREAMING

Although the association of dreaming with REM sleep is not exclusive, REM is the sleep phase that provides the optimal conditions for dreaming in its most fully realized forms. It is thus in REM sleep neurophysiology that cognitive scientists can most profitably seek the brain conditions of dreaming. Dream reports have the formal characteristics shown in Table 3. Dreams in REM sleep are mental experiences that are dominated by internally generated percepts (hallucinations) of which the predominant domain is visuomotor, so that dreamers vividly imagine themselves to be moving through a visually detailed world. So vivid are the dream percepts that people rarely recognize that they are not awake but dreaming. The deficient self-reflection leading to this delusional belief is all the more surprising in view of the bizarre cognition, the discontinuities and the incongruities that characterize the hallucinated dream world. Contributing to the delusional acceptance of the dream world as real is the presence of compellingly strong emotions (such as anxiety, elation and anger) and the activation of instinctually organized motor programs (such as sex, fight or flight) that conspire in the elaboration of gripping dream scenarios.

On the cognitive side the deficient self-reflection is compounded by a marked reduction in the prevalence of thinking of any sort and by a loss of memory capacity that makes recognition of the orientational instability of dreams so difficult for us. Our dreams change the times, places and persons of our dream plots without notice, and they may change, even radically, without our noticing it. Our inability to think critically is matched by our inability to evaluate, choose, and execute a plan of action. We do not will dreams; instead, they just happen to us.

Table 3. Formal characteristics of rapid eye movement sleep dreams, as compared with waking

Intensified	*Diminished*
Hallucination	Thought
Bizarreness	Self-reflection
Delusion	Memory
Emotion	Volition
Instinctual activity	

Two important changes in our way of thinking about dream cognition result from this formal analytical approach. The first is the replacement of the simplistic 'REM equals dreaming' model with a more quantitative and statistical statement of probability relating each formal aspect of dreaming to its physiological underpinnings. Thus, for example, the probability that mental activity will be hallucinating increases progressively as the brain moves from wake, through sleep onset, to the NREM phase, and reaches its peak in REM. Conversely, the probability that mental activity will be thought-like progressively and reciprocally declines (Figure 2). The second is a change in the interpretive agenda from an attempt to account for the formal features described above in terms of a content analytic schema (such as Freud's disguise censorship model) with physiologically based models (such as the activation–synthesis model) that attribute the cognitive changes – such as the increased probability of hallucinations and the decreased possibility of thought – to brain physiology, rather than findings of psychology. This change allows the search for the emotional salience or 'meaning' of dreams to proceed in a more straightforward, commonsense manner without the encumbrance of Freud's convoluted psychological theory.

THE NEW NEUROPSYCHOLOGY OF SLEEP AND DREAMING

Complementing the basics of sleep and dream science are data from three methodological innovations that revolutionized the field during the 1990s. The first is the development of home-based data collection methods that allow subjective experience to be quantified around the clock: humans can record the vicissitudes of consciousness that accompany sleep and waking in the natural settings of their lives. This is accomplished by combining the technique of experience sampling with novel sleep monitoring devices which can discriminate between waking, sleep onset, NREM and REM sleep by algorithmic analysis of head and eyelid movement (Figure 3). Using this approach it is possible to study people over many successive days and nights and to obtain thousands of reports of mental activity for analysis in terms of the brain states that underlie them. It is from such studies that the reciprocal relationship between hallucinations and thinking has been discovered, and it is in such data that other formal mental-state features like emotion and bizarreness can be explored in great detail. The simplicity and low cost of the

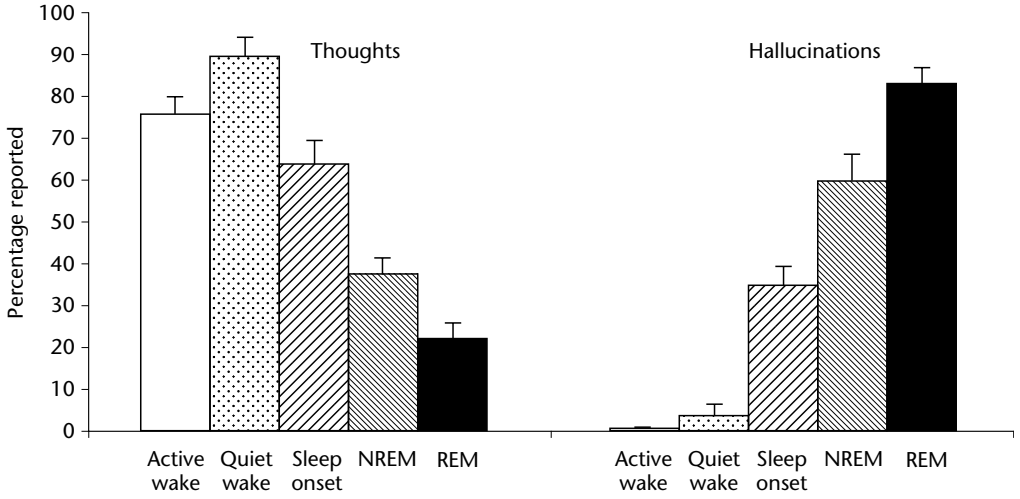

Figure 2. Reciprocal variation in thoughts and hallucinations: percentage of reports in each wake–sleep state.

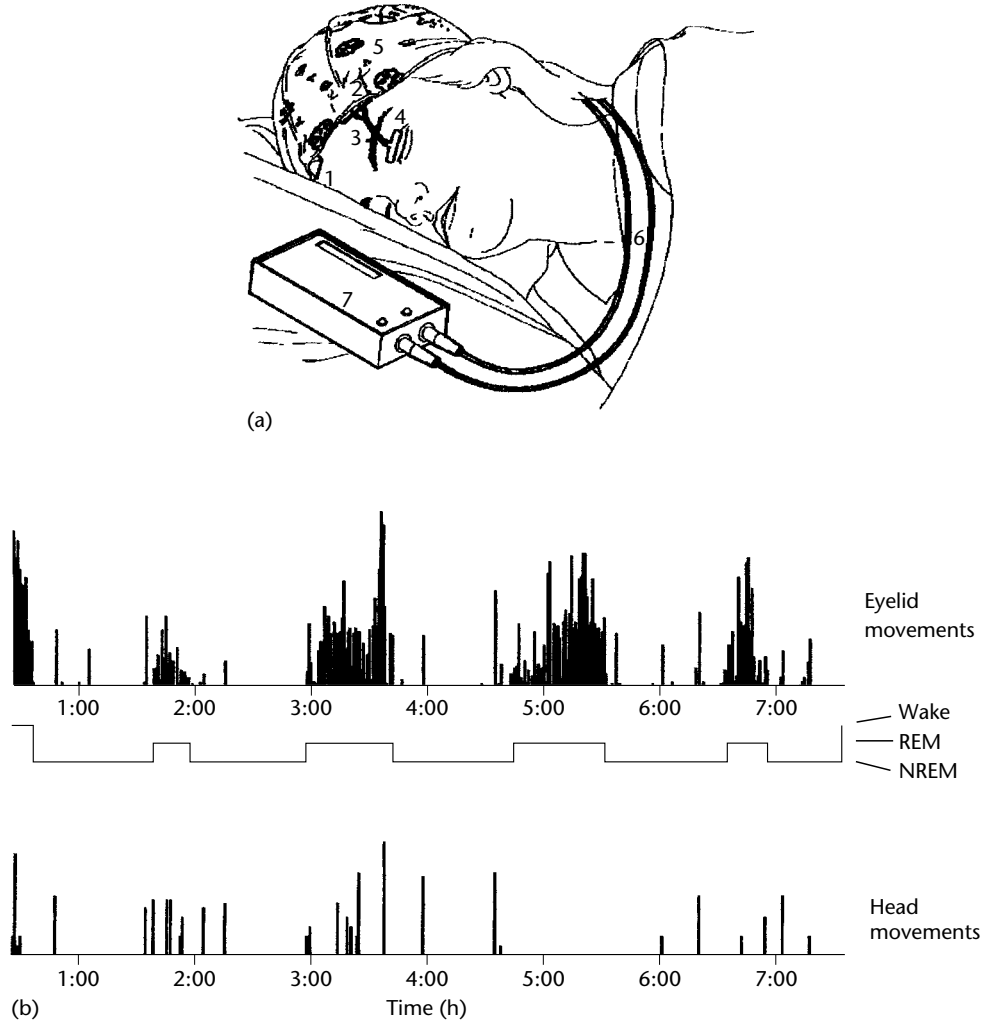

Figure 3. Sleep monitoring device, (a), recording the various stages of sleep through algorithmic analysis of head and eyelid movements, (b). 1, head movement sensor; 2, eyelid movement sensor mount; 3, eyelid sensor lead; 4, eyelid sensor with adhesive backing; 5, bandana (worn 'pirate' style); 6, wires from sensors to recording unit; 7, recording unit.

method puts sleep and dream research in the hands of any cognitive scientist wishing to study sleep–wake phenomena *per se* or the changes in memory or mood that accompany them in normal or experimental populations.

The second methodological innovation is human brain imaging, which reveals the regional differences in activation that are associated with sleep. Data derived from positron emission tomography (PET) is cross-sectional but using functional magnetic resonance imaging (fMRI) it will soon be continuous. The revelations from these images are very informative: the deactivation of the brain reflected in the EEG slowing of NREM sleep is associated with global declines in regional blood flow; the reactivation that is evinced in REM is sharply differentiated, with some structures getting more blood flow, and others less, than in waking.

The third innovation is the report of changes in the dream experiences of patients with regional brain damage. A global loss of dreaming occurs after damage to the parietal operculum or deep frontal white matter, two of the brain regions shown by brain imaging to be selectively activated in REM.

The net result of these three new approaches is a remarkably coherent picture of how the brain determines the formal nature of mental experience. For either waking or dreaming to occur, the forebrain needs to be activated by the brainstem. This activation is regionally and chemically distinct in ways that help us better understand the cognitive differences between waking and dreaming. In waking, the activation is global and aminergic neuromodulation is maximal: as a consequence the waking mind can perceive, attend to, critically evaluate and remember both externally and internally generated data. In REM sleep the activation is selective and the neuromodulation is minimal: the dreaming mind perceives only internally generated data in an unfocused, uncritical, and forgetful way. In NREM the activation is globally reduced to its low point and aminergic modulation declines by half; the deeply sleeping mind is capable of only low to nonexistent levels of information processing.

Functional Significance of Sleep and Dreaming

To what end does the brain undergo such radical changes in sleep? Before considering the mounting evidence that learning and memory are the surprising beneficiaries of their own apparent dissolution in sleep, it is important to stress the evidence that sleep is essential to life: the fact that prolonged sleep deprivation leads inevitably to death has been convincingly demonstrated in rats. En route to their demise, the sleep-deprived animals show defects in such vital physiological functions as body temperature control, dietary energy regulation, body weight control, integrity of the skin, and resistance to infection. These profound and severe defects match the mounting evidence that sleep is an integral aspect of the circadian rhythm controlled by the supracharismatic nucleus, which also regulates body temperature and rest–activity cycles. The circadian clock is intimately linked to other hypothalamic control systems via increasingly well-defined synaptic pathways to and from the neuromodulatory systems of the lower brainstem. In other words, sleep, energy regulation, sexual development and immune responsiveness are all coordinated by shared sets of anatomical circuits and physiological mechanisms in the subcortical brain.

Memory and Learning

Now that the complex and highly organized brain systems uniting sleep with other vital biological processes have been defined, it should come as no surprise to learn that cognition – that most highly adaptive attribute of the mammalian (and especially primate) brain – is also facilitated by sleep. Early work on learning and memory focused on REM sleep but more recent studies have shown that NREM sleep, for all its deficiencies in sustaining ongoing conscious experience, is also involved in the enhancement of learning. In fact, it now appears that learning of information may be a two-stage process by which information acquired in waking is consolidated in NREM sleep and then integrated in REM sleep. A new theory has even proposed that the fluctuating and regionally selective activation and aminergic-cholinergic neuromodulatory processes described earlier underlie transfer of data back and forth from hippocampus to cortex on each successive NREM–REM cycle so that associative memory can be increasingly fine-tuned over the night (Figure 4).

The evidence for this exciting hypothesis comes from four distinct sources. The first is the intrinsic dynamism of hippocampal, cortical and brainstem neuromodulatory activity as revealed by single cell and molecular level microdialysis recording in animal experiments. Although the brain is off-line in sleep, it is in constant action, and engaged in differential communications with itself even in the deepest stages of NREM sleep when conscious experience is at its nadir. This establishes the

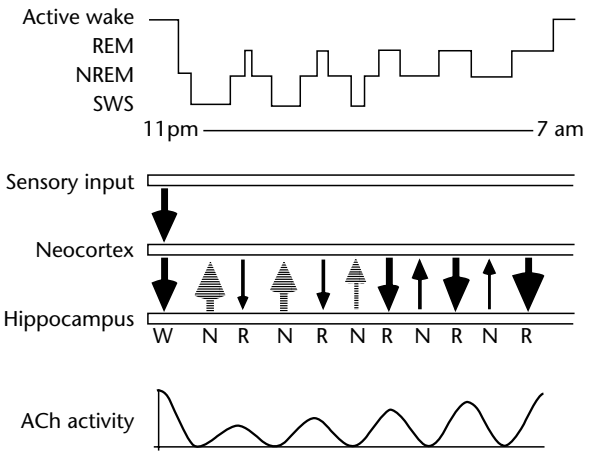

Figure 4. Neuromodulatory activities during sleep; transfer of data back and forth between the cortex and hippocampus during successive sleep cycles is believed to enhance associative memory. ACh, acetylcholine; NREM, non-REM; REM, rapid eye movement; SWS, slow-wave sleep.

plausibility of the model of sleep-learning. The second is the empirical evidence, from both single cell studies in animals and cognitive studies in humans, that recently acquired information (such as place-cell orientation data in rats, or video game-induced imagery in humans) is repetitively replayed in NREM sleep. This data corresponds to the iterative reading out of stored hippocampal data to the cortex. The third is the empirical evidence from human studies that both NREM and REM sleep are essential to optimal performance on tests of visual discrimination learnt to criterion prior to sleep. These data indicate that the two sleep phases serve not just to consolidate learning, but actually to enhance it: participants who slept deeply early in the night (NREM) and remained asleep late in the night (REM) did better when tested in the morning than they did at their peak prior to sleep. The fourth is the empirical evidence from animal studies that training on a variety of tasks leads to a subsequent increase in REM sleep that may persist at intervals from 1–6 weeks after training. Deprivation of REM sleep early in the post-training period may block the improved task performance that emerges later.

CONCLUSION

The hypothesis that sleep facilites cognition finally appears to be on a solid conceptual, neurobiological and empirical footing. By combining experimental techniques with the new neuropsychological approaches, it may soon be possible to enunciate a unified theory of brain–mind status that accounts for both phenomenological and cognitive data with the same set of neurocognitive models.

Galen V Bodenhausen, Northwestern University, Evanston, Illinois, USA

CONTENTS

Social cognition refers to the mental processes by which we make sense of our social worlds. The basic claim of the social cognition perspective is that accounting for the complex dynamics of social behavior requires an understanding of the cognitive structures and processes that shape the individual's understanding of the social situation.

INTRODUCTION

Defined broadly, social cognition refers to those aspects of mental processing that are shaped by social interaction, real or imagined, and which in turn influence subsequent social behavior. Defined more narrowly, social cognition refers to a research orientation that employs cognitive principles to analyze and investigate social psychological topics such as social inference, the self, and social perception. Social-cognitive research, with its adherence to the information-processing metaphor, is fundamentally the study of process; that is, social cognition is the part of social psychology that deals with the psychological mechanisms that mediate the individual's responses to the social environment. As such, the nature of mental representation and the dynamics of information processing are central topics of social-cognitive inquiry. (*See* **Information Processing**)

SOCIAL INFORMATION PROCESSING

A basic issue in social cognition research concerns the nature of impression formation. Interpersonal behavior is assumed to be dictated by the character of the impressions that people form of others. The impression-formation process has generally been assumed to proceed as follows. The social perceiver first identifies salient attributes of the target person; then searches memory for category representations that are similar to the detected attributes of the target; selects the most appropriate category representation; uses the content of that representation to draw inferences about the individual; and stores the resultant impression or evaluation in long-term memory. Thus, there is an initial 'bottom-up' or 'data-driven' process in which the features of the target trigger applicable material in memory; 'top-down' or 'theory-driven' processes then guide the perceiver's understanding of the person along particular dimensions. (*See* **Causal Perception, Development of**)

The Mental Representation of Social Information

Social cognition can loosely be broken down into two main elements: the mental structures that are used to represent social information, and the processes that operate on these representations. Broadly speaking, a mental representation is a record of the experienced past that can be constructed, retained in memory, and accessed and used by perceivers in the course of their dealings with others.

Social representations have frequently been assumed to take the form of schemata, associative networks, or prototypes. Although these theoretical viewpoints vary in terms of the internal organization assumed to characterize social knowledge and the degree of interconnectedness thought to exist among these structures, they all share the assumption that social information is represented in the form of general knowledge rather than knowledge of episodes bound to particular times and contexts. These models assume that representations are composed of the individual features that describe the 'typical' category member. That is, there is a generic summary representation of the social target, and the representation that best matches the target is used to guide the

categorization and inference processes. (*See* **Schemas in Psychology**; **Prototype Representations**)

However, evidence exists that people are able to use memory for specific episodes or individuals when making judgments, leading many social-cognitive researchers to endorse an exemplar-based account of knowledge representation. Exemplar representations, in contrast to more generic representational formats, consist of memory traces for specific stimuli or episodes. There is no summary representation for any given collection of targets, and different subsets of exemplar representations can be activated by different targets or contextual cues. According to this viewpoint, stereotypes, for example, do not exist as independently stored knowledge structures but, rather, are created in certain contexts when perceivers summarize the features of a collection of activated exemplars.

The abstraction–exemplar debate within social cognition has taken a similar form to the debate within cognitive psychology, focusing on whether each type of model can account for the effects presumed to be mediated by the other form of representation. More recently, mixed models of representation, in which the perceiver stores both details of specific episodes and generalities across episodes, have been proposed. Some evidence has suggested that the nature of the mental representation of a social group depends on the perceiver's degree of experience with the group in question, such that greater experience is associated with the use of generic knowledge representations (i.e. prototypes). (*See* **Representations, Abstract and Concrete**)

Nonetheless, even with expertise perceivers are able to recruit and use specific exemplars in social judgment, suggesting that the predominance of prototype versus exemplar use in social judgment may not necessarily reflect the manner in which social concepts are represented in memory but, rather, the default processing strategies that are engaged when social perceivers deal with familiar versus unfamiliar targets. Moreover, this general class of models has been criticized for failing to provide a parsimonious account of knowledge representation and memory function. More recently, connectionist (i.e. parallel distributed processing – PDP) accounts of knowledge representation have been proposed as an alternative to the more traditional symbolic approach for understanding social cognition.

Like the more traditional symbolic models, PDP models view representations as networks of interconnected units, and assume that activation spreads along these connections. However, they contend that representations, rather than being discrete, are distributed and superposed: meaning derives from the pattern of activation across many units, and the same set of units can represent different concepts depending on the pattern of activation across the units. This form of representation has been likened metaphorically to a television screen: no pixel has any specific meaning by itself, but by taking on different patterns of illumination the entire array of pixels can constitute a large number of meaningful 'pictures' or representations. In this way, distributed representation seems to be an efficient means of capturing knowledge. The distributed representation is a mechanism that both processes and stores information. This enables both greater context sensitivity and greater storage efficiency. In the area of social cognition, PDP models have been developed to explain stereotype representation, impression formation, and causal explanation.

It is important to note that all of the models described thus far are based on the probabilistic view of categorization, where targets are categorized (and judged) as a function of how similar their attributes are to the features stored in the representation. In recent years, however, a number of cognitive psychologists have argued that the feature-based probabilistic approach is insufficient and that a 'theory-based' approach to concept representation is more fruitful. Proponents of this approach have accrued evidence that categorization depends critically on factors other than similarity matching, and that similarity itself is context-dependent. Perhaps the strongest indictment of the feature-based approach is evidence that, although similarity-based approaches seem appropriate when the perceiver cannot generate an explanation for why a target belongs to a particular category, they do not seem to have strong predictive power when an explanation for category membership is available.

Although few social–cognitive psychologists have explicitly adopted the theory-based approach, evidence in the social psychology literature supports the role of theory and causal explanation in the construction of social representations. (*See* **Similarity**)

Automaticity and Control in Social Cognition

The issue of representational format aside, how does the existence of these knowledge structures influence information processing and behavior? Much of the social psychology research conducted

prior to the mid-1970s assumed, explicitly or implicitly, that people were aware of the cognitive processes underlying their judgments and behaviors and were capable of monitoring and controlling these processes. With the advent of the cognitive revolution, however, evidence emerged to suggest that the perceiver has little introspective access to higher-order cognitive processes and can be completely unaware of the role that various factors play in influencing judgments and preferences. As a result, social psychologists became increasingly interested in processes that occur outside of awareness, thereby evading the perceiver's attempts to understand and control his or her own behavior. The outcome of this revolution was an expansive literature suggesting that much of mental life unfolds in an automatic manner. Our judgments, feelings, and behaviors can be influenced by factors of which we are unaware, by factors of which we were once aware but can now no longer recall, and by factors that we can still recall but whose influence escapes our detection.

Automaticity has been observed in a variety of social judgment domains. For example, it appears that when we observe a person's behavior, we automatically make inferences about the person's underlying traits ('spontaneous trait inferences'). The mere apprehension of people, events, or objects elicits evaluative responses to these targets, and these responses are pre-conscious and automatic. Stereotypic information also appears to be activated automatically, in that it is triggered without the individual's awareness of consent. Recent research has demonstrated that even complex social behaviors can be automatic at times. Nonconscious activation of stereotypes can sometimes lead the individual to behave in accordance with those stereotypes, even if she is not a member of the relevant social category (the 'perception–behavior link'). (*See* **Automaticity**)

That these processes occur automatically is not trivial. Our automatic reactions can guide our decisions and judgments and can influence our thoughts about other people, even if we are not consciously aware of these reactions. Our evaluations of others may be inadvertently influenced by our goals, by our moods, by our stereotypes, by aspects of the situation, and by a multitude of recent experiences, without our recognition that these influences even exist.

Historically, automaticity has been defined in terms of four features: awareness, intentionality, controllability, and efficiency. Unlike controlled processes, automatic processes occur outside awareness, are carried out without intention, are uncontrollable in the sense that we are unable to stop them, and are highly efficient in that they require no attention. Most interesting mental phenomena, however, are of sufficient complexity to be composed of some automatic and some controlled features. Thus, although it appeared in earlier studies that trait inferences were automatic, further research demonstrated that the process could be circumvented by the imposition of a cognitive load, suggesting that trait inferences are conditionally rather than fully automatic. In the domain of stereotyping, some evidence suggests that imposing a processing limitation does not impede the perceiver's categorization of a target into a social group; it does, however, potentially impede the activation of stereotypes associated with that social group. Research on stereotype application suggests further that stereotypes can be automatically inhibited if the stereotypes are at odds with the perceiver's goals. Finally, it appears that the perception–behavior link is moderated by goals: to the extent that the perceiver's goals conflict with the primed concept, the perceiver will not act in accordance with that concept.

One of the most intriguing examples of how a cognitive process can be composed of both automatic and controlled components comes from the theory of 'ironic' mental control. According to this theory, the successful suppression of undesired thoughts requires the conjoint operation of an intentional, controlled search for distracters and an automatic search for the unwanted thoughts (so that they can be suppressed by distracters). When cognitive resources are scarce, the controlled search for distracters is disrupted, but the automatic search for the unwanted thoughts continues unabated, resulting in the hyperaccessibility of the unwanted thoughts. Research has demonstrated the application of this model in the context of stereotyping: actively trying to suppress stereotype use can actually lead the perceiver to rely more on the stereotype than would have been the case in the absence of these suppression attempts.

THE INTERSECTION OF MOTIVATION AND COGNITION

Not surprisingly, how we feel and what we desire can color our judgments. Beyond the level of mere knowledge activation, most cognitive activity is goal-dependent; that is, it is initiated by a perceived discrepancy between an actual and a desired state. Motivation can influence social cognition in a number of important ways. Motivational factors can determine the degree of cognitive effort

expended to process relevant information, as well as the direction that the process takes. Motivation can affect the direction of processing by facilitating the activation of goal-relevant cognitive categories, in a sense determining the 'theories' that are applicable for interpreting the available data. Finally, motivation can also affect the extent of information processing, based on how important the perceiver's goals are and how much cognitive effort (e.g. elaboration, distortion, inconsistency resolution) is required to make the current situation match the desired situation.

Cognition, of course, can also influence motivation. Motivation has a cognitive aspect, in that goals may be thought of as knowledge structures, governed by the same processes and mechanisms that govern other cognitive structures. Cognitive capacity, for example, constrains the extent to which motivation can exert its influence: to the extent that the perceiver can draw on all of her cognitive resources, motivation will have stronger qualitative and quantitative influences on processing; however, to the extent that the perceiver's resources are depleted – by virtue of distraction, anxiety, circadian rhythms, and so on – she will be less able to control both the direction and the magnitude of processing.

Affect and Cognition

The intersection of motivation and social cognition has been most clearly represented by theory and research on affect and cognition. This research has yielded several findings that suggest that encoding, elaboration, and judgment are mediated by the recall of mood-congruent information stored in memory. Ambiguous information tends to be encoded in terms of concepts of the same valence as the perceiver's current mood. Inferences that perceivers draw are often matched in valence to their current mood. Moreover, perceivers are more likely to remember information if it is affectively matched to their current mood state.

In terms of the relation between affect and cognition, three general frameworks have been proposed. The first approach views affect as an emotional state and adopts a functionalist approach to the emotion–cognition relation. Proponents of this framework assert that to make predictions regarding the direction and magnitude of cognitive activity, it is necessary to consider the adaptive significance of the emotion in question. For example, it appears that happiness, which signals to the perceiver that all is well, leads to a decline in processing activity (unless such activity is intrinsically enjoyable) – presumably because the perceiver either feels no need to engage in deep processing or does not want to risk the decline in mood that could accompany such effort. Sadness, in contrast, presumably signals to the perceiver that something is amiss. Sad perceivers tend to engage in deeper processing, perhaps to distract themselves from, or to find a remedy for, their emotional state. Interestingly, these patterns translate into greater stereotyping by happy perceivers and less stereotyping by sad perceivers, relative to perceivers in a neutral mood. High-arousal emotions such as anger and anxiety also lead to greater stereotyping; in this case, however, this appears to be a function of the capacity-diminishing nature of arousal, rather than of any appraisals of emotional significance.

The second framework is exemplified by the 'mood as information' view of affect. Proponents of this approach suggest that feelings may serve informative functions, and that perceivers use their apparent affective responses to targets as a source of information in evaluating those targets. The impact of feelings on these evaluative judgments depends on their perceived informational value: to the extent that affective reactions seem to offer relevant information, they will influence evaluations of the target; however, to the extent that affective reactions are deemed irrelevant, they will not be used as a basis for judgment.

Unlike the frameworks in which affective information can become linked to the cognitive representation of some target, a third framework proposes that emotions themselves provide a framework within which targets may be categorized and represented. That is, emotions do not simply activate congruent information; rather, they actually lead individuals to reorganize conceptual space according to emotional equivalences. This reorganization then determines how people perceive similarities and differences among objects and events and how they respond to them. Thus, emotions affect not only memory but also category construction and use. Emotional response categorization is assumed to be functional: a category of things that have elicited a particular emotion enhances the perceiver's understanding of the meaning of that experience in terms of his or her own personal learning history. This, in turn, facilitates the perceiver's ability to imagine the consequences of reactions to new objects.

THE SELF

Social cognition theorists assume that social behavior is mediated not only by mental representations

of others, but also by actors' currently active representations of themselves. Much of the research in social cognition that concerns the analysis of the self has focused on the person's mental representation of his or her own personality attributes, social roles, past experiences, and future goals, and how these representations influence social inference and social judgment. (*See* **Self, Psychology of**)

Self-knowledge

People differ in which attributes they consider central and self-defining. For each of their most central attributes, individuals may develop elaborate self-schemata (i.e. integrated sets of memories and beliefs about their relevant behaviors). Although people have many stable and enduring memories about the self, their working self-concepts (that is, their sense of self at a given moment) vary from one occasion to another, as different subsets of self-knowledge become activated. People are 'self-schematic' on dimensions that are important to them, on which they think of themselves as extreme, and on which they are certain that the opposite is not true.

Information pertaining to the self has implications for both self- and other-perception. People demonstrate a self-reference effect, such that information relating to the self is processed more thoroughly and deeply, and hence is remembered better, than other information. People who are schematic on a given trait can make judgments about their standing on that trait very rapidly, can back up these judgments with extensive personal examples, and are reluctant to accept evidence that questions these self-views. They also possess more general expertise about this trait, which they draw upon to make sense of others' behavior. We often evaluate other people by comparing their behaviors and traits to our own.

The context-specificity and flexibility of the self-concept has also been a topic of interest to social cognitive researchers in the domain of intergroup relations. Researchers in the self-categorization tradition, for example, have addressed how the self is shaped by the social context. These researchers have argued that the self is not a fixed mental structure; rather, it is viewed as the expression of a dynamic process of social judgment. Thus, self-perception and self-definition do not reflect the activation of preformed self-concepts but, rather, a flexible, constructive process of judgment in which varying self-concepts are constructed to fit the perceiver's relationship to the current social environment. These self-concepts have implications for the perceiver's inferences about other individuals and social categories: how perceivers define themselves – in relation to the other individuals or groups present in the current situation – affects the goals, beliefs, and expectancies that they bring to the situation.

Self-regulation

Although the goal of the self-categorization research was to make the case that the content of the self could vary as a function of the intergroup context, the perspective also highlighted the fact that self-concept flexibility has functional utility. Having a concept of one's self – and especially a flexible conception of one's self – is integral to social functioning. It permits the perceiver to relate to people and to be an active agent and decision-maker. That is, the self-concept does not merely provide the person with self-knowledge, it also allows for self-regulation.

In recognition of the functional utility of the self, recent social cognitive research has turned to investigations of the 'executive function' of the self. The self-concept summarizes information about oneself as an object in the world in order to serve self-regulatory functions. The 'self-digest' summarizes a person's relations to his or her world and the personal consequences of these relations. In this framework, knowledge about oneself as an object in the world is represented to the extent that it is functional in self-regulation, in agentic decision-making and behavior. The self-digest, then, helps the person fulfill needs and achieve goals when interacting with the world.

The Self as a Nonprivileged Concept

Whether or not the self merits the status of a privileged concept has been a matter of debate, largely stimulated by the phenomenal experience of the self and of self-relevant information as 'special'. Most recent social–cognitive theorizing on the self, however, has accorded it no privileged status, arguing that the extensive processing associated with self-relevant information is due to the self being a highly familiar and well-organized body of knowledge. The self-concept may be the most central, the most important, and the most complex concept available to the person, but the processes through which it is developed and through which it exerts its influence have been regarded, to date, as largely the same processes involved in the representation and use of other social (and perhaps non-social) concepts.

PERCEIVING PERSONS AND GROUPS

Perhaps the most central topic to the field of social cognition is that of impression formation, the process by which the perceiver integrates information about and evaluates target individuals. Indeed, the impetus for virtually all social–cognitive research on memory and information processing stems from interest in understanding how the social perceiver makes sense of others.

Person Perception and Impression Formation

The process of impression formation has been debated since the inception of social psychology. Early theorists assumed that the full range of information known about the target individual was integrated into one's impression of that person. From a Gestalt perspective, the perceiver was assumed to merge the diverse features of the target person into a coherent, unitary impression that took into account the meaning of individual features as well as their interrelationships. From an elemental perspective, the perceiver was assumed to assess the implications of each piece of information about the target person and then combine them algebraically into a summary impression.

More recently, models of impression formation have distinguished between top-down and bottom-up processes. These newer approaches have assumed that it is necessary to distinguish between the influences of stereotypic information on the one hand, and attribute-based or individuating information on the other. Two such models – the dual-process model and the continuum model – have received particular attention. Although the two approaches differ in the extent to which they allow for stereotypic and individuated processing to operate in tandem, both assume that perceivers first engage in stereotype-based processing and then, depending on motivation and ability, correct their impressions on the basis of individuating information. Moreover, both assume that the use of stereotypic and individuating information involves fundamentally different processes.

Recent approaches have criticized these influential models. A 'parallel constraint satisfaction' model of impression formation has been proposed and has postulated that stereotypic and individuating information are processed simultaneously and given equal weight in the impression-formation process (within certain limiting conditions). More recently, other criticisms have noted the possibility that individuated impressions may rely on a conjunction of sterotypic and idiosyncratic information, and that reliance on stereotypes may actually facilitate the perceiver's ability to simultaneously process individuating information.

Spontaneous trait inferences and effortful attributional analysis

People tend to make trait inferences spontaneously when they observe trait-relevant behaviors, even when they have no explicit intention of doing so. The term 'correspondent inferences' was coined to refer to the tendency of social perceivers to infer that observed behaviors correspond to underlying traits. Early work tended to assume that these correspondent inferences were, in fact, dispositional inferences; that is, they assumed that perceivers spontaneously infer that an actor's behavior was indicative of an underlying personality. More recent research, however, has challenged this view. At this point, it remains unclear as to whether these spontaneous trait attributions are in fact dispositional inferences. Empirical evidence suggests that perceivers do spontaneously (automatically) generate inferences regarding the trait meaning of observed behaviors, but that they do not necessarily generalize from this inference to beliefs about the stable disposition of the actor. It appears that the perceiver automatically infers the trait meaning of observed behaviors; more controlled processes then either encourage or discourage the perceiver from making judgments about the actor's chronic disposition.

Social Categorization and Stereotyping

The mere categorization of individuals into social groups initiates cognitive processes that function to promote the perception of within-group similarities and between-group differences. The most effective of these processes is undoubtedly the activation and application of stereotypes. (*See* **Stereotypes**)

Stereotype activation

By endorsing the view that semantic priming is an inevitable consequence of mere apprehension of a stimulus in the environment, social psychologists have concluded that stereotype activation must be an unconditionally automatic process. Indeed, ample evidence has emerged to suggest that once the target's group membership has been identified, the relevant stereotype is activated without intent or awareness.

As noted earlier, however, very few processes satisfy the criteria for unconditional automaticity.

Research on stereotype activation in recent years has begun to accumulate evidence that the process is only conditionally automatic. Mere exposure to a stereotyped target, then, may be insufficient to trigger category activation.

Two factors appear to moderate the activation of stereotypes: processing goals and attitudes. Goal states can function not only to interfere with stereotype activation, but also to promote stereotype application. Recent empirical work, for example, has demonstrated that participants who are motivated to view a target in a particular way are able to simultaneously activate the stereotype that favors their desired impression and inhibit the stereotype that contradicts that impression, and that these processes occur spontaneously.

Perceivers' chronic beliefs about social groups also appear to moderate the activation of categorical thinking, a finding that is at odds with conventional thinking on the dynamics of the categorization process. Until relatively recently, it has been widely accepted that both prejudiced and egalitarian individuals activate stereotypes to the same degree when they encounter members of stereotyped social groups. In fact, empirical evidence now demonstrates that egalitarians display little or no evidence of stereotype activation when presented with categorical priming stimuli. These findings suggest that stereotype activation, rather than being fully automatic, is a conditionally automatic process.

Stereotype application

Stereotype application can take two forms. First, stereotypes can serve as frameworks for the assimilation and integration of expectancy-consistent information, leading the perceiver to emphasize stereotype-consistent information to a greater extent than he or she would have in the absence of categorical information. At the same time, stereotypes can also sensitize the perceiver to unexpected information, leading to a greater emphasis on stereotype-inconsistent information following stereotype activation.

A functional analysis of stereotyping suggests that the perceiver can accrue benefits from the application of stereotypes. Stereotype-based expectancies provide a framework that facilitates the identification and comprehension of consistent information, such that the processing of that information requires little deliberative attention or thought. The fluency of expectancy-consistent information means that substantial attention may be redirected to other concurrent tasks, including the encoding of inconsistent information. The benefits of stereotype application in demanding environments are thus twofold: first, expectancy-consistent information can be processed in a relatively effortless manner; second, remaining attentional resources can be redirected to unexpected information, enabling the perceiver to process and remember this potentially important individuating information. (*See* **Attention**)

A variety of motivational factors also seem important to stereotype application. The use of stereotypes can be overridden by accuracy motivation, but can be enhanced by ego-defensive motivations by providing a basis for downward social comparisons. 'Social judgability' concerns also play a role, and perceivers are unlikely to report stereotypic judgments unless they believe there is a legitimate informational basis for such a judgment.

Stereotype suppression

As we have already discussed, several studies have documented the ironic consequences of stereotype suppression for perceivers' evaluations of, memory for, and behavior towards stereotyped targets. Notwithstanding these demonstrations, doubt remains over the generality of these effects. Low-prejudice participants, for example, are apparently not susceptible to 'rebound' effects. It also seems that perceivers may be more consistent in their efforts to avoid stereotyping for sensitive social groups, thereby preventing the emergence of rebound effects. This suggests that stereotype suppression can be effective to the extent that perceivers are motivated by concerns of egalitarianism. (*See* **Thought Suppression and Mental Control**)

Entitativity: Perceiving Persons and Groups

Although research on both impression formation and stereotyping have long and rich histories within social cognition, little research has been directed towards understanding how the two processes might be similar or different. In both cases, research is concerned with how a perceiver comes to develop a conception of a social target, either a person or a group. But do the same mechanisms and processes govern social perception in these two domains?

Recent research on 'entitativity', or the extent to which a target is seen as coherent and unified, suggests that default expectancies for individuals versus groups has implications for how the perceiver forms impressions of individuals and develops conceptions of groups. The fundamental postulate of this research is that the social perceiver

assumes unity in the personalities of others: persons are seen as coherent entities, and the perceiver's impression of a target person should reflect that unity and coherence. In general, however, perceivers do not expect the same degree of unity and coherence among members of a group as they expect in the personality of an individual.

As a result of holding this assumption, the perceiver seeks to draw inferences about the dispositional properties constituting the core of the person's personality, but not about the 'disposition' of the group. The result is that the perceiver draws inferences quickly when the target is a person, but not so rapidly when the target is a group. The expectation of consistency in the traits and behaviors of individuals, rather than groups, also leads the perceiver to strive to resolve inconsistencies in the information acquired about the target person, but to tolerate inconsistencies in the information acquired about different group members.

This is not to suggest that processing information about individuals will necessarily be different from processing information about groups. Although research on entitativity does indeed demonstrate that the default assumption is that individuals form more coherent entities than do groups, groups can also vary in their perceived entitativity. Empirical evidence exists to suggest that perceivers process information about groups and individuals in a similar manner when those groups are perceived to be high in entitativity. The nature of the social target, person or group, then, is not the crucial element in determining the impression-formation process. When expectancies of unity, consistency, and coherence are controlled or equated, the processes and outcome of impression formation are very similar for individual and group targets.

CONCLUSION

Any attempt to define and summarize a broad domain must necessarily be non-exhaustive and this article is no exception. Social cognition, with its broad mandate to investigate the mental processes that mediate relations between the individual and his or her social world, encompasses not only the topics reviewed here, but also many other mental processes central to social functioning, such as goal-setting, decision-making, and heuristics and biases in social judgment. Also important are the emerging field of implicit social cognition and recent work on the diversity of the processes (e.g., perceptual and conceptual) believed to characterize the complexity and flexibility of the social perceiver's mental life. Ultimately, the goal of social cognition is to explain how all of these processes interact to determine social behavior.

CONTENTS

Computational models of social processes formalize social processes in terms of computer algorithms. Such models, commonly investigated by means of computer simulations, provide a means by which theories of social processes can be precisely expressed, and they enable investigators to study non-obvious consequences of the assumptions underlying social theories.

INTRODUCTION

In the 1970s, social scientists began to conceptualize social processes in terms of computer algorithms, and to investigate the consequences of these computational models using computer simulations. Computational models have since become an important component of social science research. They can reveal properties that cannot be investigated by analytical (e.g. traditional mathematical) means. Computational models provide a precise formalism for social processes and enable one to test a theory's internal consistency and completeness. The computational approach, then, has added considerable precision and rigor to social science theory and research. It has also proven relevant to the solution of real-world social problems.

Computational models were first used to study large-scale social processes (pertaining to groups and societies). These models are formulated as sets of variables describing the basic properties of the modeled system. Mathematical equations specify how each variable changes in time as a function of other variables. Computer simulations are then used to study these changes. This approach is especially prevalent in the study of economic and demographic processes. However, the exclusive focus on group-level properties does not enable one to study the relationships between different scales, from individual agents through groups and organizations to entire societies. Most computational models now attempt to relate individual agents and aggregate social entities (e.g. social groups).

BUILDING SOCIETIES FROM INDIVIDUALS

To investigate how individual-level processes give rise to group-level properties, computational models specify a set of individuals, referred to as agents, and a set of rules describing the relations (e.g. mutual influence, interdependence) among the agents (and sometimes between agents and the environment). Simulation models differ with respect to the representation of agents and the rules of interaction. Some models employ very simple representations of individual agents: in the extreme, an agent may be represented by a single variable representing a single characteristic. The idea is to identify the minimal assumptions necessary to produce specific group-level properties.

For example, in modeling the emergence of public opinion, individuals are represented as cells on a two-dimensional lattice. Each individual has one of two opinions ('pro' or 'con') on a particular issue. Individuals also differ in the strength of their advocation of their opinion. Before interaction, each individual's opinion is unrelated to that of his or her neighbors. In each 'round', the individual assesses the opinions of his or her neighbors, giving greatest weight to the opinions of the strongest advocates. If this assessment leads to the conclusion that an opinion contrary to his or her own is the prevailing opinion, the individual will adopt this opinion and advocate it in the next round. Individuals maintain the same physical location throughout the simulation. Figure 1 shows

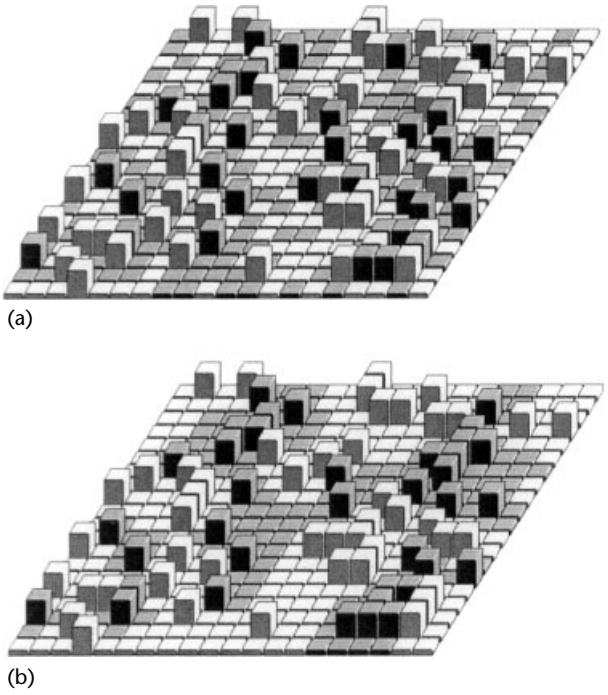

Figure 1. A simple model of emergence of public opinion. The tint of a cell denotes the individual's opinion ('pro' versus 'con'), and the height of a cell represents the strength of the individual's advocacy of his or her opinion. (a) Before running the simulation (random distribution of opinions). (b) After several iterations (polarization and clustering emerge).

the distribution of opinions in a social group before and after several rounds of such interaction. Note that the initial minority opinion declines in popularity and clusters spatially into like-minded groups. Thus, this simple simulation rule defining influence on an individual level causes the emergence of two basic group-level phenomena, polarization and clustering.

Other computational models, employing the tools of artificial intelligence (AI), take a more complex view of agents. Each agent has a repertoire of actions, and may also have other characteristics (e.g. knowledge, goals, values). The simulation rules specify how agents' actions and characteristics depend on those of other agents. The computer simulations investigate the consequences of these rules as the individuals interact with each other and with the environment. Agents are considered to be adaptive because they can improve their 'fitness' in the process of learning or evolution. Fitness typically refers to an agent's ability to maximize his or her resources (e.g. to acquire capital) in a social dilemma situation. In variations of this approach, agents may represent higher-level entities, such as social groups, organizations, or societies.

DYNAMICS OF SOCIAL INTERACTION

In computational models, social interactions are modeled as rules specifying how agents influence one another's states and actions, and the environment in which they are embedded. The dynamic behavior of the system is produced by repeated iteration of the interaction rules. After each iteration, the state of each agent is updated according to the model's rules. These updated states, in turn, provide the input for the next iteration of the program, and so on. For example, an individual may change his or her opinion in a given simulation round as a result of social influence, and subsequently influence others to adopt the new opinion.

Computational models also specify the pattern of social interactions. Although some models assume interactions among all agents, most assume that each agent interacts only with a specified subset of other agents. In models defined in terms of intelligent agents, the subsets can change in accordance with the nature of the interaction. Thus, one type of information might be transmitted only to agents with whom the agent is linked in an organizational network (direct communication), while another type of information may be made available to all other agents (broadcasting). In models that concentrate on the evolution of social relationships, the structure of social interactions is open to change.

There are two main approaches to modeling the patterns of interaction among agents. In the spatial approach, each agent resides in a particular location in space, usually a two-dimensional grid, representing the spatial patterning of social interactions (see Figure 1). Each agent interacts only with other agents in nearby locations (e.g. adjacent cells). Social relations are therefore represented as spatial proximity, and changes in social relations are represented as spatial movement. The spatial approach allows the visualization of patterns on the global level that develop as a result of local interactions.

In the network approach, social relations are conceptualized as links, representing friendship patterns, communication networks, organizational structure, and other patterns of interpersonal relations. Some network models assume that a single network of links defines all interactions among the agents. In other models, different networks may define different forms of interaction. Thus, informal communication (e.g. gossip) may take place through one network, while formal communication

(e.g. the flow of documents in an organization) may take place through a different network. The dynamics of social relations are represented by changes in the links among agents.

In both spatial and network models, the dynamics of social interaction may be represented by changes in the properties and actions of individual agents, and by changes in the interaction patterns among agents.

EMERGENT SOCIAL PROCESSES

The new theory of complexity has shown that models composed of very simple interacting elements can display highly complex behavior on the system level. The low-level interactions are often nonlinear, so that their consequences cannot be derived by analytical means. Computational models involving multiple interacting agents are complex adaptive systems. They have been fruitfully applied to emergent phenomena in diverse areas of science. In these models, behavior at the aggregate level is not directly programmed into the model, but rather emerges as a consequence of interactions between agents. These models exhibit self-organization, since regularities, patterns and complex properties are produced by interactions among system elements without the supervision of higher-order agents. For example, in a cellular automaton such as that illustrated in Figure 1, spatially coherent groups of like-minded individuals emerge from social influence rules specified on the level of individuals. The group-level phenomena (polarization and clustering of opinions) were not programmed into the model, but rather emerged from the local interactions among agents.

Two variations of this general approach have been employed in the social sciences. In one, individuals' characteristics change as a result of 'updating' rules. This type of model is useful for understanding changes in attitudes and opinions as a result of social interaction. The emergence of public opinion illustrated in Figure 1 exemplifies this approach.

In 'migration' models, on the other hand, individuals' characteristics do not change, but individuals may change their physical location. For example, in modeling social segregation, if the individual is surrounded by a local majority of individuals who are different in a relevant characteristic (e.g. race), he or she will move to a different spatial location. Migration models are used to investigate the emergence of spatial patterns on the basis of stable values and preferences.

In both of those approaches, iteration of the updating rules often produces regularities and patterns at the group level that were not directly programmed into the agents.

EVOLUTION OF COOPERATION

One of the most interesting examples of emergence in the social sciences concerns the evolution of cooperation among agents who are motivated to maximize their personal gain. The 'prisoner's dilemma' game is often used in simulations of this process. In each round, each agent chooses whether to 'cooperate' or 'defect' in his or her interactions with another agent. This choice is regulated by individual strategies, which evolve by means of genetic algorithms. Each agent begins with a random sequence of genes that generates choices reflecting some strategy. By analogy with natural selection, those individuals who acquire the least profit in their interactions with many others are eliminated from the population, while the rest are allowed to produce offspring. New combinations of genes are produced through mutations and the exchange (crossover) of genes between individuals.

Initially, there is usually a sharp increase in the frequency of defection, since defection produces higher pay-offs regardless of the choice made by an interaction partner. After some time, however, the frequency of cooperative choices increases and becomes prevalent. Although cooperative choices produce lower outcomes in any single interaction, in the long run this strategy may induce cooperation in one's partner, yielding higher profits for both. Defection strategies, on the other hand, are maladaptive in the long run because they turn partners into defectors. The elimination of such strategies corresponds with a growth in the proportion of strategies capable of both cooperation and, when faced with defection, retaliation.

SIMULATING ORGANIZATIONS

Unlike informal groups, organizations attempt to achieve specific objectives and are characterized by a better-defined structure of interactions among agents. The agents within organizations perform distinct roles defined in terms of tasks and decision-making. Each agent is capable of performing a set of actions, such as requesting information, preparing a report, helping others, wasting time, and so forth. These actions are performed in response to a specific set of conditions, such as input from other agents (e.g. orders, information, requests for help) or the appearance of new tasks. Agents are usually

heterogeneous with respect to possible actions, knowledge, and goals. Organizational dynamics thus reflect the interactions among intelligent autonomous agents, who are modeled using the tools of AI.

The computational approach is useful in investigating the mechanisms of known organizational phenomena (e.g. poor decision-making, development of trust, team effectiveness, group cooperation). It has also been employed to search for optimal organizational structures and procedures. Distributed AI models, for example, are useful in modeling effective group decision-making. Each agent is represented as a goal-oriented problem-solver (e.g. using the SOAR model), with specific knowledge. Agents can share data, judgments, and decisions. Different team decision schemes are tested for their effectiveness in reaching an optimal decision. Computational models have proven to have considerable practical value, and are used to analyze existing organizations and provide advice for the improvement of organizations.

RELEVANCE OF MODELS OF SOCIAL ORGANIZATION

Computational models have contributed to our understanding of pressing societal concerns. For example, models in which agents play the prisoner's dilemma game have generated insights into the emergence and resolution of conflict at different scales of social reality (e.g. between individuals, groups, and nations). This approach has identified the different conditions that promote cooperation and competition. It has informed policy makers about effective strategies for resolving conflicts of interest involving limited resources, and about situations that can lead to the escalation of conflicts (e.g. spiraling retaliation). This approach has also proven useful in modeling the formation of solidarity networks and various economic processes.

Models of social influence based on cellular automata have revealed the mechanisms responsible for the formation of public opinion, social change, the emergence of ideologies, and the spread of innovations. Models based on intelligent agents have proven especially relevant to issues in organization function and design. This approach has also been used to test whether hypothesized patterns of social life match the patterns known from archeological artifacts in past societies.

Computational models also play a prominent role in testing military strategies. They have proven useful in resolving Cold War and post-Cold War conflicts.

SUMMARY

Computational models of social processes have become a vital tool in social science theory and research. Social processes are represented as computer algorithms and investigated with computer simulations. Computational models provide insight into the emergence of aggregate-level properties from simple rules specifying the interactions among lower-level elements of a social system. These models are constructed as assemblies of interacting agents, which can be defined at different scales (e.g. individuals, groups, organizations, societies). The computational approach has generated insight into the nature of diverse phenomena in social science, and has been successfully applied to practical issues concerning interpersonal and inter-group dynamics.

Space Perception, Development of

Intermediate article

Albert Yonas, University of Minnesota, Minneapolis, Minnesota, USA

CONTENTS

The development of space perception refers to the changing processes that take place within an organism that make possible the control of action based on knowledge of the three-dimensional layout of the environment. Development refers to both the consequences of experience and the maturation of sensory and perceptual mechanisms.

INTRODUCTION

Human infants, unlike more precocious species, develop the ability to use vision to perceive the layout of the external environment over a period of months. Over this period, sensitivity to sensory properties, such as contrast and orientation, also improves as neural mechanisms in the eye and brain develop. This article focuses on changes in perception of the external world rather than on the development of sensory processes. While mechanisms early in the visual system respond to the orientation of contours and make it possible to detect that contours converge to a vanishing point, the detection of perspective convergence on the retina does not mean that the viewer perceives that the region in which the contours converge is more distant. For depth to be perceived as such, a higher-level perceptional process is needed.

There are many cues that provide independent information for depth. They can be placed in three classes: motion-carried information, binocular information and static monocular or pictorial information. In humans, the ability to perceive the layout of the environment develops in stages as responsiveness to motion-carried, binocular, and static monocular cues develops. There is evidence that newborns use retinal motion produced when they move their heads to perceive depth. By one month of age, infants respond to optical expansion information for impending collision, and by two months they act as if they perceive some aspects of object shape from motion. Perception of depth from binocular cues has been demonstrated in four-month-olds. Perception of spatial layout from static monocular cues appears to develop last and has only been found in infants over six months of age.

Although efforts to describe depth cues have a long history, and the list of known depth cues may seem extensive, the task is not finished. It is likely that in the future researchers will discover new cues for depth that are available in static and moving displays. Only then will research on the development of sensitivity to those cues be possible.

INFERRING DEPTH PERCEPTION FROM INFANTS' RESPONSES

Certain spatial behaviors, such as crawling (which can reveal that infants avoid moving over the 'deep side' of a visual cliff (Walk and Gibson, 1961)) and precise reaching, are excellent indicators of depth perception. However, human infants are rarely able to crawl until 7 months of age, and do not begin to reach with accuracy until they are about 5 months old, so these behaviors cannot be used as measures of depth perception with younger infants. Other responses, such as upward head rotation (which occurs in the first month of life), do not have the specifically spatial character of crawling and are open to multiple interpretations. The behavior that is most commonly used in infant research is preferential looking at one display rather than another. Looking behavior can tell us about the infant's ability to discriminate between the displays on a sensory level, but it does not necessarily indicate whether the infant perceives differences in the spatial meaning specified by the displays.

SENSITIVITY TO MOTION-CARRIED INFORMATION FOR DEPTH

Motion-carried information for depth can be obtained when observers move their heads or

bodies, or when a viewed object moves. Such information is sometimes called 'motion parallax'.

A. Slater has suggested that motion parallax gives newborn infants some degree of size and shape constancy (Slater *et al.*, 1990). Size constancy is the ability to perceive the unchanging physical size of an object although its retinal size changes when its distance is changed. Shape constancy is the ability to perceive the unchanging physical shape of an object when its orientation is changed. It is also possible that the angle between the two eyes is the source of the depth information that underlies size and shape constancy in newborns (Kellman and Arterberry, 1998).

Optical Expansion and Contraction: Perceiving Impending Collision

When an object approaches a perceiver, it projects an expanding flow pattern that serves as information for its approach. When the approach is constant in speed, the rate of retinal expansion increases and is explosive at the last moment, indicating impending collision (Schiff, 1965). Retinal contraction is information for withdrawal. Initial research found that 1-month-olds defend against collision by moving their heads back and bringing their hands between their face and the object when it is approaching them, whether it is real or simulated on a screen. Another possible explanation for these actions is that infants track the rising contour of the expanding pattern and as a result rotate their heads upward. When the head rotates upward and control of head posture is lost, the head falls backward and the young infant's arms are raised. This latter interpretation was supported by studies that varied upward optical motion and information for collision (Yonas, 1981).

Researchers have observed that in the early stages of development, infants blink when a hand is moved close to their eyes. There is a slow increase in responsiveness over the first months of life. Recent studies have found that although blinking to an approaching object is infrequent during the first month, it is even rarer when an object withdraws. The claim that maturation determines responsiveness is supported by a study which compared two groups of infants. One group was born 3 to 4 weeks after their due dates while the other was full term at birth. The former group responded more consistently than the latter group (Pettersen *et al.*, 1980).

Infants at 1 month appear to be at a lower level of perceptual specificity in perceiving impending collision than are infants between 3 and 4 months. Young infants blink equally to a display corresponding to an object slowing as it approaches and to a display that presents explosive expansion; older infants respond only to the explosive display. It is clear that 1-month-olds do respond to motion-carried information for approach, since they blink more frequently to expansion displays that specify approach than to control displays that do not (Nanez and Yonas, 1994).

Motion-Carried Information for Occlusion

Boundary flow

As described in Gibson (1966), Michotte *et al*. (1964) demonstrated that by manipulating the shape of a disk, one could make it appear to go behind the edge of an occluding surface (see Figure 1).

The horizontal boundary of the black disk in Figure 1 is not perceived as part of the disk; rather, it is perceived as the upper edge of the surface that the disk moves behind. The information that suggests this is that as the disk moves downward, the horizontal contour does not move. There is no information for depth other than the transformation of the curved and straight parts of the display. Normally, objects and their edges move in the same direction at the same speed, while objects

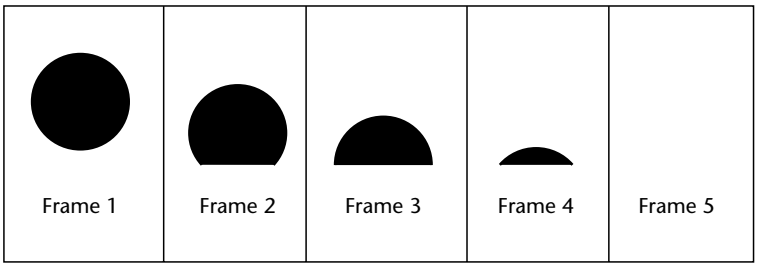

Figure 1. Five frames in which the nature of the disappearance of the disk indicates that it is moving behind a horizontal surface. (Adapted from Gibson (1966) and Michotte *et al.* (1964)).

and background do not share common motion. This assumption is the basis of the motion-carried cue for depth order called 'boundary flow'.

Accretion and deletion of texture

James Gibson (1966) proposed another potential cue for depth order, the accretion (appearance) and deletion (disappearance) of texture, which take place when one surface covers and uncovers another. Experiments that have tested the effectiveness of this cue have also included boundary flow information (Kaplan, 1969). Infants aged 5 months reach to the apparently closer side of a screen on which random dots move as if one side were a surface occluding the other. As in the prior adult studies, both cues were presented. When displays were created in which there was a gap between the texture and the boundary, so that texture did not appear or disappear, 5-month-olds consistently reached to the apparently closer side of the display (Kellman and Arterberry, 1998). Younger infants may also be sensitive to this information, but so far this has not been tested.

Motion-Carried Information for Shape

A field of random dots is perceived as flat when it is motionless. The same dots can be made to appear to be on the surfaces of a three-dimensional cube, and other shapes, by using computer animation to simulate the proper motion. Infants at 2 and 4 months are able to discriminate between different three-dimensional shapes when presented with displays in which motion is the only depth cue. A control condition rules out the possibility that discrimination is based on a two-dimensional property, differences in the velocity of the dots (Arterberry and Yonas, 2000).

BINOCULAR INFORMATION FOR DEPTH

Binocular Convergence

'Binocular convergence' refers to the angle that results when the viewer turns both eyes to fixate a target. Within a distance of about 2 meters, convergence functions as a depth cue for adults. Although 1-month-olds adjust convergence to the distance of near targets, evidence that infants can use binocular convergence to perceive depth has only been shown in 5-month-olds, who reach for an object at the distance specified by convergence (Kellman and Arterberry, 1998).

Binocular Disparity

Binocular disparity is depth information that results from the fact that our two eyes view the world from different points in space. A difference in the relative positions of objects in the images projected to the two eyes is a cue that the objects are at different distances. The tendency of infants to fixate a display that presents differences in disparity rather than one that does not (i.e. that looks flat to adults) has been used to investigate the onset of binocular sensitivity. Most infants begin to show sensitivity at between 3 and 4 months (Held *et al.*, 1980). Infants who show evidence of sensitivity to disparity in a preferential looking task also transfer the perception of shape from motion to displays in which only binocular cues specify shape. This suggests that convergence and binocular disparity function as effective cues for depth in some 4-month-olds (Kellman and Arterberry, 1998).

PICTORIAL DEPTH CUES

Pictorial depth cues, which artists have used to depict space in paintings, are also effective when we view the world around us. When we close one eye and observe the world without moving, it does not become a flat mosaic.

As the distance between an observer and an object decreases, the size of its image on the retina increases. If one assumes that the object is fixed in size, its apparent expansion can be used to infer that it is approaching (as described above). Pictorial cues rest on similar assumptions.

Linear Perspective

The assumption that lines in the world are parallel makes it possible to infer from the convergence of lines in an image that they extend away from the observer. This convergence of lines to a vanishing point is called 'linear perspective'.

Relative Retinal Size

If objects are assumed to be of similar size, differences in retinal size indicate that the smaller image is projected by the more distant object.

Familiar size

Among all the depth cues described here, familiar size is special because it must be acquired through experience. For particular objects that have only one size, there is a relationship between retinal

size and distance. If this relationship is learned, it is possible to perceive the distance of that familiar object from its retinal size.

Interposition

Information for the order of surfaces in depth is given by the way lines are joined. In the proper context, a T-shaped line junction indicates that the stem of the T is occluded by a surface that is bounded by the top of the T. This cue is sometimes called 'interposition'.

Surface Contour

While the cues of linear perspective and relative retinal size appear to be based on the assumption of equality, the surface contour cue requires an assumption that contours in an image are caused by straight lines in the world (see Figure 2).

Shading

The cue of shading can indicate shape, although it requires several assumptions. If a surface in an image is constant in reflectance, illumination is even, and the light source is above, a bulge in a wall will be lighter on its upper surface than on its lower surface. The location of cast shadows can also indicate the position of an object in space. The presence of a gap between an object and its shadow indicates that it is raised above the background, while a shadow that is connected to an object indicates that the object is resting on the background.

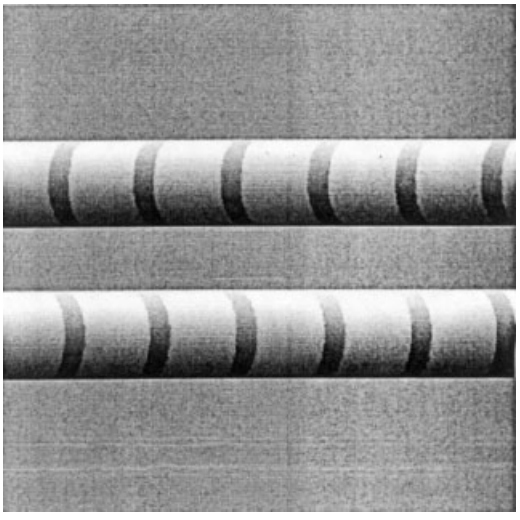

Figure 2. Surface contours indicate that the ends of the cylinders differ in depth.

Research on the development of sensitivity to pictorial cues has generally used reaching as a measure, because most infants, from 5 months, will reach to the closer of two objects when binocular depth information is present. Infants may view a display in which there are no actual depth differences, but in which pictorial cues create, for adults, an illusion of depth when one eye is covered. When viewed with two eyes, the illusion is reduced. A difference in reaching, between one- and two-eyed presentations, constitutes evidence that a depth cue is effective. Studies of pictorial depth cues with 7-month-olds have found more frequent reaching to the apparently closer part of the display with monocular presentation. In contrast, 5-month-olds do not seem to be sensitive to these cues (Kellman and Arterberry, 1998). An account for this change is needed. An interesting possibility is that, at about 6 months, long-distance neural connections become more effective. Thus, the infant becomes able to use pictorial cues and information requiring recognition and memory to direct reaching.

Spatial Cognition, Models of

Introductory article

Tom Hartley, Institute of Cognitive Neuroscience, University College London, UK
Neil Burgess, Institute of Cognitive Neuroscience, University College London, UK

CONTENTS

Neurophysiological research has led to detailed mechanistic theories about how spatial locations and headings are represented in the brain and used in memory and navigation.

INTRODUCTION

The term 'spatial cognition' covers processes controlling behavior that must be directed at particular locations, or responses that depend on the location or spatial arrangement of stimuli. There are many circumstances in which such processes are required for adaptive behavior, and they are exhibited in creatures as diverse as bees, birds, rats, and primates. At the most basic level, an organism must be able to flee from a dangerous location to a safer place. It may also need to return to a location where food is abundant or has been stored; to act upon a stimulus at one location, while temporarily ignoring other stimuli; or to navigate from one place to another by an efficient route, avoiding obstacles. All of these behaviors seem to demand some sort of spatial representation; a neural code that distinguishes one place or spatial arrangement of stimuli from another. Models of spatial cognition describe these representations and the nature of the processes that operate on them to give rise to spatial behavior.

NEURAL REPRESENTATIONS OF SPACE

Models of spatial cognition are constrained by experimental evidence from cognitive psychology, neuropsychology, neuroimaging, and neurophysiology. The picture emerging from this evidence is that spatial cognition can be divided into two modes, which are to some extent separated in the mammalian brain.

Broadly speaking, processes involved in action, attention, and perceptual constancy involve the parietal neocortex. The importance of parietal processes in spatial attention and action is illustrated by the well-known neuropsychological phenomenon of hemispatial neglect, in which patients with lesions of the right parietal cortex show an attentional bias towards the right. The presence of stimuli on the patient's right side tends to extinguish any response to a stimulus on the left, so that for instance, a patient may shave only the right side of his face, or copy only the right side of a picture. (*See* **Neglect**)

Processes involved in long-term spatial memory, orientation, and navigation take place in the hippocampus and adjacent cortical and subcortical structures. Patients with damage to these regions, especially in the right hemisphere, are impaired in a range of topographical memory tasks such as drawing maps or judging the distance between locations. Neuroimaging studies have shown that the right hippocampus is activated during the verbal recall of routes and during navigation in a virtual-reality town, and that its activation correlates with success in the navigation task. (*See* **Navigation and Homing, Neural Basis of**)

This division of labour is something of an oversimplification. Many tasks do not fall comfortably into either memory or action categories, but involve elements of both. Additionally, other brain areas are involved in some spatial tasks; for example prefrontal cortex is implicated in tasks demanding planning, while reflexes and stereotyped or overlearned spatial behavior will involve subcortical regions such as the basal ganglia and superior colliculus and cerebellum. Additionally, the hippocampus and parietal cortex have important functions that go beyond those outlined above; for example, in humans the hippocampus plays a more general role in memory for personally experienced events. However, the generalization outlined

above is useful, because it makes clear some of the important constraints on spatial processing that may pertain to different brain regions. (*See* **Planning: Neural and Psychological**; **Basal Ganglia**; **Amnesia**; **Hippocampus**; **Neural Basis of Memory: Systems Level**)

First, the processing modes differ in the spatial and temporal scales over which they operate. Hippocampal processes are concerned with large distances and long timescales, whereas parietal processes are more concerned with short timescales and the space immediately surrounding the body.

Second, the processing modes differ in the forms of spatial representation they demand. Parietal processes controlling action in the immediate environment use egocentric representations of space (i.e., locations are represented in terms of their relation to the subject). So, for instance, the firing rates of neurons in the medial interparietal area of monkey parietal cortex, which fire when the animal is about to reach for an object, vary depending on the position of the object relative to the monkey's hand. This is an example of a neural representation in an egocentric (in this case hand-centered) reference frame. Such representations are clearly useful for guiding action over the short term, or where the stimuli whose locations are to be encoded are immediately available to the perceptual system. (*See* **Parietal Cortex**)

Egocentric representations have the disadvantage that, in order to remain valid over the long term, they must be actively updated to reflect changes in the subject's location and heading. Unless corrected by new sensory information, any errors in this updating process will be cumulative, so that egocentric representations of location are unreliable for long-term storage.

In contrast, processes demanding long-term memory of a location should make use of representations that relate locations to each other and to landmarks in the environment, rather than to the subject. Such representations are called world-centered or 'allocentric'. They are map-like in the sense that there is no privileged location to which all others are related. Instead, they provide a basis from which one's current location and orientation can be computed from one's relationship to sensory cues in the environment. A set of locations represented in an allocentric framework can be thought of as a 'cognitive map'. (*See* **Animal Navigation and Cognitive Maps**)

A cognitive map has several advantages in the context of long-term memory. Over a period of days, months or years, a given place may be approached from different directions on different occasions; the viewpoint-independence of an allocentric representation will thus be useful in navigating towards or recognizing locations over such timescales. Furthermore, locations represented in an allocentric reference frame do not need to be continuously updated in the way that locations in an egocentric reference frame must be. An allocentric form of representation is thus not prone to the cumulative error inherent in such an updating process, making it particularly suitable in tasks where behavior has to be directed towards a location that is not immediately available to perception. This might occur either because it is far away (as in the case of navigation in large-scale space; for example, returning to a familiar nesting site after a protracted foraging expedition) or because it is hidden (e.g., returning to the location of a hidden food store).

For long-term memory, an allocentric representation of space could provide a solution to some of the shortcomings of egocentric representations. However, it also raises some new questions, not least of which is how a map-like representation can be abstracted from the egocentric information available to sensory systems. What form does the allocentric 'cognitive map' take, and how could it support navigation? In order to understand how allocentric representations are formed, it is useful first to consider the ways in which transformations between different reference frames might be achieved in the parietal cortex. Such transformations are certainly involved in immediate action-orientated processes, but may also occur in the encoding or retrieval of long-term spatial memories.

TRANSFORMATION BETWEEN REFERENCE FRAMES

Sensory cortices encode stimulus location egocentrically. For action, it is generally necessary to transform information about the location of a stimulus into a reference frame appropriate to the effector system involved in the response. For instance, visual information about the location of an object is encoded retinotopically in visual cortex (reflecting location in an eye-centered reference frame) and must be transformed into a hand-(or arm-) centered coordinate system in order that it can be used to direct a reaching response.

In fact, most actions are likely to require multiple reference frames, as they demand the coordinated action of many effectors moving in concert. There is neurophysiological evidence of the existence of such multiple egocentric reference frames in the parietal cortex of monkeys. As well as cells representing object locations relative to the monkey's

hand (mentioned previously), other populations of cells have been discovered where firing rates are determined by the relationship of objects to the monkey's trunk, arm, head, and so forth. (*See* **Parietal Cortex**)

How does the parietal cortex transform locations represented in one reference frame to another? A three-layer feed-forward neural network can be trained to perform such transformations (e.g., between eye-centered and head-centered coordinates). A layer of input neurons represents locations on the retina and the gaze direction (the angle of the eye in the head), and a layer of output neurons represents locations relative to the head. Between the input and output layers is a 'hidden' layer of processing neurons. During training, the strengths of connections to and from the hidden layer are gradually changed, so that the output layer produces increasingly accurate transformations of the input. Ultimately, each output neuron has a firing rate determined by stimulus location relative to the head – the connections to and from the hidden layer of neurons translate the eye-centered representation of the stimulus location into a head-centered reference frame, taking into account the gaze direction.

What is interesting about this model is the way in which the transformation is achieved. After training, neurons in the middle processing layer between the input and output layers show responses that are modulated by both the location of a stimulus relative to the head, and by its retinal location. This type of encoding is referred to as a 'gain field'. It is a useful form of representation because the combined influences of stimulus location in two different reference frames on the neural response would allow the location of the stimulus to be represented in either reference frame in subsequent processing layers. Gain field responses have been found in neurons in the interparietal sulcus of the monkey posterior parietal cortex. It is plausible that the multiple egocentric representations of location in the posterior parietal cortex are linked by intermediate gain field representations that mediate the translation of location information from one reference frame to another.

NEURAL BASIS OF SPATIAL MEMORY AND ORIENTATION

Place Cells

Experiments with rats provided some of the first evidence that the hippocampus was involved in spatial memory and the allocentric representation of space. A popular laboratory task demanding spatial memory is the Morris water maze, in which rats learn to escape from a pool of cloudy water by navigating to a platform hidden beneath its surface. Rats with lesions to the hippocampus are unable to learn the location of the platform in the water maze. The anatomy of the hippocampus is substantially similar in rats and primates, including humans, so there are grounds for believing that the mechanisms of spatial memory and navigation in these diverse species may also be similar. But how does the hippocampus represent locations, such as the location of the hidden platform?

Place cells, in areas CA1 and CA3 of the hippocampus, encode the rat's location independently of its heading. They are cells whose firing rates vary depending on where the animal is. In a typical experiment the firing of hippocampal pyramidal cells is recorded as the animal freely explores its environment (typically a low-walled box or a raised platform). A place cell might fire, for instance, whenever the rat is in the northeast corner of the environment, but not elsewhere. Each place cell responds in a different part of the environment, referred to as the cell's place field. Together these firing fields cover the entire area of the box. Each place in the box produces a different pattern of firing in the place cells. By looking at the firing rate of several place cells at once (say 30), one could know to within a few centimeters where in the box the rat is at any time.

Place cells could clearly be of importance in representing behaviorally important locations, and their discovery prompted O'Keefe and Nadel to propose that the hippocampus functions as a cognitive map. The mechanisms underlying the neural representation of place are likely to be important in understanding cognitive processes such as navigation and long-term spatial memory, and we will return to the question of how place fields are formed later.

Head Direction Cells

Whereas place cells encode the rat's location independently of where it is heading, a complementary system of 'head direction cells' represent the animal's heading independent of its location. Each has a preferred direction (e.g., north) and fires whenever the rat is facing in that direction. Head direction cells are found in the mamillary bodies, anterior thalamus and presubiculum, parts which together with the hippocampus are connected to form an anatomical circuit. Over short periods, populations of head direction cells function as a

neural compass, tracking changes in heading with a remarkable accuracy. Recorded over longer periods, they do not maintain fixed compass directions: the direction to which a particular cell is tuned depends on sensory (especially visual) cues present in the environment. Rotating all such cues causes a matching change in the head direction cell's response, and if visual cues are absent, the tuning of a cell may gradually drift. Interestingly, the responses of simultaneously recorded head direction cells remain locked together (always maintaining the same angle between preferred directions).

A neural compass could clearly be of great use in navigation, but it may also fulfil another, related role in spatial memory. As noted above, an important part of the process of forming a long-term representation of a location may involve transforming egocentric representations of the environment into an allocentric form. One of the essential properties of such a representation is that it is orientation-neutral (i.e., independent of the heading direction at the time of encoding). This means rotating sensory information about the location to be encoded, so that directions are represented in a reference frame that is fixed with respect to the world (i.e., as compass directions) rather than one that is fixed with respect to the direction one is currently facing. The transformation between orientation-specific perceptual and orientation-neutral mnemonic representations could, in principle, be achieved through a 'gain field' mechanism (see above), and would require a representation of heading (analogous to the gaze angle information in the transformation between eye- and head-centered reference frames). Thus the head direction system could be involved in the encoding of long-term memories. This may explain why the anatomical circuit involved in head direction is also implicated in amnesia.

MODELS OF ALLOCENTRIC SPATIAL REPRESENTATIONS

We now turn to the question of how allocentric representations of the kind described above might be abstracted from egocentrically encoded sensory information: what makes a place cell fire where it does?

A place field's location does not depend on the rat's position relative to any single cue. This can be demonstrated by changing various aspects of the environment while the rat is absent. For instance, the walls making up the perimeter of the box can be swapped around, or the floor of the box replaced, but a place cell will still fire in the same location. Therefore the cell does not fire in response to the distinctive smell of the wall or floor near its firing field. Similarly, removing subsets of visual cues need not affect place cell firing.

One way of explaining the independence of place fields to any single external cue is that internal information (e.g., self motion, vestibular and motor efference information) is used to track changes in location over time, with external sensory information simply serving to calibrate this system. This mechanism is often referred to as 'path integration'. Another possibility is that external cues are used, but that a conjunction of several features is required to drive a place cell to fire at a given location. As the hippocampus receives inputs from many areas of sensory cortex, both external cues and path integration information could play a part in controlling place cell activation. Experimental evidence indicates that visual cues are the most important determinants of place cell firing under normal circumstances. However, visual information is not essential; congenitally blind rats have apparently normal place fields.

The geometry of the environment is particularly important in determining place field locations. This can be demonstrated by varying the size and shape of the experimental environment. The locations of place fields remain fixed with respect to some of the walls of the environment (usually the nearer walls; Figure 1) even when the box is moved within the laboratory (and thus with respect to many distant visual cues visible over the low walls of the box). Place field locations are not affected when smaller objects placed within the enclosure are moved around, but if the same objects are placed close together so that they form a more substantial barrier to movement, they do affect place field location.

These results suggest that the distances and directions of boundaries are represented in the cortical inputs to the hippocampus. These distances and directions are probably determined by external sensory systems, as they would be difficult to compute on the basis of path integration alone. Because place cell firing rates in open environments tend to be independent of the rat's heading, it would appear that the directions of these critical features are represented in an orientation-neutral reference frame (north, south, east, etc.) rather than one specific to the current heading (left, right, ahead, etc.). This suggests that initially egocentric representations of the distance and direction of geometric features of the environment are transformed into an allocentric directional framework, by taking into

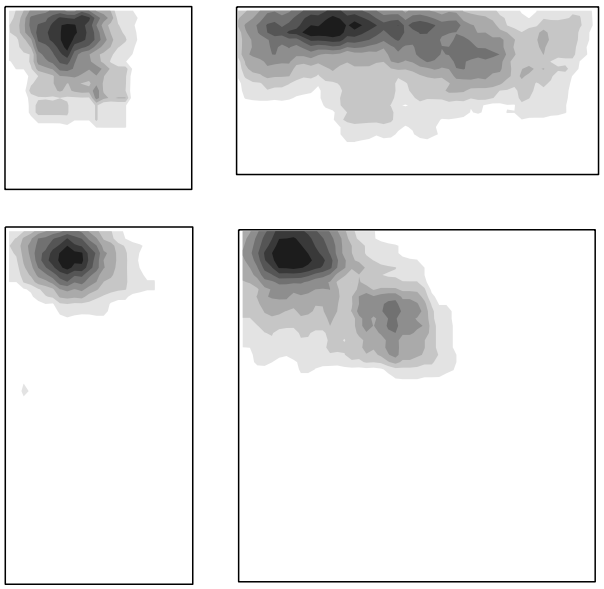

Figure 1. Place cells in area CA3 of the rat hippocampus have firing rates that vary systematically according to the rat's location. The region where the cell fires is called a place field. The shading indicates the place fields of one cell, recorded as the rat explored four different rectangular boxes. In each case, the cell fires most strongly in the northwest corner of the box (i.e., the location of the field remains fixed relative to the north and west walls). Adapted from O'Keefe J and Burgess N (1996) Geometric determinants of the place fields of hippocampal neurons. *Nature* **381**: 425–428.

account the rat's heading, as discussed previously. Consistent with this idea, manipulations that affect the orientation of the head direction system also affect place field locations. For instance, if distant visual cues are rotated about the center of the rat's environment, place fields are rotated through a corresponding angle.

A Simple Feedforward Model of Place Field Formation

The simplest models of place field formation are feedforward models. Many of these assume that the inputs to the hippocampus are sensitive to landmarks at particular distances and/or directions, but as we have seen some features of the environment (such as distant visual cues or walls) are more important than others.

As an example of a feedforward model, let us assume that the inputs to the hippocampus include some that are dependent on the geometry of the environment and in particular its boundaries (Figure 2). These hypothetical cells have the property that they fire strongly when a wall is at a given distance and allocentric direction to the rat. A place cell could receive inputs from many such cells, with the place field reflecting the overlap between the firing fields of its inputs. For instance, a place cell with a firing field in the Northeast corner of a box might have one input which responds whenever there is a wall a few centimeters North of the rat, and another that fires when there is a wall a few centimeters to its East. Either stimulus on its own might be insufficient to drive the place cell to fire (so that it does not fire in the Northwest corner, for instance), but the combined inputs of cells responding to the North and East walls drive the place cell to fire in the Northeast corner. If we change the geometry of the box (for instance by doubling its size), the cell will still fire in the Northeast corner. Note that in this model the only requirement for path integration or similar processes is in the tracking of heading.

The above model explains data concerning place field locations in boxes of different shapes and sizes, and predicts that there are cells upstream of the hippocampus, each of which fires in response to a boundary at a particular distance and bearing. It also predicts (in line with experimental observations) that even radical alterations of the shape of the environment should result in fields fixed with respect to the nearby walls of the environment. The model makes no mention of learning, and only requires that each place cell be connected to a random selection of inputs in order to account for the observed patterns of place field location in differently shaped environments. Indeed, one can use place fields obtained from the same cell recorded in differently shaped environments to infer which geometric inputs are driving the cell, and thus to predict the behaviour of the cell in a novel environment.

One potential problem with this simple model is that it makes no mention of the abundant lateral connections that are known to exist between cells in area CA3, and is at odds with data showing that markedly different place fields can sometimes be established in different boxes. This phenomenon, known as 'remapping', has been taken as evidence that the place cell system functions as an 'attractor' network.

Attractor Networks of Place and Orientation Representations

Attractor networks are neural networks with recurrent connections (i.e., connections between neurons in a single processing 'layer'). These make it possible for any neuron in the interconnected layer to affect the activation of any of the

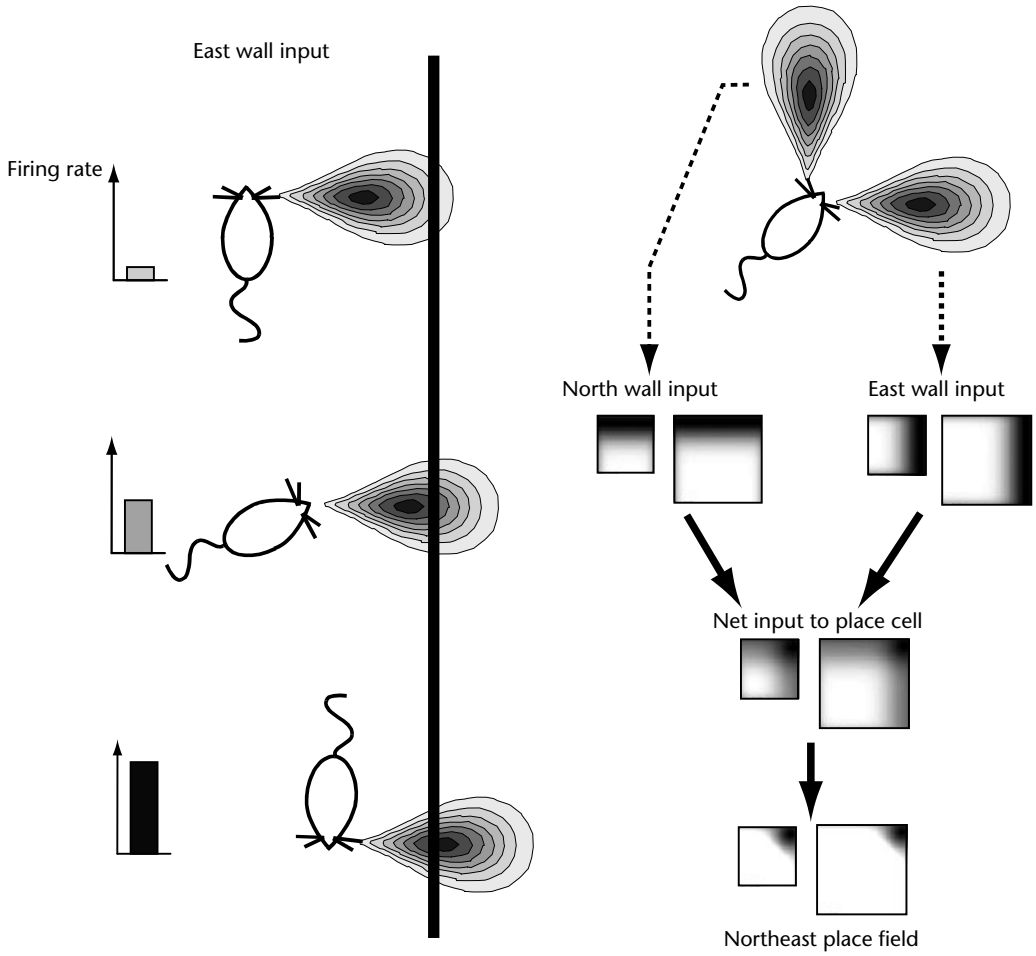

Figure 2. A simple feedforward model of place field formation. In this model place cells have inputs that respond to walls or other boundaries at particular distances and directions from the rat. The left panel shows the receptive field of one such cell (sensitive to a boundary a short distance to the East), and illustrates how the cell's firing rate varies as the rat moves nearer to the wall. Note that the direction that the input cell is tuned to does not depend on the rat's heading. Place fields could be formed by combining several such inputs. The right panel shows how a place field in the Northeast corner of two different-sized square boxes can be modeled by combining inputs responsive to North and East walls. The two input cells fire close to the North and East walls respectively (in both boxes). The net input to the place cell is greatest when the rat is in the Northeast corner of either box. The place cell's firing rate is a thresholded function of its net inputs: the cell fires only in the Northeast corner of the box. Adapted from Hartley T, Burgess N, Lever C, Cacucci F and O'Keefe J (2000) Modeling place fields in terms of the cortical inputs to the hippocampus. *Hippocampus* **10**: 369–379.

others to which it is directly or indirectly connected, a property that makes their dynamics potentially rather complex. However, with some constraints, such as symmetry in the strength of connections between neurons (connections from A to B are of equal strength to those from B to A), an attractor network is guaranteed to settle into one of a number of possible stable states (attractor states).

Place Representations

In an attractor model of place cell firing, spatial inputs from sensory neocortex activate some of the hippocampal pyramidal cells. Activation then flows between cells along the recurrent connections. This gradually changes the pattern of firing in the pyramidal cells (indirectly activating some cells that are not driven directly by the neocortical input and inhibiting some of those that are) until it settles at an attractor state.

In 'continuous attractor' networks, the connection strengths are constrained so that rather than having a number of distinct attractor states, the network will move smoothly between attractor states as the input is changed. One way this could be achieved in place cells is for cells with nearby

place fields to have strong connections, and for place fields with well-separated fields to have weak (or inhibitory) connections.

If the inputs to the hippocampus are spatially modulated, and the hippocampal pyramidal cells are connected together to form a continuous attractor network, then one would expect to find a population of place cells that shows the same pattern of activation whenever the animal visits a particular location, with some cells firing strongly, others only weakly. At another location one would see a quite different pattern of activation. As the pattern of active cells changes smoothly as the rat moves from one place to another, the firing rates of individual cells will also vary smoothly between locations; i.e., each cell will have a smooth firing field with some spatial extent – a place field. With appropriate lateral connections, any spatially modulated input could be sufficient to produce place fields, so path integration could play a more significant role in this type of model. However, it would still be difficult to account for the geometric constraints on place field location in terms of a model whose spatial inputs were exclusively internal.

A continuous attractor model requires a particular pattern of connection strengths between place cells. These connection strengths might be learned on exposure to a new environment. However, place fields appear to be present on the first exposure to a new environment (within a few minutes) and are stable for at least several days. This suggests that either learning is extremely rapid or that preexisting lateral connections are sufficient to produce the observed fields.

Orientation Representations

The head direction system can also be modeled as a continuous attractor network with inputs corresponding to visual cues to orientation and vestibular responses to left–right rotation. In this model, connections between head direction cells are such that, for any input, the network will settle into a stable state with a few cells (representing the current heading) firing, and the rest silent: cells representing opposite directions inhibit one another, while there are weak excitatory connections between cells representing neighboring directions. One can imagine the head direction cells as arranged in a circle, with excitatory connections between neighboring cells, and inhibitory connections between more distant cells. At any time a cluster of active cells will indicate the direction of the neural compass. By virtue of the hard-wired connections each head direction cell receives from the vestibular system, the activation peak can be driven clockwise or counterclockwise. The visual inputs function to calibrate the system and tie it to the external world.

MODELS OF NAVIGATION

Together, the two types of allocentric representation described above – place and heading – provide the basic tools for spatial memory and navigation. However, it is important to note that they do not in themselves constitute a cognitive map. A map also has to identify important locations and store them for later use: without some representation of an intended destination, information about current location and heading will be of little use in navigation. Furthermore, a cognitive map must also include information about the way in which different places are connected to one another (topology), so that it is possible to plan a route between places that avoids obstacles. Here we must be more speculative about the neural mechanisms, because to date no neurophysiological study has identified neurons that encode either destinations or topology.

The recurrent collaterals in region CA3 also figure prominently in models of navigation. Hebb's ideas on the modification of functional connections between cells, and the apparently related process of long-term potentiation of synapses, indicate that strong connections should develop between cells that fire simultaneously. For place cells, this would produce strong connections between cells with nearby fields (as required to form a continuous attractor, see above). However, it would also lead to the topology of space being encoded in the strength of the recurrent connections; in other words, the strength of a connection between place cells could indicate, on average, how long it took the rat to travel between the corresponding place fields. Thus the places along the shortest path between two locations could be found in principle, although how this would work in practice is less clear.

Some experiments have shown a temporal asymmetry in long-term potentiation: connections from one cell to another are strengthened most when the first cell fires before the second. This asymmetry would allow the learning of the path taken by an animal as it moved from one place to another. Place cells with firing fields near the beginning of the route will develop strong connections to place cells with fields further along the route. These directional connections could, in principle, be used to store the route but, again, it is less clear how they would be used to guide behavior in practice.

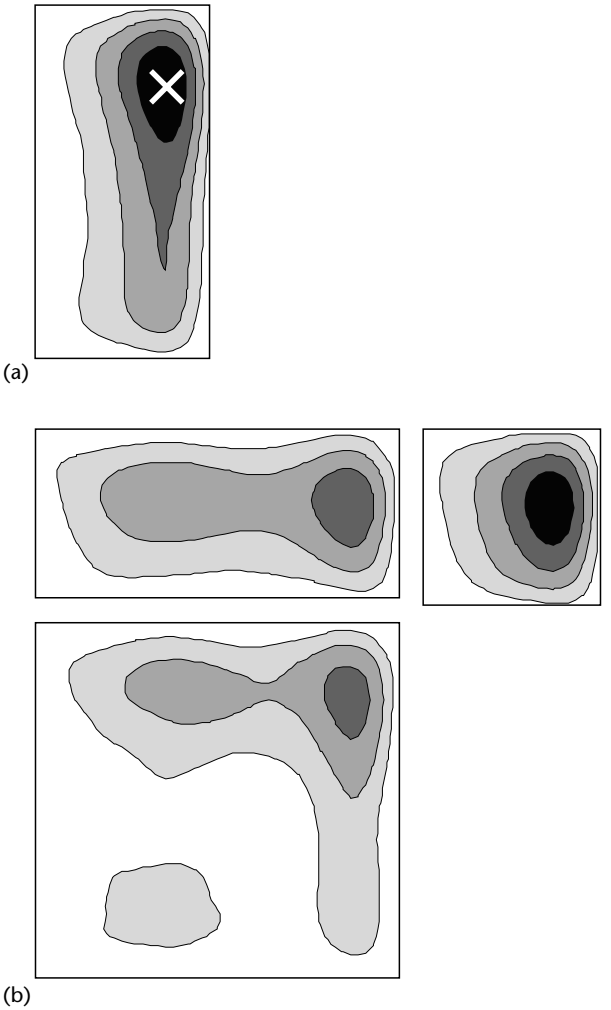

Figure 3. (a) A simple goal cell model of navigation to a stored goal location. When reward is received at location X, a goal cell is activated. Connections from active place cells to the goal cell are strengthened. The goal cell's firing rate will now vary depending on the rat's proximity to X. To return to the stored location the animal must move so as to maximize the firing rate of the goal cell. The firing rate map was made by simulating a large number of place cells each having a random selection of geometric inputs and thus producing a varied selection of place fields which overlapped and covered the entire space of the box. The goal cell firing rate is calculated as the similarity of the place cell firing rates at each location to the stored pattern (firing rates at X). (b) Where will the rat search if the shape of the box is changed? Because we can simulate the firing of the same place cells in different boxes, we can also predict the search locus in environments of different shape. Such predictions will allow us to test the model in behavioral experiments. Adapted from Hartley T, Burgess N, Lever C, Cacucci F and O'Keefe J (2000) Modeling place fields in terms of the cortical inputs to the hippocampus. *Hippocampus* **10**: 369–379.

As with models of spatial representation, simple feedforward models may suffice for modeling navigation. Perhaps the simplest model of spatial memory posits that receiving a reward at a particular location causes a 'goal cell' immediately downstream of the hippocampus to fire. This in turn strengthens synaptic connections to it from the place cells active at that location. The subsequent firing of the goal cell would indicate the proximity of the goal. As the animal moves nearer the goal location, more of the place cells with strong connections to the goal cell will fire, increasing the net current input to the goal cell. Thus the animal will be able to return to the goal simply by moving so as to increase the firing rate of the goal cell. More generally, this type of model predicts that the likelihood of searching for a remembered location in a particular place increases with the similarity of the place cell representations of the goal and the place (Figure 3).

Other models have looked at the generation of movements in navigation in more detail, enabling the animal to head directly to the goal, rather than hunting around to ascertain the right direction. These models confront the problem of translating allocentric hippocampal information (such as 'the goal is to the north') into egocentric movements (such as 'turn left'). This translation is assumed to occur in the parietal cortex or basal ganglia, again making use of the head direction system to translate between orientation-neutral and orientation-specific reference frames.

CONCLUSION

Thanks to neurophysiological data gathered over more than three decades we now have fairly detailed mechanistic theories of the processes involved in forming spatial representations, in translating between representations in different reference frames and in storing them and using them to guide behavior. These models have now progressed to the point that we can make links between physiology and complex behaviors such as navigation, and thus develop an ever more detailed understanding of spatial cognition.

Spatial Cognition, Psychology of

Introductory article

Barbara Tversky, Stanford University, Stanford, California, USA

CONTENTS

People think about space in terms of the elements in space and their spatial relations, not in metric terms. Different spaces are conceptualized differently: the space of the body, the space around the body, the space of navigation, and the metaphoric or miniature space of graphics.

CONCEPTUALIZATIONS OF SPACE

We live in space. All of our perceptions and actions are situated in space. From the moment of birth, perhaps even before, and for every minute thereafter, we are engaged in spatial cognition, in implicit awareness of or active interaction with the surrounding space. We engage in spatial cognition in our imaginations as well, in ways ranging from cognizance of the things around us that we cannot currently perceive, to judgments about environments too large to be perceived, to mental modeling of imaginary worlds. Spatial knowledge comes both directly, from perceptual experience (not only from vision, but also from audition, proprioception, olfaction, and other senses), and indirectly, from language, diagrams, and maps.

Our conceptions of space are not geometric. In mathematical geometry, space itself is primary, and things in space are located with respect to the external coordinates of the space. This view of space is unitary: it applies to all spaces, regardless of what is contained in them. Measurement is quantitative. For people, the things in space are primary, and they are located, mentally, with respect to each other and to a psychologically salient reference frame. Different spaces are conceived of differently, with different reference objects and frames, depending on the roles they play in people's lives. Our spatial measurement is qualitative and piecemeal, even inconsistent.

Knowledge of space is not just internalized perceptions of space. Nor is it simple averages or combinations of memories of space. Rather, spatial knowledge is constructed. These constructions are based on conceptions that are based on experience with space, rather than internalized perceptions of experience. Although the constructions differ for different spaces, their essential ingredients are elements and the spatial relations among them. This article will discuss some of our psychological spaces: in particular, the space of the body, the space around the body, the space of navigation, and the space of external representations.

ELEMENTS OF SPACE

Elements in space have spatial extent in themselves. Thus, although under some perspectives elements in space are treated as points, they may also be treated as spatial entities. Usually, what we refer to as 'objects' or 'entities' have integrity in the sense that their parts are connected, hence they move in concert; and they are smaller than we are, things we can manipulate. This is in contrast to 'environments', the spaces we move in or that surround us. One of the remarkable features of the human mind is that it can conceive of environments as objects – even as points, as when we represent cities in maps.

Just as different spaces are treated differently by the mind, so different elements in space are treated differently. Objects seem to be recognized by their shapes or contours. Shapes, in turn, are determined by parts in configuration. Thus our conceptions of object parts, as well as of objects, play a role in recognition. Faces are a special kind of object. Technically, they are part of a larger object, a human body. But when we refer to face recognition, we usually mean recognition at the level of the individual (e.g., recognition that it's John F. Kennedy, not Bobbie or Ted), rather than recognition at the level of the category (e.g., recognition that it's a table and not a chair, an elephant and not a giraffe). Since all faces have the same general contour,

contour is not useful for identifying faces at the level of the individual. Rather, the shapes and exact configuration of internal features seem to be critical for identifying faces. Different regions of visual cortex are differentially sensitive to faces and objects, suggesting that recognition of these different classes of stimuli differs computationally. There are brain-damaged patients who can easily recognize some classes of objects (e.g., living things), but have difficulties recognizing other classes of objects (e.g., artifacts).

Even more significant for spatial cognition is evidence that the parahippocampal place area is selectively involved in recognizing places – that is, three-dimensional configurations of walls, furniture, buildings, streets, trees and so on. This area is selectively active under viewing of scenes, and patients with damage to this area experience severe difficulties acquiring spatial knowledge of new places.

THE SPACE OF THE BODY

Bodies can be regarded as objects. But bodies have a special status as objects in that we know them from the inside as well as from the outside. Bodies can also be regarded as spaces, as in cases of sunburn or rashes. How is the space of the body conceived? Are the parts of the body most readily accessed the larger parts, or the most perceptually salient parts, or the most important parts? To address this question, observers viewed from the side bodies in many positions and orientations with one body part highlighted. The set of parts that could be highlighted was drawn from the parts that are most commonly named across languages: head, arm, hand, chest, back, leg, and foot.

Three types of theory have been proposed to explain representations of the space of the body. According to 'imagery' theories, larger parts should be identified faster; this would mean that chest and back would be identified faster than hand or head. Theories of 'object recognition by components' suggest that parts that are perceptually salient, that is, parts that extend from the object's contour, should be most rapidly identified, so arm and leg would be identified more rapidly than back. Finally, parts rated as 'good' enjoy both perceptual salience and functional significance. The third type of theory posits that parts that have functional significance should be most accessible. Perceptual distinctiveness and functional significance are correlated in artifacts and natural kinds. Parts have a distinctive appearance as well as a distinctive function so that they serve as a bridge between perception and function. For body parts, too, salience and significance are correlated, but not completely. The major exception is the chest, which has relatively low contour discontinuity but relatively high functional significance, perhaps because it protects crucial organs of the body, perhaps because it represents the forward direction privileged in perception and action.

The observers in the experiments described above had to decide if pairs of stimuli referred to the same or different parts. The comparison stimulus was always a depiction of a body with a part highlighted. The other stimulus was either a name of a body part or another depiction of a body (oriented differently) with a part highlighted. Half the comparisons were of the same body part, half of a different body part.

The results for the two tasks differed in an interesting way. For body–body comparisons, perceptual salience was the best predictor of identification reaction times. However, for name–body comparisons, functional significance was the best predictor. When two depictions of bodies appear on the screen, they can be compared as objects, even as forms devoid of meaning. The process of comparing a name to a depiction apparently involves meaning, and the meaning of a body part includes its functional significance.

In fact, rankings of salience and significance of body parts are correlated with each other; they are negatively correlated with part size; and part size is negatively correlated with identification times. Thus, larger parts are relatively less salient and significant. The space of the body, at least for these tasks, is not conceived of in terms of size; rather, it is conceived of in terms of salience and significance.

The space of the body, then, is decomposed into natural body parts. Size is not of primary importance in mental representations of the space of the body. The parts that are most accessible are not the largest parts but rather the parts that enjoy perceptual distinctiveness and functional significance, which are correlated. Perceptual distinctiveness is more important when the body is regarded as an object, but when language is involved, functional significance seems to be more important.

THE SPACE AROUND THE BODY

As we move about the world we maintain awareness of the things around us that are no longer in view. This knowledge appears to be a consequence of mental models that we form of the world around us, which we update as we move or

the surroundings change. Moreover, it seems that such mental models can be induced by language describing movements and things in the world as well as by actually moving in and perceiving the world. Our ability to turn descriptions of the world into mental models of the world underlies some of the power of literature and poetry. Research suggests that such mental models are schematic, rather than rich detailed images; and indeed, that even active perception of the extant world is schematic and lacks rich detail: major elements of viewed scenes can be changed without viewers' noticing.

In experiments designed to investigate the nature of these mental models, participants read descriptions of themselves in environments such as a hotel lobby or opera house, surrounded by objects to their front, back, left and right, and above and below them. Once they had learned such an environment, they were verbally reoriented to face another object in the scene. Then they were probed by direction terms ('front', 'back', 'left', and so on) for the objects currently in those directions from the body. Repeatedly, participants were reoriented and probed again. Performance was essentially perfect; that is, participants readily reoriented themselves in these described environments. The data of interest were the times to access objects in different directions from the body.

It might be expected that all directions should be equally accessible, as the content of the narratives did not privilege any regions of space or any objects over others. However, access times differed considerably, depending on the direction. One way in which participants might perform the task would be to mentally image the environment and then mentally scan the environment for the objects in the probed directions. This model also failed to account for the pattern of retrieval times.

The data were, however, consistent with a 'spatial framework' account. According to this account, participants construct a mental spatial model from extensions of the three body axes and attach the objects to them, updating as needed. Accessibility depends on characteristics of the body axes as well as on characteristics of the axes of the spatial world. For an upright observer, the head–feet axis is most accessible because it is an asymmetric, hence easily discriminable, axis of the body and because it is aligned with the only asymmetric axis of the world, the axis of gravity. Front–back is next, as it is asymmetric; and the least accessible axis is left–right, which lacks salient asymmetries. The situation changes when the observer reclines and no axis of the body is aligned with gravity. Then accessibility depends only on the body axes: front–back is fastest to access, as that axis separates the world that can be perceived and manipulated from the world that cannot; head–feet is next; and left–right is slowest, as before.

These patterns of accessibility of directions from the body obtain not only from worlds learned from narratives, but also from worlds learned from experience, models, and diagrams. Thus, however the knowledge is acquired, the space around the body is conceived in three dimensions, extensions of the body axes.

THE SPACE OF NAVIGATION

The space of navigation is too large to be seen from one viewpoint; rather, it is pieced together from different viewpoints, and often from different occasions and different types of experience – for example, perception, language, and maps.

Route and Survey Perspectives

Language is often used to establish mental models of spaces larger than the ones around the body. Spontaneous descriptions of the space of navigation use one of two perspectives, or a combination of both. A 'route' perspective takes the listener (addressed as 'you') on a mental tour through an environment, locating landmarks with respect to the traveler in terms of 'front', 'back', 'left', and 'right'. A 'survey' perspective takes a viewpoint above the environment and locates landmarks with respect to each other in terms of 'north', 'south', 'east', and 'west'. A route perspective is egocentric, a survey perspective allocentric.

Do the mental models established from the two perspectives differ? For well-learned restricted environments, apparently not. In a series of experiments, participants studied descriptions of spaces, such as small towns or convention centers from either a route or a survey perspective. They then answered 'true or false' questions from both perspectives, either verbatim from the texts or inferable from the texts. Response speed and accuracy were greater for verbatim statements from the studied text than for inference statements, indicating that participants retained the exact wording of the text. However, for inference statements, there were no differences in speed or accuracy between the studied perspective and the other perspective in four experiments. Maps sketched at the end of the experiments were highly accurate for both perspectives. These findings suggest that readers

formed perspective-free representations, something akin to an architect's model, which can be viewed from many different perspectives.

The environments of which people readily formed mental models were, however, schematic and restricted. They included the relative spatial relations of only a dozen or so environmental elements. For larger environments, or even smaller ones that are studied only briefly, the way the environment is learned does affect the mental representations used. Switching the perspective of a description of an environment from route to survey or vice versa slows down reading times during acquisition of the environment. Representations of complex environments can show lasting effects of the mode of acquisition. For example, participants who learned a building complex from experience were better at route distance estimates than participants who learned from a map; while participants who learned a building from a map were better at imagining adjacent rooms that were not directly linked. The latter investigations found equally strong effects of task goal, to learn the layout or to learn routes, on later mental representations. Moreover, research using brain imaging shows that route learning and retrieval activate different brain areas from map learning and retrieval.

Cognitive Maps and Cognitive Collages

In the experiments described above, the spatial mental models established from descriptions, though accurate, were highly schematic. Indeed, they were acquired from schematic summaries – either descriptions or sketch maps, both of which abstract and structure information, in similar ways. The models were also limited to small, well-learned environments.

People's knowledge of less constrained environments – which may have been acquired from experience, maps, descriptions, or some combination of these – is also schematic, but is often piecemeal and scattered. It does not seem that people have 'cognitive maps', in the sense of coherent mental representations of all the environments they have encountered, stored in memory and ready to be consulted. Rather, it seems that when people need information about an environment – perhaps to answer queries about directions or distances, perhaps to navigate, perhaps to make inferences about weather or population migrations – they retrieve whatever information seems relevant. That information might be in a variety of formats; it might be incomplete; it might be schematic; it might be difficult or impossible to integrate into a coherent whole. Because such representations are put together 'on the fly' from a multitude of media, a more apt metaphor than 'cognitive map' for the functional mental representation is 'cognitive collage'.

Much of the evidence for this conclusion comes from research demonstrating systematic errors in cognitive 'maps'. These errors can reveal the perceptual and conceptual organizing processes that people use to represent and integrate spatial information. One of the first processes in perception is distinguishing figures from ground. Once figures have been isolated, they are oriented – a critical process in their identification and located with respect to each other and a frame of reference. Systematic errors of alignment and rotation reflect each of these processes.

Errors of alignment

When asked the direction between Chicago and Monaco, a majority of people report, incorrectly, that Monaco is south of Chicago. Similarly, when asked the direction between Boston and Rio, most people report, again incorrectly, that Boston is east of Rio. In organizing the geography of the world, people seem to mentally align large regions like the US and Europe or North and South America. The US and Europe are remembered at similar latitudes and North and South America at similar longitudes. In fact, if presented with a choice between a true map of the world or the Americas and a map that has been altered so that the US and Europe or North and South America are more aligned, a majority of people choose the incorrect aligned map as the 'true' map. The alignment effect also appears in memory for artificial maps and for meaningless blobs, showing that it is a general perceptual strategy, not restricted to maps and environments.

Errors of rotation

Other systematic geographical errors show that people organize large geographic entities relative to frames of reference as well as to each other. When Stanford students were asked to indicate the direction from Stanford to Berkeley, they erroneously indicated that Stanford was west of Berkeley. They also indicated that Santa Cruz on the coast was west of Palo Alto, again erroneously. People apparently conceive of the southern region of the San Francisco Bay area to be aligned north–south, when in fact it is aligned northwest–southeast. A similar error is observed when people are asked to orient the

shape of South America in a north–south–east–west frame: they 'upright' South America, suggesting that, in their mental representation, the 'natural' axes of the figure are aligned with the axes of the surrounding frame. Like the alignment effect, the rotation effect is a general perceptual organizing principle, appearing for artificial maps and meaningless blobs.

Errors due to hierarchical organization, perspective, and landmarks

There are other systematic errors in spatial memory. The space of navigation is organized hierarchically. For spaces the size of a piece of paper or a sandbox, adults and children make location errors in the direction of the central tendency of the spatial category. Other things equal, the preferred spatial category is a quadrant around a point. For real environments, the spatial categories are often geographic units such as cities, states, and countries. These geographic units affect judgments of distance and direction. Distances within units are underestimated relative to distances between units; directions of entities like cities within units like states are distorted towards the overall direction between the larger units. The perspective from which an environment is conceived also affects distance estimates. In one experiment, people imagining themselves on the east coast of North America estimated the distance between New York City and Pittsburgh to be larger, and the distance from San Francisco to Salt Lake City smaller, than people imagining themselves on the west coast. In both cases, the participants were actually situated in Ann Arbor, so it is the imagined point of view, not the actual point of view, that affects the judgments.

Another striking refutation of the view that maps in the head are like conventional maps on paper comes from the finding that distance estimates from a landmark to an ordinary building are smaller than distance estimates from an ordinary building to a landmark. That is, imagined distances between two points can be asymmetric. This error even extends to metaphoric distances. For example, the similarity of North Korea to China is judged to be less than the similarity of China to North Korea. Likewise, sons are viewed as more similar to fathers than are fathers to sons. Such errors violate an elementary assumption about metric spaces, whereby the distance from A to B must be the same as the distance from B to A.

Together, these errors indicate that the human mind does not contain a library of maps from which distance, direction, route, and other information can be read off. Rather, it seems that a query directs a search for relevant information. That information may turn out to be more or less accurate, complete, consistent, or relevant. Why has the mind developed mechanisms to remember and use spatial information that are guaranteed to produce error? If the mind is an optimizing machine, it must be optimizing many things at once. A mechanism that produces efficient memory – in particular, schematization, both as a way of conserving memory and as a way of integrating disparate items of information – may not optimize accuracy. Erroneous, even self-defeating, actions occur in many domains of human behavior.

Navigation in the Wild

If mental representations of environments are so distorted and incomplete, how is it that people ever succeed in navigating? Actual navigation depends on more than spatial cognition. It is situated in environments that present constraints. If a turn is remembered as a right angle, but the actual angle is less or more, the roads themselves will allow only the correct angle. Similarly, if the distances between landmarks are incorrectly remembered, the landmarks themselves will correct the error. Environments serve as cues, which may elicit information and behaviors that the imagination fails to evoke.

Furthermore, other senses, as well as other information, are operative. Proprioceptive and vestibular information serve actual navigation, but are unlikely to be accessible to cognition. Path integration – that is, maintaining a sense of one's position by integrating distances and turns – while not perfect, can also help travelers. These mechanisms are used by other species as well. Even ants, bees, and rodents correct errors resulting from biased path integration by referring to features of their environments, such as landmarks.

THE SPACE OF EXTERNAL REPRESENTATIONS

Creating external representations as deliberate aids to cognition seems to be a uniquely human behavior. Such representations range from trail markers, cave drawings, tallies, and maps to architects' sketches, economic graphs, organization charts, decision trees, and tables of chemical elements. These cognitive tools capitalize on human adeptness with space, mapping abstract as well as inherently spatial elements and relations onto other spatial elements and relations in meaningful ways. Diagrams and charts use likenesses, icons,

and symbols to represent elements. Examples include icons in computer interfaces and airport signs, and picture-writing in many languages. Diagrams and charts also use space to convey relations among elements, distance in the diagrammatic space representing distance on some other dimension, such as strength or preference. External representations augment the power of the mind by relieving memory and processing, while taking advantage of the mind's ability to understand space, represent it, and make spatial inferences.

CONCLUSION

There are many kinds of spatial thinking. A great deal of human experience is spatial. Each mental space is based on and serves a particular kind of human spatial experience, extracting and schematizing information that is useful for it. These mental spaces are so useful that they subserve thinking in many other domains, including those of emotion, interpersonal interaction, and science. We feel 'up' or 'down'; one nation's culture or language 'invades' or 'penetrates' another; inertia, pressure, and unemployment 'rise' or 'fall'. Even at its most lofty, the mind rests on the concrete.

Speaking and Listening Skills

Advanced article

Leonard Abbeduto, University of Wisconsin-Madison, Madison, Wisconsin, USA

CONTENTS

Speaking and listening are conceptualized as goal-directed, collaborative activities that reflect social practices and constraints inherent in the human information processing system. Research has focused on how these activities develop and vary across individuals and cultures.

THE SOCIAL NATURE OF SPEAKING AND LISTENING

Views of speaking and listening have changed dramatically over the past 40 years. In the 1960s, research on speaking and listening was strongly influenced by the linguistic approach of Noam Chomsky (Smith, 1999). In the Chomskyan approach, abstract descriptions of the formal (phonological, syntactic, and semantic) properties of sentences were created to describe the knowledge of language assumed to be 'in the head' of all language users. For Chomsky, speaking and listening were linguistic performances that provided a window into the language user's knowledge, or competence, but they were not in and of themselves interesting. Indeed, the window provided by speaking and listening was thought to be imperfect because they were subject to the limitations of the human information processing system, such as limited memory.

In the 1970s, dissatisfaction with the linguistic approach grew on a number of fronts. Particularly important was dissatisfaction with the exclusion of the social dimensions of speaking and listening. This led to an interest in pragmatics, which is the study of the social uses of language (Levinson, 1983). Early work, or stage one pragmatics, assumed that speakers and listeners followed socially oriented rules to translate their knowledge of phonology, syntax, and semantics into real instances of speaking and listening (Duchan *et al*., 1994). Importantly, stage one pragmatics accepted many of the Chomskyan assumptions (Abbeduto and Short-Meyerson, 2002).

Stage one pragmatics is illustrated nicely by work on speech acts (Levinson, 1983). A speech act is essentially the social function that an utterance is intended to perform, such as requesting information or making an assertion. Speech acts and language forms are not isomorphic. 'That's mine', for example, could request the return of an object or make a statement of fact. In explaining how listeners arrive at different speech acts, stage one theorists (Levinson, 1983) assumed that any utterance has associated with it a literal, or direct, interpretation that is solely a function of the words it contains and the linguistic rules governing their combination. Nonliteral, or indirect, interpretations were thought to be derived from the literal interpretation according to context-dependent pragmatic rules. For example, listeners assume that speakers adhere to the rule 'an utterance must supply new information' and thus, 'that's mine' would be interpreted as a request (its indirect interpretation) rather than as a statement (its direct interpretation) if it was already obvious to the speaker and listener that the object in question belonged to the speaker (Abbeduto *et al*., 1988).

Stage one pragmatics was valuable because it focused on the social nature of speaking and listening. This work, however, suffered from a number of limitations. First, it assumed that knowledge of pragmatic rules is acquired, represented, and accessed independently of knowledge of other components of language despite evidence that pragmatic considerations motivate and shape the acquisition and use of many linguistic forms and vice versa (Abbeduto *et al*., 2001). Second, many so-called pragmatic rules reflect statistical tendencies rather than invariant patterns and, thus, they do not meet the usual definition of a rule. Third, there is a considerable amount of psychological activity that is ignored in the stage one account, such as how listeners determine what contextual information is relevant to deciding between a direct and an indirect interpretation of a sentence. Fourth, many

stage one rules have their origins in constraints on human behavior and social interaction rather than in some independently acquired and represented pragmatic knowledge (Prideaux, 1991). The 'rule' that no more than one person speaks at a time, for example, might simply reflect the difficulty of talking and listening simultaneously. And finally, stage one rules were thought to operate on sentences or smaller linguistic units. In conversation, however, a speaker's goals often can be realized only over an extended sequence of utterances (Abbeduto and Short-Meyerson, 2002).

These criticisms have led to a reconceptualization of speaking and listening, or to stage two pragmatics (Duchan *et al*., 1994). In stage two models, speaking and listening are viewed as reciprocal processes in which the participants collaborate to achieve their goals through sequences of behaviors that are inextricably bound to the dynamically evolving context in which the talk occurs and the practices of the communities to which the participants belong (e.g. Clark, 1996). This reconceptualization of speaking and listening has led researchers to focus on how participants recognize and respond to each other's goals, check on each other's background assumptions and knowledge, and solicit and supply feedback concerning the ways in which each other's utterances have been interpreted (Clark, 1996). It has also led to an expanded interest in the types of information that can serve as relevant contexts for the decisions that speakers and listeners make (Graesser *et al*., 1997).

DEVELOPMENTAL ISSUES

The development of speaking and listening skills is a protracted process that continues well into adolescence (Abbeduto and Short-Meyerson, 2002). Nevertheless, even toddlers can participate successfully in talk across a range of settings and partners, although often this success is due to the support, or scaffolding, provided by adult partners (Ninio and Snow, 1996). In this section, we focus on the developmental course of those aspects of speaking and listening emphasized by stage two models and on the skills and experiences needed to achieve proficiency.

Developmental Course

By two years of age children express and recognize many of the goals that can be achieved through language (Ninio and Snow, 1996). Even elementary school-age children, however, have difficulty recognizing another person's goals when those goals are implied rather than explicitly stated in his or her utterances (Abbeduto *et al*., 1992). There also is improvement well into adolescence in children's ability to use language to achieve their goals when doing so requires that they first achieve a subsidiary goal, such as securing the listener's attention (Anderson *et al*., 1994).

Children are able to solicit information about their partner's background assumptions and knowledge in situationally appropriate ways by the time they are three or four years of age (Short-Meyerson and Abbeduto, 1997). For example, preschoolers are less likely to talk about background experiences (e.g. 'You bake cookies before?') when they and their partners have extensive knowledge of the topic than when either of them has limited knowledge. The extent to which children engage in such talk, however, increases with age (Short-Meyerson and Abbeduto, 1997).

By the age of two years children are able to solicit and supply verbal feedback about the ways in which the utterances of the participants have been interpreted (Abbeduto and Short-Meyerson, 2002). For example, toddlers and preschoolers signal noncomprehension of their partner's messages and respond to such signals from others. However, they are more likely to respond to some types of signals of noncomprehension (e.g. 'What?') than to other types (e.g. 'Which book?'), and not all of their responses are informative. In fact, progress here continues throughout the school years (Abbeduto *et al*., 1997).

Considerable research has demonstrated that children use context to make a variety of decisions about language by two or three years of age, although they become increasingly more sensitive to an ever broader range of contextual information throughout the school years (Abbeduto and Short-Meyerson, 2002). Thus, toddlers and preschoolers tailor the complexity, politeness, and level of detail of their language according to the ability, authority, familiarity, and knowledge of the partner. They also use their partner's immediately preceding utterances as a basis for decisions about what the 'current' utterance means. Toddlers and preschoolers, however, often fail to use context that is not explicitly stated or immediately perceptible (Ackerman *et al*., 1990). There also is steady improvement with age in the effectiveness with which children track changes in context during the interaction (Ricard, 1993).

When considering the development of speaking and listening, it is important to recognize that different genres of talk require different skills and have different developmental trajectories (Ninio

and Snow, 1996). A particularly important genre is narration, or story telling. The development of facility with narrative is thought to provide the foundation for a variety of social and academic skills (Hyter and Westby, 1996). Narrative development begins early but continues into adulthood, with a particularly important shift in early adolescence from a preoccupation with talk about observable events, or a 'landscape of action', to an interest in psychological states, or a 'landscape of consciousness' (Bruner, 1986).

Necessary Skills and Experiences

Developmental progress in speaking and listening is driven in part by achievements in other domains of psychological functioning (Abbeduto and Short-Meyerson, 2002). First, acquisitions in linguistic knowledge (i.e. phonology, syntax, and semantics) ensure that the child has a fuller array of tools for collaborating in talk. Indeed, individuals who have delays in acquiring any or all forms of linguistic knowledge (e.g. those with mental retardation) have pervasive delays in speaking and listening (Abbeduto *et al*., 1998). Second, achievements in speaking and listening depend on children's increasing knowledge of the world and the increasing efficiency of their information-processing systems. For example, children achieve more success in dyadic interactions involving routine events for which they have rich scripts rather than impoverished scripts (Furman and Walden, 1990). Third, the ability to reason about other people's mental states provides the foundation for many achievements in speaking and listening, such as the ability to consider the audience's perspective in narration (Ninio and Snow, 1996) and the use of behaviors for soliciting feedback about how an utterance has been interpreted (Abbeduto *et al*., 1998).

Developmental progress also depends on participating in talk in a variety of settings and with a variety of other people. Particularly important early in development is talk with adults (Ninio and Snow, 1996). Adults provide structure and support that circumvents some of the limitations of young children, thereby ensuring the interaction's success and exposure to 'model' behaviors. Gradually, adult support allows the child to perform behaviors that were previously beyond his or her ken. These interactions with adults are complemented by participation in talk with peers and siblings which allows the child to practice speaking and listening skills that are called for less often in interactions with adults (Dunn and Kendrick, 1982).

INDIVIDUAL AND CULTURAL DIFFERENCES

In addition to age-related differences in speaking and listening, there are differences between individuals of the same age. Not surprisingly, these can be traced in part to differences in other domains of ability that are recruited for use in speaking and listening, such as working memory and theory of mind. In some instances, a child may deviate from average expectations to such a degree that he or she is classified as having a problem that warrants special educational or therapeutic attention, as in specific language impairment and mental retardation. It is interesting to note that in both of these, dissociations in speaking and listening are possible, with speaking usually being more impaired. In the case of mental retardation, the extent and nature of the dissociation varies across etiologies; for example, individuals with Down syndrome are more likely to show poorer speaking than listening skills, whereas such a dissociation is less likely in fragile X syndrome despite the fact that both syndromes can be associated with similar levels of intellectual impairment (Abbeduto *et al*., 2001).

Individual differences in speaking and listening can also be related to cultural differences (Ninio and Snow, 1996). There is evidence, for example, that children speaking African-American English are more likely to convey referential information in their narratives through gesture and prosody than are European-American children, although the narratives of both are equally rich in referential detail (Hyter and Westby, 1996). It is important to recognize that such differences in children's speaking and listening reflect more than exposure to a different language or dialect. They also reflect differences in various practices endorsed or sanctioned by the culture. Crago and her colleagues (e.g. Crago and Eriks-Brophy, 1994), for example, found that parents and teachers in the rural Inuit communities of northern Quebec are more likely to rely on nonverbal modeling than talk when interacting with children compared to adults in French-Canadian or European-American communities. Importantly, such cultural differences do not reflect differences in the adequacy of children's learning environments but rather the simple fact that they must grow up to be members of cultures with different values and practices.

Speech Perception, Development of

Intermediate article

Peter W Jusczyk, Johns Hopkins University, Baltimore, Maryland, USA

CONTENTS

To acquire a language infants must be able to perceive its basic speech sounds. Infants are born with excellent abilities to discriminate a wide range of speech sounds. During the course of their first year, these capacities become more specialized for processing the sound patterns of their native language.

INTRODUCTION

Prior to 1970, most researchers identified the beginnings of language acquisition with infants' first attempts at babbling, or even with their first words. Thanks to the development of methods for studying the perceptual capacities of young infants, it is clear that infants categorize speech sounds long before they have begun to produce speech. Early studies sought to characterize the nature of infants' speech perception capacities. Knowledge of these basic capacities led to investigations how and when infants learn about the sound organization (or phonology) of their native language. Recent evidence indicates that in a brief period (the latter half of their first year) infants learn much about native language sound structure from spoken language input.

DISCRIMINATIVE CAPACITIES OF YOUNG INFANTS

The first indication that infants can distinguish speech sounds was reported by Eimas *et al* (1971). They used the high-amplitude sucking procedure to determine whether 1-month-old infants perceive a contrast in two syllables, [ba] and [pa], differing by a single phonetic feature (voicing). Infants were trained to suck on a pacifier to hear a particular speech sound such as [ba]. This training produced a marked increase in sucking rates for several minutes until infants habituated to this sound. At this point, some infants (the control group) continued to hear the same syllable for the next 4 min; for two other groups, a new speech syllable was introduced. For the between-category group, the voicing characteristics of the new syllable were changed so it sounded like [pa] to adults. For the within-category group, an equivalent voicing change was made, but the resulting syllable was one adults perceive as [ba]. Compared with the control group, only the between-category group showed significant increases in sucking for the new syllable. Thus, even 1-month-old infants discriminate the voicing distinction between [ba] and [pa]. Moreover, like adults, infants' discrimination of voicing differences is categorical – infants detect voicing differences between sounds from different phonetic categories, but not voicing differences between sounds from the same phonetic category.

This finding raised questions about the range of infants' abilities and the mechanisms underlying their discriminative capacities. Many subsequent studies investigated infants' abilities to discriminate other types of phonetic contrasts. Infants were shown to discriminate place of articulation contrasts involving stop consonants such as [bae] and [dae] (Eimas, 1974) and fricatives, such as [fa] and [Qa] (Levitt *et al*, 1988), and manner of articulation contrasts between stops and glides such as [ba] and [wa] (Eimas and Miller, 1980a) and stops and nasals such as [ba] and [ma] (Eimas and Miller, 1980b). Moreover, the capacity for discriminating consonant contrasts is present in newborns (Bertoncini *et al*, 1987). Other findings indicate that infants perceive vowel contrasts such as [a] and [i] (Trehub, 1973) and [i] and [I] (Swoboda *et al*, 1976). With respect to the latter contrast, just as for adults, infants' perception of this contrast is continuous, as opposed to categorical. In other words, infants perceive within category differences in vowels.

Infants' discrimination of speech sounds is similar to that of adults in another way, in that it is

robust with respect to acoustic variability in the production of speech. Because of differences in the size and shape of the articulatory systems of different speakers, their productions of the same speech sound will differ acoustically. Moreover, the same speech sound produced by an individual on different occasions varies, depending on such factors as speaking rate and emotional state. Thus, identifying the same word spoken on different occasions entails ignoring the kinds of acoustic differences among speech sounds that are irrelevant for making phonetic distinctions. Kuhl (1979) first demonstrated that 6-month-old infants are able to make phonetic distinctions, even when these are produced by a variety of different male and female speakers. Furthermore, infants as young as 2 months can make phonetic distinctions, even in the face of acoustic variability produced by different speakers (Jusczyk *et al*, 1992) or by changes in speaking rate (Eimas and Miller, 1980a).

SENSITIVITY TO NATIVE AND NON-NATIVE CONTRASTS

Since the first indications of speech discrimination by infants, researchers have been interested in the extent to which infants' discriminative capacities are driven by experience. Because fetuses in the last trimester respond to sounds, and because some speech information is transmitted through the womb, even newborn infants cannot be said to lack all experience of speech sounds from their native language. Thus, assessing the effects of experience requires the use of speech sound differences that are not present in the native language. Streeter (1976) reported that 2-month-old infants from Kikuyu-speaking environments can discriminate a [ba]–[pa] difference, even though these sounds do not occur in their native language. Similarly, Trehub (1976) found that infants 1–4 months old from English learning environments discriminated two other non-native contrasts, [pa]–[pã] and [r&a]–[za]. Findings from these and other investigations (e.g. Lasky *et al*, 1975; Aslin *et al*, 1981) suggest that prior to 6 months, infants are able to discriminate non-native speech contrasts.

However, experience plays a more important role in the latter half of the second year. Specifically, infants show a declining sensitivity to certain non-native contrasts. This developmental change in speech discrimination abilities was first noted by Werker and Tees (1984). They found that although English learners could discriminate non-native contrasts from Hindi and Nthlakapmx at 6–8 months, by 10–12 months they no longer discriminated these contrasts. This decline in sensitivity to non-native contrasts has also been observed for other contrasts (Tsushima *et al*, 1994; Best *et al*, 1995). However, discrimination of some types of non-native contrasts, such as Zulu clicks, is maintained into adulthood (Best *et al*, 1988). Why lack of experience causes a decline in sensitivity to some, but not all, non-native contrasts is not fully understood. However, an important factor appears to be how similar the non-native contrasts are to ones in the native language (Best, 1995). Contrasts that map to distinct native language phoneme categories tend to be easily discriminated, whereas non-native contrasts that map to the same phoneme category are poorly discriminated.

DEVELOPMENT OF WORD SEGMENTATION ABILITIES

Because words in fluent speech are usually produced continuously without clear pauses between them, some ability to segment words is critical for understanding language. It appears that listeners use information about the sound organization of their native language to locate the boundaries of words in speech. Among the possible cues for locating word boundaries are (a) consistent word stress patterns (i.e. prosodic cues); (b) the frequency with which certain combinations of phonetic segments can occur at the beginning and end of words (i.e. phonotactic constraints); and (c) restrictions on the positions that particular variants of a phoneme can occupy within a word (i.e. allophonic cues). The relative importance of each of these cues varies across languages depending on their particular sound organization.

Jusczyk and Aslin (1995) reported that English-learning infants aged 7.5 months but not those aged 6 months, display some capacity for segmenting words from fluent speech. The 7.5-month-olds gave evidence of segmenting words, regardless of whether they were familiarized with a pair of words presented in isolation and then tested on their recognition of the words in passages, or whether they were familiarized with the passages first, then tested on isolated words. Subsequent investigations have explored the source of infants' word segmentation abilities. Prior research had shown that, between the ages of 6 and 9 months, English learners develop sensitivity to prosodic and phonotactic cues that could potentially signal word boundaries (Jusczyk *et al*, 1993 a,b). When beginning to segment words, English-learning 7.5-month-olds rely heavily on prosodic cues (Jusczyk *et al*, 1999b). Hence, they segment words

with the predominant word stress pattern of English (initial stressed syllable followed by an unstressed syllable), but they do not segment words with less frequent stress patterns until the age of 10.5 months. The latter ability depends on the infants' use of other information about word boundaries, such as phonotactic and allophonic cues. English learners can use phonotactic cues at about 9 months (Mattys *et al*, 1999; Mattys and Jusczyk, in press) and allophonic cues at about 10.5 months (Jusczyk *et al*, 1999a).

TRACKING STATISTICS AND LEARNING PATTERNS

In order to learn which sequences of sounds are possible in words in a language, infants must track the frequency of occurrence of particular combinations of sounds. As noted in the previous section, 9-month-old infants distinguish between sequences of sounds that occur frequently in the input versus those that only occur infrequently (Jusczyk *et al*, 1994). However, what is remarkable is how rapidly infants can learn about statistical regularities in the input. Saffran *et al* (1996) presented 8-month-olds with a continuous stream of speech (about 2.5 min long) composed of four different trisyllables, which were randomly ordered with the exception that the same item never followed itself in the sequence. Within each trisyllable (e.g. 'golatu'), the order of each syllable was perfectly predictable, i.e. the first syllable 'go' always was followed by the same second syllable 'la', which was always followed by the same third syllable 'tu'. However, the predictability of the syllable that followed the third syllable was only 0.33 (because each trisyllable was followed equally often by one of the other three trisyllables). This low point in the transitional probabilities of adjacent syllables provides cues to the organization of elements within the speech stream. During the test phase, infants heard two of the original trisyllables and two new trisyllables (composed of the last syllable of one trisyllable and the first two syllables of another). The infants treated the original trisyllabic items as familiar, suggesting that they had segmented the speech stream using the statistical cues. A follow-up study indicated that infants can also track statistical regularities for sequences of nonspeech sounds such as tones (Saffran *et al*., 1999). Other studies show that infants can detect relations more abstract than those having to do with how often one particular item follows another. In particular, Marcus *et al* (1999) found that 8-month-olds learn about relations among elements of a three-item sequence, even when the particular elements in the sequence change across trials. One-year-olds can even detect patterns in longer strings that vary in their overall length, just as the number of words in a sentences vary (Gomez and Gerken, 1999).

PROCEDURES FOR STUDYING INFANT SPEECH PERCEPTION

Several procedures have been used to investigate infants' speech perception capacities. The high-amplitude sucking procedure provides information about infants' discriminative capacities between birth and 4 months. Infants suck a sterilized nonnutritive nipple connected to a pressure transducer, allowing experimenters to monitor sucking rates in response to speech sounds. Among the limitations of this procedure are that it allows for only one type of contrast to be presented per experimental session and that it yields measures of group, rather than individual, performance. The operant head-turn procedure is typically used between 6 months and 12 months of age. Infants are trained to turn their heads in the direction of a visual display box whenever they detect a sound change in a stream of repeating syllables. Training and testing may require several test sessions, but this procedure can provide a measure of individual performance. One limitation of this procedure is only brief stimuli (about 1 s) can be used. The head-turn preference procedure is used between the ages of 4.5 months and 24 months. Infants are seated in a three-sided enclosure with a light mounted on the panels to the left and right of the infant. If infants turn to the light when it flashes, speech samples are played either to completion or until the infant turns away for 2 s. Advantages of this procedure are that it allows for the presentation of varied types of materials and longer speech samples (e.g. 45 s) Measures of individual performance can be obtained. One limitation of the procedure is that lack of a significant listening preference may be due either to a failure to discriminate the materials or to a lack of interest in them. For further details of these three procedures, see Polka *et al* (1995). Another method used with infants aged 1–2 years is the preferential looking procedure. Infants view a side-by-side video display of two objects. Infants' looking responses to each object are monitored in response to the presentation of an audio stimulus, such as a word naming one of the objects. This measure yields information about individual performance and has proved useful in studies of word learning and word recognition in

older infants; see Fernald *et al* (1998) for further details.

Speech Production

Introductory article

Gabriella Vigliocco, University College London, London, UK
David P Vinson, University College London, London, UK

CONTENTS

'Speech production' refers to the processes by which speakers make their thoughts and intentions known to listeners through the use of language. This includes retrieving information from memory (e.g. words), integrating different parts of information into a coherent whole (e.g. sentences), and physically producing the sounds that are required to realize an utterance.

INTRODUCTION

How can humans, by exercising their vocal organs, utter words in such a manner as to convey a meaning to a listener? This is the basic question addressed by speech production research. More specifically, the question concerns the cognitive representations and processes that underscore our ability to put a thought, an intention we want to convey, into action (a sequence of sounds that expresses that intention). Although producing language is most commonly achieved by using our vocal cords, language may be produced by other forms of action; for example, sign languages use a visual instead of an acoustical modality for their expression. This article addresses the cognitive processes involved in going from the intention to preparing a plan for articulation; motor development and execution of this plan are not addressed.

RESEARCH METHODS IN SPEECH PRODUCTION

Adult English speakers know between 30,000 and 80,000 words. The average for high school graduates has been estimated at 45,000 words. In sentences these words can be arranged in a large, possibly infinite number of ways conforming to the linguistic conventions (both grammar and phonology) of English. Sentences are built in under two seconds, and spontaneously occurring errors during production may be as rare as one out of 1000 words, indicating that production is both efficient and accurate. However, errors and dysfluencies do occur: average speakers spend half of their speaking time not speaking but hemming, hawing, and pausing; such disruptions occur between three and 12 times per minute.

Important theoretical developments in our understanding of the cognitive machinery that underlies speech have been achieved since the early 1970s. The research methods that have marked these developments can be grouped in two camps: naturalistic observations and experimental methods.

Naturalistic Observations

Two spontaneously occurring phenomena have been the focus of research: slips of the tongue, and dysfluencies. Some of the most famous and most quoted speech errors were made by Reverend William Spooner (1844–1930). He once told his congregation that 'the Lord is a shoving leopard' and his students that they had 'tasted the whole worm'. Although it is unclear whether Spooner's errors were genuine, true errors (also referred to as slips of the tongue) do occur; pioneers of speech production such as Victoria Fromkin and Merrill Garrett have collected large bodies or corpora of slips.

Such investigations assume that errors occur when mapping between representations goes wrong. By investigating the regularities in such failed mappings we can learn about the nature of the representations that are involved.

Compare '… something for my *shoulders*' [intended: elbows] to '… sat on an *envelope*' [intended: elephant]. In both cases a word is erroneously replaced by another, but in the first, the target and intruding words are similar in meaning, while in the second they are similar only in their sound. Because word substitution errors are similar in either meaning or form, researchers have

postulated that words are retrieved in two steps when we speak: first we look for the meaning we want to express, then we look for a word form corresponding to that meaning.

As another example consider 'like a *l*ilting *w*illy' [intended: a wilting lily] and 'a *mother* to my *letter*' [intended: a letter to my mother]. In these errors, two elements are exchanged, but the type of unit is different: phonemes (/w/ and /l/) in the first error, and words ('letter' and 'mother') in the second. Different constraints govern these different exchanges: sound exchanges occur between similar phonemes from the same syllabic position; word exchanges occur between words of the same grammatical class (e.g. nouns). Converging evidence has also been obtained by analyses of the speech of speakers who have become aphasic as a consequence of brain damage; errors by these speakers parallel those by non-language-impaired speakers. From the observation that different types of linguistic information are integrated in different ways, researchers have inferred that there are different levels at which stored linguistic information is integrated to form sentences.

Errors are not the only type of disruption of speech: dysfluencies, including filled pauses such as 'um' and 'uh', empty pauses, hesitations, and repetitions are also well represented. Can dysfluencies tell us something about production? The assumption here is that dysfluencies reflect ongoing difficulties, and speakers' anticipation of upcoming difficulties in utterances they are preparing. The properties of dysfluencies, particularly the points at which they occur, and how they are resolved, can reveal the nature of the elements that are involved in particular levels of language processing. For example, pauses in speaking have been found to occur not only when a speaker reflects upon what to say next, but also sometimes as an indicator of difficulty in retrieving an upcoming word.

Experimental Studies

Naturalistic data are difficult to come by, given the overall accuracy of fluent speech; the corpora of slips mentioned above took years to collect and, because they occur spontaneously, we cannot control the factors determining them. In order to investigate language production in more controlled settings, naturalistic data are complemented by laboratory experimentation.

First, following the logic of investigating the properties of naturally occurring slips of the tongue and dysfluencies, one line of experimentation is inducing errors in laboratory settings. This can be accomplished by asking participants to repeat tongue twisters, or to perform speaking tasks under time pressure. Errors produced in such settings exhibit similar patterns of constraints to spontaneously occurring errors; researchers also have the advantage of knowing precisely what the intended utterance was in each case. Most crucially, experimental error induction allows experimenters to systematically manipulate those aspects of utterances that are thought to be relevant to a particular error type.

Experimental research on language production also allows investigation of when various elements of language processing come into play. This is generally carried out through vocal reaction time experiments, in which participants are presented with a stimulus (usually a picture of an object or a printed word) and asked to name (or read) it aloud, and the time between presentation and the beginning of the spoken response is measured. By presenting such naming tasks within a sentential context, it can be determined whether, and to what extent, the context affects the time it takes to produce a word. Such effects can be facilitatory (speakers are fast in naming a pictured spoon after reading a predictable sentence context like 'He ate the soup with a …') or inhibitory (speakers are slower in naming a pictured object, e.g. 'dog', if presented in the context of a meaning-related distractor word, e.g. 'cat').

Within the realm of producing phrases and sentences, Kathryn Bock introduced experimental techniques to 'prime' speakers, that is, to induce preferences in speakers to use a particular type of structure (e.g. instead of 'Lightning struck the church', to say 'the church was struck by lightning'), demonstrating the influence of various factors on the flexibility speakers have to express a given idea. For example, priming a word often results in that word appearing earlier in the sentence (priming 'church' is more likely to elicit a passive sentence like 'The church was struck by lightning'), suggesting that words' availability influences the syntactic structure that is ultimately produced.

THE ARCHITECTURE OF THE PRODUCTION SYSTEM

Using these different tools, researchers converge in depicting speech production as a process that involves both retrieving stored information from memory and integrating this information into utterances at different levels, each characterized by specific linguistic properties. Figure 1 provides an

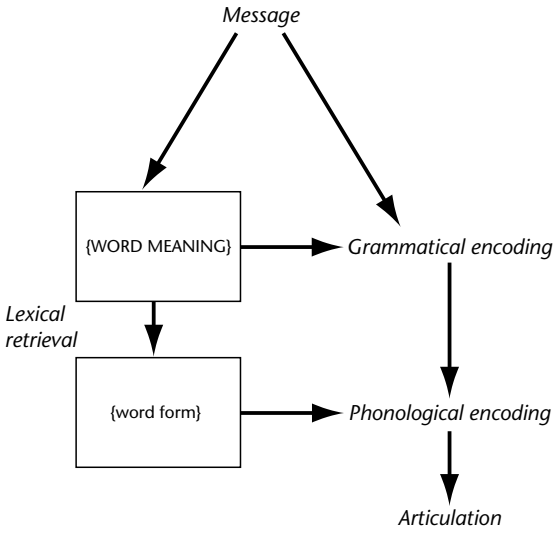

Figure 1. An overview of the speech production system.

outline of the processing steps mediating between intention and articulation. The processes are broadly divided into *grammatical* and *phonological* encoding. As Kathryn Bock described it, grammatical encoding can be conceived as building a skeleton for a sentence; phonological encoding, as fleshing the skeleton out by putting sounds into it.

Retrieving Information from Memory

It is uncontroversial that linguistic information is stored in memory; production research asks what is stored and how the retrieval process proceeds.

Within the stored information is included the intended word's meaning and its sound pattern (or word form); but because we use words in ways that must conform to the grammar of the language, syntactic information (i.e. information on how to use the word appropriately in a sentence) must also be included. How is the retrieval of these different types of information orchestrated in real time?

Retrieving words from memory involves two steps: during a first step a word corresponding in meaning to the intended concept (as represented at the message level) is retrieved. This retrieval process is competitive: other words similar in meaning are also activated and occasionally intrude, substituting for the intended word (e.g. saying 'shoulders' instead of 'elbows'). It is also generally assumed that syntactic properties of words are retrieved as a consequence of this process. During the second step, the word's phonological make-up is retrieved; when this second step goes wrong, a word similar in form is mistakenly retrieved (e.g. saying 'envelope' for 'elephant').

Further evidence for the sequentiality of the two retrieval steps comes from studies in which participants are asked to name a picture of an object, while they are presented with a distracting word. When the distracting word is presented immediately before the picture, it interferes with the retrieval of the name of the picture only if it is related in meaning; words related in form have no effect at this point in time. When the distracting word is presented immediately after the picture, it facilitates the retrieval process only if it is related in form; words related in meaning have no effect.

Such sequentiality is further demonstrated by another type of derailment in speech – the tip-of-the-tongue (TOT) phenomenon: the common experience of knowing a word but being unable to say it. Speakers experiencing TOTs know the meaning they want to express, and often also have partial information about the word's sound (e.g. it starts with a 't') although they cannot retrieve the full word form. Speakers experiencing TOTs can also report syntactic information about the word even when unable to report any word-form information; this finding suggests that syntactic information is retrieved before word form.

Besides information concerning whole words, other types of linguistic information are also assumed to be stored. This includes the specific phonemes of a given language (e.g. /m/, /u:/, /n/ as in 'moon', etc.). A further type of stored information may be the syllable. The number of different syllables in a language is not so high; for example, in English approximately 6600 syllables are sufficient to cover 38,000 different word-types. According to Willem Levelt, this fact suggests that syllables are stored as a whole. In what format would they be stored? As we will see below, this is most likely to be in terms of the action patterns, so-called articulatory gestures (movements of the lips and jaw) necessary to produce syllables.

How is the retrieval of all these different types of information orchestrated? It is agreed upon that the retrieval process is sequential: initial retrieval is meaning-based, followed by information about syntactic properties, then the word form is retrieved, then the phonemes, and finally the corresponding articulatory gestures. Theories, however, differ with respect to whether the flow of information from one level to the next is strictly unidirectional; such debate has arisen as a consequence of finding form influences on meaning-based

retrieval, as described by Gary Dell. One such influence has been observed in substitution errors. Mixed errors, in which the intended word and the produced word are similar in *both* meaning and form (e.g. 'pass me a *melon*' [intended: 'lemon']) seem to be more common than we should expect by chance. Such errors suggest that the form information can affect meaning-based retrieval, or in other words, that the retrieval process is interactive.

Integrating the Stored Information

Retrieving stored information is necessary but not sufficient to ensure the production of utterances. This information needs to be integrated in ways constrained by the current speaker's intentions and by linguistic conventions. One core linguistic convention is the grammar of a language, which, broadly speaking, can be considered as procedural knowledge concerning how words can be used in sentences.

All languages have a grammar, but different languages have different specific grammatical requirements. For example, consider the sentence 'The ferocious dog bites the boy'. In English the subject ('dog') must precede the verb ('bites') and the object ('boy'), and adjectives must precede nouns ('ferocious dog'). In Italian, however, the subject of the sentence may precede or follow the verb, and adjectives must follow nouns; hence in Italian the example above could be the equivalent of 'bites the dog ferocious the boy', which is strictly ungrammatical in English.

In parallel to the sequence of steps in retrieving different types of linguistic information from memory, a sequence of different encoding processes is also generally agreed upon by speech production theories. Because speakers produce two to three words per second in a fluent and efficient manner, it is important also to consider how such a system can ensure fluency and efficiency.

In order to speak fluently, a speaker must produce words, phrases, and sentences arrayed in time, flowing smoothly from one to the next. If a speaker must prepare each utterance completely in advance before producing it, speech would be marked by frequent 'planning pauses'. Yet such pauses are remarkably rare; they can be avoided through incremental and parallel processing of information; that is, encoding processes can begin as soon as a minimal amount of information is available, and multiple levels of processing can be in operation at once, to allow a speaker to begin uttering a sentence before its entire contents are planned. If this is to be achieved most efficiently, the units of information at a given level of processing should be as small as possible; such retrieved information is combined at several distinct levels of processing.

Mapping from cognition to syntax: grammatical encoding

The first step in going from 'mind to mouth' entails building a syntactically specified frame starting from the events specified in the message.

Assuming that the speaker wants to express the event 'The ferocious dog bites the boy', the stored meaning-based representations for 'ferocious', 'dog', 'to bite', and 'boy' are retrieved. These representations would further specify that 'dog' and 'boy' are nouns (hence usable as subject and object), 'to bite' is a verb (hence specifying a relation between the nouns), and 'ferocious' is an adjective (hence it can modify a noun). These representations also specify that 'dog' and 'boy' are common, countable nouns, and may be pluralized, and that 'to bite' may be used to refer to the past, present, or future, depending upon the speaker's intentions. The message-level information controls the assignment of the different lexical elements to their intended grammatical functions (e.g. 'dog' is assigned to be the subject, and 'boy' as the object and not vice versa, which would result in the unintended sentence: 'The boy bites the ferocious dog'). Message-level information also ensures that the appropriate specification of number for the noun 'dog' (singular) and tense for the verb 'to bite' (present) are passed along.

Functional-level processes are further responsible for establishing relationships among words corresponding to relationships among the participants in the event. In the example, at this level agreement is computed between the (singular) subject of the sentence and the verb (which consequently must also be singular). The intermediate representation for the utterance at this point does not strictly specify the order in which words will appear in the sentence, nor is it phonologically specified. This latter claim is motivated by the fact that exchange errors at this level are not constrained by the words' phonological specifications, while they are constrained by the words' grammatical properties. Grammar has been introduced as procedural knowledge, somewhat separable from information about words. Evidence for this distinction comes from the finding that syntactic structures can persist (i.e. speakers tend to reuse the same grammatical functions, regardless of the lexical content). For

example, if a speaker has just produced the sentence 'Jane gave the girl a present' it is more likely that he or she will subsequently produce 'John lent the mechanic money' instead of the perfectly grammatical alternative 'John lent money to the mechanic'. These processes, part of what we label 'grammatical encoding', are illustrated in Figure 2. This figure illustrates grammatical encoding processes involved in one possible way of expressing an event in which a dog bites a boy.

We speak one word at a time, and for each word, one phoneme at a time. Bridging from the domain of meaning and syntax to the domain of phonology, the order of words in the to-be-uttered sentence must first be specified. In English this requires that the adjective 'ferocious' be placed before the noun, while it must be placed after the noun in Italian. Evidence compatible with such a process comes from studies showing that word order can persist independently from grammatical functions. At this level, which we consider as part of grammatical encoding, as illustrated in Figure 2, a frame is built for a to-be-uttered sentence, specifying closed class morphemes (e.g. determiners, auxiliaries, prepositions, and also inflections, such as *-s* for a plural noun, *-ed* for a past tense verb). Open class morphemes (e.g. nouns, verbs, adjectives) are inserted in this frame. This distinction between

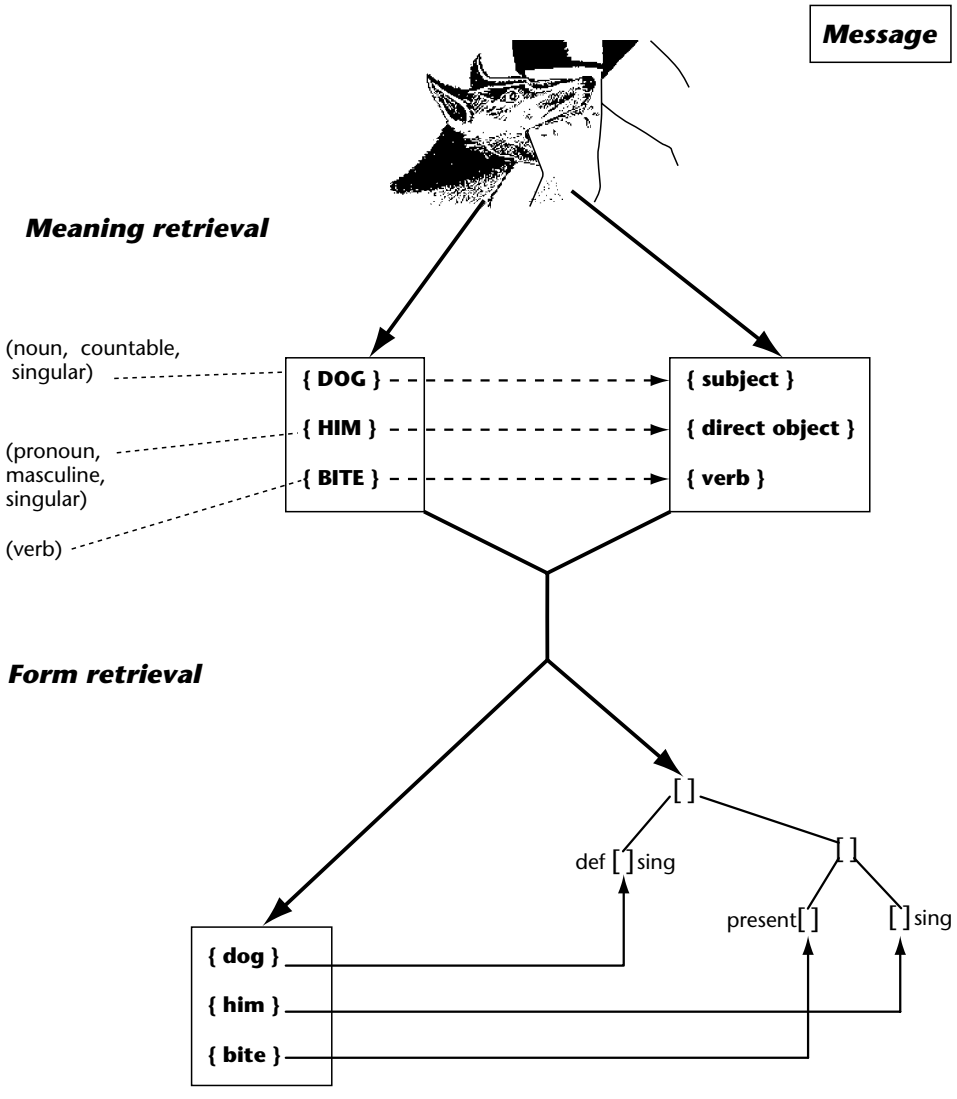

Figure 2. Grammatical encoding. On the basis of the speaker's message, abstract units specifying words' meanings are retrieved and assigned to the grammatical functions to be expressed. A sentence's syntactic structure is created on the basis of these functions, and word order is spelled out. At this point, abstract units representing word forms are filled into the sentential slots, allowing phonological encoding to begin.

vocabulary type (open/closed class) is supported by the finding that the two types of vocabulary can break down selectively in aphasia. The frame-content (or slot-filler) nature of the process is supported by exchange errors such as '… cut *rains* in the *tree*' [intended: cut trees in the rain], in which 'tree' and 'rain' swapped position. However, the plural marker *-s* of 'trees' stayed in place, suggesting that it is part of a frame in which morphemes are inserted.

Mapping from syntax to sounds: phonological encoding

Once the frame is filled, the next step consists of interpreting it in phonological terms, as illustrated in Figure 3. This involves both specifying the sounds to go in each word (the content), as well as specifying sound characteristics for the whole sentence (the frame).

Details of the frame's specification are controlled by the speaker's intentions and by linguistic conventions. For example, do I shout or whisper? Fast or slow? Fast speech is more likely to use contractions such as 'I've' instead of 'I have'. It is influenced by the speaker's emphasis in the sentence (compare 'are you coming?' to 'are you COMING?'). Furthermore, the specific words to be used force differential realization of syllables. For example, in 'the dog bites the boy', 'bites the' is pronounced with each word in its own syllable, 'bites-the', while in the sentence 'the dog bites him', the phrase 'bites him' may resyllabify into the single phonological word 'bite-sim'. Rising and declining intonation marks each phonological word, as well as larger (phrasal) chunks at this level.

Why would speakers go through the trouble of resyllabifying? First, syllables mark the rhythm of the unfolding utterance, which gives speech its specific 'musical' quality which has been argued to be particularly important in determining turn-taking during speaking. Without resyllabification, the rhythm would be broken. Second, syllables may be stored as articulatory gestures to reduce the burden of executing utterances.

The developed phonological frames are then filled with the specific phonemes. The process of filling the phonological frames with sounds is similar in nature to the process of filling the

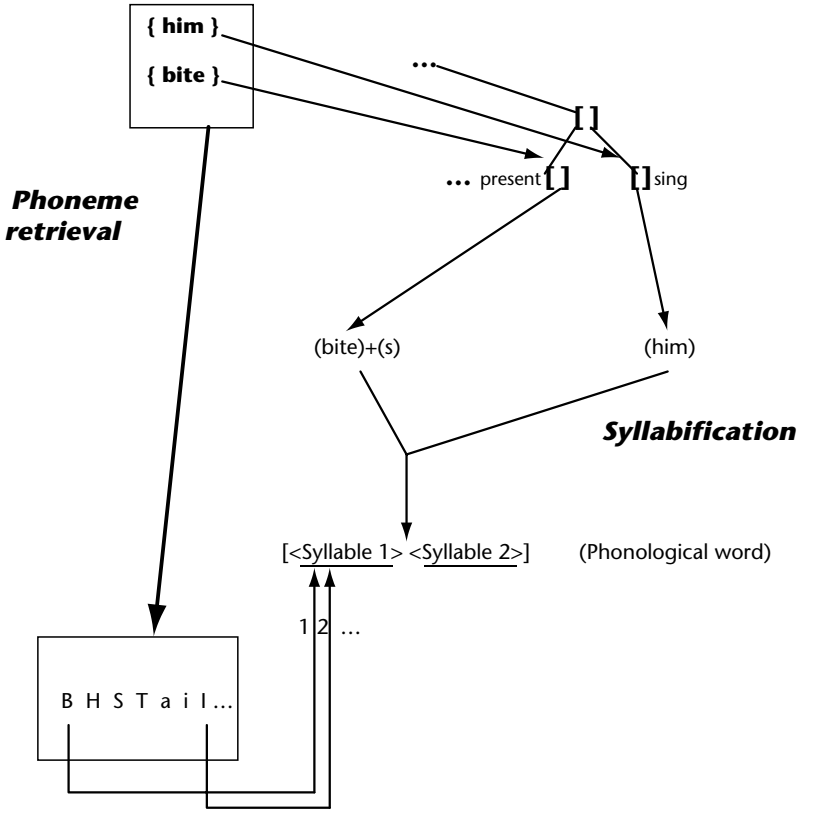

Figure 3. Phonological encoding. Abstract representations specifying word forms are inserted into the respective sentential positions. Appropriate phonemes are assigned to their appropriate positions once syllabification is carried out, and the subsequent phonologically specified syllables are then output for articulation.

syntactic frame with words as described above. A main source of evidence comes, once again, from exchange errors. Errors like '*h*eft *l*emisphere' [intended: 'left hemisphere'] indicates that phonemes can be misplaced during the filling process. Where they end up is not random; it is constrained by the elements' syllabic position. In the example, both phonemes occur as syllable (and word) onsets. In parallel to the grammatical class constraint for word substitution errors, the syllable constraint for sound errors suggests that phonemes' stored representations include information about where those phonemes can be used within a syllable. Note that error evidence suggests that retrieved phoneme representations are still abstract at this point in processing. In the error '*sp*ace' [intended: 'place'], 'p' has a slightly different sound in the error context; 'p' has accommodated to the new environment.

How does the slot-filling process proceed? Evidence from reaction time studies suggests that it proceeds in a strictly left-to-right order, consistent with the temporal requirements of speaking.

ARTICULATION

Syllables are comfortably articulated at a rate of six or more per second, calling on more muscle fibers (approximately 100) than may be required for any other mechanical performance of the human body. These muscles are distributed over three anatomically distinct structures, all of which subserve other functions beyond speech alone.

The *respiratory system* controls the steady outflow of air during speech. It has its own mode of functioning during speaking that differs markedly from non-speaking breathing. The *laryngeal system*, with the vocal folds as its central part, controls voicing and loudness of speech. During voicing it generates a periodic train of air puffs which provides a large frequency spectrum on which resonation builds. The *supralaryngeal system* (vocal tract) contains the chambers in which resonation develops, in particular the nasal, oral, and pharyngeal cavities. Their shapes determine the timbre or tone quality of vowels and consonants. Moreover, the vocal tract is the main determinant of the articulation of speech segments. Constriction of the vocal tract in different places (compare 'pa' and 'ga') and in different manners (compare 'pa' and 'ba') provides us with the large variety of speech sounds we produce.

Articulation is context-dependent. It was mentioned above that it is generally agreed that when sounds are inserted into phonological words they are abstract, namely their physical properties are not specified for their insertion environment. But context-dependency is clear. For example, compare the way in which the phoneme /t/ is pronounced in 'top' and in 'stop'. Such context-dependency does not only occur within words (if this were the case, it could be stored) but also arises between words in a sentence (note the variation in the sound of 't' of 'take' between 'Let's take it' and 'He did take it'), and goes in both directions: a sound is pronounced differently depending upon both the preceding and the following context (compare the differing sounds of 't' in 'went by' and 'went from'). In technical terms, such context-dependency has been referred to as 'co-articulation'.

A number of theories have been developed concerning motor control of speech. In these theories, major questions concern the motor commands and how they are executed. The existence of context-dependency has played a large role in this theoretical development. However, some degree of context-independence is argued for by most theories. At a general level some degree of context-independence is desirable, because otherwise we could not explain how speakers immediately adapt their motor commands to successfully speak while having food in the mouth. Context-dependency arises as an adjustment to the physical environment during the execution of a motor plan. For example, producing a 'b' may be specified as a command to close the lips with a certain force – however, *how* to reach this goal, depending upon both jaw and lip movement, is not specified and may depend on whether the speaker has something in his/her mouth. If this is the case, then the question concerns the characterization of the abstract motor commands.

Statistical Methods: Overview

Introductory article

John K Kruschke, Indiana University, Bloomington, Indiana, USA

CONTENTS

Statistical methods specify how confident we can be to confirm or deny a claim.

THE PURPOSE OF INFERENTIAL STATISTICS

Our knowledge about the world is based on a finite set of observations of it. We cannot know with certainty about the true underlying state of the world; instead, we must infer what might be true, or what is probably false, given the limited data we have. The purpose of inferential statistics is to give precision to our confidence in claims about the world.

Examples of the Need for Inferential Statistics

Suppose that someone claims that Monica is a better tennis player than Conchita. How can the claim be tested? If we could somehow directly ascertain the absolute expertise of both players, by applying some kind of 'expertisometer' to their foreheads, then we would have proof about the claim, either for or against. But we have no such direct method. Instead, we can only let the players compete in a finite number of games, and observe which player wins more games.

Suppose the competitors play a single game, and Monica wins. Does this outcome prove that Monica is better? No, of course not. There are numerous random influences in any given game, such as wind gusts, noises from the audience, small bumps on the court surface, and so on. To try to equalize the influence of these random factors on both players, we have them play several games on different courts.

Suppose that, after seven games, Monica has won four. Is Monica definitely the better player? A supporter of Conchita could argue that Monica just got lucky and happened to win four out of seven, even though Conchita is actually just as good a player. But if this were the case, just how lucky did Monica get? What is the probability that Monica could win four games out of seven, despite being no better a player? If the probability is fairly high, then Conchita's supporters can retain their hope. But if the probability is extremely low, then they may have to admit that Monica is the better player.

The role of statistical inference is to determine the probability of observable events (e.g., the probability of winning four games out of seven) from hypothesized underlying states of the world (e.g., Monica and Conchita having the same level of expertise). If the hypothesized state of the world cannot easily generate the observed events, then the hypothesis is probably wrong.

Most claims about the world are of the same status as claims about tennis expertise. Consider claims that might be made in cognitive science, such as 'my dog knows the command "stay"'. The same claim might be made instead of a robot, or of a human participant in a psycholinguistics experiment. How do we test such claims? We can only say the word 'stay' several times and observe what the listener does, whether the listener is a robot, a dog, or a human. From these observations, we infer whether it is tenable to claim that the listener knows the command.

The Logic of Hypothesis Testing: Population and Sampling Distributions

Suppose we make a claim about the world. This claim amounts to a specific description of the underlying population from which our observations are sampled. Given this model of the population, we determine the probability of getting any particular sample of observations. That is, we determine the distribution of samples that we would get from the hypothesized population. From this sampling distribution, we can ascertain the kind of sample we should expect to obtain, and we can

determine the specific probabilities of getting samples that deviate from the expected sample. (Examples of this process are given below.) If our actual set of observations deviates wildly from the expected sample, then the hypothesized population is probably not a good description of the actual world. Standard statistical inference is just the mathematical formalization of this logic for different types of populations.

POPULATION MODELS WITH DISCRETE CATEGORIES

In many situations we are concerned with discrete states of the world. Familiar examples include a tossed coin coming up heads or tails (two discrete states), or the hair color of a randomly selected person being black, brown, blond or red (four discrete states). This type of situation can be contrasted with situations in which the states of the world are ordered, or ranked (e.g., grades in an examination) or interval-scaled (e.g., response times). Situations with scaled (continuous) variables are discussed later in this article.

The Binomial Sampling Distribution

Suppose we want to test somebody's claim that a certain coin is fair; i.e., that it comes up heads 50% of the time. This is a situation in which the world has two states: heads or tails. If the coin is fair, then when we toss it a number of times, it should come up heads in about half of those tosses. For example, if we toss the coin eight times, it should come up heads about four times. Suppose that it actually comes up heads six times out of eight tosses. Is this deviation from the expected four heads large enough for us to reject the hypothesis that the coin is fair? What if the coin comes up heads seven times out of eight, or eight times out of eight? By how much can the sample deviate from what we expect before we reject the claim that the coin is fair?

To answer this question, we must calculate the probability that a fair coin would generate so many heads in eight tosses. Figure 1 shows these probabilities. The population distribution at the left assumes a fair coin; i.e., a coin for which the probability of heads is 50%. The graph shows two bars, one labeled 'H' for heads and the other labeled 'T' for tails. The height of each bar is 0.5, indicating that we are supposing that the probability of getting a head is 0.5 and the probability of getting a tail is also 0.5. Imagine repeatedly tossing the coin eight times, as exemplified in the middle of Figure 1. Usually a fair coin will come up heads about four times out of eight, but occasionally we would expect more extreme outcomes. The exact probability of each possible outcome can be mathematically derived, and the result, called a *binomial distribution*, is plotted in the graph on the right side of Figure 1. We see that the probability of getting four heads out of eight tosses is about 27%, the probability of getting five heads is about 22%, the probability of getting six heads is about 11%, and so on. Thus, a hypothesis about something we cannot directly observe (i.e., the fairness of the coin) makes specific predictions about the probabilities of what we can observe (i.e., getting so many heads out of eight tosses).

Suppose we now actually toss the suspected coin eight times, and the result is that it comes up heads seven times. From the binomial sampling distribution, we see that the probability of getting seven heads is about 3%. The probability of getting eight heads is less than 1%. Thus, the probability of getting a result this deviant or more from the expected outcome is less than 4%.

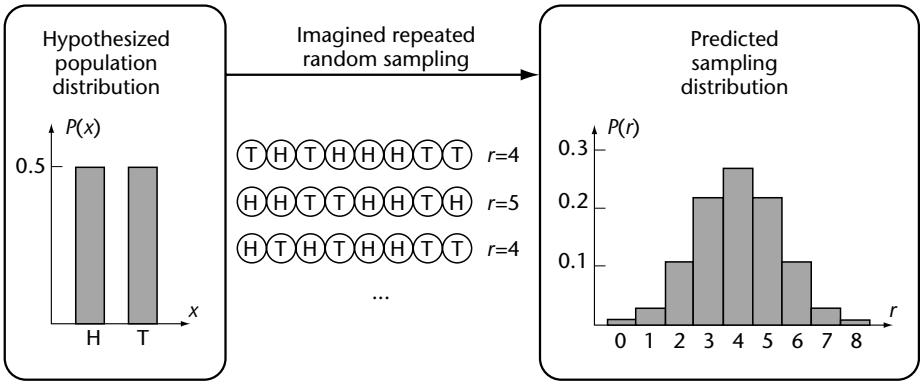

Figure 1. Illustration of a binomial sampling distribution generated by a fair coin tossed eight times. The predicted sampling distribution on the right shows the probability of getting *r* heads, for values of *r* between 0 and 8.

Therefore, because the result is so unlikely if the coin is fair, we reject the hypothesis that the coin is fair. The coin still might be fair, but it is rather unlikely given the result of seven heads out of eight flips. Note also that this is a 'one-tailed' test. A two-tailed test (in which we would have to add the probabilities of getting no heads or one head) is generally more appropriate in this and other similar situations.

The Chi-squared Distribution

An analogous procedure is applied when we have a situation with more than two discrete states. For example, suppose we want to know if four hair colors – black, brown, blond and red – are equally likely to occur in the general population. We hypothesize that each of the four colors has a probability of 0.25 in the population. We then imagine repeatedly sampling from this population. Suppose we select 40 people at random in each sample. If the four colors are equally likely, then we would expect to get about 10 people of each hair color, but by chance we would often get a few more or a few less of each color. For any given sample, a number called chi-squared (χ^2) describes how much the sample deviates from what we expect. For every possible sample of 40 people, there is a corresponding value of chi-squared which measures how deviant that sample is from the expected 10 people in each category. In most cases the samples will have moderate chi-squared values, but on rare occasions the samples will have extreme chi-squared values. The hypothesis of equally likely colors thereby generates a predicted sampling distribution for the chi-squared values. This sampling distribution shows the probability of getting each possible chi-squared value from the hypothesized population.

We now get an actual sample of 40 randomly selected people, and we determine the chi-squared value of this sample. If this actual chi-squared value is very extreme in the predicted sampling distribution, we reject the hypothesis.

The chi-squared method can also be applied to the situation of just two discrete states, and therefore subsumes the binomial distribution. Nevertheless, the binomial is often used in research because of its simplicity.

POPULATION MODELS WITH CONTINUOUS VARIABLES

The methods described above dealt with discrete variables; e.g. heads versus tails or category of hair color. The same logic can be applied to continuously scaled variables such as temperature, response time, blood pressure, etc.

The *t* Distribution

Suppose someone claims that a certain drug decreases blood pressure. (Notice that blood pressure is measured on a scale with meaningful intervals, not just discrete categories such as yellow or green.) How do we test this claim about the drug? One approach is to randomly assign people either to a group that takes the drug or to a comparison group that does not take the drug. (Usually the comparison group will be given some innocuous replacement substance, called a placebo, in a so-called 'double blind' procedure, so that neither the subject nor the person administering the drug knows whether it is really the drug or the placebo. This equalizes any psychosomatic effects in the two groups.) Then we measure the blood pressure of everyone in the two groups, and compare the mean blood pressures of the two groups. If the drug-treated group has lower mean blood pressure than the control group, are we certain that the drug works as claimed? Not necessarily. It could be that the drug has no real effect, but that the people in the drug-treated group happened to have lower blood pressure because of other random influences. So we need to determine just how probable it would be for the drug-treated group to have a mean that much lower, if the actual effect of the drug were zero.

First we create a model of the hypothesized population in which the drug has no overall effect. We conceive of the control group as having a distribution of blood pressures, some higher than average and some lower. We conceive of the drug-treated group as having the very same distribution of blood pressures: that is, the drug has no effect.

What shape of distribution should we assume? The usual assumption is a normal distribution – the well-known bell curve, as shown in the left panel of Figure 2. There are several motivations for using the normal distribution. One is that it has convenient mathematical properties for deriving probabilities in the sampling distribution. Another is that the central limit theorem shows that many different distributions become approximately normal when the processes that generate them are repeated many times and the results averaged. Finally, many distributions in the real world are approximately normal. The normal curve shows the relative probability of each blood pressure. Thus, the most probable blood pressure is the value under

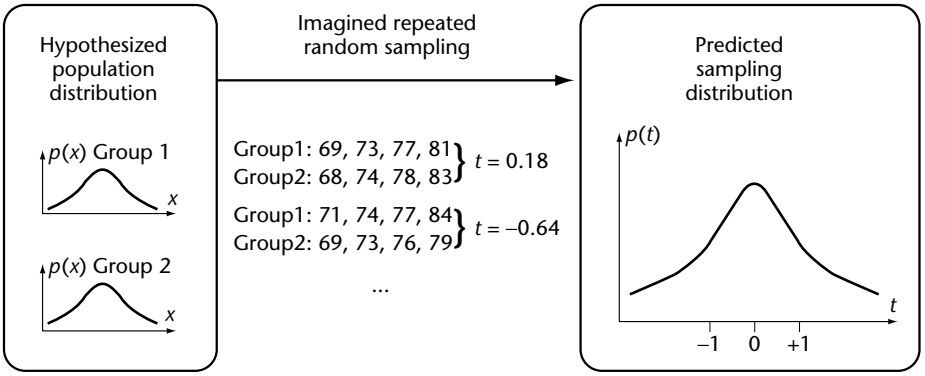

Figure 2. Illustration of the t sampling distribution generated by comparing four scores sampled from each of two identical normal distributions.

the peak of the normal curve. Blood pressures higher or lower than this average are less probable.

Having hypothesized this model of the population, we then imagine repeatedly sampling from it. Suppose we randomly select four people from each group. The mean of each sample will be about the same as the mean of the population, but the two means will not be exactly the same because of the random sampling. This difference between the group means is not very meaningful by itself, because its value depends on the scale units in which it is measured (e.g., a temperature difference of 3 degrees has different meanings depending on whether the scale is Fahrenheit or Celsius). Therefore the difference between group means is divided by the expected dispersion of this difference across samplings, and the resulting ratio is called the t statistic. Usually the difference between groups means, and hence the value of t, will be close to zero, on the hypothesis that we are sampling from a population with identical groups. Sometimes, however, it will be significantly above or below zero. The sampling distribution for t is illustrated in the right panel of Figure 2. Thus, a hypothesis about something we cannot directly observe (i.e., the equality of the distributions for the two groups) makes specific predictions about the probabilities of what we can observe – values of the t statistic.

Suppose we now actually test the drug on four randomly selected people, with four other randomly selected people getting the placebo. Suppose that we get a t value of 2.45. This value implies that the difference between the group means is fairly large compared with the expected variation of this difference. From the sampling distribution of t, it can be determined that the probability of getting a t value this extreme is less than 5%. Therefore, because this extreme value of t is so unlikely if the two groups have the same underlying population, we reject the hypothesis that the drug has no effect. Note that the drug might nevertheless have no effect, but it is rather unlikely given the result that $t = 2.45$.

The *F* Distribution and Analysis of Variance

An analogous method can be applied when there are more than two groups. For example, there might be several different drugs that are claimed to be effective in reducing blood pressure. To test whether the drugged and the control groups differ in their overall mean blood pressures, we can measure the overall dispersion among the group means relative to the dispersion within the groups. This ratio is called the F statistic. The logic of using it is the same as for other statistics. First, hypothesize identical normal populations for the groups. Then imagine repeated random sampling from these populations, each time computing the value of the F statistic. This generates a predicted sampling distribution for F. Now get actual random samples of blood pressures from people who have taken the various drugs or the placebo, and compute the F statistic. If the actual F statistic deviates greatly from what would be expected from the hypothesis of equality, then we reject that hypothesis.

This procedure is called *analysis of variance* (ANOVA) because the overall variance among the individual scores is decomposed (analyzed) into (1) the variance between group means and (2) the variance within groups. The ratio of these two components of the overall variance is the F statistic.

ANOVA can be applied when there are just two groups, and so it subsumes the t statistic. Nevertheless the t statistic is often used in research because of its simplicity.

Linear Regression and the General Linear Model

Many types of claims can be expressed as mathematical hypotheses about a population. We can imagine more and more complicated hypotheses, yet apply the same logic as in the previously discussed situations.

For example, suppose that we believe that the blood pressure drug should yield a decrease in blood pressure proportional to the amount of drug administered. We might also imagine that exercise increases blood pressure, in proportion to the rate of exertion. This type of hypothesis can be expressed mathematically as a so-called *linear model*. Denote predicted blood pressure by $\hat{y}$, drug quantity by x_d, and exercise rate by x_r.Then a linear relationship between blood pressure, drug and exercise can be described as $\hat{y} = \beta_0 + \beta_d x_d + \beta_r x_r$, where β_0 is base-line blood pressure and β_d and β_r are numbers that reflect how big an influence each factor (drug and exercise) has on blood pressure. If β_d is a large negative number, then predicted blood pressure drops rapidly as drug dosage increases. If β_r is a large positive number, then predicted blood pressure increases rapidly as exercise rate increases.

We can construct a series of hypothetical populations in which one or more of the factors (drug dosage or exercise rate) has no effect. For example, if both β_d and β_r are zero, then we are hypothesizing no effect of the drug and no effect of exercise on blood pressure. We can then imagine repeatedly randomly sampling from this hypothesized population, and for each sample computing the value of a statistic analogous to F. From this process we generate a sampling distribution predicted by the hypothesis. Then we can get an actual sample, and determine whether the hypothesized population could generate this actual sample with reasonable probability.

If the hypothesis that neither factor has an effect can be rejected, then we can hypothesize that one or both of the factors does have an influence; that is, we allow one or both of β_d and β_r to be nonzero. Suppose we hypothesize that the drug has no effect, so $\beta_d = 0$, but exercise does have an effect, so $\beta_r \neq 0$. We want to test whether this hypothesis can be rejected, but what should be the exact value of β_r for our population model? We set it to whatever value best fits the data, to give the hypothesis its best chance of being confirmed. The degree to which a model fits data is usually measured as the 'sum squared error' $\sum_i (y_i - \hat{y}_i)^2$ between actual data points y_i and predicted values $\hat{y}_i$, where $\sum_i$ indicates summation over all the data points. The value of β_r that minimizes this quantity is used for the population hypothesis. Then we proceed with the imagined sampling from the hypothesized population, to assess the probability that our actual data could have come from such an underlying population.

This type of procedure, using linear models, is called *multiple linear regression*. It turns out that models of group differences in ANOVA can all be expressed as particular cases of linear models. Therefore, the general linear model subsumes multiple linear regression and ANOVA. In much research, however, ANOVA is used because of its conceptual simplicity.

The Model Comparison Approach

It is often the case that complicated hypotheses about the world can be modeled as extensions of simpler models. More complicated models will involve more free parameters, like the coefficients in the linear model described above. As parameters are added to a model, it will usually fit data better, but only at the cost of being a more complex model. We want the model to be as simple as possible while also fitting the data well. Does the inclusion of particular new parameters improve the fit of the model significantly?

To answer this question, we use the same logic as has been described above. Assume that the 'simple' model, the one with fewer parameters, is a correct description of the world. (The parameter values in this simple model are set to whatever best fits our present data set.) The simple model incorporates an assumption about the distribution of values in the population; typically the population is assumed to be normally distributed around means specified by a linear function. We then imagine repeatedly sampling from this 'simple' population. For every sample, we compute the improvement in fit that is gained by including the extra parameters. This measure of improvement in fit is called the *generalized F ratio*. Note that a given sample from the simple population will almost surely be fitted better by a model with more parameters, because the sample will deviate randomly from the simple population's form, and this random deviation can be partially accommodated by the extra parameters.

The repeated sampling generates a sampling distribution of improvements in fit achieved by the more complex model, even when the simpler model is correct. Once we know this sampling distribution, we can see whether the improvement in

fit for our actual data set lies near the expected value of this sampling distribution. If it does, then the simpler model may be adequate. On the other hand, if the actual improvement in fit deviates greatly from what we would expect from the simpler model, then we reject the simpler model.

All of the methods described in this section are special cases of this model comparison approach. The model comparison approach is conceptually powerful and helps unify and generalize the various traditional statistical tests. However, the specific methods, such as t tests, ANOVA, and multiple linear regression, continue to be popular.

RESAMPLING METHODS

All of the methods described so far use the same basic logic: hypothesize a specific form of the population distribution (i.e., start with a model of the population) and then derive the predicted sampling distribution of whatever statistic seems useful. For example, the t statistic was sampled from normally distributed populations.

But what if we do not have a specific population distribution in mind? For example, what if a normal distribution seems inappropriate for modeling our particular population? We could just hypothesize a different, more appropriate distribution – but what if we have no theoretical commitment to any particular distribution? To answer this question, we ask another question: what is the best information we have about the underlying population? It is our actual sample. So we let the data themselves serve as the population, from which we then resample to generate a sampling distribution.

For example, suppose we are measuring scores on a statistics examination. Three students who read an encyclopedia article about statistics scored 58, 70, and 89. Three other students who did not read the article scored 50, 55, and 68. On average, the group who read the article did better, but maybe this was merely a random effect of the sampling. Maybe the two groups really come from the same underlying population, with no genuine difference between them. If we do not want to assume any specific form for this mutual underlying population, we can just let the six scores themselves be the population from which we sample. So the question becomes this: if we repeatedly sample from this population of six scores, how likely is it that a random sampling would yield a difference between groups as large as what we found in our actual sample? It turns out that there are 20 ways of sampling two groups of three from the six scores, and of these 20, there are 4 ways that yield group differences as large or larger than the one actually obtained. Because 4 out of 20 is not very low, we would probably not reject the hypothesis that the two groups come from the same underlying population.

Resampling methods are becoming increasingly popular because of the increasing availability of computer software. Their main advantage is that they do not require specific assumptions about the shape of the population distribution. A disadvantage is that important statistical concepts (such as power and confidence interval) are difficult to quantify by these methods, because to do so would require specification of alternative hypothetical populations.

BAYESIAN APPROACHES

All the methods described above are based on determining the probability of the data given a hypothesis. The logic is that if the data are very unlikely to have come from the hypothesized model, then the model is probably wrong. But this logic is incomplete. The probability of data D given a hypothesis H is not necessarily the same as the probability of the hypothesis given the data. In mathematical notation, usually $P(H|D) \neq P(D|H)$, where $P(A|B)$ means the probability of A given B. The methods described above provide $P(D|H)$, but we would really like to know $P(H|D)$.

For example, consider a deck of playing cards. If I select a card at random, and tell you that it is a king, then what is the probability that it is also a heart? The answer is 1/4, because of the four kings in the deck, one is a heart. If instead I tell you that the card I selected is a heart, then what is the probability that it is also a king? The answer is 1/13, because of the 13 hearts in the deck, one is a king. Thus $P(\text{heart}|\text{king}) \neq P(\text{king}|\text{heart})$.

The relationship between $P(H|D)$ and $P(D|H)$ is given by Bayes' theorem: $P(H|D) = P(D|H)p(H)/\sum_i P(D|H_i)P(H_i)$, where the terms H_i refer to all possible hypotheses about the situation. At first it might seem impossible to consider all possible hypotheses, and to establish the prior probability $P(H_i)$ that each is true. But in many situations this can be done in reasonable ways.

For example, suppose that we are questioning the fairness of a coin. We believe that there is a 70% chance that the coin is fair; i.e., $P(H_{.50}) = 0.70$. We believe that there is a 25% chance that the coin is biased to yield heads 35% of the time; i.e., $P(H_{.35}) = 0.25$. And we believe that there is a 5% chance that the coin is biased to yield heads 10% of the

time; i.e., $P(H_{.10}) = 0.05$. Suppose we actually toss the coin four times, and it comes up heads zero times; this result is our data, denoted D. The binomial distribution indicates that $P(D|H_{.50}) = 0.0625$, $P(D|H_{.35}) = 0.1785$, and $P(D|H_{.10}) = 0.6561$. Thus, the probability that the data could be generated by a fair coin is pretty low, and we might even want to reject the hypothesis that the coin is fair. We also see that the most biased of the three hypotheses has the highest probability of generating the data.

The most biased hypothesis, however, is also the hypothesis that we believed, before flipping the coin, was very unlikely to be true. So how much should we increase our belief in this unlikely hypothesis? Using Bayes' theorem, we obtain $P(H_{.10}|D) = P(D|H_{.10})P(H_{.10})/[P(D|H_{.10})P(H_{.10}) + P(D|H_{.35})P(H_{.35}) + P(D|H_{.50})P(H_{.50})] = 27\%$. Similarly, we find that $P(H_{0.35}|D) = 37\%$ and $P(H_{0.50}|D) = 36\%$. Thus, before tossing the coin, we thought that $P(H_{.10})$ was only 5%, but after tossing the coin, we think that the probability is 27%, more than five times as great. Moreover, before tossing the coin, we believed that $P(H_{.50})$ was 70%, but after tossing the coin, we think that the probability is 36%, only about half as likely. Nevertheless, despite the data, the chances that the coin is severely biased are still not as high as the chances that the coin is unbiased, or only moderately biased. To revise our prior beliefs more radically, we would need more convincing data.

There are several advantages of a Bayesian approach to inference. Firstly, it forces the theorist to consider multiple hypotheses and the prior probability of each. This encourages breadth of theorizing. Secondly, it takes into account the prior probabilities of hypotheses, so that bizarre hypotheses with small prior probabilities are unlikely to be accepted even if they could generate the data, and very plausible hypotheses with high prior probabilities are not necessarily rejected even if a particular data set is not easily generated by them. Thirdly, the framework can be extended to take into account the costs or pay-offs of different kinds of correct or incorrect decisions about hypotheses. On the other hand, a disadvantage of Bayesian statistics is that it is often impossible to specify the prior probabilities of all possible hypotheses.

CONCLUSION

For statistical methods to be applied, society must provide two conditions. Firstly, people must have the liberty to doubt claims. If claims about the world are dictated by authorities, without permission to doubt the claims, then there is no room for inferential statistics. Secondly, people must have the liberty to gather data that are randomly sampled and representative of the underlying population about which the claim is made. If a claim is made that Monica is better than Conchita, but the only games you are allowed to observe have the wind against Conchita, then your observations are not a good test of the claim. Thus, without liberty, statistical methods cannot be meaningfully applied, and when statistical methods have been appropriately applied, liberty has been exercised. *Ubi dubium, ibi libertas*: where there is doubt, there is liberty. Doing a statistical test is a political act, and an expression of the culture in which we work.

Liberty should not be confused with license. Scientific research depends on the liberty to apply statistical methods to random, representative samples. But care must be taken that the methodological strictures of statistical method and experimental design do not override the ethical principles of human beings. The methods of science are an exquisitely refined expression of human intellect combined with human awe and curiosity about the mysteries of nature. Statistical methods must be applied with humility and responsibility; they must not violate the rights of the very beings whose culture created the methods.

CONTENTS

Stereotypes are consensual beliefs about group characteristics that influence the perception, interpretation, and evaluation of others, sometimes blatantly but often in a manner so subtle that they are outside awareness. Because they serve basic cognitive and motivational functions, stereotypes are highly resistant to change.

INTRODUCTION

On 4 February 1999, just after midnight, 22-year-old Amadou Diallo entered his apartment building. He was spotted by members of the Street Crime Unit, an elite corps of New York City police officers who had been extraordinarily successful in reducing crime, but were often criticized for being too aggressive. In particular, in a practice known as 'racial profiling', the Street Crime Unit was routinely selecting African American and Hispanic men to be stopped and frisked. That winter night in 1999, Amadou Diallo was targeted to be one of them. Four white, plainclothes police officers from the unit spotted Diallo, who matched the general description of a suspected rapist. The police thought that Diallo looked suspicious as he appeared to duck into his building to avoid them. As they approached and ordered him to freeze, he reached into his pocket and began to pull out a wallet. Thinking that the wallet was a gun, the police opened fire. Nineteen of their 41 shots hit Diallo, and he lay dead in the vestibule. Diallo was unarmed.

In the days and weeks that followed, numerous protests erupted in New York City and around the country. The controversial use of 'racial profiling' came under national attention and renewed attack. The four officers responsible for the shooting of Diallo were acquitted of any wrong-doing, but many felt that their stereotypes of African Americans played a critical role in their misperception of his wallet as a gun, and their decision to fire so many bullets. In contrast, various politicians, columnists, and citizens defended the police, noting how difficult it is to make life-or-death decisions in the blink of an eye. Although we'll never know what role stereotypes played in the Diallo shooting, the research discussed in this article makes it clear that things might have turned out very differently if Diallo had been white.

The Diallo tragedy, and much of the research discussed in this article, focus on race. Nevertheless, race is but one kind of group membership that can influence people's thoughts, feelings, and actions towards others. Stereotypes, prejudice, and discrimination also emerge as a function of people's gender, sexual orientation, age, physical appearance, economic class, religion, and a variety of other social categories. Watch the news and you might see stories about genocide in Rwanda, 'ethnic cleansing' in Bosnia, neo-Nazi violence in Germany, and hate crimes against gays, Jews, and blacks in the USA. Despite the magnitude and prevalence of all this violence, it is really just the tip of the iceberg, as stereotypes change the way that people interact with each other in countless subtle ways all over the globe.

This article is divided into four parts. First, we consider the origins and formation of stereotypes. We then examine how stereotypes are maintained, often in the face of inconsistent information from the environment. Next, we discuss how and when stereotypes are applied, with special attention to the consequences of stereotype application for those who are the targets of stereotyping. We conclude with a discussion of ways that stereotypes can be changed.

STEREOTYPE FORMATION

Stereotypes are consensual beliefs about the characteristics and traits of a group of people. Although stereotypes are not necessarily negative (e.g. blacks

are stereotyped as athletic), even positive stereotypes tend to take on negative connotations when used to describe members of other groups (e.g. black athleticism is seen as a sign of a primitive nature). This is one of the ways in which stereotypes and prejudice (negative attitudes towards members of other groups) are interrelated. There are numerous origins of such stereotypes. From a historical perspective, it has been argued that slavery in America gave rise to the portrayal of blacks as inferior, just as the surprise attack on Pearl Harbor in the Second World War fostered a belief that the Japanese are sneaky. From a political perspective, stereotypes are viewed as a means by which groups rationalize war, religious intolerance, and economic oppression. From a social/cultural perspective, it has been argued that different social roles and real differences between groups contribute to perceived differences.

The formation of stereotypes involves two related processes. The first is *categorization,* by which people sort themselves and others into groups. The second is a process by which people perceive groups to which they belong (ingroups) as being different from groups to which they do not belong (outgroups). These two processes reflect not only basic cognitive operations but also cultural and motivational factors. Because these two processes are fundamental to social interaction, stereotypes form very early in life. For example, children in the USA have been shown to endorse stereotypes concerning blacks by the age of five, and to endorse gender stereotypes at an even earlier age.

Social Categorization

People routinely sort objects into groups rather than thinking of each as unique. Just as we categorize a new piece of furniture as a chair, and thereby know how to properly interact with it, we also sort each other into groups on the basis of gender, race, age, and other attributes. In a manner similar to object categorization, social categorization is natural and adaptive. By grouping people the way we group foods, furniture, and other objects, we form impressions quickly and use past experience to guide new interactions. In this way we are able to 'go beyond the information given', making inferences about people whom we've never met without expending a great deal of energy or effort.

There are, however, serious drawbacks to the information gained and energy saved through social categorization. First of all, our categorizations may rely on erroneous beliefs, or may lump together people who have little in common. Second, even in cases in which the stereotype is associated with real group differences, categorizing people leads us to overestimate the differences between groups and to underestimate the differences within groups.

Third, once people are sorted into categories, they often are evaluated and remembered with reference to the category. Thus, people tend to notice minority group members more than majority group members, one consequence of which is that negative behavior from a minority group member tends to stand out in people's minds more than negative behavior from a majority group member. This process is known as *illusory correlation*, and it leads people to favor majorities over minorities even when the overall pattern of behaviors is identical across groups.

Finally, because people can't choose many of the groups they belong to (e.g. gender and race), all members of the group tend to be associated with the stereotypic labels whether these labels accurately describe them or not. This process is often unfair and demeaning to those who are targets of stereotypes, and as the Diallo case shows, it can be dangerous to members of groups who are marginalized in society or perceived as violent.

Ingroups versus Outgroups

The second process that promotes stereotyping follows directly from the first. Although grouping humans is much like grouping objects, there is a critical difference. When it comes to social categorization, the people doing the categorizing are members or nonmembers of the categories they use. The tendency to carve the world into ingroups and outgroups, or 'us' and 'them', has a number of important consequences. Perhaps the most important consequence is ingroup bias, or the nearly universal tendency to favor members of one's own group over members of other groups. Ingroup bias is so ingrained that the simple act of placing people into randomly determined groups can create it, and indeed the mere mention of the words 'us' and 'them' leads automatically to associated positive and negative emotions.

Social, Cultural, and Motivational Factors

Social categorization and ingroup/outgroup distinctions reflect basic cognitive processes; they are

by-products of how people think. They are also influenced, however, by situational factors, such as the motivations that people have in particular settings and the cultural context in which they live. For example, people are more likely to rely on stereotypes when they are feeling bad about themselves, as stereotypes help them denigrate others and thereby feel relatively better by comparison. Stereotypes and prejudice are also magnified when people are in conflict with each other, as the act of stereotyping facilitates dehumanization, which in turn enables people to be more ruthless with each other than they might otherwise be. It is also clear that people learn stereotypes through role models, conformity to group norms, and immersion in their culture more generally. As with hairstyles and taste in music, stereotypes are affected by peers, family, and immediate culture.

STEREOTYPE MAINTENANCE

People tend to perceive and explain events differently as a function of whether the events are consistent or inconsistent with their stereotypes, and these perceptual and explanatory processes are biased in favor of stereotype maintenance. A large number of experiments show that even when members of two groups behave identically, people who hold different stereotypes of the two groups will typically see them as different from each other in ways that are stereotype-consistent. In addition, subtyping and self-fulfilling prophecies are two important processes that help maintain stereotypes in the face of what otherwise might be disconfirming evidence.

Subtyping

One of the unnerving paradoxes of stereotyping is that people often manage to hold negative views about a certain group even when they like individual members of the group. Gordon Allport recognized this phenomenon many decades ago, when he wrote: 'There is a common mental device that permits people to hold prejudgments even in the face of much contradictory evidence. It is the device of admitting exceptions. … By excluding a few favored cases, the negative rubric is kept intact for all other cases.' Confronted with a woman who does not seem particularly warm and nurturing, for example, people can either develop a more diversified image of females or toss the mismatch into a special subtype – say, *career women*. To the extent that people create this subtype, their existing stereotype of women-in-general will remain intact.

Self-fulfilling Prophecies

Stereotypes not only influence perceptions of other groups, they can also influence how other group members actually behave. Through the mechanism of self-fulfilling prophecies (whereby people hold a belief that causes them to change their behavior, which in turn causes their original belief to come true), stereotypes can bring about their own reality.

For example, when teachers think that their poor or minority students are more likely to be disruptive, and less likely to perform well academically, they tend to challenge them less and discipline them more. The consequence of this pattern of treatment is that poor and minority children don't learn as much, and because they aren't intellectually stimulated they tend to act out in the classroom. This behavioral pattern only confirms the teachers' original stereotypes, leading to more discipline and less mental challenge. The unfortunate consequence of this spiraling behavioral sequence is that poor and minority children tend to perform much worse in school than their well-to-do and majority counterparts, in the USA, the UK, and around the world. Self-fulfilling prophecies also emerge in a variety of settings outside the classroom, and all groups are occasionally victims and perpetrators of the process.

STEREOTYPE APPLICATION

Stereotypes often color the interpretation of events, particularly events that are ambiguous or learned second-hand. For example, imagine learning that a nurse got into a fight at work. Now imagine learning that a construction worker got into a fight at work. What images of these actions come to mind? Research shows that people interpret 'getting into a fight' differently as a function of who did it, and then falsely remember that they learned rather than imagined the stereotypic information (e.g. that the nurse got into an argument and the construction worker got into a fist-fight). This is a fundamental effect of stereotyping: people are likely to think of others as more stereotypic than they actually are, and often do not recognize that they are interpreting behaviors in a stereotypic fashion.

The Importance of Ambiguity

Because most people do not want to admit (either to themselves or to others) that they are stereotyping, they tend to rely on their stereotypes only when the situation provides them with ambiguity about the cause of their behavior. As an illustrative

example, consider a classic experiment conducted by Melvin Snyder and his colleagues at Dartmouth College. Snyder and colleagues brought people into the laboratory under the auspices of completing a questionnaire, and asked them to have a seat in a nearby room to fill it out. In reality, Snyder wasn't interested in the questionnaire; he only cared where the people sat down. Only two seats were available, one of which was next to a physically disabled person and one of which was next to a person who wasn't disabled. In front of each empty chair sat a television; half the time the two TVs were presenting the same program and half the time they were showing different programs. When the two TVs were showing the same program, most people sat down next to the disabled person. But when the two TVs were showing different programs, most people avoided the disabled person (and it didn't matter which TV was showing which program).

The reason that the television programming was so important is that when the two TVs were showing different programs, they provided an excuse for participants to avoid the disabled person. The different programming on the TVs created ambiguity (for both self and other) about whether the choice of seating had anything to do with the person in the next seat, or was really caused by the program being shown. In contrast, when the two TVs were airing the same program, if the participant avoided the disabled person the meaning of this behavior would be crystal clear to both self and other. Under this circumstance, there would be no ambiguity about whether people were avoiding the disabled person, a behavior that most of us would be embarrassed just for considering.

These results suggest that stereotypes and prejudice will influence behavior towards members of other groups only when other aspects of the situation could legitimately be the cause of the behavior. Numerous other studies have supported this general idea that people will typically show evidence of stereotyping only when the situation provides an excuse for what would otherwise be obviously stereotypical judgments or behavior. Because the everyday world provides numerous situational details that could potentially be the source of what is really stereotypical behavior, these results suggest that subtle stereotyping should be quite common, and indeed it is. From shopping malls to employment agencies to the courtroom to housing and schools, blacks and other minorities face stereotypes that limit their opportunities in ways that are so subtle that frequently they themselves are unaware that stereotyping is at work.

Automatic Stereotyping

Because most cultures are suffused with stereotypes, people often automatically activate their stereotypes when they are exposed to members of groups for which popular stereotypes exist. Just as most of us automatically think of 'butter' when someone says 'bread', we also tend to automatically think of concepts relevant to a stereotype when we think of members of a stereotyped group. We can try to prevent the stereotype from influencing our judgments or behaviors (and nonprejudiced people do just that), but because we are often unaware that a stereotype has been activated, it can affect us despite our best intentions to the contrary.

That being said, there are people for whom automatic stereotype activation is less likely, and there are circumstances in which automatically activated stereotypes are more or less likely to be applied. In particular, people are likely to form stereotypic impressions when they're busy, pressed for time, or unable to think carefully (e.g. due to exhaustion or intoxication) about the unique attributes of the person encountered. In contrast, people often manage to inhibit or replace their stereotypic thoughts, and even prevent their activation, when they are highly motivated to form an accurate impression or be egalitarian in their judgments.

Stereotype Application from the Target's Perspective

In a provocative theory that has attracted a great deal of attention, Claude Steele has proposed that in situations in which a negative stereotype can apply to someone, people may fear being seen 'through the lens of diminishing stereotypes and low expectations'. Steele calls this predicament *stereotype threat*, because it hangs like 'a threat in the air' when the individual is in the stereotype-relevant situation. This predicament can be particularly threatening for individuals whose identity and self-esteem are invested in domains in which the stereotype is relevant. Steele argues that stereotype threat plays an important role in diminishing the performance and identification of stereotyped group members.

According to Steele's theory, stereotype threat can hamper achievement in two ways. First, the 'threat in the air' can directly interfere with performance, by increasing anxiety and triggering

distracting thoughts in performance situations. Second, if stereotype threat is chronic in a particular domain, it can cause people to *disidentify* from that domain – to dismiss the domain as no longer relevant to their self-esteem and identity.

To illustrate, imagine a black and a white student who enter high school equally qualified in academic performance. Imagine that, while taking a particularly difficult test at the beginning of the school year, each student struggles on the first few problems. The white student may begin to worry about failing, but the black student may also have a large set of additional worries about appearing to confirm a negative stereotype of blacks. Even if the black student doesn't believe the stereotype at all, or doesn't believe that it describes himself, the threat of being reduced to a stereotype in the eyes of those around him can trigger anxiety and distraction, impairing performance. And if he experiences this threat in school frequently – perhaps because he stands out as one of only a few blacks in the school, or perhaps because he is treated stereotypically by others – the threat can eventually wear him down. To buffer himself against the threat, he may learn to disidentify with school; if so, his academic performance will become less relevant to his identity and self-esteem. In its place, some other domain of life, such as social success or a particular nonacademic talent, will become a more important source of identity and pride.

The unfortunate consequence of this process is that once people disidentify with school, their academic performance tends to suffer because they no longer put the same time and energy into academic activities.

STEREOTYPE CHANGE

Intergroup Contact

Modern stereotypes are difficult to overcome because they manifest themselves in indirect ways, and even the perpetrators are often unaware that they are relying on stereotypes. Is there a solution to this problem?

According to Gordon Allport's contact hypothesis, one way to reduce stereotyping is to bring members of different groups into contact with one another. The contact hypothesis states that four conditions facilitate the positive effects of intergroup contact: people should have equal status, common goals, and cooperative means to achieve those common goals, and intergroup contact should be sanctioned by relevant authorities. The results of hundreds of experiments in dozens of countries have generally confirmed this hypothesis, although this research has also shown that intergroup contact can make stereotypes worse if people feel anxious or threatened in a contact situation.

The Jigsaw Classroom

As is noted above, cooperation and shared goals are important for intergroup contact to be successful. They can break down the psychological barrier between groups, leading members to recategorize the two groups into one and reducing ingroup favoritism: 'they' become part of 'us'. Yet the typical classroom is filled with competition, a factor that usually leads to increased stereotyping.

To combat this problem in the classroom, Elliot Aronson and his colleagues developed a cooperative learning method called the *jigsaw classroom*. In newly desegregated public schools in Texas and California, they assigned fifth-graders to small racially and academically mixed groups. The material to be learned within each group was divided into subtopics, much like the way a jigsaw puzzle is broken into pieces. Each student was responsible for learning one piece of the puzzle, after which all members took turns teaching their material to one another. In this system, everyone – regardless of race, ability, or self-confidence – needs everyone else if the group as a whole is to succeed.

This method produced impressive results. Compared with children in traditional classes, those in jigsaw classrooms grew to like each other more, liked school more, were less prejudiced, and had higher self-esteem. What's more, academic test scores improved for minority students and did not diminish for majority students. Much like an interracial sports team, the jigsaw classroom offers a promising way to create a truly integrated educational experience. It also provides a model of how to use interpersonal contact to promote greater tolerance of diversity.

Undoing Automatic Stereotype Activation

The situations in which people find themselves have an important influence on the degree to which they rely on stereotypes, but long-term personal decisions not to stereotype others can be important as well. Low-prejudice people in particular are often successful at regularly bypassing their stereotypes, as they seem to focus on personal information about individual members of

stereotyped groups and thus have an easier time keeping stereotypic thoughts out of mind.

This may be the best strategy for avoiding the influences of stereotypes: rather than trying to suppress thoughts about a stereotyped group, try instead to activate thoughts about the individual who happens to be a member of that group. Keep in mind, however, that unlearning stereotyping is much like trying to break other bad habits; it takes a long time, needs lots of practice, and you should not be discouraged if you slip up on occasion. Indeed, accidentally relying on stereotypes and thereby being unfair to someone is one of the most important motivators that helps low-prejudice people maintain vigilance so that they don't make such mistakes in the future.

In addition to a personal commitment to breaking the stereotyping habit, there are two other factors that may help put the brakes on stereotype activation. These are:

Take the perspective of a member of a stereotyped group. For example, in one experiment people spent a few minutes writing about a day in the life of an elderly man. Some of the participants were asked to suppress their stereotypes about the elderly while writing, and others were asked to take the perspective of the elderly man himself while writing. Both groups were equally good at not using stereotypes in their stories. But on a subsequent task in which their activation of the elderly stereotype was measured, those who had earlier tried to suppress the stereotype showed strong evidence of stereotype activation, but those who had taken the perspective of the elderly man did not.

Be motivated to be fair and egalitarian towards other groups. A number of experiments have shown that this motivation can be very effective in reducing stereotype activation. This goal is constant in some people, but it also can be induced temporarily in others, such as when people are made to feel that they recently have *not* been fair to others. When people feel that they have violated their own personal or cultural standards of fairness and morality, they become less likely to activate negative stereotypes of others. Conversely, if they feel that they have demonstrated their fairness and virtue, they may ironically become more likely to activate negative stereotypes.

CONCLUSION

A variety of cognitive, motivational, and social/cultural factors come together to cause people to rely on stereotypes even when they would rather not. This combination of factors contributes to the pervasiveness and perniciousness of stereotyping. When situations or personal standards and motivations cause people to see and value others as individuals rather than group members, however, they often can put stereotypes aside. Learning and applying stereotypes tend to be all too easy; resisting stereotypes, in contrast, requires effort, practice, and motivation. Nevertheless, the benefits to society that such resistance can bring are enormous, and thus researchers continue to study when and how stereotypes can be changed, weakened, and undone.

Theory of Mind

Introductory article

Andrew Whiten, University of St Andrews, Fife, Scotland, UK

CONTENTS

Theory of mind refers to the everyday psychology that we use to understand and explain our own and others' actions by reference to mental states, such as 'desiring', 'knowing' and 'believing'.

INTRODUCTION

The expression 'theory of mind' (ToM) was introduced into psychology by David Premack and Guy Woodruff in 1978. Asking, 'Does the chimpanzee have a theory of mind?', they described experiments to assess whether the primate most closely related to us shares our tendency to interpret others' actions by attributing to them 'states of mind' (or 'mental states'). Premack and Woodruff referred to these attributions as an everyday 'theory' because they are rather like scientific theories, first in being about theoretical entities – mental states, in this case – that are not directly observable; and second, in generating testable predictions about how others will behave, according to the state of mind they are presumed to be in.

These authors' attempts to investigate whether chimpanzees construe others as 'wanting' or 'intending' things are now generally seen as inconclusive, but they laid the foundations for what is now a large and influential area of research. Psychologists realized that the question of how humans – let alone chimpanzees – achieve 'everyday mindreading' remained largely unanswered. Developmental psychologists in particular saw that the growth of the child's ToM was a topic ripe for investigation, and during the 1990s they completed hundreds of experimental investigations. Meanwhile, the topic continued to preoccupy those studying our closest primate relatives, and also became a natural focus for new work by philosophers. As a result, ToM has become a topic of highly productive interdisciplinary debate and investigation in several branches of the cognitive sciences.

FOLK PSYCHOLOGY

Various terms have been used as rough synonyms for ToM, sometimes with slightly different connotations. For example, unlike ToM, 'mindreading' provides a useful verb – to mindread – and tends to be preferred by those who dislike talk of a 'theory' when we are just talking about people's everyday ideas about mind, rather than the science of psychology. Of course, in the present context 'mindreading' does not imply telepathy, as it can in common discourse! Another related expression is 'folk psychology'. Again, this is sometimes used simply as an alternative way of talking about ToM, but can imply something either broader or narrower. The broader sense of folk psychology refers to all the ways in which people act like amateur psychologists, explaining and predicting how and why people behave as they do. This may include certain rules expressed in behavioral terms, rather than appealing to the mind, as ToM specifically does; there is a folklore, for example, about how men and women might typically act differently in certain situations. In this respect folk psychology can include more than ToM. However, folk psychology is often taken to include only the folklore about the mind that people consciously and verbally express. In contrast, at least some conceptions of ToM include elements that a person is unaware of (a useful analogy is with the grammar that an infant acquires and applies, without being able to verbalize its rules), and from this perspective folk psychology may be seen as narrower than ToM.

DEVELOPMENT OF A THEORY OF MIND

Philosophers commenting on the original chimpanzee study by Premack and Woodruff suggested that clearer evidence of ToM would be the attribution to another individual of a false belief, because

this requires recognizing that another mind might represent the world in a way different from how one knows it truly to be. Developmental psychologists studying ToM in children accordingly made this achievement the priority in their research. In what has become one of the most frequently used tests for this ability, the child watches a scene in which Sally hides a special object (here a ball) in a covered basket, then leaves (Figure 1). While she is out, Anne transfers the ball to a closed box. Sally then returns and the child is asked the critical question: where will Sally look for her ball? By the age of 5 years, a child typically answers in the adult way, saying that Sally will look in the basket. Three-year-old children, however, are more likely to say that Sally will look where they themselves know the ball to be, in the box. They seem unable to appreciate that Sally will search under the guidance of a false belief, which is different to the child's own belief about the ball's location.

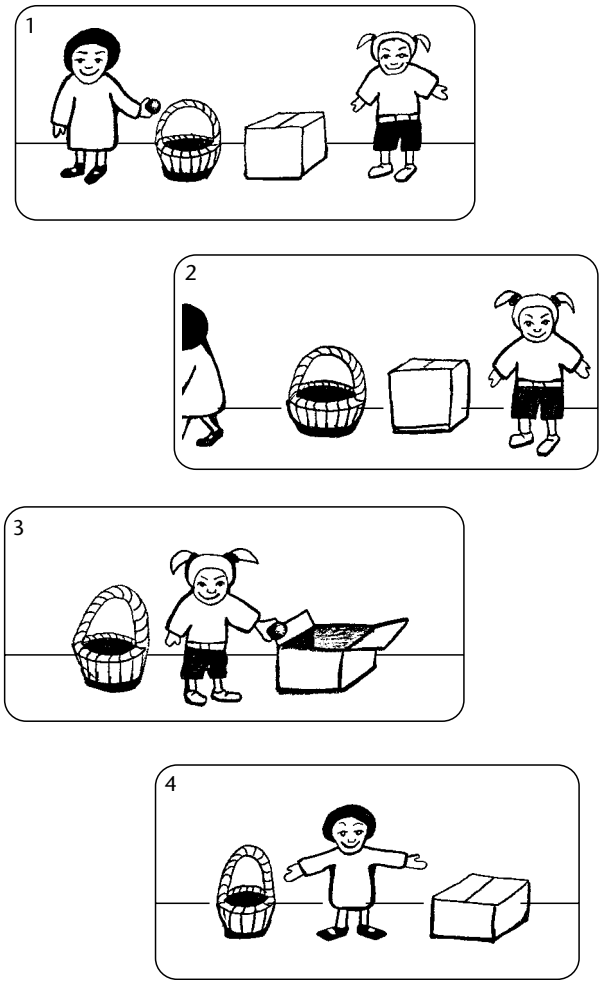

Figure 1. The 'Sally–Anne' test. Sally puts her ball in the basket (1) and leaves (2). Anne takes the ball from the basket and puts it in the box (3). Sally returns (4). Having watched the story unfold, a child is asked: 'Where will Sally look for her ball?' A three-year-old will tend to answer 'in the box,' a five-year-old 'in the basket.'

A major step is thus made between these ages in the operation of a theory of mind, and it can be detected in several other social contexts. One that has important ramifications in the child's everyday social life is the ability to create false beliefs – to lie and deceive. Although at earlier ages the child may have learned some social tactics that work by misleading others, only with this theory of mind 'watershed' at around 4 years of age is there a true understanding about why such tactics work. The child is a mentalist long before this, however. A variety of ingenious experiments and careful observations have provided evidence that 2-year-old children typically understand and talk about the rudiments of 'seeing' (whether something is hidden or visible to someone else, for example), as well as aspects of emotions, desires, attention and intentions. These states of mind do not require a recognition of the possibility of misrepresenting reality and they appear easier for young children to understand than false belief. More controversial evidence points to an ability to recognize goal-directed action at even earlier ages.

AUTISM AND THE 'THEORY OF MIND' MODULE

Individuals with autism, a condition in which social interaction is typically disturbed, have been found to fail the 'Sally–Anne' test for recognition of false beliefs even when their overall level of mental functioning is quite high. It has been suggested that this autistic 'mind blindness', as Simon Baron-Cohen has called it, has much to do with the social difficulties characteristic of the condition. A more general conclusion drawn from this result is that theory of mind is an example of a mental module, which develops and operates somewhat independently of other components of the mind. The hypothesis is that it is a device that evolved specifically for recognizing states of mind, so it is possible for it to become a relatively isolated malfunctioning unit even in an otherwise intelligent mind. The malfunctioning probably begins well before the stage at which the child would normally begin to attribute false beliefs, however. There is evidence it can often be detected earlier in a failure to engage in sharing the attentional focus of companions, an activity common in normal 2-year-olds and one generally regarded to indicate

the beginnings of engaging with the mental perspective of others.

Conversely, difficulties also tend to remain at later stages of development. Some individuals with autism eventually pass tests like the Sally–Anne one, that require first-order attribution of mental states, but yet fail to make more complex second-order attributions that would normally be expected for their mental age. Where a first-order attribution might be that Sally thinks her marble is in the basket, a second-order attribution embeds Sally's thought in another mental state, such as John believing that Sally thinks her marble is in the basket. This illustrates an important outcome of possessing a theory of mind: because such embedding can in principle continue indefinitely, mindreading can come to involve great social complexity (for example, 'I think you realized I didn't want you to believe what I said yesterday') that taxes even its most proficient users. In the case of autism, the findings about first-order and second-order difficulties have suggested that in this condition ToM suffers delayed development, rather than some fixed deficit.

DOES THE CHIMPANZEE HAVE A THEORY OF MIND?

The possibility that ToM might be an ability shared with other primates gained added support in the context of the 'Machiavellian intelligence' hypothesis, that the special intelligence of apes and monkeys is due more to the complexities of their social environments than anything else. This hypothesis is supported by evidence that the social complexity characteristic of a species is correlated with the relative size of their neocortex. If social intelligence provides the reproductive advantage this theory suggests, it might have encouraged the evolution of at least some elements of a ToM that could help primates to exploit possibilities for deception, for example. However, by comparison with the number of studies of children's ToM, studies on primates remain few and have concentrated on chimpanzees. The earliest studies offered some support for chimpanzee ToM, but then the pendulum of evidence swung the other way. In particular, chimpanzees failed to match young children even in the relatively elementary attribution of 'seeing', choosing randomly between two people from whom to request food, even when one had their eyes covered by an opaque screen and the other did not. More recently, chimpanzees placed in a more natural competitive situation with other chimpanzees did discriminate between situations in which their opponent could or could not see a piece of food, and they even did this in relation to what the opponent would or would not have seen earlier, which appears close to attributing 'knowledge' to the other. The question of primate ToM thus remains one of active research and controversy. What the data suggest is that if nonhuman primate ToM exists, it is not the robust and routine social tool that becomes so evident in human childhood.

HOW IS MINDREADING DONE?

Two rather different ways in which mindreading might operate have been distinguished. One is that connoted by use of the term, 'theory' in 'theory of mind' (which gives this theory the unfortunate name of the 'theory theory'): an individual becomes a mindreader by observing and experimenting in the social world rather like a little scientist, and comes up with a theory-like recognition that imputing specific states of mind (e.g. that Sally wants her doll, and believes it is in the cupboard even though it is not) predicts and explains actions rather well (Sally searches in the cupboard, only to be disappointed). In the case of child development, simple ToMs are superseded by more sophisticated ToMs as the former are found wanting, in a fashion somewhat analogous to the progress of science.

The main alternative idea is that instead of constructing such a 'theory', mindreaders put themselves in the position of the other, and use their own mind to simulate what the other might think or believe. Accordingly this is known as the 'simulation' theory. So far, there has been little evidence that can decide between this and the 'theory' theory in practice. A finding that 'theory' theory adherents have claimed in support comes from comparing children's mental attributions to self and others. One test begins with a child answering, 'Smarties' when asked what is inside a well-known sweet package. Then the child is shown that the package actually contains a pencil. When asked what another, approaching child will think is inside, a 5-year-old will tend to say 'Smarties', a 3-year-old 'pencil', consistent with the Sally–Anne results outlined earlier. Interestingly, however, each child will give similar answers about what they had originally thought was in the package (i.e. the young child will say 'pencils'). This has been taken to indicate that children would not find simulation helpful as a way of ever advancing the sophistication of their mindreading, because it appears to show they 'know their own mind' no better than that of others.

THE BRAIN BASIS OF THEORY OF MIND

How mindreading is done by the brain has begun to be investigated through three main kinds of evidence. First, at a crude level, it is known that damage to frontal cortex can impair social behavior. Second, brain scanning methods have been applied to people performing ToM tasks like the Sally–Anne one outlined above. The different methods converge on implicating medial prefrontal cortex in ToM operations, along with other areas including lateral inferior frontal cortex. The third kind of evidence comes from single neuron recordings in monkeys that focus on the coding of information about social actions likely to form the foundations for ToM, such as gaze direction and goal-directed action. These studies show activities in regions of the brain such as the superior temporal sulcus and area F5, adjacent to those regions identified with ToM in humans. We are finally beginning to glimpse how actions are processed in what are necessarily complex ways, such that 'brains can read minds'.

Theory-of-mind in Two-person Experiments

Introductory article

Mary Rigdon, George Mason University, Fairfax, Virginia, USA

CONTENTS

The theory of mind or folk psychology is appealed to by game theoretic concepts and explains behavior in a variety of bargaining environments.

THEORY OF MIND AND COMMON KNOWLEDGE IN GAMES

As cognitive agents we routinely predict and explain the behavior of others by ascribing to them a cornucopia of mental states *See* **Theory of Mind**. How we do this – what the information processing mechanisms are for these ascriptions, and how these ascriptions are used – is still very much an open question. Another interesting question is what role theory of mind (ToM) or folk psychology plays in other aspects of our cognitive lives. One such aspect is the class of strategic interaction contexts which can be modeled using game theory. ToM shows up in two different ways in economics experiments. First, even the simplest solution concepts of game theory tacitly appeal to agents' folk psychological abilities. Second, facts about ToM constrain those theories which attempt to explain how people behave in strategic environments.

Consider first how ToM is appealed to by even the simplest solution concepts in game theory. All classical solution concepts assume that the structure and rationality of the players are items of common knowledge among the players in the game. This information then is sufficient to derive predictions about plays of the game. Consider, in particular, the solution concept of rationalizability. The concept is that players predict the play of others given the assumption of common knowledge of rationality. So if a player i's action A_i is part of a rationalizable strategy, we know that i has made a prediction about what each player $j \neq i$ will do. But what is the prediction supposed to be based upon? Common knowledge of rationality, no doubt, but can we unpack this further? Suppose we say that a player is rational only if i best responds to what she justifiably believes the other players will do. Common knowledge of this fact would entail that player i's predictions about j are based on a host of mental states: beliefs about j's desires, beliefs, and so on. The same applies to j with respect to i's mental states. In fact, game theory assumes that both players will expect that each possesses self-interested intentions. The bottom line is that rationalizability depends tacitly on folk psychology. The same sort of inspection of other solution concepts – e.g. subgame perfection – leads to the same conclusion: players are assumed to have beliefs about and be motivated by the beliefs, desires, and preferences of other players in the game. This is just to say that these solution concepts tacitly appeal to agents' folk psychological abilities.

EVIDENCE FOR THEORY OF MIND IN ECONOMICS EXPERIMENTS

Now let us consider more concrete, empirical effects of ToM in strategic environments. One hypothesis is that an agent's ability to read the intentions of others plays a central role in achieving cooperative outcomes in personal exchange. One question is whether agents possess a 'friend-or-foe' mental mechanism for evaluating the intentions of another person. This module can be thought of as providing the needed information about one's counterpart in order to determine a course of action. If someone is detected as a friend, then this increases the likelihood of positive reciprocity from this person following a trusting action; whereas if someone is detected as a foe, then a different strategy may be followed to avoid a defection outcome. Perhaps such a mechanism can be primed in an experimental setting via simple changes in the instructional protocol.

Consider the following sequential decision problem; see Figure 1. In this decision problem, Player 1 begins by choosing between the outcome ($7, $14)

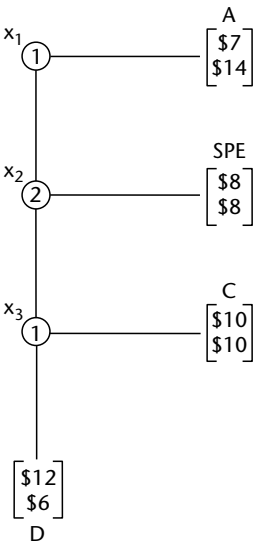

Figure 1. Trust game (extensive form).

or passing the game to Player 2, his counterpart. Player 2 then has a choice to move right, resulting in the outcome of ($8, $8) or passing the game back to Player 1, her counterpart. If the game is passed back to Player 1, then he decides between ending the game at the cooperative outcome of ($10, $10) (i.e. a move right at x_3) or ending the game by defecting from his counterpart, yielding the outcome of ($12, $6) (i.e. a move down at x_3).

Assume that it is common knowledge that each player acts in his or her own self-interest. So if Player 2 were to choose down at x_2, Player 1 would move down, ending the game at ($12, $6). The cooperative outcome would never be reached. Given that Player 2 knows this is the case, Player 2 will choose to move right at x_2 because the outcome ($8, $8) will be reached for sure, and $8 is certainly better than $6. Player 1 will therefore move down at x_1, preferring $8 to $7. The ($8, $8) outcome is predicted to be reached by agents using backward induction and eliminating dominated strategies. This is called the subgame perfect equilibrium (SPE) of the game.

The experimental protocol used in the laboratory involves 12 or 28 subjects participating in a session. Each receives $5 for showing up on time, is randomly assigned the role of Player 1 or 2, and randomly paired with another individual. The session begins with a single play of the sequential decision problem and then subjects are paid according to their decisions. The experimenter announces that there is another experiment where all of the above is the same except that the decision problem is repeated 10 times, each time with a new counterpart. At the completion of the second experiment, subjects are privately paid their earnings in cash. A total of 156 pairs have participated.

We can manipulate how subjects think about each other by using the descriptive labels of 'opponent' or 'partner' in the instructions, rather than the more neutral description of 'counterpart'. This small variation in the reference to the other individual in the pairing has a significant impact on behavior in the above game. Players 2 are more trusting (i.e. choose down at x_2) in the Partner treatment than in the Opponent treatment: 29 percent versus 21 percent. This difference is statistically significant ($p < 0.001$). Furthermore, Players 2 are twice as likely to be trustworthy (i.e. choose the cooperative outcome) in the Partner condition than under the Opponent: 68 percent versus 33 percent. This difference is also statistically significant ($p < 0.04$). These results demonstrate that by providing subjects with a subtle cue to aid mind reading in the decision problem, behavior moves toward more cooperation.

NORMAL VERSUS EXTENSIVE FORM GAMES

In the above experiment, agents make their decisions sequentially – Player 1 moves first, followed by Player 2's move, until an outcome is reached. Player 2 sees the move of Player 1 before Player 2 chooses to move. This is known as the *extensive form* of the game. In the *normal form* of the same game, each player chooses a move at each node without knowing whether that node will be reached in the move sequence. That is, players make their decisions simultaneously, not knowing the choice of the other.

To represent the trust game in Figure 1 in the normal form (see Figure 2), we express the payoff consequences of all possible sequences of moves. Each row represents a strategy for the first player. Similarly, each column represents a strategy for the second player. The first row contains the strategy choose right at x_1, ending the game. The strategy is indicated by R^*. The outcome reached is *(7, 14)*

	r	*d*
*R**	(7, 14)	(7, 14)
D, R	(8, 8)	(10, 10)
D, D	(8, 8)	(12, 6)

Figure 2. Normal form representation.

regardless of what the second player chooses. The second row contains the strategy down at x_1 and right at x_3, *D,R*. If the second player chooses right (*r*) then the outcome is (*8, 8*), but if she chooses down (*d*), then the outcome reached is the SPE *(10, 10)*. Lastly, the third row contains the strategy down at x_1 and down at x_3, *D,D*. If the second player chooses right (*r*) then the outcome is cooperative *(10, 10)*, but if she chooses down (*d*), then the outcome reached is defection *(12, 6)*.

The standard game-theoretic prediction is that rational behavior will be equivalent regardless of the form; behavior is invariant to the form of the game. However, when decisions are made sequentially, it allows intentions to be detected from the actual move. Only upon observing an actual move down at x_2 can Player 1 interpret Player 2's intentions; namely, that both parties can be better off at the cooperative outcome relative to the SPE. As a result, if the reading of intentions is an important component to whether or not cooperation is achieved, then we arrive at a different prediction – namely, cooperation levels in the extensive form (see Figure 1) will be greater than those achieved under the same game in the normal form (see Figure 2).

A total of 26 subjects participated in the extensive form trust game (see Figure 1) and a total of 29 participated in the normal form trust game (see Figure 2). The data being reported here is across-subject comparisons and are for experiments where the subjects participate *once* and only once in the decision problem (data are also available for repeated matching with the same counterpart).

Individual behavior does differ between the two game forms. Table 1 reports the frequencies of decisions. The proportion of ($10, $10) cooperative outcomes being reached is higher in the extensive form than in the normal form: 50 percent in the extensive form, and only 14 percent in the normal form. Using a one-tailed binomial test, the null hypothesis that the proportion of cooperative outcomes is the same under both game forms can be rejected at the 95 percent level of significance. Also the proportion of ($8, $8), subgame perfect, outcomes reached is higher in the extensive form than in the normal form: 100 percent in the extensive and a smaller 82 percent in the normal. Again using a one-tailed binomial test, the null hypothesis that the proportion of SP outcomes is the same can be rejected at the 95 percent level of significance. These results suggest that the extensive form allows better coordination among non-cooperators as well. Both results are not predicted by the standard game-theoretic analysis, but are indeed explained by a reciprocity interpretation which relies on ToM and intentionality detection.

Table 1. Frequencies of play in extensive versus normal form

Outcome	*Extensive form*	*Normal form*
($7, $14)	$\frac{0}{26} = 0.0$	$\frac{0}{29} = 0.0$
Down by P2	$\frac{12}{26} = 0.46$	$\frac{7}{24} = 0.29$
($8, $8)	$\frac{6}{12} = 0.50$	$\frac{6}{7} = 0.86$
($10, $10)	$\frac{6}{12} = 0.50$	$\frac{1}{7} = 0.14$

CONCLUSION

If intentions and ToM were unrelated to behavior in experimental exchange games, then these differences would be puzzling. That we see such differences across variations in labeling (partners versus opponents) and in game form (normal versus extensive) suggests that ToM and folk psychology play an important role in how agents solve game theoretic problems.

The experimental data reported here are from undergraduates with a variety of majors attending the University of Arizona. Another interesting population of individuals, whose behavior has yet to be explored in these particular exchange games, is autistics. Individuals with autism suffer from 'mindblindness', blind to the existence of beliefs, intentions, and other mental states. Given this, perhaps their behavior would be significantly less trusting and less trustworthy. Experiments have been run with children using a variety of bargaining environments to explore whether trust and reciprocal tendencies change with age. Results suggest that this is the case.

Standard solution concepts and the concept of common knowledge rely tacitly on folk psychology anyway, but the ToM standard theory the latter relies on is impoverished. By making the relationship between ToM and economic behavior explicit, we can better understand how real economic agents solve problems of strategic interaction.

Thought Suppression and Mental Control

Advanced article

Daniel M Wegner, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

Consciously attempting not to think about something is a mental control strategy known as thought suppression. This strategy can be successful under certain conditions, but it often promotes an increase in the accessibility of the thought to consciousness, and along with this, a number of ironic processes and unwanted effects.

INTRODUCTION

In the fifth act of *Macbeth*, the king is distraught over his wife's apparent mental illness. He asks the doctor:

> Canst thou not minister to a mind diseased,
> Pluck from the memory a rooted sorrow,
> Raze out the written troubles of the brain
> And with some sweet oblivious antidote
> Cleanse the stuff'd bosom of that perilous stuff
> Which weighs upon the heart?

The doctor replies:

> Therein the patient
> Must minister to himself.

Shakespeare's observation in the voice of this doctor still holds true some four centuries after it was written. In the matter of unwanted memories, sorrows, troubles, and weights upon the heart, we are often alone in life – left with no one who can clear our minds and solve our problems for us. Instead, we must somehow deal with these things by ourselves.

When unwanted thoughts arrive, people often minister to themselves by trying not to think about them. They attempt to exert mental control. The realization that everyone does this led to much of Freud's insight into human psychology, and more recently has led to a number of inquiries into the nature and effectiveness of people's attempts to control their own minds (Wegner, 1989; Wenzlaff and Wegner, 2000). The general finding from research on this topic to date is that thought suppression is sometimes possible, but that it can produce a host of side effects that are sometimes more damaging, and certainly more far-reaching, than the pain the person may experience on allowing the unwanted thought to dwell in the conscious mind.

UNWANTED THOUGHTS

What are the thoughts that people want to keep out of their minds? The thought of an old love affair that went wrong, the thought of a cake that will break one's diet, the thought of a feared event in the future, the thought of a secret one is hoping not to divulge: these are all examples of thoughts that normal individuals might not want. And people who are suffering from psychopathological disorders such as depression, anxiety, phobia, or obsessive–compulsive disorder, often find that the central feature of their psychological problem is the struggle to avoid a particular set of thoughts.

One approach to avoiding such thoughts is simply to try not to think of them. People who are asked to suppress a thought in the laboratory while they report their stream of consciousness usually mention selecting distractor thoughts to think about instead.

REBOUND AND HYPERACCESSIBILITY

In many laboratory studies, people have been asked to suppress thoughts in just this way. Individuals were prompted not to think about a white bear (something once mentioned by Dostoevsky as impossible to keep out of mind) (e.g. Wegner *et al*., 1987). In think-aloud recordings taken over the course of five minutes, people continued to mention white bears about once per minute. These participants were then asked to go ahead and think

about a white bear for a subsequent five-minute session. Their reports of the thought became more frequent over this expression period, but in a pattern radically unlike that of other participants who had been asked to think about a white bear without prior suppression. Those who were invited to express the thought after suppression appeared to become preoccupied with it – exhibiting a post-suppression rebound effect. This effect has since been observed when people are asked to suppress thoughts of pain, to suppress unhappy thoughts that are spoiling their mood, or to suppress thoughts of a lost love whose absence they grieve. In each case, initial suppression increases the frequency of return of the thought once suppression is discontinued.

Suppression appears to yield even more intense levels of preoccupation with a thought than does concentration. This is apparent not only after suppression is released, but even during suppression when the person is working under stress or mental load. People trying not to think about a target thought show hyperaccessibility – the tendency for the thought to come to mind more readily even than a thought that is the focus of intentional concentration – when they are put under an added mental load or stress. Trying not to think about a target word under conditions of mental load (while rehearsing a long phone number, for instance) makes people unusually slow at identifying the color in which the target word is presented (e.g. Wegner and Erber, 1992). The word seems to jump into the mind before the color, and interferes with the task of naming it. By this measure, unwanted thoughts are more accessible even than thoughts on which a person is intentionally concentrating.

IRONIC PROCESSES OF THOUGHT

These observations can be explained by a theory of ironic processes. The attempt to suppress a thought seems to conjure up an ironic psychological process which then works automatically against the very intention that set it in motion. The suppressed thought is brought to mind in sporadic intrusions because of this sensitivity. Later, when suppression is over, the automatic and intrusive return of the thought apparently continues, in a post-suppression rebound.

Why might such ironic processes occur? One explanation is that ironic processes are part of the machinery of mental control (Wegner, 1994). It may be that in any attempt to control our minds, two processes are instituted: an 'operating' process that works consciously and effortfully to carry out our desire, and an 'ironic' process that works unconsciously and automatically to check whether the operating process is failing and needs renewal. In the case of thought suppression, the operating process involves the conscious and effortful search for distractors (as we try to fasten our minds on anything other than the unwanted thought), whereas the ironic process is an automatic search for the unwanted thought itself. The ironic process is a sort of monitor, which determines whether the operating process is needed, but which also has a tendency to influence the accessibility of conscious mental contents. It ironically enhances the sensitivity of the mind to the very thought that is being suppressed.

An ironic process theory can explain more than the paradox of thought suppression. Such processes may be involved in almost everything we try to do with our minds. If an ironic process is inherent in the control system whereby we secure whatever mental control we do enjoy, then it ought to be evident across many domains in which we do have some success in controlling our minds. Because the operating process requires conscious effort and mental resources, it can be undermined by distraction, and evidence of ironic processes will then arise. When people undertake to control their minds while they are burdened by mental loads – such as distractors, stress, or time pressure – the result should, according to this model, often be the opposite of what they intend. Studies have uncovered evidence of many ironic effects. Ironic mood effects occur, for example, when people attempt to control their moods while they are under mental load. Individuals following instructions to try to make themselves happy become sad, whereas those trying to make themselves sad actually experience a happier mood.

Ironic effects occur in the self-control of anxiety. People trying to relax under load show psychophysiological indications of anxiousness, whereas those not trying to relax show fewer indications.

Ironic effects occur in the control of sleep. People who are encouraged to 'fall asleep as quickly as you can' as they listen to raucous, distracting music stay awake for longer than those who are not given such encouragement.

Ironic effects occur in the control of movement, arising when people try to keep a handheld pendulum from moving in a certain direction, or when they try to keep from overshooting a golf putt. In both cases, an imposition of mental load makes individuals more likely to commit exactly the unwanted action.

Ironic effects also arise from thoughts of death. After people have been asked to reflect for a while on their own death, they spontaneously suppress the thought. Those who are then distracted with stressful tasks show high levels of accessibility of death-related thoughts.

Ironic effects have also been observed in person perception. When people are put under mental load while they are forming impressions of a person, they project a personality trait onto the target when they are suppressing thoughts of that trait – whether they are suppressing in response to suppression instructions, or spontaneously because they dislike the trait in themselves.

Ironic effects also occur when people try to control their prejudices. Bodenhausen and Macrae (1998) report, for example, that people who are trying not to stereotype a skinhead as they form an impression of him show greater stereotyping under mental load. Individuals in this circumstance have been found to avoid even sitting near the skinhead. And people under mental load who are specifically trying to forget the stereotypical characteristics of a person (in a directed forgetting study) have been found to be more likely to recall those characteristics than people without such load.

THE ABILITY TO CONTROL ONE'S MIND

These studies illustrate how things can go awry when we 'minister to ourselves'. People often begin on the path towards ironic effects when they try to exercise good intentions – to behave effectively, to avoid prejudice, to be happy, to relax, to clear their minds of negative thoughts or thoughts of personal shortcomings, or even just to sleep. The intention is to minister to oneself, but it may be the first step towards ironic effects.

The next step towards ironic effects is the pursuit of such goals in the face of a shortage of mental resources. When there is insufficient time and thought available to achieve the intention, people do not merely fail to produce the mental control they desire. Rather, the ironic process goes beyond 'no change' to produce an actual reversal. The opposite of the desire happens. Ironic effects are precipitated when we try to do more than we can with our minds.

Why would we do this? At the extreme, we do this when we are desperate: we will try to achieve a particular sort of mental control even though we are mentally exhausted. These circumstances are very reminiscent of the circumstances of many people suffering from various forms of psychological disorder. People who are anxious, depressed, traumatized, obsessed, or suffering from disorders of sleep, eating, movement, and so on, might frequently try to overcome their symptoms – and might be inclined to attempt such control even under adverse conditions of stress or distraction. Evidence from correlational studies suggests a possible role for ironic processes in several such forms of psychopathology.

Another line of evidence suggesting a role for ironic processes in the beginnings of some disorders comes from studies of what happens when mental control is rescinded. When people are encouraged to express their deepest thoughts and feelings aloud or in writing, and so to suspend any suppression of these thoughts, they experience subsequent improvements in psychological and physical health (Pennebaker, 1997). Expressing oneself in this way involves relinquishing the pursuit of mental control, and so eliminates a basic requirement for the production of ironic effects. The motive to keep one's thoughts and personal characteristics secret is strongly linked with mental control. Disclosing these things to others, or even in writing to oneself, is a first step towards abandoning what may be a futile quest to control one's own thoughts and emotions. In the pursuit of mental control, we may sometimes be most successful when we choose not to minister to ourselves.

Time Perception

Introductory article

Russell M Church, Brown University, Providence, Rhode Island, USA

CONTENTS

People and other animals are able to perceive the duration of intervals between events, and the accuracy of their perceptions can be assessed. In situations in which there are many different time intervals, these can be combined for the assessment of the typical interval. Associative learning is dependent upon time perception, and the mechanisms of time perception involve an internal clock.

PERCEIVED TIMING OF EVENTS

A clear distinction should be made between the perception of time as a psychological dimension and the measurement of time as a physical dimension. For the perception of the time interval between two events, a person does not need to use any special timing devices such as a watch. Without any external aids, a person can report reasonably accurately the duration between two events (the method of estimation) or make two responses separated by approximately the same interval that separated the two events (the method of reproduction). Such methods are known as 'psychophysical methods' because they have a physical input (the physical duration between the two events) and a psychological output (the reported duration or the interval between two responses). Such outputs could equally well be called 'behavioral', because the person makes some verbal, motor, or other response. (*See* **Psychophysics**)

The accuracy of the perception of time measured in absolute units, such as seconds, generally decreases as the physical duration of the interval increases. But the accuracy of the perception of time measured in relative units (the proportion of the physical duration) is roughly constant over a wide range of intervals from fractions of a second to hours. The increment in physical time required to produce a particular change in perceived time in some experiments with human participants has been found to be about 5 percent of the physical time. This ratio has been called the Weber fraction, and the rule that it is approximately constant is an example of Weber's law. Deviations from constancy, such as a higher Weber fraction at very short intervals and low fractions at certain intervals such as the circadian range of about 24 hours, has provided evidence regarding the biological mechanisms responsible for the perception of time.

Because the psychophysical methods used for the study of the perception of time involve measurements of behavior as a consequence of physical input, such as the interval between two events, they can be used with nonverbal animals. For example, a rat or a pigeon can be readily trained to make one response if a noise stimulus is short (such as two seconds) and another response if a noise stimulus is long (such as eight seconds). The training consists of rewarding a correct response, but not an incorrect response. Then stimuli of intermediate durations can be added. The probability of the long response (the response that was rewarded following an eight-second stimulus) increases as a function of the duration of the stimulus. This is evidence that animals perceive the duration between two events – in this case, the onset and termination of the noise stimulus. Similar experiments with human participants have produced similar results. The similarities between humans and other animals are more than superficial because the relationships between the stimulus duration and the response have many of the same characteristics. For example, these functions are approximately the same for different stimulus ranges when time is examined in relative units (Weber's law); the duration that individuals are equally likely to call short or long is approximately at the geometric mean between the original training durations. Such similarities have led to the hypothesis that humans and other animals use similar mechanisms for the perception of time. (*See* **Animal Cognition**; **Animal Learning**)

TEMPORAL INTEGRATION

With the ability to estimate time intervals, people and other animals are able to choose rewards that occur immediately in preference to those that occur only after some delay. For example, a rat in a maze with two paths will choose the path that leads immediately to food rather than the one in which it receives food only after some delay interval; and a pigeon in a box with two plastic disks will peck the one that leads to immediate rather than delayed delivery of food. Of course, the preference for immediate food can be reduced by delivering substantially more food if the animal chooses the delayed reward. The choice of a larger, more delayed, reward has been called 'self-control', and the conditions influencing it have been studied extensively.

In foraging situations, an animal may obtain many rewards spread over time in some irregular manner. In some patches the rewards may occur at a higher rate than in others, and the animals tend to choose the patch with the higher reward rate. The behavior is often well characterized by the 'matching law' such that the proportion of time spent in each patch is equal to the proportion of rewards obtained in each patch. The basis for this behavior may be related to the way in which animals combine the many times between successive rewards. For example, animals choose a situation in which food occurs at random times over one in which food occurs at fixed times at the same average frequency. One proposal is that they average the local rates of food delivery, rather than the times between food deliveries.

TIMING AND ASSOCIATION LEARNING

Until recently, the study of time perception and classical conditioning have had quite separate histories. The origin of the study of time perception was in the psychophysical laboratories, in which investigations were made of the effect of various conditions on the accuracy of temporal judgments. The conditions included variations in the stimulus to be judged, other task variables, and drug effects. Most of the research was conducted with human participants. In contrast, the origin of the study of classical conditioning was in the learning laboratories of Pavlov, in which investigations were made of the conditions affecting the acquisition of performance of a particular response. The research was conducted on animals. Many of the animal studies of association learning involve time perception. (*See* **Conditioning**; **Learning, Psychology of**)

Pavlov's experiments were based on salivary conditioning of dogs. They involved the presentation of stimuli (visual, auditory, or tactile conditioned stimuli) and reinforcements (unconditioned stimuli, such as food), and the recording of responses (salivary responses). Temporal conditioning involved the presentation of the reinforcements at fixed times. This procedure led to salivation primarily near the end of the interval – a result that indicated that the time interval between successive reinforcements was serving as a stimulus. Another procedure, delayed conditioning, involved the presentation of a reinforcement after a stimulus had been ongoing for a particular length of time. This procedure also led to salivation primarily near the end of the interval – a result that indicated that the time interval from the onset of the stimulus serves as a stimulus. These, and many other, procedures used by Pavlov provided convincing evidence that a stimulus change can serve as a time marker and that the behavior of animals can be related to the time following a time marker. The conclusions of Pavlov have been verified and greatly extended by subsequent research with other animals (mostly rats and pigeons, but also many other species) on a wide variety of classically conditioned responses.

OSCILLATORS, INTERNAL CLOCKS, AND OTHER METHODS OF KEEPING TIME

Although people can approximate the time without the use of external aids, they can do so much more accurately with the use of clocks. As needs have arisen for synchronization of activity and other purposes, increasingly accurate and smaller timekeeping devices have been developed and become available to people. Although these are human inventions designed to solve particular problems, it is possible that these engineering solutions used some of the same features that have evolved into an internal, biological, clock.

One type of internal clock that has been proposed consists of a pacemaker, a switch, and an accumulator. The pacemaker emits pulses with some mean rate and distribution form; the switch is either open or closed, and when the switch is closed the pulses are sent to the accumulator. The perceived duration that the switch was closed is represented by the number of pulses in the accumulator. Another type of internal clock that has been proposed consists of an oscillator that has some mean period. The perceived duration is the phase of the oscillator (or the phase difference, if the oscillator is not reset

at the onset of the time marker). Any process that regularly changes as a function of time following a time marker provides the basis for an internal clock, and many other processes have been proposed. In addition to a single accumulator, oscillator, or other function, a time marker may elicit multiple processes such that the perceived duration is the state of all of these functions.

The relationship between an internal clock for the perception of durations between arbitrary intervals and a circadian clock is uncertain. The circadian clock is an oscillatory process with a period of about 24 hours that can be entrained to light that occurs within a few hours of this period, and that can run freely at about that period even in a constant environment without periodic cues. The phase of a circadian clock provides a time-of-day that can be used as a discriminative stimulus, and such periodic processes may be involved in the timing of arbitrary intervals. (*See* **Circadian Rhythms**)

An internal clock mechanism provides a representation of the time, but it is not sufficient for timed performance. This requires a temporal memory and decision process. On the basis of previous experience, temporal memory stores the perceived time of previous reinforcement. The decision to respond is based on a comparison of the perceived time (from the internal clock) and the remembered time (from temporal memory). If these two values are close enough, a response is made; otherwise it is not.

Quantitative models of timing involve specific assumptions about the perception of time, temporal memory, and decision processes. One example is *scalar timing theory* that makes explicit assumptions about the internal clock as a pacemaker–switch–accumulator system, temporal memory as a memory of specific examples, and a decision process that involves a ratio comparison of the current value in the accumulator and a random sample of a value from temporal memory. Another example is the *behavioral theory of timing* that makes explicit assumptions about the representation of time as a behavioral state and temporal memory as based on the strength of each of the behavioral states due to their frequency of reinforcement. The goal of these theories is to provide a simple and accurate description of behavior in a wide range of conditions.

CONTENTS

Spatial representation as registered in vision and language appears to be sensitive to topological properties, which are among the most general spatial properties.

INTRODUCTION

We can see that a smiling face changes smoothly into a sad face; we can appreciate the difference between stretching an object and tearing it apart; we can distinguish between an object's being inside or outside another; we see the difference between a pretzel and a donut, or between a broken and a whole glass; we can understand that in a sense the letter B has the same configuration as the digit 8 and that both differ from the digit 2. In all these cases, we acknowledge the topological structure of the scene we perceive or think about. Some important topological properties and relations are those of continuity, interior, exterior, tangential part, boundary, and the presence and number of holes. Such properties have attracted the interest of cognitive scientists, as they may also implicitly enter into descriptions or explanations of cognitive performances. In a visual scene, our ability to distinguish between an area corresponding to a figure and an area corresponding to the background is related to the fact that the figural area is assigned the boundary. Sensitivity to subtle topological differences has been proposed as an explanation of our understanding of spatial prepositions such as 'across' or 'between'. Some psychological theories explain children's understanding of physical objects in terms of sensitivity to topological properties.

A consideration of topological properties seems to be required to account for some of the contents of spatial representation. However, there has so far been no systematic study of topology in cognition. This article will concentrate on some aspects of current research on cognition where topological notions and properties play a key role, whether as subject matter of explicit judgment, or as hidden components of psychological explanation. Although the visual and the linguistic domains will be our main focus, topology enters into the study of other faculties. For instance, haptic continuity has been described, and in the domain of action it has been proposed that reaching is guided by the hypothesis that objects move on continuous paths. In the auditory domain one can find loose analogies for the notion of contact (such as collisions, which may be heard).

We will not discuss the various applications of topology in cognitive science, such as the topology of neural networks, or the topology of color and other quality spaces: these are instruments for studying cognition, not objects of cognition.

WHAT IS TOPOLOGY?

Topology as a branch of mathematics focuses on basic abstract spatial properties. For example, topologically, a square and an ellipse are equivalent. Roughly, topological properties are those that are not altered by 'distortion' and 'stretching'.

In general, we can classify the geometric properties of a shape by noting whether they are preserved in some classes of transformations. Thus, copying or rotating a square will preserve all of its shape properties, such as the length of its sides or the size of its angles. Stretching a quadrilateral may change its angles and the lengths of its sides; therefore, these are not topological properties of the quadrilateral. The transformation that carries a square onto an ellipse seems to destroy all geometrical properties of the square. The square is no longer 'recognizable'; yet some of its properties are preserved in the ellipse. Both the square and the ellipse are closed curves. The projection on the ellipse of a set of points with a certain order on the square will have the same order on the ellipse.

The order of points is not altered through distortion and stretching, and counts as a topological property of the square.

Cognitive science deals with relatively simple and intuitive topological properties of objects, such as being in one piece, or having holes. The mathematical theory of topology encompasses situations that are not as easily graspable as the above examples, but the basic idea is simple. A topological characterization of a set S of 'points' is defined in terms of subsets of S. Subsets of S allow one to separate points of S.

Formally, a 'topology' on a set S is a set T of subsets of S, containing both S itself and the empty set which is closed under arbitrary unions and finite intersections.

A 'topological space' is a set S with an associated topology T. A given set S can have many different topologies, with a different discriminatory power. The 'discrete topology' consists of all subsets of S, and is able to discriminate all points in S.

Continuous functions between topological spaces may be defined in terms of 'neighborhoods' (a generalization of the metric notion of distance). In this way, the notion of a topological space becomes a tool for classifying remarkable properties of figures. A topological space is 'connected' if in its topology no two disjoint nonempty sets exist whose union is the whole space. A topological space S is 'path-connected' if for any two points a and b in S there is a continuous path (that is, a continuous function from the closed unit interval [0,1] to S) whose extremes are a and b. In general, there will be many paths connecting any two points of a path-connected surface. These paths can be grouped into 'homotopy' classes (two paths in the same homotopy class can be transformed into one another via a continuous mapping). If there is only one homotopy class, the space is said to be 'simply connected'.

For instance, a sphere is simply connected. Consider paths whose ends coincide (i.e. loops). Many loops will pass through a given point on a sphere, but they are all homotopic, as they can all be continuously shrunk to a point. On the other hand a toroidal (donut-shaped) surface is not simply connected: not all loops through a given point can be shrunk to a point. Nor is a plane from which a finite portion has been removed.

In general, surfaces can be classified in terms of the homotopy classes of the loops we can draw on them. The presence of distinct homotopy classes in a space intuitively indicates the presence of features that prevent loops from shrinking. These features are typically holes and handles.

RELEVANCE OF TOPOLOGY TO COGNITION

Topology enters cognitive science as the object of a special, indeed fundamental, case of spatial representation. Topology-related spatial representation can be isolated within the class of 'non-immersed' spatial representations, as opposed to immersed representations such as 'to the right of', whose interpretation depends on a viewpoint embedded in the representation (be it object- or view-centered). For instance, 'is one meter long' or 'is inside the box' are non-immersed representations, as their applicability is not affected by changes in point of view. This ball is or is not inside this box no matter how we look at these two objects, whereas this ball is to the right of this box only from a certain viewpoint.

Within the class of non-immersed spatial representations one can further distinguish the representations that are size- and shape-related from those that are not. We can perceive and make judgments about spatial facts without necessarily having to assess the size and distance of the objects involved. One can, for instance, judge that John is between Paul and Mary without accessing any specific metric information concerning the relative sizes and distances of these three people. Typically, topological representation abstracts from size and shape. Moreover, the output of a topological judgment is discrete (e.g. 'yes' or 'no') whereas the output of a metric judgment is continuous.

Topological properties appear to be required to describe some of the contents of spatial representation. But do we possess an implicit knowledge of topology? At what level is this knowledge accessed, and how is it used? Are topological relations computed 'online' at some level?

We can distinguish here two types of evidence: direct evidence, from personal or sub-personal assessment of topological facts, and indirect evidence, stemming from an analysis of data that do not concern an explicit topological representation but seem to require some access to topological representation or processing.

Direct Evidence for Topological Analysis

Consider an object such as the Möbius strip (a long rectangular strip one of whose ends has been twisted by 180° and glued to the other end) (Figure 1). If one is asked to predict the result of cutting it along its median line (a line running

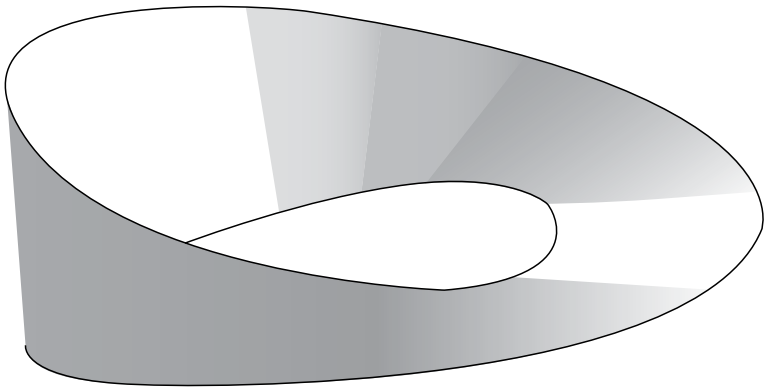

Figure 1. The Möbius strip.

parallel to its borders), one may predict that two strips will result. Actually, one gets one doubly-twisted Möbius strip. The border of a Möbius strip is strange. It contravenes the intuitive principle that a border must separate two sides, so that one cannot reach one side from the other without crossing the border.

Exposure to some technical topology does not, by itself, correct one's propensity to misjudge some topological facts. Those who understand and master simple topological tasks, such as the detection of the topological equivalence between a sphere and a cube, or of a donut and a cup of coffee, may be unwilling to accept that a cylindrical surface (such as the portion of a tube) and a disk with an internal portion removed (such as a CD) are topologically equivalent. (Popular topology books emphasize the oddity of the topological equivalence among objects that look utterly different.) The situation is reminiscent of intuitive physics. It has been found that subjects' understanding of Newtonian physics is blocked by their implicit and automatic reliance on an intuitive theory that is at odds with Newtonian physics. Analogously, there may exist an 'intuitive topology' that prevents us from appreciating actual topological equivalences (or non-equivalences).

Intuitive topological classification may be a by-product of independent criteria of classification that emphasize some other spatial aspects of objects, such as the presence of holes, conceived as objects in themselves (Casati and Varzi, 1994, 1999), or else of higher-order physical principles that dictate plausible shapes for physical objects. Sub-personal direct evidence is methodologically problematic, because of the generality of topological properties. Experimental designs may be insufficiently fine-tuned to detect sensitivity to topological structure. For instance, in experiments about numerosity, a test display with two black spots may follow a habituation setting in which a single black spot is present. Sensitivity to the change can be related to a sensitivity to numerosity (implying a sensitivity to disconnection, hence to a topological property of the setting) but it may as well reflect a sensitivity to the overall quantity of blackened space or to the overall length of the perimeter of the two spots. The experimental setting should control for some of these factors, but topological properties are so basic and ubiquitous that almost any factor interferes with them.

There is evidence that perceptual priming can be independent of size, location, and orientation (Biederman and Cooper, 1990, 1992). Therefore, recognition processes can abstract from these spatial features of objects. Does abstraction go all the way down to the most basic, topological features? Experiments so far have provided little evidence. Chen (1982, 1990) proposes that the extraction of topological properties is one of the primary functions of the visual system. This claim may be supported by the experimental finding that subjects are better at discriminating pairs of topologically distinct figures than pairs of topologically similar but metrically distinct figures, and by the occurrence of illusory conjunctions in displays that involve holes. However, it has been pointed out (Rubin and Kanwisher, 1985) that other factors (such as differences in luminous flux and in the overall perimeter of the figures) could account for most of these results.

Indirect Evidence for Topological Analysis

If sensitivity to topological structure is difficult to assess directly in relation to configurational properties of perceptual displays, it is nevertheless

possible to postulate that some mechanism for evaluating the topology of the display is activated in visual perception.

Some cognitive abilities do not relate directly to topology, but turn out to presuppose sensitivity to the topological parsing of a scene. We shall consider, in turn: the assessment, at personal level, of object unity; the sub-personal segregation of perceptual units; part–whole parsing; infants' mastering of the notion of a physical object; and representational advantages. Further evidence related to language will be discussed afterwards.

Personal assessment of object unity

The display in Figure 2 could be described in two mutually incompatible ways: as two black objects, one on the left and one on the right; or as one black object, partly on the left and partly on the right.

Although the second description sounds utterly artificial, there are no obvious reasons for ruling it out. It seems that in judging what counts as one object in the display we rely on background assumptions concerning some topological properties of the display itself: there are two mutually disconnected black patches, each of which is maximally self-connected. This suggests that we use connectedness as a criterion of unity, and that the visual system is able to compute it. If topology biases the choice, this in turn entails that cognition takes topology into account.

However, topological self-connectedness is not always interpreted as a necessary and sufficient condition for unity. Two juxtaposed objects may count as two even though they are connected; and some kinds of causal unit (such as two objects in coherent motion) may not require connection.

Segmentation of the visual field

Gestalt psychologists have proposed an explanation for perceptual organization (e.g. figure–ground articulation) of the visual field in terms of our tendency to group perceptual units according to principles such as similarity or relative proximity. Perceptual units are discrete elements that are put together and considered as parts of superordinate units in virtue of some organizing factors. However, this account takes for granted the formation of the perceptual units that get grouped, the 'atoms' of the visual field. Palmer and Rock (1994) claim that these units are regions of the visual field that are 'uniformly connected'. Uniform connectedness is not a principle of grouping, insofar as it does not presuppose units but creates them, and so it must operate prior to any grouping activity.

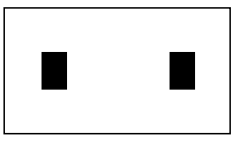

Figure 2. Two black objects or one disconnected black object.

For example, consider Figure 3, in which dotted lines demarcate various regions of the display (they are not part of the image). In (e) the demarcated region is the total black area, and in (f) it is the total white area.

What makes the left black rectangle in Figure 3(a) a "unit", whereas the areas delineated in Figure 3(c) and 3(e) do not correspond to unitary objects? A simple answer is that the area in 3(a) is both uniform (it is all black) and connected (it is a piece). The area indicated in Figure 3(c) is connected, and that indicated in 3(e) is uniform, but neither is a perceptual unit. The areas indicated in Figures 3(b) and 3(d) are uniformly connected, but even they are not perceptual units. One must add the condition of maximality: an image is partitioned into maximal self-connected regions of uniform quality. Note that the complement of the total black area in Figure 3(f) is maximally uniformly connected, and so counts as a unit.

The notions of object unity and unit formation are subtle. Should two regions that are tangent on a point be taken as one region or two? Shape may sometimes influence judgments about unity. Moreover, a 'unit' can still have clearly demarcated parts depending on its shape (if we connected the two black regions with a black line, we would obtain a unitary object with salient parts).

Part–whole parsing

Parsing is the labeling of some perceptual items as salient parts of other items. (Not all parts of a perceptual unit need be salient at all.) Thus, parsing is subsequent to unit segregation. It may follow topological principles, though topological properties and relations are cognitively intertwined in a complex way with part–whole relations. Attempts to reduce topological connectedness to part–whole relations have only shown once more the bias towards topological unity. One may think that the two boxes in Figure 2 are disconnected because any 'bridging' object that has parts in common with them will have parts in common with their complement. But this is so only if the bridging object is a connected unit. If one accepts disconnected units, one may have

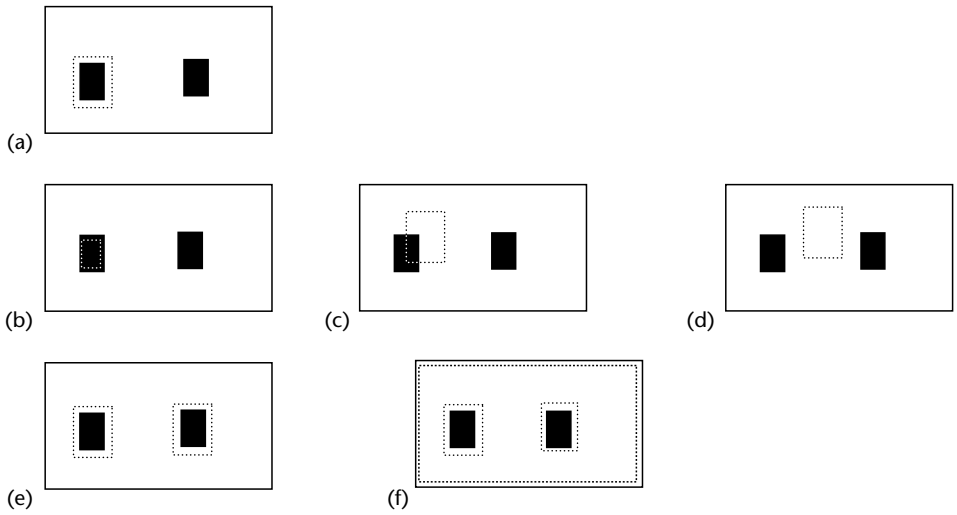

Figure 3. Various candidate 'perceptual units' of a display. Dotted lines demarcate regions of the display (they are not part of the image). In (e) the demarcated region is the total black area; in (f) it is the total white area.

a disconnected bridging object that is exactly composed of the two boxes.

Part–whole relations hold between entities that may not be labelled as salient parts, such as a square and its top half. Surely, a disconnected object such as a broken glass has as many salient parts as there are self-connected units composing it. But a self-connected object may still have salient parts that are individuated by the geometry of the object, typically by concave discontinuities on an object's contour (Hoffman and Richards, 1984). A V-junction is a topologically unitary object and is topologically equivalent to a U; but unlike the U it is parsed as the conjunction of two elements. Similarly, the topological identity of a Y-junction and a T-junction can be overruled by their configurational differences, so that we do make a difference and consider the Y as composed of three bars and the T of two bars.

Physical objects in infant cognition

Infants appear to divide up the world into objects according to some basic principles (Spelke, 1990). In particular, objects are assumed to move along continuous paths, and to interact if and only if they are in contact. These principles require that infant cognition take into account topological features, such as contact and continuity, though not necessarily an explicit perceptual representation. For example, a hidden connection may be inferred from a display if there is an occluder in view.

Same-object advantages

Subjects are faster and more reliable at assessing local changes within a unitary object than they are across disconnected objects. This 'same-object advantage' means that topological unity is relevant at the sub-personal level.

TOPOLOGY IN LANGUAGE

Linguistic data provide a further body of indirect evidence for topological evaluation. English contains a vast number of geometry-related terms for spatially describing objects ('square', 'circle') and properties ('circular'). In principle, we can describe countless shapes by simply building a predicate that mentions an object having that shape ('star-shaped'). Some linguistic uses, though, presuppose an appreciation of rather abstract geometric properties. For instance, the correct use of the preposition 'in' largely abstracts from the shape and size of the objects that stand in the corresponding relation. A fish can be in a pool and in the same sense of 'in' a submarine can be in the ocean.

A broad distinction between two general classes of linguistic items, the open or lexical class and the closed or grammatical class, is believed to reflect two levels of cognitive generality (Talmy, 2000). Membership of the open class is subject to great variability, whereas membership of the closed class is rather fixed. Grammatically significant items (prepositions, suffixes, prefixes, etc.) cluster in the closed class. For instance, prepositions rarely get added to or disappear from English ('betwixt'). A popular hypothesis is that closed-class items tend to capture general facts of cognitive import. This would explain the stability of the class over time. In particular, only certain concepts are

expressed by items in the closed class, and these concepts have a cognitive structuring role. Language does not have grammatical expressions for size, shape, or color. There is no preposition that can be used to convey the idea that an object is square or red. By contrast, the presence of a plane so curved as to define a portion of space is conveyed by uses of the preposition 'in', and these uses abstract from size ('in the thimble', 'in the volcano') and shape ('in the well', 'in the trench').

An important subclass of these 'structuring' concepts concern space and spatial properties and relations that are shape- and size-neutral, as in the example of 'in' above. Similarly, in the sentence 'I walked through the woods', the preposition 'through' expresses a concept that is indifferent to the shape and size of the path followed. These abstract concepts come close to the abstract notions of topology; and it has been suggested (Talmy, 2000) that there could exist a language-based topology whose notions are akin to those of mathematical topology. The notions of this language-based topology would include the notions of point, linear extent, locatedness, withinness, region, side, partition, singularity, plurality, sameness, difference, and adjacency of points. It can be argued that topology as a mathematical theory is a normative refinement of these notions. However, not all topological relations are lexicalized. Thus, there are words for three-place relations, such as 'between', but not for four-place relations.

THEORIES OF TOPOLOGICAL REPRESENTATION

Topological Classification

Topology as a mathematical theory provides a classification of objects' shapes. But cognition does not appear to match closely the classification provided by mathematical topology, except for some very simple surfaces (as demonstrated by the counter-intuitiveness of many topological equivalences). So far there has been no systematic study of the classifications endorsed by cognition. One hypothesis is that shapes are classified in terms of the number and position of holes (tunnels, indentations), where holes are counted as parts of the object or as objects in their own right.

Schematic Spatial Representation

Linguistic representation appears to be relatively independent of the size, the shape, and often the type of the object represented. It has been proposed that the language system may access a particular level of spatial representation, the level of geometric schematization, which is also interfaced with the visual system (Herskovits, 1997). At this level objects are assumed to be represented by simplified geometric schemata that may or may not take into account their metric properties. The structure of prepositions can be used as a heuristic for the study of the level of schematization. How does language access this level? According to Herskovits, prepositions do not refer to schemata, but express constraints on allowable schemata. It is an open question how a proposition such as 'the ball is in the box' is evaluated. Possibly the evaluation relies on a computation performed at the schematization level that answers a 'command' from the linguistic system.

Online Computing

If topological facts are computed at some level in spatial representation, the problem arises of finding the mechanisms that do the computing (Ullman, 1996). Various algorithms have been proposed. For instance, a simple routine to find out whether two marks lie on the same line or on different lines may explore the line starting from one mark (first in one direction and then in the opposite direction) and stop at an endpoint or at the other mark. In order to determine whether a given point is within or without a certain closed region, a 'filling-in' algorithm can color the field starting from the point until the boundaries of the shape are met.

Algorithms of this sort may be too powerful, delivering definite answers where the visual system does not. For instance, in Figure 4, we may not be able to decide whether point *a* is inside or outside the closed curve, or whether point *b* is on the same line as point *c*, whereas a filling-in

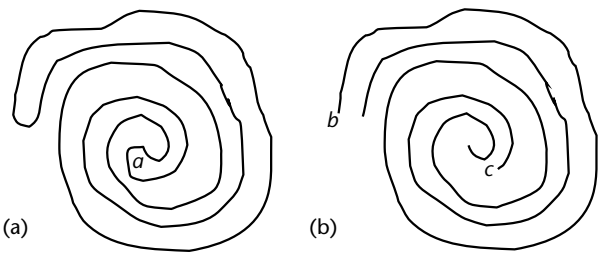

Figure 4. The visual system may not be able to decide (a) whether the point *a* is inside or outside the closed curve, or (b) whether points *b* and *c* are on the same line.

algorithm or line-exploring algorithm, respectively, would deliver a definite answer.

From the fact that topological properties are basic and ubiquitous it does not follow that their determination is simply accomplished. Minsky and Papert (1988) argue that evaluating topological properties may be a complex task. They discuss the limitations of perceptrons, devices capable of assessing whether a given configuration satisfies a given predicate by computing the linear (purely additive) results of collections of weighted predicates, each of which is true or false locally (say, a nonmaximal cell assembly on a retinal sheet). They prove that some spatial predicates, such as 'is convex', can be easily computed by perceptrons, but others, such as 'is connected', are resistant to computation for most classes of perceptrons, and may be computed only by fairly complex systems.

Vision: Early Psychological Processes

Intermediate article

Patrick J Bennett, McMaster University, Hamilton, Ontario, Canada

CONTENTS

Early visual processes encode the spatial and temporal distributions of light intensity in the two retinal images that carry information about the arrangement of surfaces in a scene. These early processes are important for visual perception because they constrain higher-level processes such as object recognition.

INTRODUCTION

Vision is a process whereby the information contained in the two retinal images is used to create representations of the layout of surfaces in a scene. These representations are derived from various sources of information (e.g., the spatial arrangement of image contours, patterns of retinal motion, gradients of texture, etc.) and are used for a variety of purposes, including object recognition, regulation of posture, and the control of reaching and grasping movements.

This diversity of tasks and information sources means that it is unlikely that visual processing is performed with a single set of algorithms or representations. Instead, there is ample evidence to support the view that the primate visual system consists of a collection of modules, each specialized to use a particular source of information to perform a specific task (Marr, 1982). Nevertheless, it is important to note that all such modules ultimately depend on an accurate representation of the structure in retinal images. The primary function of early visual processes is to create this initial representation by first detecting changes in intensity that produce contours in the retinal image, and then encoding the size, orientation, and motion of these contours. These early processes must create a rich and detailed representation of image structure, because information that is lost in these initial stages will constrain higher-level processes such as object recognition.

SENSITIVITY OF THE EYE

Sensitivity to changes in intensity depends on many factors, including stimulus size, duration, wavelength, position on the retina, and intensity of the background. In a classic paper (Hecht *et al.*, 1942), Hecht and colleagues adjusted these factors to create viewing conditions that maximized sensitivity, and they found that human observers could reliably detect spots of light that delivered 50–150 quanta to the surface of the cornea. Taking into account the number of quanta that were reflected and absorbed by the pre-retinal media, this just visible stimulus results in 5–15 quanta being absorbed by rhodopsin, which is the photopigment contained in rod photoreceptors. Because the retinal image of the spot covered approximately 500 rods, the probability of any single rod being stimulated by two or more quanta was very low, so Hecht and colleagues concluded that a single quantum is sufficient to produce a response in a rod. It was not until 35 years later that this startling result was confirmed by physiological measurements.

Such exquisite sensitivity offers tremendous advantages in conditions of dim illumination, which probably explains why rods that respond to a single quantum are common among vertebrates. However, it also presents a problem, namely how the large range of visual inputs can be represented by sensitive neurons that have a limited dynamic range. The range of light intensities that we encounter in our natural environment is enormous (approximately 12 log units), but visual neurons respond differentially to light only over a much narrower range. To overcome this problem, the visual system has multiple mechanisms for adjusting sensitivity to match ambient light levels. These mechanisms underlie the phenomena of dark and light adaptation.

ADAPTATION

If you walk into a dimly lit theater after being outside in bright light, everything appears dark. However, after a few minutes your eyes adapt to the darkness and it is surprisingly easy to perceive objects. Conversely, you can be dazzled by bright sunshine after emerging from the theatre, but your eyes adjust rapidly. Recovery of sensitivity in total darkness is referred to as dark adaptation, whereas recovery of sensitivity to a non-zero background of light is called light adaptation. In both cases, the time needed for recovery is a function of the change in illumination, but dark adaptation is typically a much slower process. Complete dark adaptation occurs within several minutes after exposure to moderate intensities of light, but requires more than 30 minutes after exposure to a very bright flash. The amount of adaptation can be substantial. After exposure to a bright light, the detection threshold can drop by more than a factor of 10 000 after about 30 minutes in the dark (Figure 1).

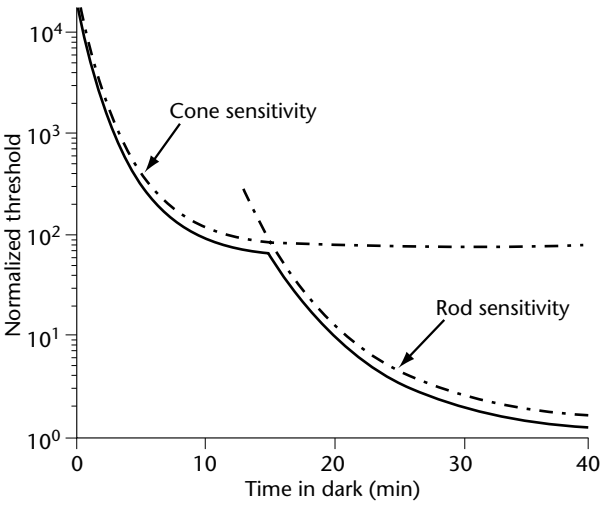

Figure 1. The effects of dark adaptation on detection threshold after exposure to a very bright light. A typical experiment begins with the observer looking at a large bright uniform light for several minutes. At time zero, the uniform light is extinguished and the observer must detect a small spot of light presented against a dark background. The detection threshold is measured periodically, and the solid curve illustrates how it changes as a function of time in the dark. In this graph, the threshold has been normalized so that the lowest threshold has a value of 1. Notice that the threshold declines rapidly during the first 5 minutes, levels off at around 10 minutes, and then drops again after approximately 15 minutes. Over a 40-minute period, the threshold declines by more than four log units. Occasionally it is possible to test observers who lack rod photoreceptors (and who therefore have vision mediated solely by cones), and observers who lack cones (and who therefore have vision mediated entirely by rods). Dark adaptation curves for these two types of observers are illustrated by the broken curves labeled *cone sensitivity* and *rod sensitivity*, respectively. It can be seen that cone-mediated vision adapts quickly but levels off at a high threshold, whereas rod-mediated vision adapts relatively slowly but eventually reaches a much lower threshold. Dark adaptation curves for normal observers contain both cone- and rod-mediated components.

Mechanisms of Adaptation

The pupil area decreases by a factor of 16 as illumination is changed from very dim to very bright levels. This change in size contributes to adaptation, but it is much too small to compensate for the enormous changes in illumination that are encountered in natural conditions. Clearly, other mechanisms must contribute to adaptation. One obvious possibility, outlined by Selig Hecht in a series of papers in the 1930s, is that the visual threshold is proportional to the amount of bleached photopigment in the retina. During Hecht's time it was known that absorption of light causes a photopigment molecule to change shape, thereby rendering it insensitive to light, and that a series of biochemical processes converted photopigment from this bleached state back to a light-sensitive state. With proper adjustment of these rate parameters, which were unknown at the time, Hecht's photochemical theory was able to account for a wide range of adaptation data. However, we now know that the photochemical theory is incorrect. Measurements of the proportion of bleached photopigment in the living eye have shown that threshold and bleached pigment are related logarithmically, not linearly as predicted by the photochemical theory. In other words, very small changes in the proportion of bleached photopigment produce very large changes in the visual threshold (Cornsweet, 1970).

The failure of optical and photochemical factors to account for adaptation led to the search for neural adaptation mechanisms. One way of solving the dynamic range problem is to stagger multiple neural mechanisms that differ in sensitivity. The visual system certainly adopts this strategy, with rods mediating vision in dim light (i.e., scotopic conditions) and cone photoreceptors operating in brighter light (photopic conditions). Dark adaptation experiments provided evidence for this duplex retinal organization by showing that the threshold does not drop monotonically as a function of time in the dark. Instead, it first drops rapidly and then levels off. After about 10–15 minutes,

the threshold begins to decline once more. A great deal of research with human observers who lack rods or cones, as well as experiments using techniques that isolate rods or cones in normal observers, has demonstrated that the first and second stages of dark adaptation reflect changes in cone and rod sensitivities, respectively (Figure 1).

Although the duplex retinal organization contributes to adaptation, it cannot be the whole story because significant adaptation occurs within the scotopic and photopic regimes. Thus theories of adaptation have postulated one or more gain control mechanisms that adjust the sensitivity of the scotopic and photopic systems. At least part of this gain control exists in the retina, because adaptation can occur separately for each eye. Physiological recordings in the cat have shown that changes in illumination shift the dynamic range of retinal ganglion cells, so that the cells continue to give differential responses across a wide range of light intensities. Physiological recordings suggest that rods and cones in the mammalian retina do not adjust their dynamic range in response to changes in illumination, so post-receptoral mechanisms must contribute to adaptation in ganglion cells. The details of this mechanism are still unknown.

Weber's Law

The high sensitivity reported by Hecht and colleagues (Hecht *et al*., 1942) occurs only when the target is presented against a dark background. As the intensity of the background (I_b) increases, adaptation processes reduce the visual sensitivity so that the change in intensity (ΔI) necessary to detect an object is proportional to the background: $\Delta I = kI_b$. This relationship between threshold and background is known as Weber's law, and it implies that the visibility of an object depends on the ratio of object to background intensities. A common measure of stimulus contrast is $\Delta I/I_b$, so another way of stating Weber's law is to say that pattern visibility depends on contrast, not intensity.

At first glance, this law appears to make perception more difficult, because a just noticeable difference in intensity increases with background intensity. However, Weber's law in fact makes it easier to recognize objects under different levels of illumination. To illustrate this point, consider what happens when we change the intensity of illumination that is falling on an object presented against a uniform background. Let the intensities of the light coming from the object and background be I_o and I_b, respectively, and the intensity difference ($\Delta I = I_o - I_b$) be set to detection threshold. Changing the intensity of illumination alters the object intensity (I_o), the background intensity (I_b) and the intensity difference (ΔI), but the stimulus contrast ($\Delta I/I_b$) remains constant. Thus the fact that sensitivity obeys Weber's law means that contour visibility remains approximately constant across a wide range of illumination levels.

CONTRAST SENSITIVITY FUNCTION

Classical studies of visual sensitivity used very simple stimuli (usually a spot presented against a uniform background) to probe early visual processes. However, it is known that the detection threshold is strongly dependent on the spatial distribution of contrast in a stimulus. For example, the visibility of circular and rectilinear black and white stripes differs dramatically even when the two types of patterns have the same contrast (Kelly and Magnuski, 1975). If the threshold depends on the shape of a pattern, then how can we develop a general characterization of visual sensitivity? One common index of the visual system's sensitivity to spatial patterns is the contrast sensitivity function (CSF). The CSF relates the visibility of a sine-wave grating (a repeating, striped pattern whose intensity varies sinusoidally) to the grating's spatial frequency (Figure 2). For each spatial frequency, threshold is measured by adjusting the grating's contrast until the stripes are just detectable. The CSF plots contrast sensitivity, defined as the reciprocal of the contrast detection threshold, as a function of a grating's spatial frequency (Figure 3).

Sensitivity for sine-wave gratings would seem to have little application to the perception of other patterns. However, such a view would be mistaken. Fourier's theorem implies that any pattern can be represented as the sum of a unique set of sine-wave gratings. Thus the latter can be thought of as a set of elements from which all other patterns can be constructed, with different bands of spatial frequencies corresponding to different types of structure in complex images (Figure 4). Moreover, there is a rich mathematical framework (referred to as linear systems analysis) that can be used to relate the CSF to the perception of arbitrary patterns (Cornsweet, 1970).

Strictly speaking, the application of linear systems analysis requires that the system under study must satisfy certain assumptions. Although the visual system does not satisfy these assumptions in detail, under certain conditions the assumptions are met with sufficient precision for the CSF to be used to characterize the perception of a variety of patterns. For example, the shape

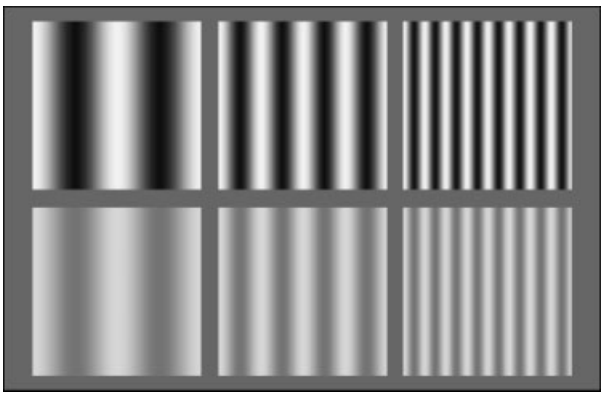

Figure 2. Illustrations of sine-wave gratings at three spatial frequencies and two contrasts. Spatial frequency (the number of stripes per unit distance) is 2, 4 and 8 cycles per image in the left, middle and right panels, respectively. Sine-wave grating contrast is commonly defined as $(I_{max} - I_{min})/(I_{max} + I_{min})$, where I_{max} and I_{min} are the maximum and minimum grating intensities, respectively. High and low contrasts are shown in the top and bottom rows, respectively. A grating with zero contrast is a uniform gray field. It is important to note that changing contrast does not alter the total amount of light in the stimulus, and therefore grating detection depends on encoding the pattern of light, rather than total intensity.

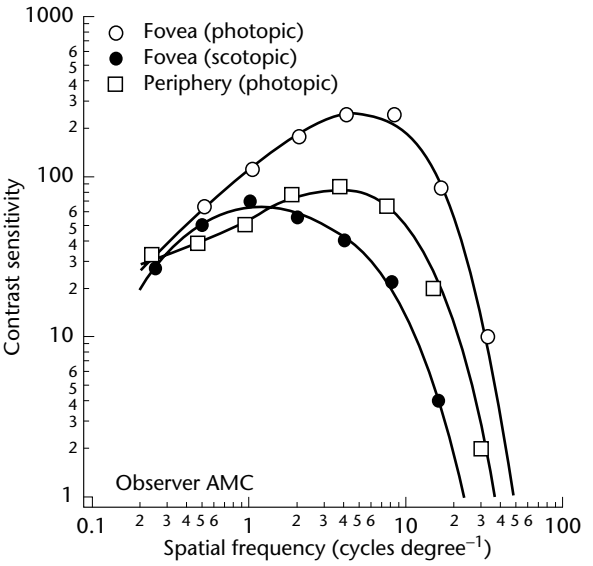

Figure 3. Contrast sensitivity functions measured in three conditions in one observer. The patterns were sine-wave gratings presented within a circular aperture (diameter = 4 degrees of visual angle), presented either directly on the line of sight, so that the retinal images were centered on the fovea, or 5 degrees below the line of sight in the peripheral visual field. Gratings were presented either on a background that was bright enough to stimulate cone photoreceptors (photopic conditions) or on a dim background that was 2 log units lower in intensity and primarily stimulated rods (scotopic conditions). Contrast sensitivity is defined as the reciprocal of contrast detection threshold. For patterns presented in the fovea and in bright light, contrast sensitivity peaks at approximately 6 cycles degree^{-1} and drops significantly at higher and lower spatial frequencies. Presenting the patterns in the peripheral visual field or against a dim background reduced contrast sensitivity significantly at high frequencies, but only slightly at low frequencies.

of the CSF can be used to predict the image structure that is visible in different viewing conditions. Many studies have shown that presenting patterns in the peripheral visual field, or viewing them in dim light, reduces contrast sensitivity significantly at high but not low spatial frequencies (Figure 3). High spatial frequencies correspond to fine details (Figure 4), so reduced sensitivity at high frequencies implies that only coarse structure will be visible in those conditions. This prediction is consistent with our visual experience, as detailed features of objects are visible only when we fixate them, and visual tasks that depend on fine spatial detail (e.g., reading) are difficult to perform in dim light. It is possible to go beyond these qualitative predictions and use the CSF to make accurate quantitative predictions about detection and discrimination thresholds for a variety of patterns (Campbell and Robson, 1968; Campbell *et al*., 1969; Kelly and Magnuski, 1975). The shape of the CSF has also been important for identifying the constraints imposed by optics and retinal mechanisms on pattern sensitivity (Banks *et al*., 1987, 1991).

FEATURE EXTRACTION

Recovering the three-dimensional structure of visual scenes from images requires more than merely detecting the presence of patterned stimulation. In addition, it is necessary to encode the size, orientation, and motion of pattern elements. There is now abundant evidence that these dimensions are encoded, at least initially, by sets of multiple, feature-selective channels. For example, recordings of visual cortical neurons in monkeys have demonstrated that each location in the visual field is encoded by multiple cells that respond selectively to different spatial frequencies, orientations, and direction and speed of motion. Evidence from many psychophysical studies in humans also suggests that pattern information is processed by feature-selective channels which have properties closely resembling those of cortical cells (DeValois and DeValois, 1988).

It is instructive to consider how one psychophysical technique, based on pattern-selective

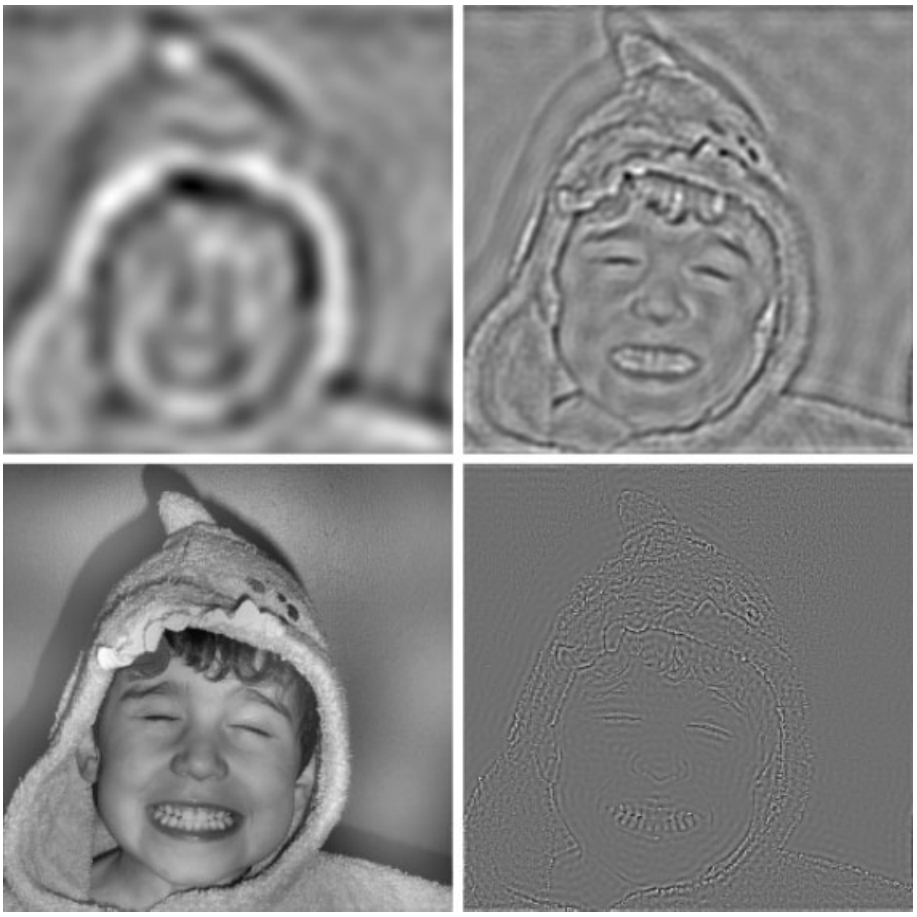

Figure 4. Illustration of the types of spatial structure in natural images that are carried by different bands of spatial frequency. The spatial frequency content for each pattern (moving clockwise from the upper left) is 3–12, 12–48, 48–192 and 3–192 cycles per image. All of the images have the same average intensity, which is referred to as the zero-frequency component. Note that low spatial frequencies carry information about large coarse features, whereas high spatial frequencies carry information about fine details.

adaptation, can be used to probe the properties of feature-selective channels. Blakemore and Campbell (1969) compared CSFs measured before and after an adaptation period during which observers viewed a high-contrast sine-wave grating. They found that adaptation reduced contrast sensitivity significantly, but only for spatial frequencies similar to that of the adaptation stimulus. Reduction in sensitivity after adaptation is a common phenomenon, and presumably occurred because prolonged viewing of a high-contrast grating fatigued the mechanisms that were responding to that stimulus. However, the fact that adaptation was frequency specific implies that the adaptation stimulus evoked responses in some mechanisms but not in others. In other words, frequency-specific adaptation implies that patterns are encoded by frequency-tuned mechanisms. Furthermore, reduced sensitivity was found only for gratings at the same orientation as the adaptation stimulus, so pattern-encoding mechanisms must also be tuned to particular orientations. Finally, Blakemore and Campbell (1969) found that adaptation in one eye reduced sensitivity in the other eye, which suggests that adaptation occurs at or beyond the primary visual cortex, as that is where signals from the two eyes first interact. All of these psychophysical findings – spatial frequency tuning, orientation tuning, and binocularity – are consistent with the known properties of neurons in the primary visual cortex.

These kinds of results suggest that properties such as size, orientation, and motion are represented by distributions of responses across populations of feature-selective mechanisms, and that different populations are responsible for coding different pieces of the retinal image. Any given visual stimulus might activate many mechanisms, but the distribution of activation across

mechanisms will be more or less unique for a particular stimulus. It might seem that there would not be sufficient numbers of cells to construct population codes for all of the information in the retina, but recent analyses suggest that there are enough cells in layer IV of the primary visual cortex to create many complete representations, at least for the part of the retinal image near the fovea. Population codes have several useful properties. They are robust (in the sense that damage to individual cells or channels does not greatly alter the population response), and they make it possible to discriminate much smaller changes in size, orientation, and motion than would be possible by using the output of a single mechanism. Computational advantages such as these might explain why population codes are found in many parts of the nervous system.

CONCLUSION

Visual mechanisms are exquisitely sensitive in dim light, but adaptation processes act to reduce sensitivity with increasing illumination. An important consequence of adaptation is that the visibility of a pattern depends on the relative amounts of light falling in different regions of the image (i.e., contrast), rather than on the total amount of light. However, the visibility of a pattern depends not just on contrast magnitude, but also on the spatial distribution of contrast. The contrast sensitivity function provides an economical account of this dependence of sensitivity on pattern shape, and has been used to predict thresholds for a variety of stimuli. The findings of psychophysical studies suggest that aspects of image contours such as size, orientation, and motion are encoded by multiple, feature-selective channels, the properties of which are strikingly similar to the properties of cells in the primary visual cortex. The result of these early visual processes is a representation of image structure near the fovea that is sufficiently rich to support higher-level visual processes.

CONTENTS

Human vision constructs the perceived two-dimensional and three-dimensional shapes of visual objects and scenes from retinal images that are inherently ambiguous. In the process it consults a variety of sources of information, including motion, shading, texture, occlusion, binocular disparity, and image contours.

INTRODUCTION

The human eye focuses an image onto a light-sensitive sheet of neural tissue called the retina (Dowling, 1987). This image is captured by a discrete array of cells in the retina, called photoreceptors. Each photoreceptor generates a signal which varies in time with the discrete number of photons of light that the photoreceptor catches. This discrete array of time-varying signals is the starting point of vision. The only information this array makes explicit is the varying number of photon catches at each individual photoreceptor. It does not make explicit lines, curves, two-dimensional regions, three-dimensional shapes or any other aspect of the visual forms of objects and their environments. The perception of visual forms is the consequence of sophisticated processes of construction which engage literally billions of neurons and trillions of synaptic connections between neurons. Every line, curve, 2D region or 3D shape that we see is a construction of our visual system, created rapidly starting with just the photon catches at the retina. Vision researchers have made substantial progress in describing the constructive processes underlying the perception of visual form. (*See* **Pattern Vision, Neural Basis of**)

CONTOUR DETECTION

The construction of contours occurs early in the flow of visual processing. In many mammals the primary visual cortex, which is the first stage of cortical visual processing, begins the construction of contours with neurons called 'simple cells', which construct oriented line segments (Hubel and Wiesel, 1959, 1962; Hubel, 1995). These cells construct lines such as the short black lines shown in Figure 1. Computational theories of vision also place the construction of contours early in the flow of visual processing. In the influential theory of David Marr, the flow of visual processing leads to a sequence of visual representations: the primal sketch, the 2½D sketch, and the 3D model (Marr, 1982). The primal sketch makes explicit structure and grouping in the 2D image, the 2½D sketch represents the surface geometry of objects relative to the viewer, and the 3D model represents the volume of objects in coordinates centered in the objects.

The primal sketch contains contours as a key element of the representation. In Marr's theory these are constructed by first linearly filtering the retinal image with a spatial filter whose shape is defined mathematically as the Laplacian of a 2D Gaussian (Marr and Hildreth, 1980). This filter is circularly symmetric, and its shape resembles a Mexican hat. Edges correspond to those places where the values of the filtered output pass through zero. Marr and Hildreth proposed that simple cells in the primary visual cortex are in fact detectors of these zero crossings. Their computational theory of edge detection has been superseded by later approaches that filter the image with spatial filters that are not circularly symmetric, but are designed to optimize the signal-to-noise ratio in the edge construction process (Canny, 1986; Deriche, 1987).

Linearly filtering an image is a key first step in the construction of contours. The steps that come after filtering are complex and highly nonlinear. This is also illustrated in Figure 1: in square 1, one sees not only the short black lines, but also a square with clear edges. The square appears to be slightly

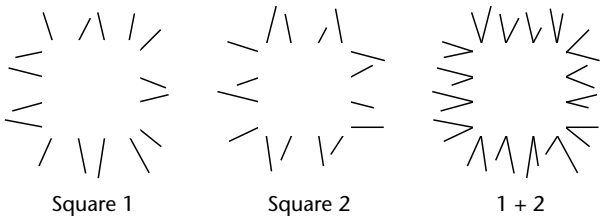

Figure 1. Constructing visual contours is not a simple linear process. In square 1 and square 2 we see a square with clear edges. When these two figures are linearly superimposed, as in the right-hand image, we no longer see a square with clear edges: this is the opposite of what one would expect from a linear process.

brighter than the background. In fact, measurement of actual light intensities would indicate that the white region inside the square is identical to the white region outside the square, and that no edge has been drawn around the square. The brightness of the square, and the clear edges that mark its border, are entirely constructs of the visual system. The square region is called a subjective (or illusory) surface and its edges are called subjective (illusory) contours (Petry and Meyer, 1987). Square 2 also appears to have a subjective square region surrounded by clear subjective contours. If we superimpose square 1 on square 2 so that their subjective squares are perfectly aligned, we obtain the image labeled '1 + 2'. Here the subjective square and subjective contours are weak or missing altogether; this is the opposite of what one would predict if the construction of contours were an entirely linear process (Albert and Hoffman, 2000).

Neurons that signal subjective contours have been found in the primary visual cortex, area V1, of the macaque monkey (Grosof *et al*., 1993) and also in area V2, the next stage of cortical visual processing (von der Heydt *et al*., 1984). Several artificial neural network models have been proposed to explain the properties of these cells (von der Heydt and Peterhans, 1989; Francis and Grossberg, 1996).

THREE-DIMENSIONAL SHAPE FROM IMAGE CONTOURS

The visual system not only constructs 2D contours, it also constructs the 3D shapes of objects and represents these 2D contours and 3D shapes in terms of parts and their spatial relationships. In the process of constructing 3D shape, human vision consults a variety of sources of information, including shading, texture, motion, occlusion, binocular disparity, and 2D contours. (*See* **Object Perception, Neural Basis of**)

Figure 2a illustrates the construction of 3D shapes from 2D contours. The figure uses just a few contours to depict a doughnut shape. The contours are called 'occluding contours' because they depict points where the visible portions of the 3D shape just begin to occlude the hidden portions. Yet these few occluding contours are sufficient to trigger the visual system to construct the smooth 3D shape of the doughnut. Human vision uses several geometric facts and assumptions in the process. The qualitative shape of a 3D object can be described at each point as being convex, concave, cylindrical, or saddle-shaped. Convex regions of a doughnut are denoted by plus signs in Figure 2a, and saddle-shaped regions by minus signs. As can be seen from Figure 2a, the outer occluding contours are in convex regions, whereas the inner occluding contours are in saddle-shaped regions. Jan Koenderink showed that human vision can, in principle, infer the qualitative shapes of smooth 3D surfaces from their projected occluding contours (Koenderink, 1984). The visual system also assumes in this case that the surface varies smoothly between the occluding contours. Since the qualitative shape changes from convex to saddle between these contours, it must be cylindrical at the boundary between convex and saddle. The cylindrical points are indicated by the dashed circle on top of the doughnut. This gives a complete qualitative description of the 3D shape of the doughnut, which Koenderink has shown can be derived entirely from its occluding contours and some built-in knowledge of geometry and projection.

Human vision organizes 2D and 3D shapes into parts as an aid to recognition, manipulation, and naming. It often uses concave regions, and especially points of highest magnitude of curvature

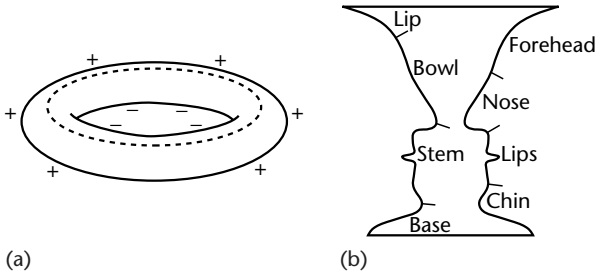

Figure 2. (a) Human vision can construct 3D shapes from simple 2D drawings of contours, as illustrated by the doughnut in this figure. (b) Human vision has rules for carving 2D curves and 3D shapes into parts. In the face–goblet ambiguous figure these rules divide the faces into parts corresponding to the forehead, nose, lips and chin; they divide the goblet into a lip, bowl, stem and base.

within these concave regions, to divide shapes into parts: this is called the 'minima rule' (Hoffman and Richards, 1984; Hoffman and Singh, 1997; Singh *et al*., 1999). This is illustrated in Figure 2b, which shows the well-known face–goblet ambiguous figure. If the faces are taken as the object, then the extrema of curvature within the concave regions of the faces are used by human vision as the boundaries between parts. These extrema are indicated by the short dashes on the right-hand side of the figure, and divide the faces into parts corresponding to the forehead, nose, lips and chin. If the goblet is taken as the object, then the regions of the curves that are concave and convex are reversed from when the faces are taken as the object. Since only concave regions are used to create part boundaries, human vision creates a new set of part boundaries for the goblet that are different from the part boundaries of the faces. These are shown on the left-hand side of Figure 2b, and divide the goblet into a lip, bowl, stem and base. Neurophysiological studies of visual area V4 have found many cells that signal the extrema of curvature of 2D contours (Pasupathy and Connor, 1999).

SHADING

Consider Figure 3a. It contains a pattern of gray-level intensity values distributed on a flat sheet of paper. However, it is quite difficult to see this figure as simply a two-dimensional pattern. One cannot help but see a light-colored wrinkled surface extended in three dimensions, lit from the left. The ability of the visual system to construct a 3D surface shape from 2D shading information is a striking computational feat. When viewing a surface, the light intensity at any given location on the retina is a combined function of (at least) three different variables: the reflectance properties of the surface, the local orientation of the surface, and the position and intensity of the light sources. In order to construct the percept of a 3D surface, the visual system must somehow decompose the pattern of luminance values into the separate contributions of surface reflectance, surface shape, and illumination.

In principle a unique solution to the shape-from-shading problem can be derived under restrictive conditions: the reflectance function of the surface is known, the surface is smooth, and the illuminant is a single point source (Horn, 1977). These assumptions allow variations in image luminance to be attributed entirely to gradual changes in surface orientation. Humans, however, are able to perceive shape from shading in many situations where the reflectance is unknown, the surface contains

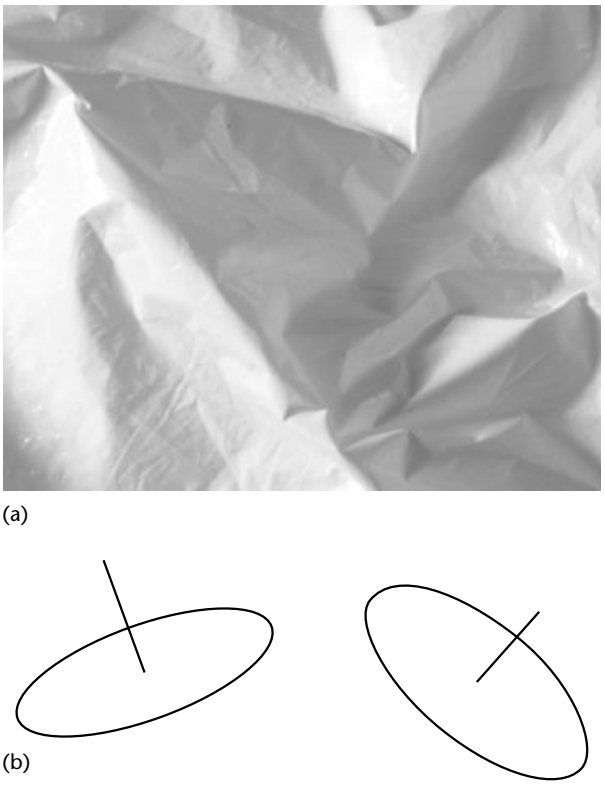

Figure 3. (a) Human vision can construct three-dimensional surface shape from two-dimensional images depicting shading information. To do so, it must separate the contributions of surface shape from those of surface reflectance and illumination (photograph by Marc Talusan). (b) The gauge figure is used to probe the surface structure perceived by observers (Koenderink *et al*., 1992). Observers adjust the 3D orientation of the gauge figure until it 'fits' a depicted surface locally.

tangent discontinuities, and is lit by more than one light source. This suggests that human vision brings to bear other constraints in computing 3D shape from shading information – although it is fair to say that the precise constraints used by human vision remain largely unknown.

Koenderink and colleagues have probed psychophysically the human perception of surface relief from gray-level images (these typically contain both shading and occluding contours). One technique uses a gauge figure – the projection of a circular disk oriented in 3D, with a short line segment sticking perpendicularly out of its center (Figure 3b). In a typical experiment, a gauge figure is superimposed at a large number of locations on a shaded image, and the observer adjusts its perceived 3D orientation using a trackball, in order to match the perceived local orientation of the surface (Koenderink *et al*., 1992). These local measurements can then be integrated to construct the global

surface structure perceived by the observer (this presupposes internal consistency in the observer's responses, which is typically the case). Although this perceived surface structure is qualitatively similar to the depicted surface, it is not quantitatively the same. In particular, surface reliefs seen by different observers differ by depth scalings (i.e. flattenings and elongations in depth), and similarly, surface reliefs seen by the same observer under different illumination conditions differ by depth scalings. Moreover, different parts of the depicted surface are often seen depth-scaled by different amounts (Todd *et al*., 1996), providing further evidence that human vision represents surface shapes in terms of parts.

Qualitatively similar surface reliefs are obtained using a different technique in which pairs of points are presented at different locations on a shaded image, and observers are asked to indicate which of the two points appears closer in depth (Koenderink *et al*., 1996). This method, however, yields results that are less precise than those obtained by the gauge figure method by an order of magnitude. This, in itself, is a significant finding: it suggests that a depth map – a pointwise specification of relative depth at each image location (e.g. Marr, 1982) – is not the primary way human vision represents surface structure, from which it then derives local surface orientation. Rather, surface orientation itself appears to be a perceptually fundamental variable. Moreover, the fact that quantitatively different surface reliefs are obtained with different experimental methods suggests that the visual system may not have a single representation of surface shape, but rather may invoke distinct representations depending on the task at hand (Koenderink, 1998).

CONCLUSION

Human vision starts with just the shower of photons that hit the retina of each eye, and proceeds to construct two-dimensional contours and three-dimensional forms by consulting various sources of information, including shading, texture, motion, occlusion, binocular disparity and image contours. In the process it uses many rules of construction, some of which are based on laws of geometry, reflectance, lighting and projection.

Vision: Object Recognition

Intermediate article

Michael Tarr, Brown University, Providence, Rhode Island, USA

CONTENTS

Object recognition is the process whereby observers are able to recognize three-dimensional objects despite receiving only two-dimensional input that varies greatly depending on viewing conditions. Theories explaining this process differ in the nature of the underlying features, varying from two-dimensional image properties to three-dimensional parts.

INTRODUCTION

One of the most impressive feats of perception is the interpretation of the ever-changing pattern of light that falls on our retinas. From this undifferentiated pattern of illumination, we extract meaning in the form of objects. Although there is basic agreement about the steps necessary for the brain to solve the problem of visual object recognition, the specifics of this process have led to one of the more spirited debates in the study of vision (Biederman and Gerhardstein, 1995; Tarr and Bülthoff, 1995). Unquestionably, recognition requires the matching of representations of visual input to like representations in memory. Moreover, there is a general sense that the form of the representation includes information about surfaces and contours extracted from the image. However, there is disagreement regarding how such information is organized into high-level object representations. The image-based approach posits that collections of viewpoint-dependent surfaces and contours constitute the basic features of object representation and recognition. In contrast, the structural-description approach posits that the basic features are viewpoint-invariant, three-dimensional (3D) volumes that are derived from surfaces and contours.

THE PROCESS OF OBJECT RECOGNITION

Early and mid-level vision takes the unstructured array of visual stimulation that falls on the retina and organizes it into coherent perceptual entities that form the bases of high-level vision. The end results of these processes – object representations of visual input – are then compared with like representations encoded in long-term visual memory. This process of object recognition begins with perceptual organization in which meaningful units such as local contours and surfaces are inferred from variations in the intensity array (Marr, 1982). These local features are then subjected to further, more global, perceptual organization which results in the mental representations that we rely on for visual recognition. Because these representations of the input and representations of familiar objects in visual memory are assumed to be in the same format, a search or indexing process can be conducted to establish the most probable matches between input and memory. The most likely candidate representations are then directly compared with the representation of the input, with the best match providing information regarding the identity (or familiarity) of the object in question.

Although this recognition process may seem straightforward, two factors make finding the 'best match' a difficult problem. First, objects can vary in their appearance from one moment to the next. An object can rotate, shift position, or change configuration; an observer can move; and the lighting of the scene can change. All of these transformations can produce dramatic changes in the image of an object presented to our visual system. However, the goal of object recognition is object constancy – that is, we want to be able to recognize a given object regardless of how its appearance changes over different viewings. Second, objects can vary at the level they are recognized. An object can be visually identified at the entry ('dolphin'), subordinate ('bottlenose dolphin') or individual ('Flipper') levels (Jolicoeur *et al*., 1984; Tarr and Gauthier, 2000). Thus, the question of what constitutes an appropriate match and what information within the representation is relevant to that match depends on the task at hand as well as the

information currently available in the environment. For example, information across the representations of many specific objects might play a role in entry-level recognition, while information within a single object representation might be relevant to individual-level recognition. The issues of object constancy and recognition at varying levels of specificity are two of the most important problems addressed by different models of object recognition.

IMAGE-BASED AND STRUCTURAL DESCRIPTION MODELS

One of the largest sources of variation for an image of an object is viewpoint change. Given that rotations in depth alter an object's visible geometry and surfaces, how does one recognize that a new view of an object depicts a familiar object seen from a different vantage point? This question is perhaps the most-studied in the object recognition literature, in part because competing models offer different predictions regarding how the human visual system compensates for variations in viewpoint.

Image-based models postulate that an object's features are encoded as they appeared in the original image. Thus, image-based object representations, sometimes referred to as 'views', are viewpoint-dependent to the extent that they capture the appearance of objects from specific viewpoints. One important implication of viewpoint dependency is that a single view is unlikely to adequately represent the appearance of a 3D object; therefore, multiple views must be learned for each object in order to support recognition from many different vantage points (Tarr and Pinker, 1989). A second implication is that, owing to changes in the viewpoint of the observer or in the orientation of the object, the currently observed image may still not correspond directly to any known view; therefore, mental transformation or generalization mechanisms must be included to support the alignment of familiar and unfamiliar views (Jolicoeur, 1985; Tarr and Pinker, 1989; Ullman, 1989; Poggio and Edelman, 1990; Perrett *et al*., 1998). Although not a strict constraint, nearly all generalization mechanisms are assumed to be viewpoint-sensitive in that as the magnitude of normalization increases (i.e. larger viewpoint differences) the costs associated with recognition increase as well (i.e. longer response times and higher error rates; Shepard and Metzler, 1971). Taken together, these two implications delineate a viewpoint-dependent model of object recognition in which observers represent oft-seen (Tarr and Pinker, 1989) or geometrically regular views of objects (Palmer *et al*., 1981) that are matched to new, unfamiliar views using viewpoint-sensitive generalization procedures.

In contrast to image-based models, most structural description models postulate that object features are encoded in a viewpoint-invariant manner and that the same representation of an object is derived regardless of the viewpoint of the observer or the pose of the object. Thus, a single structural description should match a known object from a wide range of viewpoints (Marr and Nishihara, 1978; Biederman, 1985) and there is no need to posit either multiple views or generalization mechanisms. Behaviorally such models predict that the costs associated with recognizing an object in a given viewpoint should be independent of whether that viewpoint is familiar or unfamiliar (Biederman, 1985). Note, however, that some structural description models do not assume complete viewpoint invariance. Consider what happens if we view the front and the back of an object: the visible features and parts for the two views will be different and, in some structural description models, will give rise to different object representations. Consequently, although structural description models typically posit viewpoint invariance, they do so only over a limited range of viewpoints for each distinct structural description of an object. Such models must also assume that new structural descriptions are encoded for views of the same object that show different features or parts (Biederman, 1985; Biederman and Gerhardstein, 1993). In some sense these structural description models are also viewpoint-dependent, but only at a coarse level relative to image-based models.

BEHAVIORAL EVIDENCE

How do we evaluate these competing pictures of object recognition? At the simplest level one could name familiar objects at their most common, upright orientation or at less familiar orientations (e.g. upside down) and observe whether recognition performance is viewpoint-dependent or viewpoint-invariant. Such experiments often reveal a pattern of viewpoint dependency, with longer naming times and more naming errors as objects are rotated away from their most familiar orientations either in the picture plane (Jolicoeur, 1985) or in depth (Palmer *et al*., 1981), although there are other studies in which orientation had little effect on naming performance. One problem with such results is that, regardless of familiarity, some views of objects are more readily recognized than other views: that is, views that provide stable

information about an object's shape are processed more efficiently, leading to faster responses and lower errors compared with less stable or less informative views of the same object. Thus, if the most familiar viewpoints are also views that are easy to recognize, then viewpoint dependency might result from the difficulty of perceiving the object's shape, not from viewpoint-dependent recognition processes. A second concern is that most of us have already seen many different objects in many different viewpoints. Therefore, a participant in an experiment using familiar objects might have previously acquired either multiple views or a structural description for each object – both types of representations would support viewpoint-invariant recognition (Tarr and Pinker, 1989). Accordingly, it is difficult to draw any strong conclusions about the nature of object representations with respect to viewpoint from any behavioral results obtained with familiar objects.

To address these concerns, several studies were designed in which participants had to learn novel 2D or 3D objects in a small number of viewpoints (Tarr and Pinker, 1989; Bülthoff and Edelman, 1992; Biederman and Gerhardstein, 1993; Tarr, 1995; Hayward and Tarr, 1997; Tarr *et al*., 1998). For example, in a study by Tarr and Pinker (1989; see also Tarr, 1995) participants named visually similar shapes until recognition performance was equivalent at several orientations. As with familiar objects, this viewpoint invariance might have arisen from learning either multiple views or a viewpoint-invariant description. These two alternatives were tested by presenting the shapes in never-before-seen orientations. For these new orientations recognition performance was monotonically dependent on the distance from a familiar orientation. This pattern indicates that participants encoded each shape at each familiar orientation (an image-based 'view') and then generalized from unfamiliar orientations to the nearest known view. Similarly, there is evidence that neural representations of objects are viewpoint-dependent, with individual neurons being 'view-tuned' (Logothetis *et al*., 1995). That is, neurons in the inferotemporal cortex (IT) that are selective for a particular object are also maximally responsive to specific viewpoints of that object, with different neurons coding for different views. Thus, the most diagnostic task we can use, the recognition of novel objects, is often viewpoint-dependent. At the same time, there is some evidence for viewpoint-invariant mechanisms in recognition. However, the conditions under which such evidence has been obtained are quite constrained. Indeed, the best-known model of viewpoint-invariant recognition (Biederman, 1985; Biederman and Gerhardstein, 1993) places specific limits on when viewpoint invariance is predicted.

FEATURES OF REPRESENTATION

The nature of the features encoded in the representation is a second dimension along which different models may be compared, and is critical to how objects can be recognized at multiple levels. Image-based representations are generally considered to be composed of large numbers of local measures of the image: orientation, shape, surface slant, bounding contour, color, luminance, shading gradient, and potentially many more (Edelman, 1993; Mel, 1997; Riesenhuber and Poggio, 1999; Ullman and Sali, 2000). Because the fundamental units of object representation are a natural consequence of earlier perceptual processing (e.g. Livingston and Hubel, 1987), image-based representations capture not only object shape, but also surface properties such as texture, color, shading, and local depth. This rich feature set supports recognition at multiple levels of access and the same approach can account for entry, subordinate, and individual-level visual recognition.

In contrast, structural descriptions are typically thought to be composed of 3D volumes, such as parameterized generalized cylinders (Marr and Nishihara, 1978), or restricted sets of qualitatively defined 3D parts. The best-known version of the latter approach assumes that configurations of local shape features are combined to specify particular 3D parts known as 'geons' (Biederman, 1985). The geon model makes two critical assumptions that may be empirically evaluated. First, geon structural descriptions must be recovered by processing steps beyond those normally associated with mid-level perception. That is, the shape features that specify geons must be identified, combined, and remapped into the appropriate 3D primitives. One consequence of this recovery process is a many-to-one mapping of feature configurations into geons whereby many visually similar objects come to be represented by the same geon structural description. Therefore, a theory based on geons is necessarily restricted to explaining only entry-level recognition – information relevant to subordinate-level or individual-level recognition is lost in the process of redescribing an image. Consequently, mechanisms different from those that rely on structural descriptions must be posited to account for both subordinate-level and individual-level recognition abilities. Second, geon structural

descriptions rely on 3D parts, not separable image features: that is, so long as the visible part configuration of an object does not change, the same description should be derived. However, Hayward and Tarr (1997) found that, despite the same geons being visible in every image, viewpoint sensitivity was determined by changes in the visible qualitative image features (e.g. curved versus straight).

CONCLUSION

Image-based and structural description models have emerged as potential explanations for our ability to recognize objects. Empirical evaluation of these competing approaches suggests that current versions of both models leave something to be desired. For example, the geon structural description model is limited in the kinds of recognition tasks that it can explain. Similarly, image-based models should incorporate sensitivity to qualitative features above and beyond metric variations. Thus, more sophisticated models must be developed before we have a complete understanding of the complex process of visual object recognition.

Vision: Occlusion, Illusory Contours and 'Filling-in'

Intermediate article

Philip J Kellman, University of California: Los Angeles, Los Angeles, USA

CONTENTS

Visual interpolation processes allow humans to perceive complete objects despite input that is fragmentary in space and time owing to occlusion. Mental representations of objects and surfaces, and their correspondence to real objects, depend heavily on interpolation processes that create both contour and surface connections among visible areas.

INTRODUCTION

Perceptual systems provide information about the world that is used to guide thought and action. For detailed knowledge of objects and the spatial layout, obtained at a distance, vision is preeminent. Vision is studied at many levels. A rich scientific tradition, for example, has sought to characterize the eye as an optical instrument, investigating its sensitivity and responses to light. To understand vision, however, we need to address another set of questions involving how visual information leads to descriptions of objects, spatial arrangements and events.

The ease of seeing conceals many complexities. A fundamental one is the problem of fragmentation. Whereas both the world and our representations of it contain coherent objects and continuous surfaces, the input from the world to our eyes is fragmentary. Most objects are partly occluded by other objects: only parts of their surfaces reflect light to the eyes of an observer. A building viewed through foliage consists at the retina of many separate patches of building separated by the projections of branches and leaves. How does the visual system assign hundreds of visible patches to a representation of a single, continuous, and complete building, separate from the foliage? These problems grow even more complicated when observers or objects move, as patterns of occlusion continuously change. Fortunately, human vision employs processes that overcome the problems of fragmentation and occlusion. These segmentation and grouping processes produce perception of objects and surfaces from the fragmentary input.

PHENOMENA OF VISUAL INTERPOLATION

Visual interpolation is the connecting of contours and surfaces across gaps. Figure 1 illustrates this phenomenon. Figure 1a shows an example of partial occlusion: six noncontiguous gray regions appear, yet the observer's visual system connects them into a single object extending behind the black occluder. The object's overall shape is apparent. Perceptual organization of this scene also leads to the perception of circular apertures in the black surface, through which the gray object and a more distant white surface are seen. Figure 1b illustrates the related phenomenon of illusory contours or illusory objects. Here, the visual system connects contours across gaps such that these interpolated contours appear in front of other surfaces in the array. Illusory contours were discovered by Schumann (1904), but they have become an important topic of vision research since the seminal work of Kanizsa (1979). In Figure 1c, an additional effect, one of transparency, can be observed in the figure that is created across the gaps. Finally, in Figure 1d, a homogeneous black region splits into two visible figures, a phenomenon sometimes referred to as "self-splitting objects".

These phenomena are formally similar in that equivalent or similar visible contours and surface fragments become linked to form objects, despite intervening gaps. Those in parts a, b and c of Figure 1 are actually even more similar: the completed object in each case is defined by the same collection of physically specified and interpolated contours.

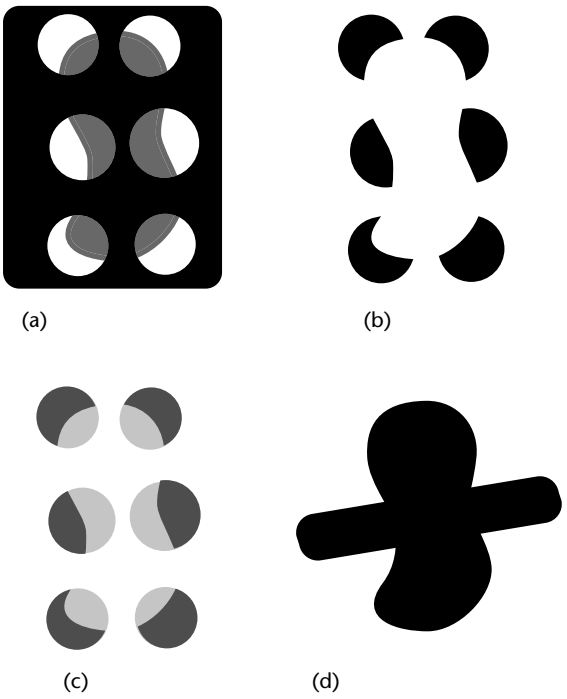

Figure 1. [*Figure is also reproduced in color section.*] Visual interpolation phenomena. In each case edges and surfaces are connected perceptually across gaps in the input: (a) partly occluded object; (b) illusory object; (c) transparent object; (d) self-splitting object.

PROCESSES OF VISUAL INTERPOLATION

How do visual filling-in processes occur? The answer begins with the available information in light reflected from objects. Broadly speaking, the visual system uses relationships among visible contour segments and relationships of surface properties in visible areas.

Contour Processes

Visible contours provide the primary information used to segment scenes into objects. Contours are one-dimensional entities marking abrupt changes in some visible property. Researchers have most often considered changes in lightness or color; however, contours based on differences in texture, depth or velocity also provide important information. The importance of contours derives from the fact that objects will tend to be relatively homogeneous in their composition (and thus in their lightness, color, texture, depth, etc.) and will often differ from nearby objects and surfaces. Visible contours often mark the locations of object boundaries. Computations using abrupt changes in visible properties across a scene to locate contours are an important starting point of object perception, both in biological and artificial vision systems.

Because of occlusion, however, visible contours seldom delineate a whole object. Most objects are opaque and three-dimensional; in projecting to a two-dimensional retina, they occlude parts of themselves. Moreover, in normal scenes, most objects are partly occluded by others. Contour interpolation processes connect visible contours across gaps caused by occlusion to produce perceptual units that correspond more accurately to the actual objects in a scene. These computations begin with contour intersections or junctions. Whereas points along contours have unique orientations (tangents), junctions are points where there are ordinarily two orientations – those of two intersecting contours. As can be seen in Figure 1, interpolated contours in all cases begin and end at these tangent discontinuities in the image. These points include all of the places where edges go out of sight and need to be interpolated. It has been proposed that 'end-stopped' cells in visual cortex (cells sensitive to the contours that end or abruptly change direction within their receptive fields) underlie junction detection (e.g. Heitger *et al*., 1993).

Interpolated contours agree with the slopes of visible contours at their connection points (Figure 1). Contour interpolation can be summarized by saying that visual system interpolates according to a smoothness principle, called contour relatability, such that interpolated contours are smooth (differentiable at least once) and monotonic (singly inflected), and at their end points they match the slopes of real contours (Kellman and Shipley, 1991). The notion of relatability in perceptual grouping is not the same as (but is related to) the principle of good continuation, proposed as one of several principles of perceptual organization in the early twentieth century by the Gestalt psychologists (Wertheimer, 1923).

The contour interpolation phenomena of Figure 1 have different appearances. Occluded objects, illusory objects and other interpolation cases involve different assignments of depth and boundary ownership relative to adjacent surfaces. Despite these differences in the final appearance, research indicates that an identical interpolation process – connecting visible edges across gaps – operates in all of these cases (Kellman *et al*., 1998; Ringbach and Shapley, 1996). At an early processing stage, oriented edge fragments signaled by cortical cells sensitive to small regions are integrated into visible contour fragments. Interpolation processes produce connections among these, based on the

geometry of relatability. The final perceived arrangement depends on constraints imposed, both early and late in processing, by boundary ownership, depth, and scene consistency.

Figure 2 illustrates two phenomena that have provided insight into a common interpolation process. Figure 2a consists of two images which if shown to the two eyes (by free-fusing or using a stereoscope) produce a single display with parts at different depths. The central circle in the figure has four interpolated contours, each of which is an illusory contour along part of its length and an occluded contour along another part. That these can join to form a single perceived contour (or rather, that interpolation occurs between these two different kinds of end points) suggests an interpolation process that accepts either type of input. Figure 2b (after Petter, 1956) shows a homogeneously black display that, because of interpolation processes, splits into two perceived objects. Where these objects cross in the image, one appears in front, having illusory contours, and the other appears to pass behind, having occluded contours.

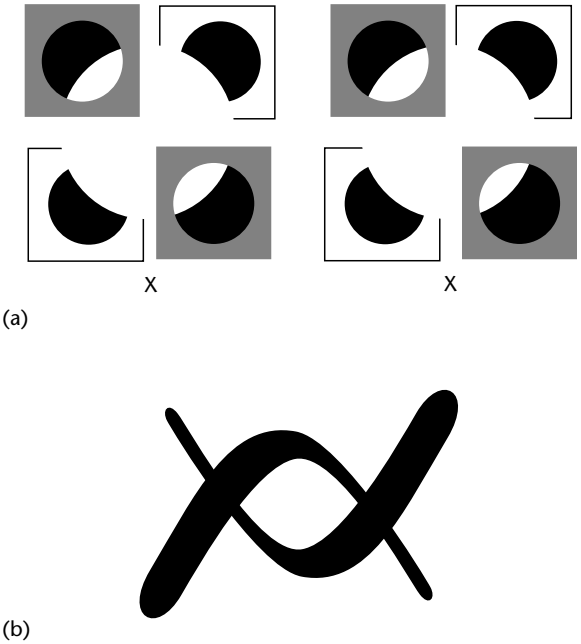

Figure 2. Examples of a common contour interpolation process in illusory and occluded object perception. (a) The central circle appears by virtue of interpolated contours that combine occluded and illusory portions. The effect is visible in each of the paired images. Viewing the display as a stereo pair, in which one image is shown to each eye, reveals the effect more vividly. The display may be free-fused by crossing or diverging the eyes, or viewed using a stereoscope. (b) Example of Petter's effect.

Petter noticed an interesting regularity in such displays. Where interpolated boundaries cross, the pair crossing the smaller gap appears in front, having illusory contours, whereas the other object's boundaries are seen as occluded in that region. Petter's claim, which has been confirmed experimentally, provides a strong argument for an interpolation mechanism common to illusory and occluded contours. The reason is that the determination of illusory versus occluded appearance here depends on a comparison of interpolated contours. That the outcome is determined by the relative lengths of crossing contours implies that the system must determine the locations and extents of contour interpolation prior to the determination of final appearance as illusory or occluded.

Surface Processes

Contours are not the only means by which the visual system links visible areas; surface relations also play a part (Figure 3). Some of the circles in the display, such as the gray ones, appear as spots on the surface. In contrast, most of the black circles appear to be part of a single, occluded, black figure, visible through holes. The white spots also appear to be holes rather than spots; through them, the white background surface is seen. These perceptual experiences arise from the surface interpolation process. Visible regions are connected across gaps in the input based on the similarity of their surface qualities (e.g. lightness, shade and texture). These connections cannot be given by contour interpolation, as the circles have no contour junctions. Certain rules govern surface interpolation; for example, it is confined by real and interpolated edges (Yin *et al*., 2000). In Figure 3, note that the rightmost black circle does not link up with the occluded object: this is because that circle does not fall within the real or interpolated contours of the black object. Whereas contour interpolation processes are relatively insensitive to relations of lightness or color, the surface process depends crucially on these. Notice that the gray dot on the lower left does not appear as part of the occluded object, despite being within the interpolated and real contours of the black object.

This phenomenon of surface interpolation under occlusion appears to be one of a family of surface spreading or 'filling-in' phenomena. A related spreading phenomenon, studied by Yarbus (1967), involved images stabilized on the retina. When an image or part of one is stabilized on the retina, it disappears in a few seconds. In Yarbus's displays, a red circle was shown on a blue background. The

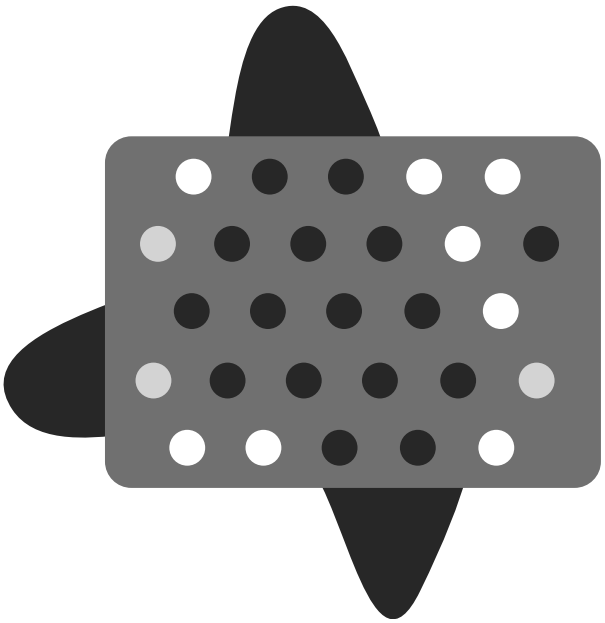

Figure 3. [*Figure is also reproduced in color section*.] Surface interpolation process.

contour between the red and blue areas was retinally stabilized, although the border of the blue background was not. After a few seconds, the central circle disappeared. Instead of the homogeneous gray that observers would see if an entire image were stabilized, the center circle took on the color of the surround – it appeared as blue. With the stabilized boundary 'removed', the surrounding surface color appeared to spread into the central region.

Another example is completion across the blind spot, an area of the retina about 15° off center (toward the nose) where blood vessels and nerves pass through the retina and no receptors exist to pick up light information. We do not ordinarily notice the blind spot; no hole appears in the visual field when we stare at a wall. This fact may seem remarkable if one knows that the blind spot has a diameter that is approximately 5° of the visual field. (In contrast, the fovea, responsible for all of our finely detailed vision, is only 1–2° in diameter.) Similarly, in certain neurological injuries or acute events, including migraine headaches, there may be a functional scotoma, or hole in the visual field (such that no local information is received there); here too, no gap is observed visually, as surrounding surfaces fill in.

These filling-in phenomena suggest general processes that serve to represent continuous surfaces in the world despite gaps in the local information.

THREE-DIMENSIONAL AND MOTION INFORMATION

Most studies of filling-in phenomena have involved static, two-dimensional displays, as these are more easily created and manipulated. Given that the world is three-dimensional and contains moving objects, we might expect that contour and surface processes use three-dimensional and motion-carried information and produce representations of three-dimensional objects. Study of these aspects has made it clear that both expectations are correct.

Visual contour and surface interpolation processes use the orientations and relations of visible object parts in all three spatial dimensions. Figure 4 shows two examples. Both are stereo pairs containing two X-shaped images. Each pair may be free-fused by crossing the eyes until a single image appears. Because of depth information given by differences in the images shown to the two eyes, the resulting displays in Figure 4a and 4b have very different outcomes in terms of their segmentation into objects and interpolated contours and surfaces. In Figure 4a, two separate, vertically oriented objects are seen, with illusory contours in the

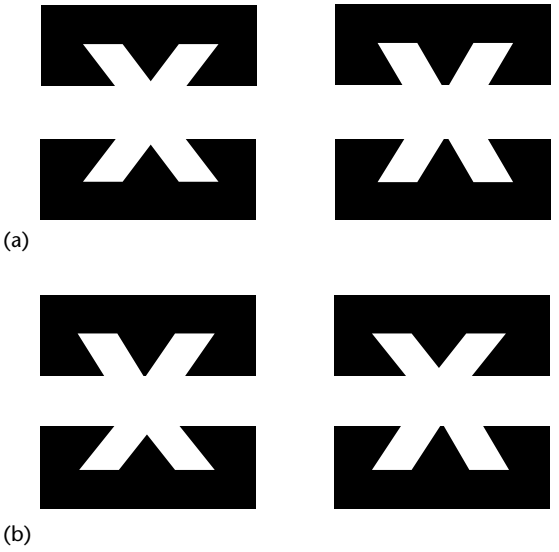

Figure 4. Three-dimensional interpolation. Each display is a stereo pair, in which the left and right images are separate views to be shown to the two eyes (the display is designed to be free-fused by crossing the eyes). The displays in (a) and (b) have the same visible parts; however, their positions have been shifted in the two eye's views to create binocular disparity, giving them different apparent positions in depth. (a) Three-dimensional relations of the visible parts favor completion as two upright, curved objects, separated horizontally. (b) Three-dimensional relations of the visible parts favor completion as two crossing bands curving in depth.

middle of the right-hand object and occluded contours for the left-hand object. In Figure 4b, two diagonally crossing objects are seen, one bowing outward with illusory contours and the other receding behind, having occluded contours. Experimental studies confirm that interpolation processes use three-dimensional information and produce three-dimensional representations of contours and surfaces.

The fourth dimension – time – is also important to our perception of coherent objects. Moving observers looking through foliage or other occluding objects see a constantly changing set of patches from objects behind. Visual processes handle this kind of situation by holding visible fragments in a brief memory buffer, along with information about their motion relative to the observer. Motion information is used to extrapolate the positions of these stored fragments over time. As new contours and surface patches become visible, these are connected to the previously viewed pieces following the same geometry of relatability, here applied to currently visible and previously stored fragments in updated spatial positions.

CONCLUSION

Many aspects of these processes and their implementation in the brain have yet to be explained. Although these remarkable interpolation abilities pose complex challenges for researchers, their seamless operation in daily life empowers thought and behavior by allowing us to perceive complete objects from fragmentary views of the world.

Vision: Top-down Effects

Intermediate article

Mary A Peterson, University of Arizona, Tucson, Arizona, USA

CONTENTS

'Top-down effects' are effects that originate in high levels of the hierarchy of visual processes and exert an influence at lower levels. Examples of visual information thought to reside at, or arise from, high levels in the hierarchy are: the perceiver's intentions, expectations, attentional goals, and memories established on the basis of past experience.

INTRODUCTION

It is now generally acknowledged that the perceiver's past experience, intentions, expectations, and attention influence visual perception. These are called 'top-down' effects because they are thought to originate at high levels within the hierarchy of visual processes and to exert their influence on lower levels in the hierarchy. In contrast, the sources of 'bottom-up' effects are thought to reside at low levels in the visual hierarchy and to be immune to influences from higher levels.

Following the Gestalt revolution (*circa* 1920–1940), most theorists believed that much of visual perception occurred in a bottom-up fashion and was immune to influences from higher levels (Fodor, 1983). High-level processes were thought to exert their effects only postperceptually – that is after the products of early perceptual processes were available (on decision processes, for instance). Since the 1980s, however, improved and varied methods have revealed that high-level processes can affect perceptual processes *per se*, and not just postperceptual processes. Plausible mediators for these top-down effects have been identified through both computational modeling efforts and neuroanotomical and neurophysiological experiments.

This article discusses both interactive activation models that allow for top-down effects on perception, and empirical evidence indicating that the perceiver's past experience, perceptual intentions, expectations, and attention affect visual perception.

INTERACTIVE ACTIVATION MODELS

Traditionally, visual perception and cognition were thought to be related hierarchically, with the higher stage (cognition) operating on the completed outputs of the lower stage (visual perception). As an alternative, McClelland and Rumelhart (1981) proposed an interactive activation model (IAM). In the IAM, processes residing at higher levels operate on the partial outputs of lower levels; they need not wait for processing at lower levels to be completed. Further, the partial outputs from higher-level processes are fed back to influence lower-level processes, thereby allowing for interactions between levels.

The first of many behavioral effects to be modeled by the IAM was the word superiority effect – that observers can tell which of two letters has been shown in a brief exposure more accurately when the target letter is presented as part of a word rather than alone. Word superiority effects are observed even when there is no reason to expect the word context to be useful (e.g., when the words 'hit' and 'hot' serve as the context for the target letters 'i' and 'o'). In the IAM, at least two stages of processing are involved in letter discrimination: a letter identification stage and a higher-level word recognition stage. Partial outputs from the letter stage are fed forward to the word stage. At the word level, representations compete. Over time, one word dominates; consequently feedback from that word enhances processing of the target at the letter stage, increasing discrimination accuracy. More recent experiments have revealed evidence of interactions between higher and lower levels.

As originally proposed the IAM was considered to be biologically implausible, but recent refinements have increased its plausibility. The discovery of ubiquitous feedback connections in the brain identified a potential neural substrate for top-down effects. Furthermore, behavioral research demonstrated that top-down effects from past

experience, attention, intention, and expectation can affect perception *per se*, rather than postperceptual processes, as described in the following sections.

PAST EXPERIENCE

In this section, three types of past experience effects on perception will be discussed: effects on figure assignment arising from previous exposure to objects, the role of past experience in determining the parts of an object, and how seeing objects in their typical context affects perception.

Object Memory Effects on Figure Assignment

A process that is thought to occur early in the visual processing hierarchy is figure–ground assignment. Figure–ground assignment occurs when two adjacent regions share a border. The border is typically assigned to one of the two regions and not to the other. The region to which the border is assigned has a definite shape, and is called the 'figure'. The region to which the border is not assigned lacks a shape near the border, and typically appears simply to continue behind the figure; this region is called the 'ground'. Thus, figure assignment partitions the visual field into shapes; until this organization is accomplished, no shaped entities are perceived.

It was long thought that figure–ground organization had first to partition the visual field into shaped figures and shapeless grounds before memories of previously seen shapes or objects could be accessed. Following figure–ground assignment, object memories were thought to be accessed by figures and not by grounds. This 'figure assignment first' assumption was based on the Gestalt argument that past experience needed an organized substrate to operate upon; the unorganized input was insufficient to constrain past experience. Shaped entities were deemed the necessary substrate for the type of past experience coded in shape or object memories. The belief that shapes necessarily serve as the substrate for matches to object memories rests on a naive understanding of the nature of object memories, however, inasmuch as object memories are not themselves shapes. Another reason to hold the 'figure assignment first' hypothesis is the belief that early vision must provide an accurate representation of the external world, and it can only do so if it is unaffected by past experience. The faulty assumption that top-down effects necessarily dominate bottom-up processes is implicit in this reasoning, however.

Contrary to the traditional view, recent research has revealed that at least partial memories of previously seen objects are accessed before figure assignment and can affect its outcome (Peterson, 1994). For instance, the white regions in Figure 1 are more likely to be seen as shaped figures when the displays are upright (as in Figure 1) rather than inverted (as can be seen by viewing the page upside down). Changing the orientation of Figure 1 from upright to inverted does not change the bottom-up factors known to influence figure assignment (e.g., the depth cues and the Gestalt configural cues of symmetry, enclosure, smallness of relative area, and/or convexity). However, it takes longer for object memories matching the white region to reach some threshold activation level for inverted displays compared to upright displays. This delay is sufficient to diminish or remove the influences from object memories on figure assignment.

Peterson (1994) and Peterson *et al*. (2001) proposed that these effects are mediated by edge-based access to partial object memories; thus, neither shaped entities nor whole regions are necessarily the substrate for access to object

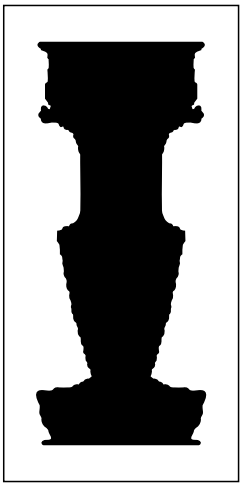

Figure 1. A figure–ground display drawn by Julian Hochberg and used by Peterson and colleagues in which two adjacent regions – black and white – share a boundary. The Gestalt configural cues of symmetry, enclosure, and smallness of relative area favor the interpretation that the black central region is the shaped figure. The white surround portrays portions of two women shown in partial silhouette from head to foot. Thus, object memory cues, effective for upright but not inverted displays, favor the interpretation that the white regions are the shaped figures. Reprinted from Peterson, Harvey and Weidenbacher (1991) with permission from the American Psychological Association.

memories. Furthermore, Peterson and colleagues showed that object memory cues do not always dominate bottom-up cues to figure assignment; object memory cues seem to be simply one of an ensemble of cues to figural status. Therefore, concerns that top-down effects might reduce the ability for early visual processes to model the external world are unfounded.

Are Parts of Objects Innate or Learned?

Object memories store past experience with objects. But what are the critical features or parts of object memories? Are they innate or are they determined by past experience (i.e., learned)? Some theorists propose that a small, fixed alphabet of geometrical components is used to represent all objects (e.g., Biederman, 1987). Other theorists argue that the features, or parts, used to represent objects are flexible and depend upon the observers' past experience or current goals. Consistent with the latter idea, Goldstone and his colleagues (e.g., Goldstone *et al*., 2000) asked two different groups of observers to use different rules to classify generated novel outline objects. The different rules required observers to attend to different parts of the same objects. In both cases, the parts on which the classification response depended were perceptually good parts that were highly visible to both groups of observers. After observers learned the classification task, they performed a different task in which they judged whether a part displayed after a whole object had been present in the object. Observers' 'present' responses were faster for parts that had been diagnostic for the classification task they had learned rather than the other classification task, even though the parts were equally good parts *a priori*. Thus, top-down effects instantiated in the participant's classification strategy have a powerful influence on perception by selecting the parts used to code objects in memory.

Context Effects on Object Perception

Visual perception can also be influenced by knowledge gained from past experience with scenes where objects were likely to be found. For instance, observers' ability to perceive objects is affected by knowledge regarding physical laws such as support relations (e.g., couches are likely to be found resting on the floor rather than floating in the sky). The ability to identify objects is also influenced by the likelihood of finding an object in a given context (e.g., airplanes are more likely to be found in the sky than in the living room). When pictures of scenes are presented briefly, objects are more likely to be detected or identified if they are portrayed in appropriate contexts (or in appropriate locations within a context) rather than in neutral or inappropriate contexts or locations (Biederman *et al*., 1974). Such context effects might be 'top-down' effects in that they reflect feedback from higher, semantic, levels of processing. Alternatively, context effects might reflect the statistical regularities in the environment, extracted over repeated exposures to similar scenes and used to guide attention to the location of a target (Chun and Jiang, 1998). It is not yet clear where knowledge regarding statistical regularity is stored; it may not be stored at a sufficiently high level in the hierarchy of visual processing to be considered a top-down effect.

Summary

In summary, behavioral evidence indicates that past experience can affect a variety of visual processes, including those thought to reside at very low levels in the processing hierarchy and, consequently, to be immune to effects of past experience. Past experience can change the manner in which objects are segregated from backgrounds and the manner in which parts are segregated from each other. However, it is not clear whether past experience necessarily operates in a top-down fashion. Effects of past experience might be stored at many levels in the visual processing stream. A challenge for future research will be to determine which effects of knowledge and past experience reflect top-down influences and which are coded at low levels of the hierarchy.

INTENTIONS, EXPECTATIONS, AND ATTENTION

Effects of perceivers' intentions and goals would seem to be truly top-down effects. Such top-down effects on perception have been observed in a number of settings. For instance, Hochberg and Peterson (1987) showed that an observer's perceptual intentions can affect the perceived depth organization of two-dimensional (2-D) and three-dimensional (3-D) cubes. Observers viewed small cubes that were biased near one corner toward one of the two possible depth organizations (facing upwards and to the right or downwards and to the left) but remained unbiased near another, nearby, corner. A sample is shown in Figure 2. Observers intentions were manipulated through instructions to try to see the cube facing downwards and to the left on some trials, and upwards and to the right on

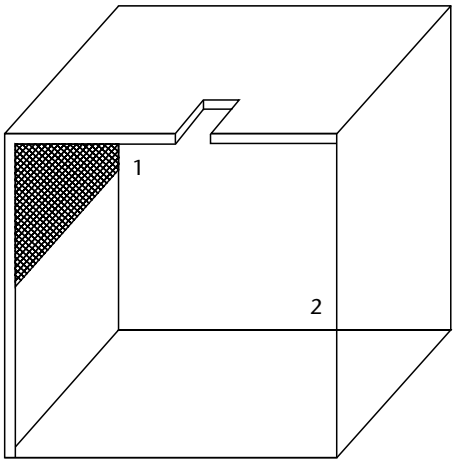

Figure 2. A schematic of a 2–D display used by Hochberg and Peterson. The cube is biased at its upper left corner toward the interpretation that it faces downwards and to the left rather than upwards and to the right but remains unbiased at the lower right corner. Point 1 marks the intersection that was fixated near the upper left corner; point 2 marks the intersection that was fixated near the lower right corner. Reprinted from Peterson and Hochberg (1983) with permission from the American Psychological Association.

other trials. The critical finding was that, despite the proximity of the biased corner, observers' intentions exerted a strong influence on perception when they fixated on the unbiased corner. For both 2-D and 3-D cubes, instructed intentions affected the perceived ordering of depth planes, even though fixation remained constant. (The viewer's intentions did not eliminate reversals, however, consistent with the idea that top-down factors do not dominate all other factors. In other words, intention affects perception but does not dominate it.)

These results could not be interpreted in terms of postperceptual processes because reports about perceptually coupled variables agreed with direct reports about perceived depth. Perceptual-couples are variables that co-vary in perception, even if they do not co-vary in the stimulus. The knowledge coded in these couplings is implicit but not explicit. Hence, reports regarding perceptually coupled variables can be used to index whether viewers' reports correspond to what they truly perceive. For example, for moving observers viewing a stationary 3-D cube, illusory concomitant motion is coupled to a perceived depth reversal. Similarly, for stationary viewers, the perceived direction of rotation of an oscillating cube is coupled to perceived depth organization. Experiments showed that viewers' reports about these perceptually coupled variables varied as expected if perceptions were altered by their attempts to follow the intention instructions, providing strong evidence that intention can affect perceived depth organization (e.g., Hochberg and Peterson, 1987).

Recent investigations have focused on whether the viewer's goals and task expectations determine which aspects of a display will attract attention or whether salient stimulus features can 'capture' attention regardless of the viewer's current goal. Evidence suggests that observers may be unaware of stimulus features unrelated to their task. Yet the same features are easily detected when they are task-relevant. For instance, Mack and Rock (1998) asked participants to determine which of the two arms of a cross was longer. The task was difficult because the cross was displayed briefly and the arms were only slightly different in length. After just a few trials, Mack and Rock changed something about the background against which the cross was presented. In one such experiment, they exposed a simple geometric shape (a square, a circle, or a triangle) in one of the four quadrants sketched by the cross. Of their observers, 25 percent failed to detect the unexpected shape; indeed, they failed to notice that anything unusual had occurred on that trial. Thus, it seemed that the shape onset did not necessarily capture attention if observers were focusing on another task.

Visual information unrelated to the observers' goals might be processed outside of awareness; the critical question is to what extent the perceiver's expectations close off access to awareness. A recent model proposed by DiLollo *et al*. (2000) posits that attention plays an important role in maintaining low-level activation long enough to allow top-down processes (feedback or 're-entrant' processes) to confirm expectations established at higher levels. With this model, expectations unconfirmed by re-entrant processes do not enter awareness.

CONCLUSION

Behavioral evidence indicates that past experience, intentions, expectations, and attention interact with bottom-up processes to structure visual perception. Neural connections capable of subserving these effects have been identified and biologically plausible computational theories have been proposed to account for them. A task for the future is to delimit which types of knowledge and past experience can affect vision; some types clearly can, whereas other types cannot (Peterson *et al*., 1991). It will also be important to determine where various types of knowledge are stored in the visual hierarchy and where various tasks are accomplished. Only by

doing so can we determine which effects reflect within-level versus between-level (top-down) interactions.

Visual Art

Introductory article

Robert L Solso, University of Nevada, Reno, USA

CONTENTS

Many neurological pathways and interactions are involved in viewing art. Our perceptions are based not only on visual stimuli but also on higher-order cognitive associations which give meaning to what we see.

INTRODUCTION

When we humans look at art a fascinating sequence of neurological, perceptual, and cognitive phenomena emerge in which the art work is seen and understood in less time than it takes to read these words. Cognitive scientists have unraveled many of the strands of the tangled neurological pathways and interactions involved in the process of perceiving art. Here, some of the main ideas regarding cognitive science and art are reviewed.

PSYCHOLOGICAL PRINCIPLES AND ART

Looking at art (as well as visual perception) engages two major systems: nativistic perception and directed perception.

Nativistic Perception

Perception of visual events is based on the idea that people have certain inborn ways in which visual stimuli, including art, are initially organized and perceived. Sometimes nativistic perception is called 'natural' perception as it is the way people look at visual events intrinsically, or as we might view them without learning. These perceptual qualities are genetic and affect all human perception uniformly. Casually speaking, they are 'hard-wired' in our neural system, by which it is meant that the way visual information is initially processed starts with an analysis of basic visual elements. Thus, when one looks at a particular painting the eye and brain distinguish one object from another, detect different intensities of reflected light, see colors, and discern basic shapes and forms. Nativistic perception shares many features with 'bottom up' perception in which basic objects, lines, and geometric primitives are detected and then combined to make more complex, meaningful forms.

The full comprehension of art involves more than the fundamental identification of basic features. These include the sociology of the period, the meaning of the subject, and the personal relevance of the piece among other factors – a topic called directed perception, to which we now turn.

Directed Perception

Directed perception is based on the idea that we interpret the world through our past learning experience. In the early halcyon days of behaviorism a radical view suggested that all human characteristics were the consequence of environmental experiences and learning. The concept was related to the idea that children are born into the world as a *tabula rasa*, or blank page upon which experiences are recorded.

This extreme position has been largely discarded but the view that past experiences influence the perception of objects, especially meaningful objects, has an important role in the psychology of art. Sometimes this approach to the viewing of art has been called a 'top down' process, as it implies that the observer begins with a schema or plan as to what might be seen in a work of art. Thus, in directed perception, the viewer attends to art with a rich background of personal experiences. Directed perception has been conceptualized as 'seeing the world with a thousand hypotheses', as one looks for meaning, relationships, and intentions when viewing art. While the different theories represent different views, most believe that viewing art incorporates features from both ideas – an approach called the 'holistic' perception of art.

Holistic Perception

Holistic perception is a comprehensive approach to the viewing and understanding of art which engages both nativistic and directed perception. During the initial stages of processing visual events, basic features, contours, figures, and colors are sensed and perceived. These perceptions are then blended with one's knowledge of the world, information about the art object, and personal beliefs, which leads to a 'deeper' understanding of the viewed object.

ART PERCEPTION: A COGNITIVE VIEW

The modern period in psychology has emphasized an information processing model in which external events, such as a work of art, are sensed, perceived, and processed in a series of stages as we think about the object and interpret its meaning. The advantage of an information processing model over older models (such as behaviorism or psychoanalysis) is that it provides an analytic system in which various stages may be studied more or less independently of other stages. Applying this model to the perception and understanding of art might follow the following sequence (with physiological structures in parentheses):

1. Sensing and perceiving the object (retina and primary visual cortex).
2. Identification of primitive structures (primary visual cortex).
3. Processing of basic content such as location, forms, color, and faces (subsequent dorsal and ventral streams in the brain).
4. Derivation of complex meaning such as social or political significance (many parts of the brain including the associative centers in the frontal regions).

Both nativistic and directed perception take place in the various stages of information processing, as shown in the following example.

Take a look at the reproduction of the painting by Raphael shown in Figure 1. What do you see? Before you go on reading this section, take a moment to think about what you see and how you see it.

The painter Raphael (1483–1520), one of the most celebrated and talented artists of the Renaissance, produced this exquisite painting in 1505. From a cognitive or perceptual view Raphael shows great sensitivity to the way a scene might be parsed by a human viewer; from an artistic view it is an example of superb technical skill; and from a religious view, it is a poignant representation of the Madonna, St John the Baptist (on the left) and Jesus (on the right).

Figure 1. [*Figure is also reproduced in color section.*] *Madonna of the Meadows* by Raphael (detail). Used by permission of the National Gallery of Art.

The human eye and brain look for stable elements in the perceptual field and, in the case of this picture, tend to organize the scene by means of a triangle (Figure 2). When viewing this painting our eyes are drawn to the face of Mary which forms the apex of a perfect triangle that subtends an angle embracing the principal figures of the piece. Furthermore, the triangle is one of the most pleasingly stable of all geometric forms, which satisfies our natural yearning to organize visual scenes into stable, discernible views of the world. Metaphorically, the triangle in Christian symbolization represents the Holy Trinity – God the Father, the Son, and Holy Ghost. In this painting three people (Mary, John the Baptist, and Jesus) represent important people in Christendom. Note that the left foot of Mary is brightly portrayed and thus frames the view of the observer. John is presenting a bamboo cross to the infant Christ (years before the crucifixion) which animates an otherwise static picture. Mary's gentle hands caress Jesus, which lends a tender, calming atmosphere to the scene. An analytic, information processing examination of the painting reveals both nativistic and directed perception which is carried out by human neurological structures and processes.

THE BRAIN AND ART

Investigations of the neural pathways in the brain activated by visual perception have broadened our

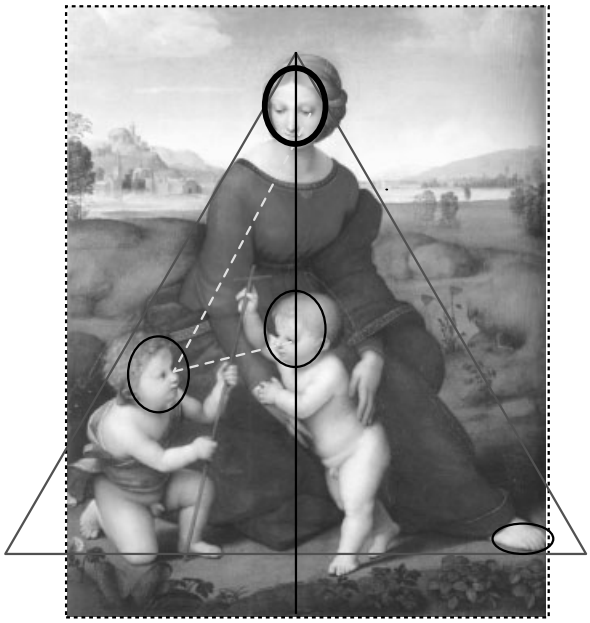

Figure 2. [*Figure is also reproduced in color section.*] *Madonna of the Meadows* (detail) showing major perceptual-organizational features. We tend to organize the painting in terms of basic shapes (triangle) and balance (ellipses). Art perception is influenced by the natural inclination to parse perceptual scenes into basic shapes, colors, and patterns.

understanding of how art is perceived and processed by human observers. These studies have been greatly enhanced by the use of imaging technology such as functional magnetic resonance imaging and positron emission tomography which give accurate views of the regions of the brain active during information processing. From the moment the retina in the eye senses energy within its level of receptiveness, a series of predictable routes of neurological information processing are followed. Two types of early processing of art have been found in the pathways in the brain. The ascending route, the dorsal stream, is associated with location and motion and has been called the 'where is it?' pathway, whereas the descending route, the ventral stream, is associated with color, form, detail, and faces and has been called the 'what is it?' pathway. The neurological pathways implicated in visual perception are extremely complicated, and there appears to be considerable 'cross-talk' between the streams.

The viewing of and understanding of art initially engages both of these pathways and many more. From our knowledge of these routes it would appear that two important questions about the world in general, and the perception of art in particular, are addressed by the brain's neural circuitry: where is the object, and what is it? These neurological mechanisms originated during our long evolutionary history for the purpose of survival and procreation. Now, such pathways are used in the processing of art as well as other forms of visual processing.

PAST EXPERIENCE AND ART PERCEPTION

The viewing and understanding of art is influenced by one's past experience and current inclination. Thus, someone interested in biology might see the details of plant and animal life in a painting, while another person interested in psychology might attend to the people shown in the same painting. Succinctly stated, we 'see' what we find interesting or are encouraged to see. As an example of this idea, students of art who already know about the theme of a particular painting, its style, the techniques used, its historical setting, and other important features, will probably see more details in the piece than a novice. In addition, those who view art with an 'intelligent' eye will comprehend a piece in a larger intellectual context than one unschooled in art. (The same is true of experts in other fields – radiologists, for example, who examine an X-ray are able to see in a glance much more than a novice could see in minutes.)

Such effects of experiences have been discussed since the beginning of psychology. William James, America's foremost pioneer psychologist, suggested in 1890 that if several people of different backgrounds visited Europe one might bring home picturesque impressions, while another might come back with impressions of the cost of the trip, and yet another would see and remember the restaurants and theaters. In modern terms, we conceptualize the way people organize the impressions of the world, including their perception of art, in terms of personal schemas. Experimental evidence has been presented which confirms the idea that we see and remember components of a visual scene according to the schema that is operating. In one study people were asked to write a paragraph about what a member of an occupational group would do on a typical day: for example, the day of a nurse, an architect, or a police officer. With these induced schemas the groups were shown a series of pictures like the one in Figure 3. Afterwards they were asked to recall as much as they could about the pictures. In general, the group who had written about a nurse saw matters related to health and caring, the architect group saw things dealing with the structure of the building, and the

Figure 3. [*Figure is also reproduced in color section*.] Scene in an art gallery. People with different vocational schema 'see' different aspects. An architect might attend more to the physical characteristics of the room such as the absence of windows, while a police officer might attend to the surveillance camera. Art perception is influenced by who we are and what we are encouraged to see. Photograph by R. Solso.

police officer group saw details related to criminal activities. From studies of this type we can see that the perception of art is critically affected by who we are, what we know, and what situational schema is activated. From studies of naturalistic perception we also know that art perception is influenced by the natural organization of forms, shapes, colors, and the like.

Modern cognitive science has shown that the perception and understanding of art are based on our basic apprehension of primitive stimuli and accessing higher-order cognitive associations about the contents of a painting which gives meaning to the things we sense.

CONCLUSION

Studies in cognitive science have shown us that the viewing of art is dependent upon two systems which work together to provide an integrative appreciation of art. Upon viewing a work of art the visual signals are initially processed by the brain in featural analysis. These basic elements are combined with our knowledge, interest, and viewing proclivity to construct an overall understanding of the art object.

Visual Attention

Intermediate article

Ronald A Rensink, University of British Columbia, Vancouver, British Columbia, Canada

CONTENTS

Visual attention is the factor controlling the selective access and integration of visual information.

INTRODUCTION

Although much of vision appears to be effortless and all-encompassing, nevertheless there are limits to what it can do. For example, consider air traffic control, where it is imperative to keep track of all moving items in a display (corresponding to the airplanes in an airspace). If only a single item is present, it can generally be tracked without problem. It is also possible to track four or five items simultaneously, although some effort is needed to do so. However, for 20 or 30 items, even a maximal effort will not suffice, and the task must be shared among several controllers. What appears to be happening in such cases is that visual perception is constrained by a consciously controlled factor within the observer – a factor that enables certain types of processing to take place, but which is limited in the extent to which it can be applied. This factor is termed *visual attention*.

Interestingly, although most observers immediately know what to do when asked to 'pay attention' to a stimulus, it has been rather difficult to give this an objective characterization. Indeed, until recently there was no general consensus on the basic function of attention, and at various times it was associated with such things as clarity of perception, intensity of perception, consciousness, and selection.

SELECTION

During the past few decades, considerable progress has been achieved by focusing on *selection* as the basic function of visual attention. Two types of selection are of particular importance. The first is *selective access* (i.e., allowing only certain parts or properties to be sent on to later processes). It was originally believed that selective access protected processors at higher levels from being overwhelmed by too much information. However, more recent research has tended to view selective access as a way to delimit control of various actions (e.g., focusing on the locations of items that are to be grasped).

The second type of selection is *selective integration* (i.e., combining selected parts or properties into structures that then form the basis of further processing). For example, three adjoining lines could be combined into a complete figure. This figure (and not the lines themselves) might then provide the basis for subsequent control of grasping. It was initially believed that such integration had to be selective in order to make good use of a limited amount of processing 'resource'. However, more recent research has tended to view selective integration in terms of the selective *coordination* of the outputs of multiple processes.

According to this more recent view, therefore, visual attention is not a unitary faculty. Instead, it is simply the selective control of information in the visual system, achieved in various ways by various processes. When considered from this perspective, several of the unresolved issues in earlier treatments of visual attention simply vanish. One such example is the issue of whether selection is 'early' or 'late' (i.e., whether it acts on simple, precategorical structures or more complex ones). Given that selective control may be carried out by a number of systems, there may not be a single site where attention acts, so this issue becomes meaningless.

Since a complete understanding of visual attention is still a long way off, this article will survey only the major behavioral techniques that have been used for its exploration and several of the more important results that have been obtained. Furthermore, it will focus entirely on the purely visual aspects of the processes involved (i.e., on how the stimuli themselves are handled, rather

than how responses to them are generated). Issues such as the sequencing of multiple responses are considered to involve central control at higher levels, so will not be discussed here. (*See* **Attention**)

VISUAL ORIENTING

Consider the situation where a driver is at a red traffic light, anxiously waiting for it to turn green. Here the stop light becomes the center of the driver's perceptual world, and when the light turns green the driver will respond almost immediately. This is an example of *visual orienting*. More generally, orienting can be defined as the alignment of the perceptual apparatus to allow optimal perception of what is happening (or expected to happen). Judging by the near universality of its occurrence, orienting is highly important to our survival in the world.

Orienting is usually studied by determining how well an observer can use advance information about a target item (e.g., position) to improve performance. Typically, the observer tries to detect, identify or locate the target. Two performance measures are generally used, namely *accuracy* and *response time* (RT). The effectiveness of orienting is measured by comparing performance when the observer has advance knowledge with performance when no such knowledge is available (Figure 1).

Overt Orienting

Perhaps the simplest form of orienting is the *overt orienting* of the eyes towards a stimulus. This is not usually a matter of eye movements alone, for the torso and head also contribute to it. Thus, for example, there is a reflexive orienting of the head towards items that suddenly appear in peripheral vision; this behavior is so basic that it is found even in newborn infants.

The net result of these movements is that the eye fixates on some part of the world. Since the resolution of a human retina is highest at its center, estimates of shapes or positions are most accurate for those items at the fixated location. As such, overt orienting is essentially a form of selective access. (*See* **Eye Movements**)

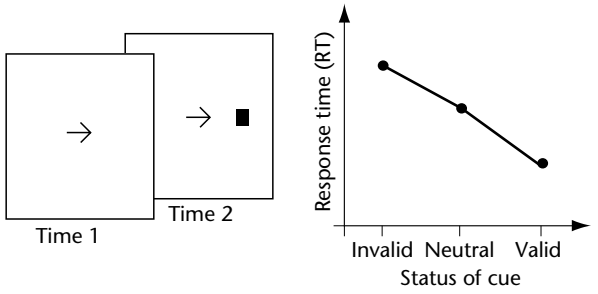

Figure 1. Covert orienting. When a cue indicates the location of the stimulus in a subsequent display, responses are faster and more accurate if the cue is valid (i.e., if the arrow points correctly to the location of the stimulus) than if the cue is uninformative (if it contains only the stem of the arrow). This improvement is considered to be due to the covert orienting of attention. Note that performance is impaired if the cue is invalid (the arrow points to the wrong location), presumably because attention needs to be reoriented from the incorrect location.

Covert Orienting

Observers can detect a target faster and more accurately if they are presented with a cue containing advance information about its location. Given that eye movements can be prevented, such improvement indicates the existence of a *covert orienting* performed by neural mechanisms. Enhancement begins within 50 ms of the cue and increases thereafter, reaching a peak about 200 ms after cue onset.

One explanation for this facilitation is that location is selected via a *spotlight of attention* (Posner *et al.*, 1980), which allows input only from the area that it 'lights'. Studies of this have been largely based on interference caused by irrelevant items, which can cause performance to degrade if near the target. Interference effects indicate that the spotlight covers about 1° of visual angle in central vision, although it can 'zoom out' to cover a larger area if necessary. The minimum area increases with eccentricity from the fovea, and appears to be greater in the upper visual field.

The relationship between covert and overt orienting is not a direct one. Attention does not have to be given to the fixated location – people can move their attention without moving their eyes. Moreover, although some form of attention is needed to select the target of an eye movement, this selection need not be accompanied by a withdrawal of attention from other items.

Space-based Versus Object-based Selection

Although there is considerable agreement that orienting is concerned with selection, there is less agreement about what exactly is being selected. For overt orienting, the situation is straightforward – orienting involves aligning the eyes to a particular two-dimensional location in space, and if the eyes are properly coordinated, they can select a

particular depth as well. Similarly, covert orienting need not be limited to a two-dimensional location in the visual field, but can also be based on three-dimensional depth.

An important issue is whether covert orientation selects for a particular location in space (that happens to be part of some object), or for a particular object (that happens to be at some location), or for both. When two overlapping items are presented, it is easier to report two properties from a single item than to report one property from each of the pair, indicating that covert orienting can be influenced by object structure (Duncan, 1984). The extent to which selection depends on spatial location and object structure has not yet been fully elucidated.

VISUAL SEARCH

Another task that is important in everyday life is *visual search*. For example, when looking for a friend in a crowd, an observer must check each person in turn until the friend is seen. More generally, a search task involves scanning through various items (cars, keys, people, etc.) until the desired item is found.

In studies of visual search, observers typically attempt to detect, identify, or locate a given (target) item among a set of other (distractor) items in a visual display. One of two performance measures are generally used: (1) accuracy on briefly presented displays, or (2) RT on displays that are continually visible. The central issue is the way in which performance is affected by the properties of the items in the display (Figure 2).

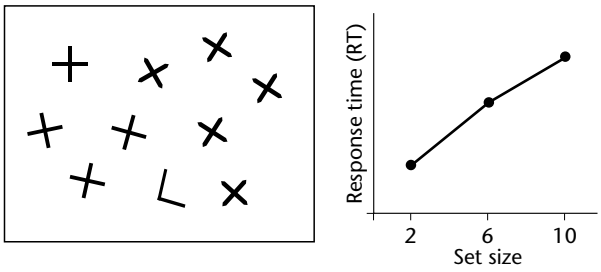

Figure 2. Visual search. The observer is asked to detect, identify, or locate a unique target placed among a set of distractor items. When the target contains a unique feature, performance is largely independent of set size (the number of items in the display). When the target is a strong conjunction of the distractor's features (when it contains the same basic features, such as the same line segments), performance is strongly dependent on the number of elements.

Pop-out

It is easy to see a single yellow dot among an array of blue dots. More generally, a target with a unique property can often be detected rapidly and with little dependence on the number of items in the display. Such *pop-out* is believed to indicate the presence of a distinctive property (or *feature*) in the target item. According to this view, various features (e.g., color or orientation) are computed rapidly and in parallel across the visual field. A unique feature will be *salient*, and so attract attention to its location, causing it (and its properties) to be selectively accessed. Salience can also arise via *differences* between adjacent features. An item will pop out if it is the only one with an orientation that differs greatly from those of its neighbors, even if its orientation occurs elsewhere in the display.

Support for this view comes from the existence of *search asymmetries*, where a switch in the role of target and distractor items strongly affects performance. For example, a 'Q' among a set of 'O's pops out, whereas an 'O' among a set of 'Q's does not. This can be explained by the 'Q' having a unique feature (the tail) that is not present in the 'O's, and thereby becoming salient. Since 'O' is distinguished from 'Q' by the absence of a feature, it can never be salient. Search asymmetries yield a powerful method for identifying features – pop-out if some feature in the target does not exist in the distractors, and a slower search otherwise.

Emergent Features

Many features have been found that are simple properties of the image (e.g., orientation, size, and color). However, other features are *emergent*, being derived from the image in a relatively complex way. For example, when targets are triangles and distractors are forked-shaped items constructed of the same line segments, the triangles pop out, indicating that some property of the line arrangement (presumably closure) acts as a feature. The existence of such features is due to processes operating *preattentively* (i.e., prior to the application of selective integration).

Several types of preattentive process are known to exist. These include grouping between items, grouping within items, and completion of occluded items. Features have also been found that are based on the (recovered) three-dimensional scene rather than the two-dimensional retinal image (e.g., surface convexity and three-dimensional orientation).

Although preattentive processes can make search easy under some conditions (i.e., if the target

contains an emergent feature), they can also sometimes make it more difficult. For example, if target and distractors are both line configurations with distinctive line segments, search can still be difficult if the overall length of the configurations is the same. This indicates that selective access is easiest not for simple attributes of the image (e.g., individual line segments), but rather for the more complex structures formed by preattentive processes.

Conjunctions

An important type of search is the *conjunction task*, where the target and distractor sets contain the same features but differ in how they are assembled. Conjunctions can be either *weak* (at the level of sets) or *strong* (at the level of items). An example of a weak conjunction is search for a red vertical line among green vertical lines and red horizontal lines. Here the set of distractors contains all of the features in the set of targets. However, at the level of individual items, the target remains unique. In contrast, in a strong conjunction each target item would contain the same features as a distractor item (e.g., an 'L' among 'T's).

If highly discriminable properties are involved, search for weak conjunctions can be relatively easy. This has been explained in terms of *guided search*, where a guidance mechanism either inhibits items with non-target features, or excites items with target features. Once these mechanisms have reduced the number of possible items, the remainder can be searched more easily – if a target has a unique feature, it will pop out. Thus, for example, if searching for a red vertical line, all green items can be inhibited, leaving the single remaining (red) vertical line to pop out. According to this view, therefore, search for weak conjunctions may simply involve selective access.

In a strong conjunction, items differ only in the way in which their features are arranged, and so guidance cannot be used. Search for strong conjunctions is often difficult, requiring at least 30–50 ms for each item. This has been taken to indicate the serial application of a spotlight of attention that binds the features of each item together, integrating them into an *object file* (i.e., a coherent collection of features) (Kahneman *et al*., 1992). As such, search for strong conjunctions is primarily an issue of selective integration.

Several issues with regard to strong conjunctions are currently unresolved. Although it has been proposed that selective integration acts on one item at a time, at a rate of 50 ms per item, it has also been proposed that it might act on clusters of four or five items, at a rate of 200–300 ms per cluster. Indeed, a serial mechanism may not even be involved – search could be carried out via a parallel process with a processing speed dependent on the number of items in the display. It is also not known what happens to object files after attention has been withdrawn. Although it has been suggested that object files exist for some time, it may be that they dissolve almost immediately (Wolfe *et al*., 2000).

INDUCED FAILURES OF PERCEPTION

Suppose that we are looking for a pencil, and we believe that it is yellow. If the pencil is indeed yellow, the attentional control based on our belief can facilitate its perception. However, if the pencil is blue, this same control can be detrimental – indeed, we may completely fail to see a blue pencil that is directly in front of us. More generally, failures of selective access and selective integration can provide important insights into the operation of the mechanisms involved. Such studies can also provide information about what aspects of perception continue when selective access and selective integration fail.

Change Blindness

A number of studies have examined the ability of an observer to detect, identify, or localize the occurrence of a change in a display. Performance is measured in one of two ways, either by accuracy on a pair of displays containing a single change, or by RT on displays that continually alternate between an original and a modified image. In both cases, observers often experience great difficulty in reporting the presence of a change that is made simultaneously with another event, such as an eye movement, blink, or flash (Figure 3).

This *change blindness* has been regarded as evidence that attention is needed in order to see change (Rensink, 2000). According to this view, when the local signals due to the change are swamped (or otherwise neutralized) so that they no longer capture attention, a time-consuming attentional scan of the display is needed. The observer will be blind to the change until the appropriate item is attended.

Although a selective process of some type is involved in perceiving change, the nature of this selectivity has not yet been established. One possibility is that a complete representation of the original display is formed, and that change blindness results from a limited ability to compare this representation with the current image. According to this view, the key factor is selective access to a

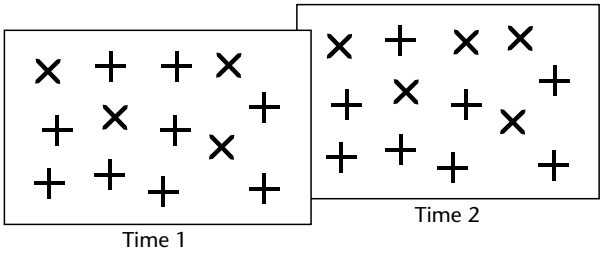

Figure 3. Change blindness. The observer is asked to detect, identify, or locate a unique change among a set of distractor items. This change can either be shown just once, or it can be continually presented by alternating between the two displays. Performance is extremely poor, provided that successive displays are separated by an interval of at least 80 ms.

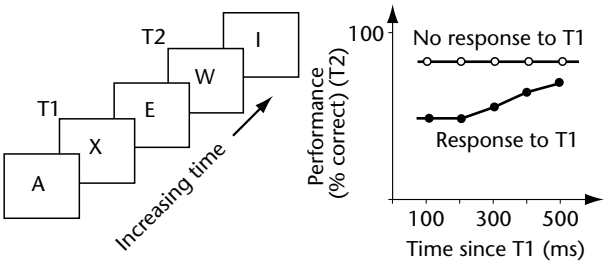

Figure 4. Attentional blink. When the observer is asked to report on two items (e.g., the colors of the consonants in a stream of letters), performance on the second of these (T2) is impaired if it is made within several hundred milliseconds of the occurrence of the first (T1). However, this degradation does not occur if no response is required of the first letter (e.g., if the observer reports only the color of the W).

comparison mechanism. Another possibility is that a complete representation of the display is never formed – representations of unattended items are volatile, and are simply replaced by representations of subsequent stimuli. Here attention is believed to act much as it does in visual search for strong conjunctions, integrating selected items over time and space so that they have a degree of spatiotemporal continuity, which then allows them to be seen to change.

Attentional Blink

Another phenomenon involving the failure to perceive stimuli is the *attentional blink*. Here a stream of successive items (usually letters) is presented at a location, and the observer attempts to report the presence of an item that has been designated in some way (e.g., by its color or its identity). Performance is measured by the accuracy of response. Whereas it is easy to detect a target when items appear at a rate of less than about 10 items per second, it becomes much more difficult to do this if the observer also has to respond to a target (T1) appearing earlier in the stream. Somehow, responding to T1 induces a 'blink' that makes it difficult for the observer to see – or at least respond to – a second target (T2) for the next few hundred milliseconds (Figure 4).

Control experiments have shown that this blink is not due to perceptual, memory or output limitations. Instead, it appears to result from attention being given to T1, leaving subsequent stimuli unattended and thus vulnerable to replacement by the items that follow them. Evidence in favor of this explanation is provided by the fact that T2 is difficult to report only if it is followed by another item. (Note that this replacement mechanism is similar to that proposed for change blindness.) Unseen T2 items can also facilitate the processing of semantically related items (Shapiro *et al*., 1997), providing further evidence that a considerable degree of processing can take place in the absence of awareness (and thus presumably in the absence of attention).

The time course of the blink itself has also been taken to correspond to an attentional *dwell time* (the time needed to integrate the properties of an attended object into a coherent form). According to this view, once attentional processing has started on T1, it cannot be simply halted when T2 is encountered, but must run its course. The duration of this blink appears to be about 300–400 ms.

Inattentional Blindness

A different approach to exploring attention involves asking observers to attend to a given event, and then introducing an unexpected item at some point. Performance is measured by the accuracy of responses to questions about the intrusive stimuli. Interestingly, observers often have great difficulty in reporting such stimuli, even though the items are easily seen if they are expected. This failure to report unexpected – and therefore unattended – stimuli is called *inattentional blindness* (Figure 5).

Early studies were *selective*, requiring the observer to attend to a subset of the stimuli (e.g., to attend only to the white-shirted or black-shirted players in a basketball game). Observers often had difficulty noticing the appearance of the unexpected stimulus under these conditions. Although superimposed images were used initially, later studies showed that these failures occurred also even when the stimuli were elements of a single scene and the unexpected stimulus was a person

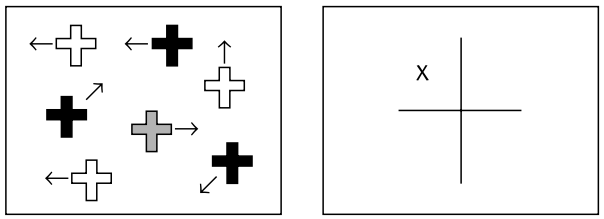

Figure 5. Inattentional blindness. (a) In a *selective* task, the observer must select a subset of the items in the display (i.e., track a set of moving black crosses among a set of white ones). While engaged in such selection, the observer will generally be blind to the occurrence of an unexpected item, even if it is unique (e.g., a gray cross moving in a unique direction). (b) In a *nonselective* task, the observer is presented with a pair of lines and asked to judge which of the two lines is longer. After a number of such tests, a display is presented that contains an extra element (e.g., a letter). Again, detection of these unexpected elements is generally quite poor.

dressed as a gorilla (Simons and Chabris, 1999). For selective tasks, inattentional blindness appears to be at least partly due to observers inhibiting the features of the irrelevant stimuli. If this were so, it would illustrate a failure of selective access.

Mack and Rock (1998) introduced a *nonselective* variant, where attention could be given to all stimuli that were present before the appearance of the unexpected item. Here observers attended to an overlapping pair of lines (one horizontal and one vertical) and had to judge which line was longer. Again they often failed to see the unexpected item under these conditions, even when it was at the center of fixation. It is still unknown whether inhibition is also an important factor in nonselective tasks.

Although observers may not report seeing an unexpected item, such items can still influence conscious perception. For example, surrounding lines can induce a length illusion in the test lines that are perceived, even if the surrounding lines themselves are not reported. Again this indicates that representations of considerable sophistication are constructed in the absence of awareness (and thus presumably in the absence of attention).

ATTENTIONAL CONTROL

Whereas much of the research on visual attention has centered on the nature of the mechanisms involved (e.g., their speed, or what they select), an equally important issue concerns the way in which these mechanisms are controlled. Two types of control appear to exist, namely goal-driven *direction* and stimulus-driven *capture*. These behave quite differently, with direction corresponding to a slow, sustained process, and capture being faster and more transient. It has been argued that these mechanisms control different types of attentional process, direction being involved with selective access, and capture being involved with selective integration (Briand and Klein, 1987).

Attentional direction occurs, for example, when observers in an orienting task engage their attention on the stimulus to which an arrow is pointing. It also occurs in guided search, where observers select the features to be enhanced or suppressed. In both cases, observers voluntarily select the appropriate locations or features in order to facilitate performance, and they are able to refrain from this if performance is adversely affected (e.g., if cues are misleading).

In contrast, attentional capture is largely involuntary, and interference can result from any features consistent with an *attentional control setting*. For example, visual search for a unique orientation is impaired if one of the distractors has a unique color, even though color is irrelevant to the task. In this case, capture occurs because the control setting can be set only for a *difference* in some feature; the relevant type of difference (e.g., orientation) cannot be represented. Indeed, a unique feature of any kind will capture attention when this control setting has been selected.

The sudden appearance of an item has a privileged status, in that capture can occur regardless of the setting. Interestingly, the relevant factor is not the motion signal that accompanies the appearance, but rather the appearance of the object itself (Yantis and Hillstrom, 1994). However, this type of capture has its limits, in that it appears to be effective only if attention is not already engaged on some task.

RELATIONSHIP TO CONSCIOUSNESS

Although recent research views attention primarily in terms of selection, an older tradition (stemming from William James) viewed it primarily in terms of conscious perception. Traces of this older tradition persist in two functions that are currently ascribed to attention, namely selective access or integration for a process that eventually affects conscious perception, and selective entry into consciousness itself. With regard to the first of these, the relationship between attention and consciousness is unproblematic for a process that is under conscious control. However, there is increasing evidence that many actions are performed without

any involvement of consciousness. Given that such actions require selection for effective operation (e.g., manual grasping may need to select items with a horizontal orientation), there may be selective mechanisms acting on processes that never involve consciousness, at least in terms of immediate control. Whether these mechanisms should be described as 'attentional' would seem to be a matter of convention. (*See* **Motor Control and Learning**)

With regard to the entry of stimuli into consciousness, there may well be selective processes with exactly this function. For example, change blindness, the attentional blink, and inattentional blindness are all phenomena in which the failure to report an otherwise highly visible stimulus could be attributed to a failure of consciousness to access the appropriate representation. However, it is not yet clear whether this is actually the case – although a failure to report could be due to a failure to consciously see a stimulus, it could also be due to a failure to remember it. It is also not yet clear whether conscious experience necessarily arises via attention – non-attentional processes may exist that can provide conscious experience of at least some aspects of the visual field. As with many of the issues relating to attention, a clearer understanding of these matters must await future developments.

Visual Evoked Potentials

Intermediate article

Brian F O'Donnell, Indiana University, Bloomington, Indiana, USA

CONTENTS

Visual evoked potentials are deflections in the electroencephalogram which are evoked by a visual stimulus, time-locked to stimulus onset, and generated by neural activity.

INTRODUCTION

Since the development of experimental psychology in the late 1800s, behavioral measures such as reaction time and accuracy have been used to test models of perceptual, cognitive and motor processes. While behavioral measures have proved highly successful in testing models, they have several limitations. First, the processing of stimuli or events that do not elicit behavioral responses is difficult to characterize. Second, the timing of mental processes between stimulus and response can only be indirectly measured. Visual evoked potentials (VEPs) provide a direct, noninvasive measure of neurophysiological activation which can complement behavioral measures in the study of cognitive mechanisms. Because of the high temporal resolution of VEPs (milliseconds), they are particularly well suited for investigation of the temporal dynamics of cognition.

EVOKED POTENTIALS

In 1929 Hans Berger reported that electrical activity from the human brain could be noninvasively recorded using scalp electrodes, and that this activity could be altered by sensory stimulation. This recording was called the electroencephalogram (EEG), popularly known as 'brain waves'. The EEG represents the synchronized activity of several separate populations of neurons which is conducted to the scalp. Stimulation may result in subsequent positive and negative deflections in the EEG, referred to as evoked potentials (EPs) or event-related potentials. Magnetoencephalography (MEG) has also been used to obtain measures of event-related neuromagnetic activity. Because of their smallness relative to the background EEG, evoked potentials are often averaged together over several stimulus presentations or trials to increase the signal-to-noise ratio. This technique, called signal or transient averaging, was applied by Dawson in 1951. It results in noise reduction that is proportional to the square root of the number of trials, and can resolve signals in the microvolt range. Signal averaging requires the assumption that the EP signal is stationary from trial to trial. Other signal processing techniques, such as adaptive filters or response locked averaging, can be used when the latency of the EP signal varies from trial to trial. (*See* **Electroencephalography (EEG)**)

TRANSIENT VERSUS STEADY STATE VEPS

Visual evoked potentials have been used since the 1960s to investigate sensory and cognitive processing. Unlike reaction time or accuracy, VEPs are spatiotemporal measures which vary over time and the surface of the head. Transient VEPs are elicited by a single stimulus, and consist of a series of deflections in the EEG which usually return to baseline. Steady state VEPs are elicited by synchronization of the EEG to the temporal frequency of a periodic visual stimulus, such as a flickering pattern, producing a repetitive waveform in phase with the stimulus frequency.

A wide variety of signal processing techniques have been used to measure VEP phenomena, which can be broadly categorized into time and frequency domain measures (Regan, 1989). Transient VEPs are usually analyzed in the time domain: measures are obtained from the averaged transient waveform elicited by a stimulus onset or other time-locked event, usually displayed with time on the x axis

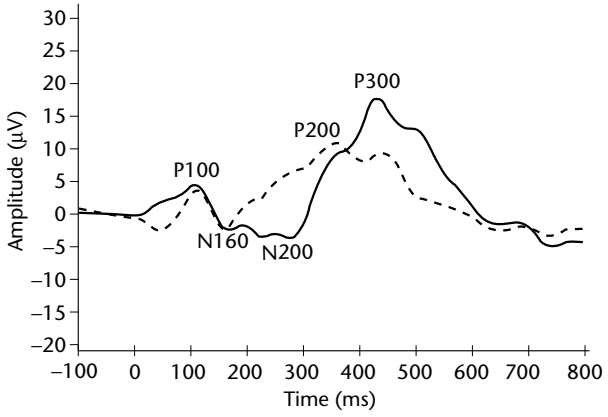

Figure 1. Transient visual evoked potentials elicited by frequently presented nontarget line segments (solid line) and infrequently presented (probability 0.15) target line segments (dashed line). The segments differed in orientation, and the participant pressed a button to the target segments. The frequent, nontarget stimuli elicit a negative deflection about 160 ms after stimulus onset (N160) and a positive deflection that follows it (P200). The target stimuli elicit a prolonged, negative shift in the event-related potential, sometimes called the selection negativity, followed by a large positive deflection, the P300 component. Because a difficult discrimination was used in this paradigm, the P200, N200, and P300 peaks are delayed in time of appearance.

and voltage on the *y* axis (Figure 1). The simplest approach to measuring the waveform is 'peak–picking', in which the latency and amplitude of a peak voltage is measured. Because the peak voltage in a given latency range may vary from recording site to site, average voltages over a latency window may be used. The dependent measures for the transient VEP are latency, amplitude (voltage) and topography (variations in voltage across recording sites on the scalp). Steady state VEPs are usually analyzed in the frequency domain, and have been extensively used in studies of sensory processes. These techniques usually require transforming the time domain measures into the frequency domain using Fourier analysis. The Fourier analysis transforms a time domain waveform into a sum of sinusoidal waveforms differing in power and phase. The power spectrum, which displays power in a segment of EEG as a function of frequency, is shown in Figure 2 for a steady state waveform.

COMPONENTS

Cognitive scientists often describe a transient VEP waveform in terms of 'components' associated with a specific polarity, latency and scalp topography. Components are typically labeled in terms of their polarity and latency relative to a sensory or motor event. Polarity is indicated by 'P' for positive and 'N' for negative. Latency is indicated in milliseconds. For example, 'N400' indicates a component with negative polarity which occurs about 400 ms after stimulus onset. Other techniques such as principal components analysis or independent component analysis have been used to identify components on the basis of covariation of voltage among recording sites or conditions. Because the characteristics of VEP components are highly dependent on stimulus properties and task demands, components are usually implicitly or explicitly associated with specific types of experimental protocols. In the next section, VEP components and methods are described which have been applied to the investigation of visual processing in humans. These include the characterization of mechanisms underlying perception, selective attention, language comprehension, recognition memory, and perceptual integration. In neurological disorders, VEPs are highly sensitive to lesions that affect conduction along the retinal-striate pathway, such as neuritis of the optic nerve or multiple sclerosis. In addition, VEP components are sensitive to illnesses that affect visual attention, such as neurodegenerative illness or schizophrenia.

VISUAL CHANNELS

Psychophysical studies suggest that early stage vision entails the operation of channels tuned to such simple stimulus features as spatial frequency, motion, contrast and color. Both psychophysical and cellular evidence suggests the existence of two major visual channels or pathways in humans. The magnocellular, transient, or broadband system is sensitive to contrast, high temporal frequencies, and low spatial frequencies. The parvocellular, sustained, or color opponent channel is sensitive to color, low temporal frequencies and high spatial frequencies. (*See* **Vision: Form Perception**)

Steady state and transient VEP studies have provided neurophysiological support for multiple visual channels in humans. For example, studies using flickering gratings indicate that low spatial frequencies yield the largest response amplitudes at high temporal frequencies, while high spatial frequencies show the largest amplitudes at low temporal frequencies (Regan, 1989). Transient EPs to patterns modulated at low temporal frequencies (about 1 Hz) have been shown to be sensitive to luminance, contrast, visual field location, and possibly color. Selective attention to particular

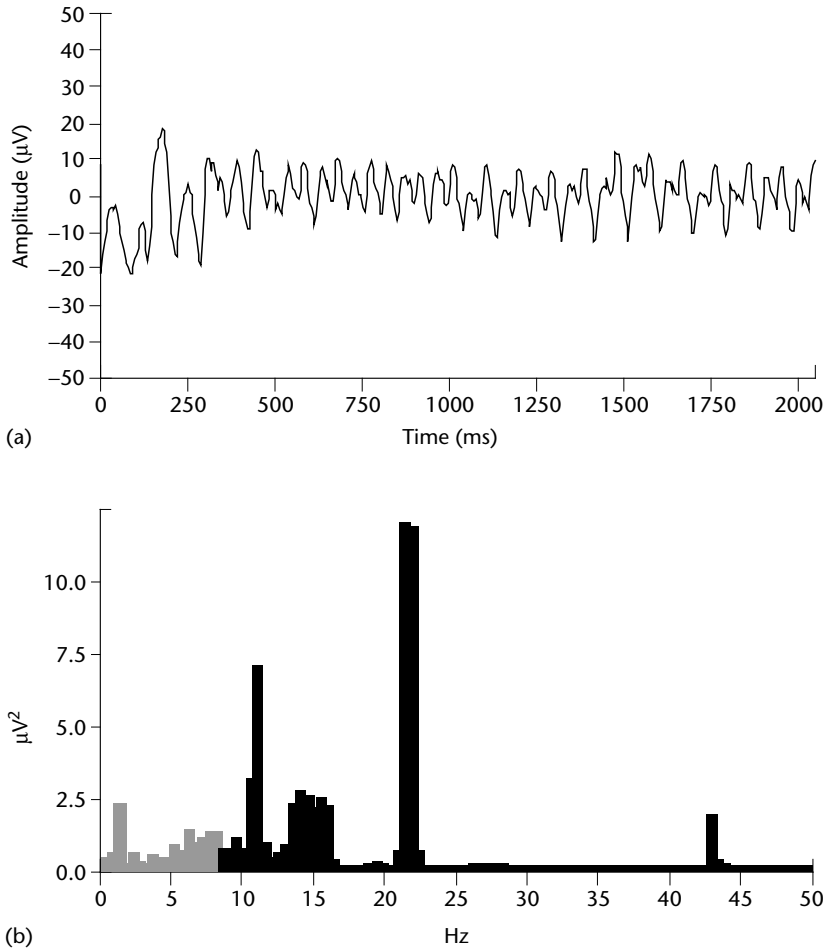

Figure 2. Time and frequency domain representations of a visual evoked potential (VEP). (a) Averaged VEP elicited by a flickering white and black patch, presented at a flicker rate of 21 Hz. Notice the synchronization of the VEP with the oscillating stimulus. (b) A Fourier transform was applied to the time domain data to obtain a power spectrum, which shows peak power at the stimulation rate (21 Hz).

stimulus features such as orientation, size, location, and color can have marked effects on VEP components, as described below (O'Donnell *et al.*, 1997; Luck and Hillyard, 2000).

ATTENTION

Visual EPs are highly sensitive to attentional demands. Most VEP studies of attentional mechanisms have characterized VEP components in the transient, or time, domain (O'Donnell *et al.*, 1997; Luck and Hillyard, 2000). Typical VEPs to nontarget and target stimuli in a discrimination task are shown in Figure 1. Selective attention effects may be apparent in the VEP as early as 80 ms after stimulus onset, and continue to affect processing after execution of a response. From an electrophysiological standpoint, then, selective attention is neither an early nor a late process, but subsumes a variety of mechanisms which span the perceptual, semantic and working memory domains. (*See* **Attention, Models of**; **Attention, Neural Basis of**; **Visual Attention**)

Spatial attention towards a specific visual region enhances the P100 and N160 components to stimuli presented in that region. This effect is largest over posterior electrode sites contralateral to the attended location. Under conditions of high stimulation rate and task demands, P100 and N160 show a graded diminution of amplitude as the target becomes more distant from the attended region. Since P100 effects may be detected to both target and nontarget stimuli, and probably occur prior to stimulus identification, it may reflect spatial-filtering mechanisms engaged before categorization of stimuli.

Target stimuli in a discrimination task usually elicit two long-latency components, the N200 and

P300 components, particularly to low-probability, novel stimuli (Donchin and Coles, 1988). Both N200 and P300 appear to index operations involved in selective attention. The amplitude of P300 is inversely proportional to global stimulus probability in a sequence, as well as the sequence of immediately preceding stimuli. Both N200 and P300 can be elicited by omitted stimuli in a sequence, indicating that these components can arise from internal representations or operations in the absence of a stimulus. The N200 and P300 latencies are proportional to difficulty of discrimination and classification. Both P300 amplitude and latency are sensitive to the mental workload imposed in a dual-task paradigm, suggesting that it may provide a physiological measure of the attentional resources required by a task. The P300 amplitude is usually maximal over the parietal region, with a symmetric distribution for both auditory and visual stimulation, while N200 voltage topography varies with visual task demands and stimulus properties. These findings suggest that the N200 component reflects activation of cortical tissue directly involved in the representation and comparison of a sensory input and the working memory representation of a target stimulus; P300, on the other hand, is much less sensitive to the physical characteristics of stimuli, and may represent a higher-order process which is minimally influenced by perceptual representation, such as expectancies, context updating, and stimulus meaning.

LANGUAGE

Event-related potential components have been used to probe the temporal course of semantic and syntactic processes. In 1980, Kutas and Hillyard (Kutas and Van Petten, 1994) showed that a large negative deflection occurred when an incongruent word terminated a sentence read by a subject. For example, the sentence 'He spread the warm bread with —' could be terminated with a word that is congruent with the preceding context, such as 'butter', or instead with an incongruent word, such as 'socks'. The incongruent word elicited a negative deflection at about 400 ms, the N400 component, which was smaller or absent in the VEP to the congruent or appropriate word. This effect was not observed when a word differed in font size, but was semantically appropriate. The N400 component can also be evoked in word-pair priming paradigms; the deflection is larger to the second word of a pair if the words are semantically unrelated, such as 'doctor – goose', than in the case when the second word of the pair is related to the first, such as 'doctor – nurse'. The amplitude of the N400 component is inversely related to the predictability of the word from the preceding context. Within a sensible sentence, N400 amplitude is larger for words at initial positions than at later positions, again suggesting that it directly reflects contextual constraint. At early sentence positions, N400 amplitude is also affected by word frequency, in that low-frequency words produce larger N400 amplitudes than high-frequency words. Word priming effects have suggested that N400 indexes automatic spread of activation through semantic networks. In terms of sentence processing, it may also reflect specific mechanisms in working memory which integrate a new word into the preceding context. The N400 component is often followed by a large positive component at about 600 ms, the P600 component. The functional significance of the P600 component is still unclear, but it may be more sensitive to syntactic than semantic anomalies (Kutas and Van Petten, 1994; Osterhout *et al*., 1997). (*See* **Syntax and Semantics, Neural Basis of**; **Natural Language Processing, Disambiguation in**; **Lexical Ambiguity Resolution**)

MEMORY

Visual evoked potentials are highly sensitive to the occurrence of novel stimuli and target stimuli in a sequence, showing sensitivity to mechanisms involved in recognition memory. Evoked potentials may also reflect encoding processes (Rugg, 1995). Visual EPs to words to be subsequently recalled or recognized show greater positivity than to words that are not subsequently remembered. This effect usually occurs after several hundred milliseconds of processing. Repetition effects have also been noted, although the relative contribution of implicit versus explicit memory in these effects is still under investigation. Words that are repeated in a series of words show a more positive VEP than those that are seen for the first time, similar to repetition priming observed on behavioral measures.

NEURAL SYNCHRONIZATION

Cellular studies suggest that neural activity in the gamma frequency range (> 30 Hz) reflects the synchronization of neural assemblies involved in 'binding' or integration of various features of an object within a sensory modality, across modalities, and across time. Both EEG and MEG methods have been used to measure human neural synchronization during perceptual and cognitive processing. In experimentally induced binocular rivalry, for

example, MEG coherence across widely separated sensor sites was largest to the temporal frequency of the stimulus which was consciously perceived (Srinivasan *et al*., 1999). While still controversial, this finding supports the hypothesis that neural synchronization may be an important mechanism for late stage integration of percepts. (*See* **Neural Oscillations**; **Gamma Oscillations in Humans**)

Visual Scene Perception

Introductory article

Helene Intraub, University of Delaware, Newark, Delaware, USA

CONTENTS

When studying a scene, viewers can make as many as three or four eye fixations per second. A single fixation is typically enough to allow comprehension of a scene. What is remembered, however, is not a photographic replica, but a more abstract mental representation that captures the 'gist' and general layout of the scene along with a limited amount of detail.

INTRODUCTION

The visual world exists all around us, but physiological constraints prevent us from seeing it all at once. Eye movements (called saccades) shift the position of the eye as quickly as three or four times per second. Vision is suppressed during each saccade, and then resumes during the next eye fixation (the period of time that the eye pauses to receive visual input). It has been postulated that the mental representation of a scene that is maintained across a saccade ('transsaccadic memory') is surprisingly sparse. This information, in conjunction with expectations about upcoming layout, provides a means for integrating successive views into a coherent representation of a scene. (*See* **Perception: Overview**)

SCENE COMPREHENSION AND ITS INFLUENCE ON OBJECT DETECTION

Perception occurs so quickly and automatically that individuals cannot discern the amount of time they need to understand a scene. Are multiple eye fixations necessary for scene perception, or are we able to perceive the meaning of a scene right away, based on the first eye fixation? One way to address this question is to ask whether viewers can understand unrelated scenes presented in rapid succession at a rate that mimics the rapid pace at which we normally make eye fixations (e.g. three per second). The reason for using unrelated scenes is to allow an assessment of what can be gleaned from a single glimpse without any bias from prior context. Immediately after viewing a rapid sequence like this, viewers participate in a recognition test. The pictures they just viewed are mixed with new pictures and are slowly presented one at a time. The viewers' task is to indicate which pictures they remember seeing before. Following rapid presentation, memory for the previously seen pictures is rather poor. For example, when 16 pictures were presented in this way, moments later, viewers were able to recognize only about 40 to 50 percent in the memory test. One explanation is that they were able to perceive only about 40 to 50 percent of the scenes that had flashed by and those were the scenes they remembered. However, contrary to this plausible explanation, many viewers adamantly claimed that they had indeed momentarily perceived most of the scenes but that the onslaught of new scenes interfered with their ability to remember what they had momentarily grasped. (*See* **Memory Consolidation**; **Memory Distortions and Forgetting**)

To determine whether viewers were good at momentarily grasping the meaning of a scene under these conditions, it was necessary to design a task that could tap into the early stages of scene processing at a point before forgetting is likely to take place. Subjects were shown the same rapid sequences as in the previous experiments, but in this case a brief description of one of the pictures (e.g. 'a road with cars') was provided in advance. They were instructed to look for a picture matching that description and to immediately press a response key as soon as they saw it. Because the detection task required them to respond immediately (without waiting until the end of the sequence), this minimized the likelihood of forgetting. At speeds as fast as three and four pictures per second, the ability to correctly detect a scene based on a description was excellent, usually reaching about 90 percent correct or better. This performance far exceeded the 40 to 50 percent

correct obtained from subjects who took the recognition test. Other experiments were conducted in which the description provided at the outset was nonspecific (e.g. 'a type of furniture'), and viewers were again better at detecting pictures than remembering them. These results indicate that scene perception is very rapid: a single 'fixation' is frequently sufficient to allow identification, even under the demanding conditions of rapid serial visual presentation.

Scenes, however, usually contain multiple objects. There are two ways that the identification process might proceed: (a) first, objects are identified, and then viewers begin to understand what kind of scene they are looking at, or (b) first, the scene's general meaning and layout are perceived holistically, and then identification of specific objects follows. Although a controversial topic, many studies suggest the second alternative. In a series of experiments, outline drawings of scenes were each briefly presented (e.g. 50–150 milliseconds) one at a time. Prior to the presentation of each scene, viewers were provided with the name of an object (e.g. fire hydrant), and immediately after each presentation a dot appeared on the screen at the location previously filled by one of the objects in the scene. Viewers had to say whether or not the object named at the outset (in this example, a fire hydrant) had been present at that location. In some cases the object did fit with the general meaning of the scene (e.g. a fire hydrant in a street scene) and in others it did not (e.g. a fire hydrant in a kitchen scene). If objects are identified before the scene's meaning is grasped, then the ability to detect the object should be unaffected by whether or not it fits with the context of the scene. However, contrary to this possibility, the object's relation to the scene as a whole did affect the speed and accuracy of the response. Other relations of the object to the scene, such as whether its relative size did or did not fit the scene, or its location in the scene was plausible or implausible, had a similar effect on the response. This suggests that we may grasp the meaning and general layout of a scene rapidly enough to affect our ability to detect specific objects in the scene. (*See* **Vision: Object Recognition**)

A similar conclusion has been drawn from other experiments in which eye movements were monitored. Pictures were presented for relatively long intervals that allowed viewers to make many eye fixations. Prior to the picture's onset, viewers fixated the center of the screen. Frequently, the first saccade brought the eyes to an object that didn't belong, and subjects maintained longer fixation times on that object, as if they were trying to understand it. Again, this suggests that a scene's meaning and layout is understood very rapidly in processing, occurring prior to identification of all its objects. How does this information become integrated with new information obtained from the next eye fixation?

TRANSSACCADIC MEMORY

Initially, many researchers who studied the relation between eye movements and cognition thought that, after each eye fixation on a scene, a detailed sensory record of the fixated region was stored in a very short-term memory system called an 'integrative buffer'. Within the buffer, information from a new fixation would be integrated (i.e. knitted together) with the stored information from the previous fixation. By integrating the details of successive views, the system was thought to provide the viewer with a seamless, detailed perception of the world – like piecing together parts of a jigsaw puzzle. However, research on memory for briefly glimpsed scenes, and research on reading and eye movements, has led to a different proposal about how views are integrated across saccades. The idea is that our perception of a detailed, continuous world is to some degree illusory. Instead it is proposed that 'transsaccadic memory' (memory for information that is maintained across a saccade) includes the scene's meaning, along with the general layout, and only some detail.

Transsaccadic memory allows the visual system to relate the information obtained from one eye fixation to the contents of the next – but not by integrating detailed photograph-like views. It is somewhat surprising to think that our perception of the world is built up from relatively sparse information, but there is a lot of evidence to support this claim. You can get a sense of this yourself if you look at a complex visual scene (e.g. a bookshelf with books of different sizes and colors) and then close your eyes and recount all the details. You will probably find that your visual memory is missing a lot of information. Of course, the claim is best supported by controlled experiments that carefully address the viewer's ability to detect changes.

Various types of change detection experiments have been conducted in which a change is made in a display at exactly the same time that the eyes make a saccade. Using computer technology, a viewer's eyes are monitored, and when a saccade is launched, a change is made before the eyes land again and begin the next fixation. Therefore, the change in the scene takes place while vision is suppressed. When the eyes land, the change has

already occurred. In these situations, many kinds of changes go unnoticed both in scenes and in text. For example, in one case, researchers presented sentences in an AlTeRnAtInG cAsE on a computer screen. Each time the viewer made an eye movement, the case was reversed (capital letters became small and small letters became capitals). This did not disrupt the ability to read, and understand the text. Amazingly, the viewers didn't even notice the changes.

PERCEPTION OF 'GIST' VERSUS DETAILS

Although the research described earlier shows that viewers can rapidly understand the general meaning or 'gist' of a scene, they are remarkably poor at noticing changes from one look to the next: a phenomenon called 'change blindness'. One of the best examples of change blindness uses a presentation technique (the 'flicker' technique) that is very similar to the rapid picture presentation technique described earlier. So it is interesting to make a comparison. (*See* **Object Perception, Neural Basis of**; **Change Blindness**; **Visual Attention**; **Illusions**)

In preparation for the study, the experimenter selects scenes and then uses computer graphics to edit each one, changing a particular feature (e.g. a lamp disappears or changes color; diagonal stripes on a wall are reversed). The original and the altered version are each presented for a brief duration that mimics a single eye fixation. The two versions keep alternating throughout the sequence with a blank interval in between presentations. This interval is meant to simulate the suppression of vision during a saccade. The viewers' task is to identify the change. Even though they can clearly identify the scene every time it appears, they do not notice the change right away. The most difficult cases required more than 80 alternations (more than 50 seconds) before even large changes were detected. What is most interesting is that the changes were actually very easy to see if the viewer received a hint about the location, or just fixated the location. This demonstrates that memory for a scene, just a fraction of a second later, does not provide a detailed, picture-like representation – but does provide sufficient information to allow the viewer to recognize that the same basic scene is being repeated.

BOUNDARY EXTENSION

How does the visual system integrate the relatively sparse information held in transsaccadic memory from one fixation to the next, thus providing a coherent representation of the scene? A phenomenon called 'boundary extension' provides one answer to this perplexing question. It also shows that although the representation of a scene lacks detail, it has an overabundance of another type of information that may serve to facilitate integration of views. After looking at photographs for as long as 30 seconds each, people tend to make an interesting error. They remember having seen beyond the edges of the picture! They remember seeing information that was *not* in the picture but that was likely to have existed just outside the camera's range of view.

This overinclusive memory is so convincing, that when they see the same photographs again (in a recognition test) they reject them as being the same: they claim that the test picture doesn't show as much of the scene as had the 'original' picture they studied earlier. Boundary extension can also be seen when other viewers draw the photographs from memory. The first two pictures in Figure 1 (panels (a) and (b)) show a close-up view of a scene and a viewer's drawing from memory. Notice that the drawing extends the boundaries of the view. Although the trashcans, fence, and lid are all cropped by the photograph's edges, the subject remembered seeing them as whole, and also

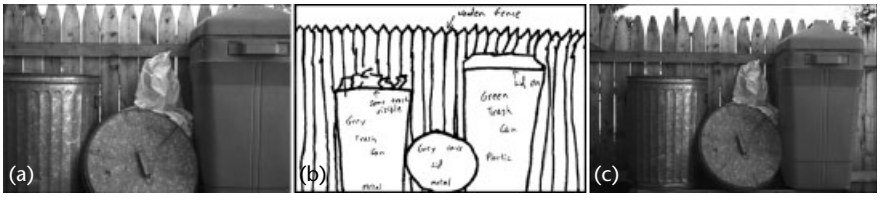

Figure 1. (a) A photographic close-up of a scene, (b) a viewer's drawing of the close-up from memory (note the extended boundaries), and (c) a more wide-angle photograph of the same scene. (Based on H Intraub and M Richardson (1989) Wide-angle memories of close-up scenes. *Journal of Experimental Psychology: Learning, Memory and Cognition* **15**: 179–187).

remembered seeing parts of the fence on the left and right of the scene, some sky above the fence, and more of the scene at the bottom. It is tempting to think of this as just an error, but if you look at a wider-angle photograph of the same scene in panel (c), you will see that the viewer's 'error' actually provides an excellent prediction of what really did exist outside the boundaries of the close-up. The drawing looks more like the wide-angle view than the close-up that the subject had actually studied. This effect appears to be the rule rather than the exception in memory for scenes (particularly close-ups). In one experiment it occurred in 95 per cent of the 133 drawings made by 20 different people. Other research showed that even when people tried hard not to make this mistake, they couldn't prevent it from happening.

Boundary extension reveals the remarkable ability of the visual system to predict the continuation of scene layout and may serve to facilitate the integration of views by (a) 'priming' the visual system to see the upcoming layout, and (b) placing the view within a larger context. To determine whether boundary extension would occur rapidly enough to aid integration of views during visual scanning, rapid sequences of pictures were again used in an experiment. Subjects viewed three pictures in rapid succession, and one second later, one picture was repeated and remained on the screen. Viewers rated the picture on a 5-point scale to indicate whether the view was the same, was more wide-angle, or more close up than the view they had seen a second earlier. Subjects tended to rate the repeated picture as showing less of the scene than the 'original' picture – thus indicating that they had remembered it as showing a more wide-angle view. The visual system very rapidly extrapolated the picture's layout – so that the viewer remembered having seen more of the scene than they actually did. Recent research has shown that the same anticipatory error occurs in memory for real three-dimensional scenes that are viewed through a window. People remember seeing expected information from just outside the view. (*See* **Imagery**; **Memory Distortions and Forgetting**; **Vision: Occlusion, Illusory Contours and 'Filling-in'**)

Taken together, experiments on scene perception and memory suggest that the visual system strikes a compromise between the speed of scene comprehension and the amount of detail that will subsequently be stored. Rapid serial visual presentation of pictures in conjunction with detection tasks shows how quickly complex scenes can be identified, whereas change detection research suggests that viewers cannot retain all the details in a scene – even a fraction of a second later. Although memory from one fixation to the next is less detailed than a photograph, this 'sparseness' may aid integration of successive views as the eyes visually scan a scene. Indeed, it has been argued that we don't need to have a detailed visual memory because if we want to see a detail in our environment, we can rapidly fixate the region in question – an act requiring only a fraction of a second. Research on boundary memory indicates that the exact location of the borders of each view is not retained. The visual system apparently systematically extrapolates beyond those borders, so that the viewer remembers not only the layout that was actually seen but also the expected layout just beyond the edges of the view. This combination of rapid identification, limited detail retention and predictive extrapolation would seem to allow considerable economy in the way we perceive and remember the visual world. (*See* **Spatial Cognition, Models of**; **Social Processes, Computational Models of**; **Vision: Top-down Effects**)

Williams Syndrome

Introductory article

Howard M Lenhoff, University of California, Irvine, California, USA

CONTENTS

Williams syndrome is a rare genetic condition caused by the absence of a small portion (containing about 20 genes) from one copy of chromosome 7. Individuals with Williams syndrome have a mean IQ of 55 and exhibit a strange array of impairments and behaviors. Their abilities in language and music intrigue both cognitive scientists and geneticists.

INTRODUCTION

Individuals having the neurodevelopmental congenital condition called Williams syndrome (WS) share a number of features, including 'elfin' facial traits, talkative and friendly behavior, an average intelligence quotient (IQ) of 55, and a number of physiological and motor impairments. Williams syndrome is presumed to be present in 1 out of every 20 000 births. This syndrome is of special interest to cognitive scientists for a number of reasons. First, in addition to their cognitive and physical defects, people with WS also possess a range of unusual abilities, and even talents. Unlike most populations of cognitively disabled people, those with WS show particular strengths in using language, in recognizing and discriminating among faces, and in their proclivity for and abilities in music. Second, people with WS are genetically homogeneous, exhibiting a common loss of a particular group of genes from one strand of chromosome 7. In this way they differ from other atypical populations who show unusual abilities, such as people with autism, who are poorly defined genetically. Third, new research on the presence and relatively high incidence of absolute (perfect) pitch among people with WS shows promise of being useful in understanding links between musical abilities and the acquisition of language by young children, and the relationship of specific genes to those behaviors.

Scientific knowledge of WS, first described in 1961, is relatively new. In 1993 we learned that most individuals affected by WS have a common microdeletion of about 20 genes from the band region q11.23 of chromosome 7. Three of the missing genes (*LIMK1*, *FZD3* and *WSCR1*) are active in the normal brain – a sign that they could influence brain development and function. In accord with the findings of the human genome projects, it would seem that the unusual behaviors found in people with WS are polygenic in origin, i.e. they are influenced by many genes during the development of the brain and related structures.

SYMPTOMS

People with WS tend to look like one another, especially in the years before puberty. Examination of their faces shows eyes that appear puffy and relatively close together. They have a small, upturned 'pug' nose, a wide mouth with full lips, and a small chin with receding jaw (Figure 1). At birth many of these babies possess minor to severe cardiovascular problems, some requiring surgery. Other common medical problems in infancy are difficulty with feeding and severe stomach pains, sleeplessness, and (in some cases) high levels of blood calcium. They experience delays in motor development, and begin walking at about 21 months, usually with an awkward gait. As the children grow older they show further delayed physical and mental development. Many of the childhood physical problems gradually become less severe, whereas musculoskeletal problems become more noticeable. Problems with connective tissue, such as diverticuli of the bladder or colon, may develop later in life. Their hair turns gray and their skin ages prematurely.

PERSONALITY TRAITS AND TALENTS

Cognitive Profile

Most people with WS share a number of personality and behavioral traits. Their average IQ is 55,

Figure 1. Typical facial characteristics of children with Williams syndrome.

some scoring 80. They are generally weak in basic academic and cognitive skills such as visual closure and spatial tasks. They have short attention spans (although not to music), are overly anxious, and have poor relationships with peers who do not have WS. On the other hand, they are generally viewed as friendly, outgoing and loquacious; they have been documented as good storytellers and as possessing good language abilities compared with others of similar IQ. They also are reported to have good visual recall skills and to perform well on tasks of face recognition and on those requiring recall of verbal material. Most possess the trait of hyperacusis, an extreme sensitivity to loud sounds, which they find painful.

In the early 1980s researchers compared the performances of people with WS with that of the general population and of people with Down syndrome. People with WS, in contrast to their generally weak performance on overall tests of cognitive ability, commonly used well-formed grammar in their spontaneous speech. They performed significantly better than those with Down syndrome on tasks of grammatical comprehension and production. They also had vocabularies larger than expected for their mental age: when asked to list some animals, for example, they often chose exotic examples rather than simply listing monosyllabic names such as 'cat' or 'cow'. They are also said to have strengths in prosody, i.e. the meter and tone of speech that carries meaning.

Children with WS seem more expressive than other children. When asked to provide a story for a series of pictures, as they told their tale, they often altered their pitch, volume, length of words or rhythm to enhance the emotional tone of the story. Unfortunately, these traits often mislead teachers and counselors into thinking that the children have better reasoning skills than they actually possess; thus, some do not receive the academic support they need.

People with WS do poorly on visual processing tasks, such as copying drawings. They fail, however, in different ways from people with Down syndrome, suggesting that the deficits in the two groups stem from different abnormalities in brain anatomy or processing. People with WS give more attention to details of images but fail to recognize overall patterns, whereas people with Down syndrome are more likely to perceive the global organization but overlook details. Individuals with WS also show strengths in recognizing and discriminating among photographs of faces previously unfamiliar to them.

Neurological Studies

Examination of brains by magnetic resonance imaging and at autopsy supports the probability that in Williams syndrome the brain is altered in complicated ways. For example, anatomical changes (such as abnormal clustering of neurons in visual areas) occur, which might lead to deficits in visuospatial abilities. Research linking specific structures in the brain with specific cognitive functions will potentially give us a better understanding of how differences in the brain in WS account for some of the unusual behaviors in this syndrome. In people with WS the brain volume is about 80% that of normal individuals, but we do not know how this deficiency affects specific behaviors.

MUSICAL ABILITIES

The peaks and valleys in the cognitive abilities of individuals with WS constitute a sort of mental asymmetry. Some major peaks, first observed by parents and music teachers, represent the unusual musical interest and abilities of these individuals. Their attention span for listening to and participating in musical activities is surprisingly long. People with WS have strengths in rhythm, many showing excellent skills on the drums. Many are able to retain the lyrics and melodies of complex music (some in a variety of languages) for periods of years. Those who speak and sing in languages other than their own have near-perfect accents; one is known to sing in thirty foreign languages. Most of those examples are anecdotal, however, and have not been extensively studied or quantified by researchers.

Absolute Pitch

Research on absolute pitch – the rare capacity to recognize, name and produce the pitch of a

musical note without a reference pitch – shows promise of elucidating a link between music and language, and of providing insights into how genes affect brain development to account for the unique mental asymmetry in WS. Absolute pitch occurs in 1 in 10 000 normal individuals in Western populations and in higher proportions among some Asian populations. Despite their low IQs, five individuals with WS participating in the research exhibited near-ceiling levels of absolute pitch, scoring, out of 1084 trials, 97.5% correct as a group; well-trained normal musicians with absolute pitch averaged 84.3% correct on similar tests. The exceptional abilities of people with WS support the view that they excel in a major component of 'musical intelligence', as defined by Gardner. That the five participants with WS tested all possessed absolute pitch suggests that its incidence in the WS population may be greater than that found in the general population of the Western world. The number of people with WS in North America on record is 4500; even if none of the others had absolute pitch, its incidence in this population in North America would be about 1 in 1000, which is still 10 times greater than the general population.

Critical Period

Cognitive scientists believe that in developing brains of normal individuals there is a critical period, a 'window of opportunity', for individuals to possess absolute pitch in adulthood. During that period, which covers infancy through age 6 years, normal people need to have had intense musical training. In contrast, most people with WS to date did not begin their study of music until later in life (including four of those in the pitch study) and their musical training is usually not rigorous because most do not read musical notes or name them. In WS the genes affecting brain development may damage not only those parts of the brain dealing with normal cognitive function, but also the brain mechanism for closing the window allowing for absolute pitch in adulthood. This change in brain development may also account for some of their other remarkable musical abilities.

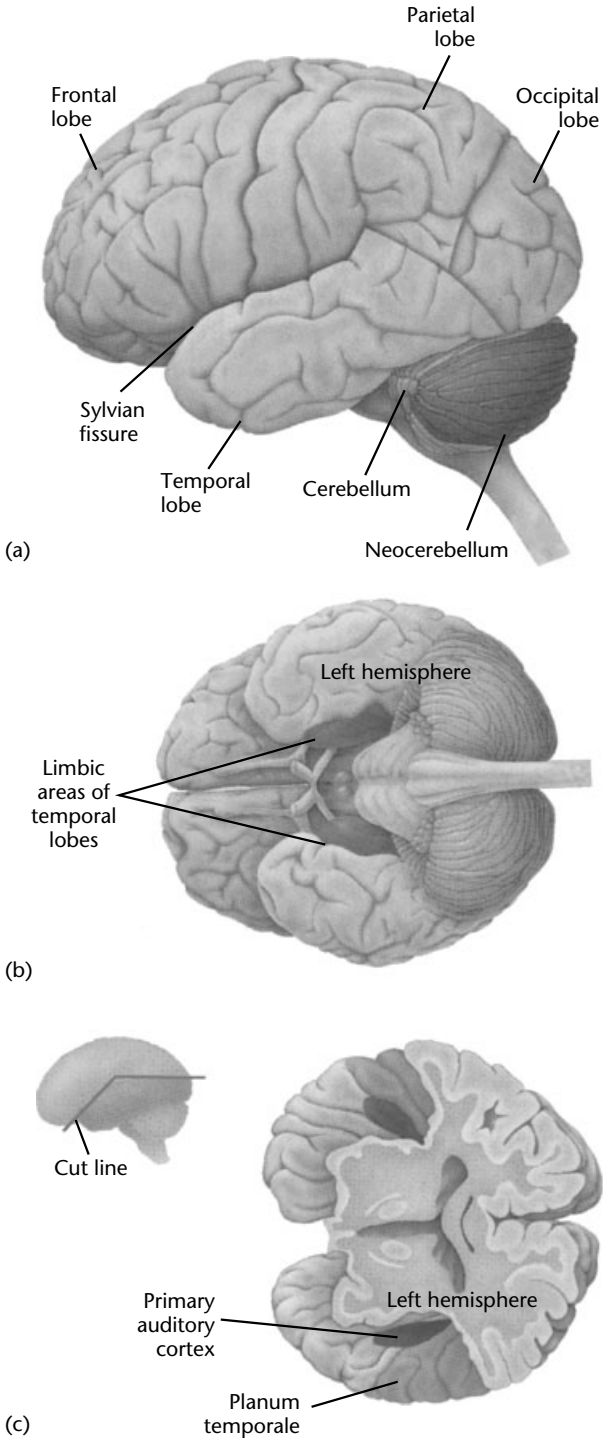

Figure 2. [*Figure is also reproduced in color section.*] Anatomy of the brain. (a) Side of brain; (b) underside of brain; (c) cut in plane of sylvian fissure.

Brain Anatomy

Preliminary anatomical analyses of the brain have identified features that could help explain the presence of musical talent in this syndrome. The primary auditory cortex (located in the temporal lobe) and an adjacent auditory region, the left planum temporale, thought to be important to language as well as to musicality, are relatively enlarged in musicians having absolute pitch. This

left–right asymmetry of the planum temporale is also observed in the few WS brains examined so far (Figure 2).

Much research on correlating parts of the brain with processes of learning language and music has studied sporadic cases of individuals whose brains have been damaged in specific regions by an accident, stroke or surgery. People with WS, whose brains have been specifically damaged in the neurodevelopmental processes affected by the lack of specific genes in chromosome 7, may offer cognitive scientists a different method to pinpoint areas of brain function in cognition.

Pitch and Language

What is the evolutionary advantage to the species of having absolute pitch? A possible answer comes from two different lines of research: one shows that infants are more attracted to absolute pitch than to relative pitch, whereas the opposite is true of adults; the other study shows that absolute pitch is relatively high in peoples who speak tonal languages, such as Mandarin and Vietnamese, where the same word can have different meanings dependent upon the tone used. Because a third of the world's people speak in tonal languages, researchers propose that absolute pitch allows humans to acquire languages and accents. Because the critical period for the development of absolute pitch appears to remain open in WS, adults with this syndrome may also offer opportunities for understanding the brain processes involved in the normal acquisition of language.

CONCLUSION

Research into the cognitive processes in people with WS may help elucidate the neuronal mechanisms by which the brain is involved in the acquisition of language. It is also making investigators see individuals with learning disabilities in a new light. Close study of WS has shown that low IQ scores can mask the existence of such capacities as the possession of absolute pitch. It also signals that other such individuals could have untapped potentials waiting to be uncovered if only researchers and society would take the trouble to look for and cultivate them.

Word Learning

Intermediate article

CONTENTS

The ability to learn the meanings of words is central to the development of language, and requires rich mental capacities – linguistic, conceptual, and social – that interact in complicated ways.

THE PROBLEM OF WORD LEARNING

Word learning is a remarkable feat. The communication systems of nonhumans contain nothing akin to words, and attempts to teach words to primates in captivity have met with, at best, limited success – even by the most enthusiastic estimates, none of these primates has attained the vocabulary size of a normal two-year-old human. And there is as yet no computer or robot that can do something as apparently simple as learning a word like 'dog' or 'mommy'. The unique power of humans to learn words has profound consequences, since word learning is obviously essential to language learning, and, more controversially, may play an important role in cognitive development.

What makes word learning so difficult? Developmental psychologists often cite an example by Quine (1960), who imagines a linguist regarding a rabbit and hearing it called 'Gavagai'. What does *Gavagai* mean? Quine notes that there exists an infinity of possible interpretations of this new word: it could refer to rabbits, to mammals, to animals; to tails or legs; to whiteness or furriness; to running or moving. It could, from a logical point of view, refer to the top half of the rabbit, or to its outer surface, or even to undetached rabbit parts. Since all of these interpretations are consistent with how the word is used, how does the linguist – or the child – ever learn what this word, or any word, means?

The answer is that the hypothesis space of the word learner must be somehow constrained; the learner must be biased, either innately or through prior experience, to favor some interpretations over others. Much research in word learning concerns the nature of these constraints and how they emerge in the course of development.

In fact, Quine's example actually understates the difficulty of word learning, as it assumes that the linguist is regarding the rabbit at the moment the word is being spoken. Words are not usually presented in such 'transparent' circumstances. In some cultures, there is no explicit labeling of objects, and even in Western societies, the mapping between a word and what it refers to is far from obvious. Gleitman (1990) argues that this is particularly the case for verbs. Most of the time, for instance, that the verb 'opening' is spoken, nothing is being opened, and most of the time something is being opened, 'opening' is not spoken – and yet children have no special problem realizing that 'opening' means opening. Plato was perhaps the first to point out the even more serious puzzles that arise when one considers the learning of abstract terms, such as those for numbers or ideal geometrical forms.

FIRST WORDS AND THE TIME COURSE OF WORD LEARNING

Despite the problems, children begin to understand the meanings of some words as early as nine months of age, and start to produce words on or soon after their first birthday. Early words, regardless of the culture, consist mainly of names for important individuals ('Mommy'), social routines ('bye-bye'), common nouns ('cookie', 'milk'), and hard-to-classify expressions such as 'more', 'up', and the ubiquitous 'no'. Later on, verbs and adjectives start to appear, and, still later, function words such as determiners ('the') and conjunctions ('or') appear. While children sometimes get the precise meaning of a word wrong (calling a cat 'a dog', for instance), serious confusions (calling a cat 'a cookie', say) are virtually nonexistent.

Vocabulary growth starts slowly. One-year-olds learn less than one word a day, and two-year-olds learn about two or three words a day. This rate gradually increases and eventually, in part through the onset of literacy, children come to learn well over 12 new words a day. Early on, there is a correlation between vocabulary size and syntactic knowledge, even with age factored out (Fenson *et al*., 1994), but the reason for this is unclear – it could be because syntactic knowledge facilitates word learning (see below), because word learning facilitates syntactic development, or both.

It is often said that a sudden shift in word learning occurs at about 18 months of age, or when a child has about 50 words in his or her vocabulary; this is often called a 'word spurt' or 'vocabulary spurt'. Surprisingly, however, this might well be a myth; more recent studies find, for the most part, that the increase in word learning speed tends to be gradual, without any periods of sudden acceleration.

CONCEPTUAL CONSTRAINTS AND WORD LEARNING

One key factor in how children learn words involves conceptual constraints. While learning words may sometimes lead to the development of new concepts, there is considerable evidence that much of word learning can be understood as the process of mapping pre-existing concepts onto the sounds and signs that people produce.

Indeed, children can grasp aspects of the meanings of new words with very few exposures, without training or feedback and without ostensive naming – a process called 'fast mapping'. For instance, if a three-year-old hears an object being referred to in passing as a 'koba', over a month later she will tend to remember which object (from a group of ten) received this novel label (Markson and Bloom, 1997). Children under the age of two can fast map new nouns (e.g. Waxman and Markow, 1995), and the meanings of these early acquired words seem to be much the same as they are for adults. This suggests that word learning is supported by a pre-existing conceptual repertoire, one that includes the notion of rabbits, but not the notion of undetached rabbit parts. This position is supported by research with prelinguistic infants showing that they possess a rich understanding of objects, actions, and other ontological kinds.

Specific products of these pre-existing conceptual structures may be the 'whole object bias' and the 'taxonomic bias' (Markman and Hutchinson, 1984). These work together to predispose children to treat new words as referring to kinds of objects – and so 'Gavagai' is naturally thought of as referring to the rabbit, not to the tail, or to the top half of the rabbit. An alternative view, however, is that these biases are the product of innate mechanisms that are dedicated to the task of word learning (e.g. Waxman and Markow, 1995).

SOCIAL KNOWLEDGE AND WORD LEARNING

A second system central to word learning involves children's appreciation of the mental states of other people, what is sometimes called 'naive psychology' or 'theory of mind'. There is abundant evidence that children will take a word as referring to a given object if and only if there is evidence that the speaker intended to refer to that object. In one study, children were given one object to play with while another object was put into a bucket that was in front of the experimenter. When a child was looking at the object in front of her, the experimenter looked at the object in the bucket and said a new word, such as 'It's a modi!'. Eighteen-month-olds looked at the experimenter and redirected their attention to what she was looking at, in this case, at the object in the bucket. And when later shown the two objects and asked to 'find the modi', they assumed that the word referred to the object the experimenter was looking at when she said the word – not the object that the child herself was looking at (Baldwin, 1991).

More sophisticated intentional capacities are displayed by 24-month-olds. In one study, an adult announced her intention to find an object – 'Let's find the toma!' – and then picked up and nonverbally rejected (by frowning) two other objects before picking up a third object and smiling. Despite the temporal gap, children inferred that this third object was what 'toma' referred to. In another study, an adult used a novel verb to declare her intention to perform an action (e.g. 'I am going to blork!'), proceeded to carry out an action 'accidentally' (saying 'Whoops!') and then performed another action, with satisfaction (saying 'There!' with a pleased expression). Children connected the verb with the action the speaker seemed satisfied with, not the accidental one.

Such studies indicate that even very young children infer the intention of the speaker (through attention to cues that include line-of-regard and emotional indications of satisfaction) when determining the referent of a new word, for both nouns and verbs (Tomasello and Barton, 1994).

SYNTACTIC CUES AND WORD LEARNING

Young children attend to the syntax of a word when determining what the word means. The classic study showing this was done by Roger Brown (1957), who showed preschoolers a picture of a strange action being performed on a novel substance using an unfamiliar object. One group of children was told: 'Do you know what a sib is? In this picture, you can see a sib' (count noun syntax); a second group was told: 'Have you seen any sib? In this picture, you can see sib' (mass noun syntax); and a third group was told: 'Have you seen sibbing? In this picture, you can see sibbing' (verb syntax). The preschoolers tended to construe the count noun as referring to the object, the mass noun as referring to the substance, and the verb as referring to the action.

Subsequent research has found that syntactic cues can help even younger children learn words. For example, 2-year-olds who hear 'This is ZAV' expect the word to refer to a specific individual, as with a proper name like 'Fred' (Katz *et al*., 1974). Two-year-olds hearing 'John ZAVS Bill' expect the word to have a meaning similar to that of 'hit', while those who hear 'John and Bill ZAV' expect it to have a meaning similar to that of 'stand' (Naigles, 1990). It might well be that a sensitivity to syntactic cues is what guides children to appreciate the meanings of words such as verbs and prepositions, explaining why these words are not present at the very onset of vocabulary development.

CONTENTS

The psychology of word meaning concerns how words are organized, mentally depicted, and processed cognitively.

INTRODUCTION

The study of the psychology of word meaning has been decidedly interdisciplinary. Linguistics, philosophy, artificial intelligence, anthropology, education, and psychology have all contributed major ideas. Key questions concern how words are organized, mentally depicted, and processed cognitively. The *mental lexicon*, our mental dictionary, is thought to contain upwards of 40,000 words in the average high school graduate. However, the mental lexicon appears to be organized more like a thesaurus than a regular dictionary because it is organized both conceptually as well as alphabetically (or, rather, according to the words' sound characteristics or phonologically, and orthography in literate people). This organization seems to be designed to connect speakers and listeners to the right words and conceptual domains quickly and effortlessly. There are a number of views regarding the characteristics of this mental lexicon.

FEATURE THEORIES

The *feature comparison view* proposes that word meanings are represented as sets of *semantic features*. Semantic features are simple word-meaning parts which taken together serve to comprise the word's meaning, much like basic elements join together to form whole molecules. The feature comparison view suggests that there are two different types of semantic features inherent in concepts. The first type is *defining features*, which are in themselves necessary and sufficient for defining the concept: that is, something must have all of the defining features to be considered an example of the concept. The second type is *characteristic features*, which are more optional but which tend to be present in good examples of the concept. For example, the concept *bachelor* has the defining features [unmarried], [male], and [human]. Technically speaking, any person possessing these features might be considered a bachelor including male babies, priests, and centenarians. However, good examples of bachelors also [are marriageable], [are 20–50 years old], and [date women].

Presumably, to decide that something is an example of a concept (such as when one decides whether a robin is a *bird*), the features of the example are compared to those of the concept. If they share most of the features, as in the case of robins and birds, then one can quickly decide that it is an example of the concept. If they share few features (such as when one compares a brick to a bird), then one can quickly decide that it is not an example of the concept. However, occasionally, this match-up is intermediate, such as in deciding whether a bat is a bird. Bats share several features in common with birds such as the fact that they [fly], [have wings], and [have two feet], but they cannot be classified as birds. In such cases, one uses only the defining features to decide whether something is an example of the concept. However, going through these defining features takes time. Therefore, perhaps the best evidence for this model is the fact that people take longer to decide that bats are not birds than to decide that bricks are not birds.

The *analytic prototype view* is similar, but does not make the qualitative distinction between defining and characteristic word features. Instead, word features are said to be merely weighted in their importance. This model of lexical organization suggests that concepts that match the central

tendency of a category are considered prototypes. Concept features, then, are compared to those of the category prototype to determine category membership. Perhaps the best evidence for this view of lexical organization comes from the fact that children learn prototypical prior to atypical examples of a concept (that robins are birds sooner than that ostriches are birds).

THEORY-THEORY VIEW

The *theory-theory view* proposes that representations of concepts are rooted in our knowledge about how the world works. Murphy and Medin have argued that important and coherent concepts in a domain are embedded in deeper, underlying theories that people have about the domain. These theories determine the features that are used to distinguish one concept from another. Theories also serve to relate concepts in the domain to each other. They determine which features are key to the domain.

Thus, most people know that the feature [burnable] refers to both *money* and *wood*, but the feature would appear in our representation of wood only because of its use as a fuel. [Burnable] plays no similar role in our concept of money, and, in fact, other features are more important to the role that money plays in our lives. The theory surrounding [burnable] would then relate wood to other fuels such as gasoline and other items for which its ability to be burned is a key feature.

This view extends feature theories by providing a rationale for which features become attended to, how they derive their importance and are combined to produce coherent concepts. Perhaps the best evidence for this view is the finding that a developmental change in the theory underlying a domain is accompanied by a reorganization of and appearance of new concepts in the domain. For example, when children come to view the mind as intentional, effortful, and constructive, the concepts of *divided attention* and *inhibition* emerge (which are effortful subtypes of attention), and they reorganize other attention processes according to the effort they entail.

NETWORK THEORIES

The *spreading activation network view* is qualitatively different from the feature comparison, analytic prototype, and theory-theory views of lexical organization. This view of word meaning depicts words as nodes connected to other concepts through association. Nodes are merely abstract representations of words that serve to identify the location of the word in memory. Word meaning is said to be the sum of concepts with which a given word is associated. The key difference between this and feature theories is that meaning is represented by associative links between nodes representing the relationship between words (such as *is a* and *has*) and not overlapping word features, as in the feature theories.

A second aspect of this view is that this interlinked network is designed to permit one concept to activate others associated with it. In this view, hearing or seeing the word 'robin' would activate the node for *robin* in one's memory. The activation of this node would then send activation along the associative links to other concepts connected with it such as *bird*, *feathers*, etc. This process is called *spreading activation*. In this view, the length or strength of the links between nodes represents the degree of association between concepts. Shorter or stronger links represent greater association and faster spreading activation between concepts. For example, the link between *robin* and *bird* is probably stronger than the link between *ostrich* and *bird*. Because spreading activation moves across strong links faster than weak ones, it is faster to decide that a robin is a bird than that an ostrich is.

Perhaps the best evidence for the spreading activation view is the finding of *mediated association priming*. The spreading activation model assumes that when words are activated, activation spreads rather far and wide to related concepts and their associates. For example, *lion* and *tiger* are both associatively linked. *Tiger* and *stripes* are also associatively linked. However, *lion* is associatively linked to *stripes* only through *tiger*. *Stripes* can be activated by *lion* only if *lion* activates *tiger* first. It has been shown that people are faster at recognizing the word *stripes* when preceded by *lion* than when preceded by some completely unassociated word, suggesting that activation spreads through mediating links from *lion* to *tiger* to *stripes*.

Distributed connectionist models of the lexicon view the representation of concepts as comprising subsymbolic nodes rather than word nodes. These subsymbolic nodes are said to work together like computer bits that are turned either on or off. The lexicon is said to contain different types of nodes that correspond to the letter features (orthographic units), sound features (phonological units), and word-meaning features (semantic units) of words. Like the spreading activation network view, these node types are interlinked in the network with varying strengths between their

connections. Unlike spreading activation views of word meaning, these aspects of lexical representation are thought to be distributed throughout the memory system, rather than localized with specific information around a word node itself. In fact, the concept of a *word* in these models is merely the pattern of activation of units that are activated when a particular word is presented. With each presentation of a new word comes a change in the strength of the links connecting the orthographic, phonological, and semantic feature units for that word, making that pattern of units more easily activated the next time the word is presented.

This kind of system is said to be dynamic. That is, partial activation of one type of node causes the resulting partial activation of another type of node. For example, when a person is presented with a written word such as 'girl', the orthographic units *g*, *i*, *r*, and *l* become partially activated and quickly begin to send activation corresponding to both the phonological units (*g*, *er*, *l*) and semantic units (*female*, *human*, *young*) associated with the word pattern. When the phonological and meaning units become partially activated, they each send activation back to the other two types of units, combining their influences on each other until the person recognizes the word. In this model, related words (such as *girl–boy*) tend to benefit the processing of each other because the semantic units of the two words have similar patterns of activation (that is, both words activate *human* and *young*). After reading or hearing the first of two related words, the shared meaning units of the two words remain activated upon presentation of the second word. This enables the pre-activated meaning units of the second word to send activation to the phonological and orthographic units, so that the person recognizes the word quickly.

Perhaps the best evidence for this kind of model comes from experiments where a single unrelated word is interspersed between two related words (*girl–book–boy*) and the person has to name the final word. This model predicts that, while reading these three words, the meaning units associated with *girl* will be activated at first, but then become deactivated after reading the second word *book*. Consequently, the meaning units of *boy* will have to become reactivated anew when *boy* is presented for naming, eliminating any benefit from meaning-unit activation from *girl*. In fact, studies show that presenting an unrelated word between two related words disrupts the processing benefits normally seen between related words.

FRAME (SCHEMA) VIEWS

Frame (sometimes called *schema*) views describe word meaning as comprising 'slots' and 'fillers' organized to represent basic regularities and expectations that people have for concepts. Slots are a kind of variable that needs to be filled; fillers provide value to the slots. For example, the word 'goldfish' might be represented with slots that represent basic properties of goldfish such as *habitat* and *eats*, which might be typically filled with the concepts *aquarium* and *fish food*, respectively. Such typical slot fillers are said to form default values for the concept. However, slots usually have alternatives to these default fillers that may represent the knowledge that, say, *goldfish* might also live in *ponds* and eat *insect larvae*.

The information represented by the frame view differs from the relations represented by the spreading activation model in that they represent a larger number and a more concept-specific set of relations than semantic network models. Further, frames represent more extensive knowledge about a concept because of the representation of typical defaults and other permissible fillers. In this sense, the knowledge contained in frames for a word is encyclopedic in nature, rather than precise or analytic.

One of the strongest arguments for this form of representation comes from the fact that verbs seem to require complex, frame-like knowledge to represent them adequately. For example, any context using the verb *sell* needs to provide some indication of (or filler for) the *seller*, *buyer*, and *goods sold*, suggesting that all three of these are part of the frame for this verb.

SOME IMPORTANT PROBLEMS FOR THE PSYCHOLOGY OF WORD MEANING

One interesting problem for the psychology of word meaning is *polysemy*. Polysemy refers to the issue that two words that mean something quite different can sometimes sound and look the same. For example, the word 'duck' is polysemous because it describes both the bird and the act of lowering quickly to evade something. It is generally agreed that we possess two different semantic representations for such words to which the orthographic and phonological features are attached.

One intriguing question is whether we always retrieve both meanings for ambiguous words when we read or hear them. For example, if we heard the sentence 'To avoid the tree branch, Carlos

had to duck', would we actually retrieve the *bird* meaning as well as the *lowering* meaning? Most researchers think that for a very short time after reading or hearing an ambiguous word (around 300 milliseconds), we actually retrieve both meanings as long as both meanings are reasonably common interpretations for the word. After this short time, we quickly select the meaning that makes the most sense in the context and lose awareness that the alternative meaning was ever activated.

A second problem for the psychology of word meaning is how words are represented in *bilinguals*. The bilingual lexicon is interesting because it requires a distinction between the actual words from each language and the concepts with which they are associated. One way the concepts might be represented is to assume that there is an associative link between words in a bilingual's first language and those of his or her second language. To figure out the meaning of a word in a second language, one would first have to translate a second language word into a corresponding word in one's first language and then retrieve that word's meaning. Another way the concepts might be represented is to assume that words in each language are indirectly connected to each other through the common meanings that they share. Word meaning would be accessed directly from words of each language, and there would be no need to translate first. In fact, translation from one language to the other would be performed by going through the word meaning system first. There is some evidence that beginning bilinguals might operate according to the word association depiction and advanced bilinguals according to the concept mediation view, but this has not yet been fully determined.

Word Recognition

Introductory article

Jonathan Grainger, University of Provence, Aix-en-Provence, France

CONTENTS

Psychological research on visual word recognition aims to describe the information processing involved in identifying a given string of letters as a specific word during the reading process.

INTRODUCTION

Visual word recognition is one of the most highly researched areas of cognitive psychology. Researchers in this field apply the information processing paradigm adopted by cognitive psychologists since the 1950s: this paradigm is used to understand how the light pattern reflected by a written word is transformed from activity in the retinas of our eyes to meaning in our heads, by specifying the mental representations involved, and the processes that operate on these. Although strictly speaking the study of visual word recognition is concerned only with the extraction of meaning from strings of letters (i.e. silent reading), the term is often extended to include the act of reading aloud (i.e. how a specific pronunciation is assigned to a given string of letters). The following discussion is limited to the case of silent reading of isolated words, and is also restricted to alphabetic writing systems (as opposed to non-alphabetic languages such as Chinese); it is based on research performed primarily in English. (*See* **Lexicon, Computational Models of**; **Language Comprehension**; **Reading, Psychology of**)

PRINTED WORDS

Written words come in all shapes and sizes, yet skilled readers manage to abstract away from such variation in surface form (e.g. word, WORD, wOrD) to reach the common underlying meaning. This skill could be analogous to our ability to recognize other familiar visual patterns, such as everyday objects. However, printed words are very special visual patterns composed of a small number of clearly identifiable subunits, their component letters. Unlike spoken language, printed alphabetic script marks word boundaries plus the boundaries of individual letters in the word. Another important property of printed words in alphabetic languages is that the individual letters are linked to a word's component sounds in a nonarbitrary way.

METHODS

Following the general methods of experimental psychology, researchers vary certain properties of the stimulus while recording the responses of human participants who are requested to react in some way to these stimuli. The way the participants' performance varies systematically as a function of variations in stimulus properties is used to infer the information processing that would generate the observed response pattern. In studying visual word recognition, various properties of printed words are manipulated, and the selected sample of words presented to participants who are asked to perform a given task.

Lexical Decision

In the standard lexical decision task, participants see a random mixture of word and nonword stimuli one at a time on a computer screen, and must press one of two response keys as fast as possible to say whether the stimulus is a word or not. The time between stimulus onset and the participant's response is measured (response time, RT) as is the number of errors made.

Perceptual Identification

In contrast to the lexical decision task, perceptual identification tasks use impoverished stimulus presentation conditions in order to make words harder

to recognize than usual. In this type of task it is the percentage of correct identifications that is the measure of interest. In some variants the stimulus gradually becomes visible over a short period (typically 1–2 s), and the time taken to recognize the word is recorded. This has the advantage of providing a measure of performance (RT) on each trial rather than having performance averaged over several trials.

Semantic Categorization

In semantic categorization participants are asked to classify words as belonging to a predefined semantic category or not. These categories can either be general (e.g. animate versus inanimate) or more specific (e.g. flower, body part). After being informed of the target category, participants are presented with a series of words, to which they must respond as rapidly as possible, indicating which category the word belongs to.

Priming

The priming technique involves presentation of two successive stimuli, the prime and the target. The goal is to see whether performance on a given target word varies as a function of the type of prime stimulus that precedes the target. Will the word 'butter' be recognized more quickly when preceded by the prime 'bread' than when it is preceded by 'train'? This particular question addresses the issue of semantic priming, but the same technique can be used to examine all possible relations that exist across words of a given language. In a variant of the priming paradigm, prime stimuli are presented so briefly that they cannot be identified by the participants ('subliminal' priming). The influence of such subliminal primes on target word recognition is thought to reflect the operation of fast, automatic and largely unconscious processes engaged in identifying printed words.

BASIC PHENOMENA

Research on visual word recognition provides an example of science at its best. Phenomena in this research area have been clearly defined, and hypotheses have been developed to explain them and predict the existence of new ones. Here we will examine some of the key phenomena, from low-level visual and orthographic processing to higher-level lexical and semantic operations.

Orthographic Processing

The identities of a word's component letters must be coded for successful word recognition. Evidence for the role of individual letter representations has been provided by orthographic priming studies that vary the number of letters shared by prime and target, all other factors being held equal. These orthographic priming effects occur over and above effects of visual similarity, being unaffected by changes in case and type font. However, letter identity information is a necessary but not a sufficient condition for correct word identification. One also needs to know the position of these letters. Current evidence suggests that the initial coding of letter position is somewhat approximate, providing only relative position information (e.g. the letter 'b' in 'table' is somewhere in the middle, just after 'a' and just before 'l') and not absolute position information (e.g. the letter 'b' in 'table' is the third letter in a string of five letters).

Orthographic processing is complicated by the fact that on any given eye fixation in a word, letter visibility varies as a function of letter position relative to the fixation point (higher visibility closer to fixation), and whether the letter is the first, last or a middle letter (better visibility for external letters). These variations in letter visibility determine how accurately a word can be identified at a single glance. As eye fixation in the word shifts from the first to the last letter one obtains an inverted U-shaped function of word recognition accuracy. However, the function is not symmetric, with a definite advantage for fixations to the left of the center of the word (at least for languages that are read from left to right). This asymmetry is also evident with lateralized presentation of stimuli. Words presented to the right of fixation are easier to recognize than words presented to the left. This lateralization effect is thought to be due to the fact that brain areas involved in word recognition are located in the left hemisphere of the brain, and this hemisphere receives information directly from the right visual field.

Phonological Processing

A key finding in word recognition research is that a word's phonology (its component sounds) influences the recognition process. For example, when presented with the target word 'make' in a masked priming experiment, participants found it easier to recognize following the subliminal prime 'mayk' (a nonword called a pseudohomophone because it

can be pronounced like a real word) than following the prime 'malk'. Our ability to recognize target words is influenced by the amount of phonology they share with prime stimuli over and above any orthographic overlap. This phonological priming arises about 30 ms after orthographic priming, showing how fast the brain has been able to translate orthographic information into a phonological code. Phonological influences have also been demonstrated in semantic categorization tasks without priming. It is harder for participants to say that 'rows' is not a flower than to respond negatively to the word 'robs'. Indeed, homophony (when different words share the same pronunciation) has a systematically negative influence on the process of printed word perception.

Lexical Processing

The extraction of orthographic and phonological information from a string of letters eventually allows the human brain to identify the stimulus as a known word and to recover the meaning associated with that particular form. The speed with which this occurs depends on that word's frequency in a given language. Word frequency is measured by counting the number of times a given word occurs in large corpuses of text. Thus, in one particular corpus of the English language, the word 'table' occurs 198 times per million words, while the word 'tablet' occurs 3 times per million. Although this measure of printed word frequency is often partially confounded with other possible measures of word usage, such as the age at which a word is learned (age of acquisition), it is generally assumed that it exerts the most significant independent contribution to word recognition fluency. Word frequency can be situated on a general continuum of stimulus familiarity, with unfamiliar nonword stimuli situated at one extreme. The familiarity of letter strings determines how easy it is to recognize the component letters of these stimuli. Letters in words are easier to identify than letters in nonwords (the 'word superiority' effect).

Semantic Processing

The priming paradigm has been extensively applied to investigate semantic processing in visual word recognition. Three kinds of semantic priming effect have been isolated: categorical, associative, and similarity-based priming. Categorical relations are defined *a priori* by taxonomists. Associative and semantic similarity relations are obtained by normative measures. When asked to provide the next word that comes to mind on hearing the word 'table', the majority of native speakers of English will reply 'chair'. The associative norms derived from such a procedure are then used to create associatively related primes and targets in a semantic priming experiment. Semantic similarity measures are obtained by rating judgments – how semantically similar are these two words? All these measures of semantic relatedness have been shown to facilitate target processing in semantic priming experiments.

MODELS

Faced with these various phenomena to explain, word recognition theorists have come up with a number of different approaches. One early account considered visual word recognition as analogous to how we look up a new word in a dictionary. The idea is that we have a mental dictionary (mental lexicon) listing all the words we know, and given some minimal information about the stimulus (i.e. a few letter identities) we can guide our search to the appropriate section of the dictionary and begin a detailed verification process comparing information extracted from the stimulus with information stored in memory.

More recent approaches have abandoned the notion of search for the concept of activation (or parallel information accumulation). On presentation of a printed word, orthographic, phonologic, and semantic codes are activated in an interconnected network of simple processing units. Activation builds up in the network until a stable state is achieved and the system has settled on a unique combination of orthography, phonology, and semantics. Much modeling work today is concerned with describing how the brain has learned to map orthographic codes onto phonological codes on the one hand, and onto semantic codes on the other. There is increasing evidence that such mapping occurs in a highly interactive system: orthographic codes send activation onto phonological and semantic codes which mutually activate each other, and send activation back to the orthographic level.

CROSS-LINGUISTIC RESEARCH

Languages vary in the type of visual code they use to represent speech. Compare, for example, the logographic code of Chinese with the alphabetic code of English. Cross-linguistic research in visual word recognition has also revealed interesting

differences across languages that share the same alphabet. One such difference is the way in which individual letters are associated with the component sounds of a given language. The amount of ambiguity in the mapping of orthography onto phonology and vice versa (one-to-one, one-to-many, many-to-one) varies considerably across languages. This has a major impact on the speed with which children learn to read in these different languages, and subsequently influences the nature of the sublexical representations involved in printed word perception. Degree of consistency in the mapping of orthography to phonology is also thought to determine the division of labour across an orthographic–semantic processing route and an orthographic–phonological–semantic route in silent reading.

Finally, individuals vary in terms of the number of languages that they know, and this affects processing within each language. Current evidence suggests that people who are bilingual cannot 'switch off' the irrelevant language (when reading a book in one language, for example). There have been a number of reports of cross-language interference during word recognition in bilingual participants. The amount of interference depends on how similar the target word is to words of the other language. Thus words from different languages interact in a way that mimics within-language interactions. Nevertheless, bilingual people can, to some extent, control these between-language interactions by use of knowledge about which language each specific word belongs to.

Working Memory

Intermediate article

Barbara A Dosher, University of California, Irvine, California, USA

CONTENTS

Working memory is the capacity to manipulate and maintain information over short periods (2–15 seconds) in order to support simple memory tasks such as remembering a telephone number, or more general cognitive tasks such as problem solving, simple reasoning, or reading. Working memory consists of several distinguishable memory capacities, together with executive functions that manage information retrieval, reactivation, and transformation.

THE ROLE OF WORKING MEMORY IN INFORMATION PROCESSING

Human memory – that is, the retention of information over short or long delays – is critically important for cognitive function. *Working memory* is the capacity to manipulate and maintain information over short temporal delays. Working memory supports cognitive activities such as solving mathematical problems, evaluating spatial layouts, or comprehending sentences, and it may be critical in language learning. It is one of several closely related short-duration memory systems. Working memory is of longer duration than the relatively unprocessed and very-short-duration (< 2 seconds) visual sensory memory (iconic memory) and auditory sensory memory (echoic memory). It maintains information over a period of several seconds or longer through proactive control and rehearsal mechanisms. Thus working memory goes beyond the short-term or immediate memory function that briefly maintains information to include attention and information management – the capacity for manipulation and transformation of information that is required during cognitive tasks.

WORKING MEMORY FRAMEWORK

According to one classic view, working memory is a system of three interacting modules (Baddeley, 1986). These include an *executive control module*, a *visual–spatial sketchpad*, and an *articulatory loop* (Figure 1). Evidence for the separable visual and verbal modules arises from the differential impact of visual distraction on memory for visual information, and the differential impact of verbal distraction on memory for verbal information. The executive control module manages task goals, manipulation of information, and complex rehearsal. The visual–spatial sketchpad maintains visual information (visual content) and spatial information (spatial layout). The articulatory loop maintains temporally ordered verbal information. The sketchpad and the loop are subservient to the executive control module.

The modular working memory framework was originally developed partly to account for capacity limitations in verbal tasks that require correctly ordered recall. In verbal recall tasks, a written or spoken list of verbal items is presented in temporal sequence, and the list is then recalled in order. Several phenomena in serial ordered recall were critical in the development of the modular working memory framework. First, lists of phonologically more dissimilar or distinct items are recalled more accurately than lists of phonologically similar items. This *phonological similarity effect* implies that a phonological or articulatory representation is dominant in working memory. Secondly, the number of items that can be recalled depends upon word length. Longer lists (up to 7–9 items) can be correctly recalled if those items are 'short', with a smaller number of syllables or a shorter time required to pronounce them, but recall is reduced for lists of items that are 'long' (a *word-length effect*). The sensitivity of working memory performance to word length suggested the existence of a cyclic rehearsal loop in which items were refreshed or rehearsed in turn in order to maintain memory. This emphasizes the importance of control processes. Thirdly, the repeated speaking of a distracting word or phrase during the memory task dramatically reduces the length of list that can be

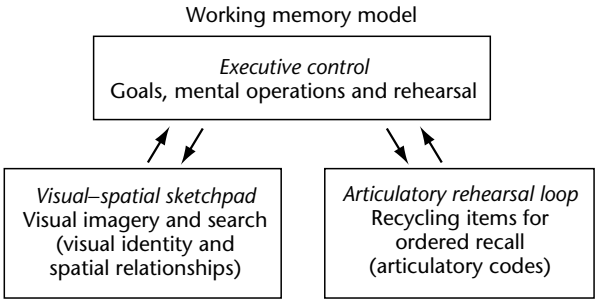

Figure 1. The modular working memory model (Baddeley, 1986) consists of three modules. The executive control module manages rehearsal and other executive functions to transform and maintain information in working memory. The visual–spatial sketchpad maintains visual (content) and spatial (layout) information for forms, patterns, and faces. The articulatory loop maintains item and order information through verbal, articulatory codes for digits, letters, words, and sentences.

recalled. This is known as the *articulatory suppression effect*. Articulatory suppression also eliminates phonological similarity effects for visual presentation.

These phenomena and their complex interplay suggested the operation of an articulatory/phonological rehearsal mechanism, verbal recoding of visual inputs, and the importance of control or rehearsal activities – all critical concepts in the modular working memory framework. For a review of these and related phenomena see Neath (1998).

Other alternative frameworks and computational models based on quite different principles may also account for a wide range of these data. One alternative view inspired by human cognitive neuroscience and neural network representations is that short-term memory is the currently active subset of long-term memory, and that working memory is the system of short-term memory plus the strategy and attention functions that reactivate fading short-term memory traces (Cowan, 1995). Other formal models have been developed for several specific tasks (Page and Norris, 1998; Henson, 2001), or to specify more precisely the representation of the abstract and modality-specific features of items in working memory (Neath, 1998). As the brain areas relevant to working memory function are identified, and the temporal properties of the responses in these regions are more fully understood, the description of the modular working memory framework may be transformed into a more detailed specification of the computational implementation and the brain circuitry, consisting of processing structures and more complex computational network representations. Nonetheless, the modular working memory architecture (Baddeley, 1986) provides a structural-level description of memory function, and has provided a framework for an extensive body of behavioral and physiological studies of working memory in a range of memory tasks. The important distinctions between classes of working memory tasks will be considered in the following sections.

FORMS OF WORKING MEMORY

Working memory operates somewhat differently in tasks with differing complexity or cognitive processing demands. One task that is used extensively in animal models and in physiological analyses requires a single item to be maintained through a delay period. More demanding working memory tasks involve the full recall of a list of items during complex distracting activities (Daneman and Carpenter, 1980). Some tasks focus on visual coding, while others focus on verbal coding. Each form of working memory task places different demands on information retrieval and executive function.

Working memory tasks are of several major types (Figure 2). *Item memory tasks* require the evaluation of an individual item or individual position, although the memory set may consist of multiple items or positions. *Relational memory tasks* require the evaluation of some relational property, such as relative temporal order or the spatial location of several items. Finally, *complex memory tasks* require extended reproduction of a memory set with a sequence of temporally or spatially ordered responses. Item, relational, and complex tasks vary further in difficulty depending on the level of the memory load or of distraction.

Item Working Memory Tasks

Item working memory tasks test memory for a single item, possibly from among a set of items, following a brief delay. In the simplest item task (Figure 2(a)), recognition memory for a single item is tested after a retention delay, usually of between 1 and 60 seconds (Figure 3(a)). Recognition of the item declines with increasing delay. This task has been important for studying short-term retention in animals (the 'delayed match to sample' task). It has also been important in studies of delay period activity of cortical neurons, and sustained neural activity during the retention interval, that has been associated with working memory (Chafee and Goldman-Rakic, 1998). For humans, delayed

(f) Temporally ordered working memory load

Figure 2. Item, relational, and complex working memory tasks are successively more demanding of working memory. (a and b) Examples of item working memory tasks. (a) The delayed recognition task (a simple item working memory task) measures forgetting over short time delays. In this example, the stimuli require visual rather than verbal coding. (b) Item recognition with memory load task requires memory for an individual item from a memory set, or recognition after filled delays. In this example, the stimuli utilize verbal coding. (c and d) Examples of relational (order) working memory tasks. (c) In the temporal order task, the most recent of two items from a working memory set is selected. (d) In the *n*-back task, an item repetition is detected at a specified delay, 1-back (immediate repetition), 2-back (repetition with one intervening item). (e and f) Examples of complex working memory tasks. (e) In memory span tasks, items are recalled in the correct order. (f) In running span tasks, identified items from a series of mental tasks (e.g., simple mathematical problems) are recalled in the correct order. Reproduced with permission of B. Dosher.

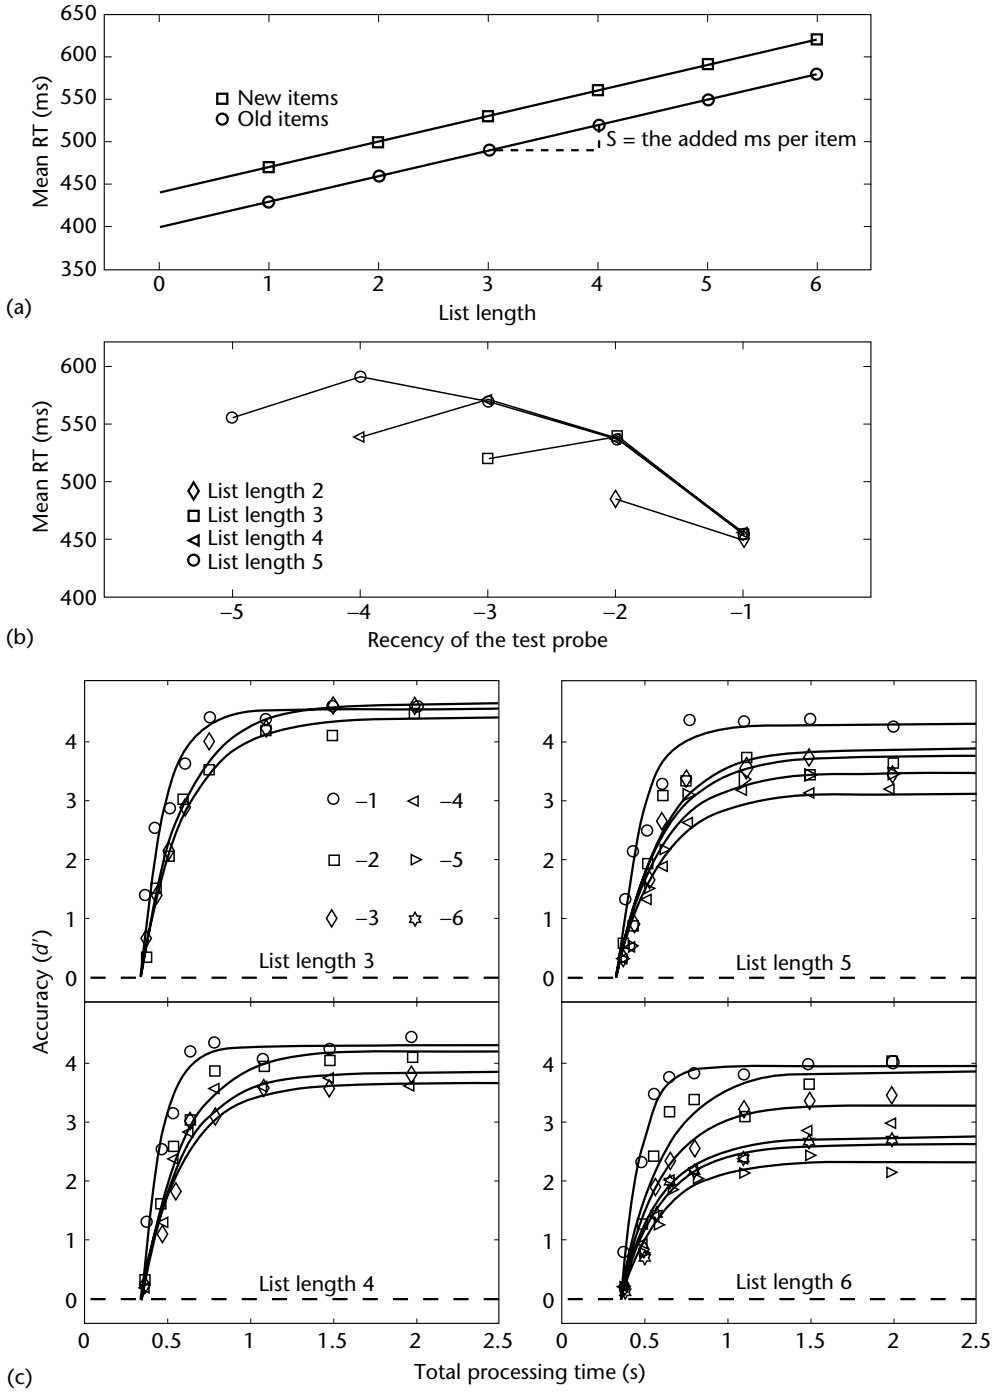

Figure 3. Item tasks are characterized by simple decay functions and load-independent retrieval. Schematic results of a delayed item recognition task are shown. (a) Mean reaction time (RT) to recognize a single item in working memory increases with the memory load or list length. These aggregate results reflect faster response times for more recent list items. (b) Reaction time (and accuracy) of item recognition depends upon recency. Response times are shortest for list-final (most recent) positions, and they increase as items become less recent. (c) Recognition accuracy (bias-free strength d') is measured as a function of retrieval time by interrupting recognition after various amounts of time for working memory loads (list lengths) of from 4 to 6 items (data from McElree and Dosher, 1989). Limiting accuracy is higher for more recent items. However, the time course of item recognition reflects parallel processing – it does not depend on working memory load or item recency. Reproduced with permission of B. Dosher.

recognition of a single study item may be too simple to tax working memory, especially for simple verbal items, so task complexity is increased by increasing the memory load, or the number of items to be remembered. Alternatively, the complexity or demand of the memory load might be increased.

One of the most extensively studied working memory tasks tests recognition of one item from a multi-item memory load presented over time (Figure 2(b)). Item recognition takes place immediately following a study list when error rates are relatively low, and response time is used to index memory. The memory load may consist of new items, in which case the judgment may reflect familiarity, or it may consist of highly repeated items from a small set, in which case the judgment must reflect not familiarity with the items themselves, but specific list membership. The average time taken to recognize an item as a member of the memory load increases approximately linearly with the load size (Figure 3(a)), which has often been claimed to reflect a serial process in retrieval from working memory (Sternberg, 1975). Recent evidence instead suggests that in simple item recognition tests, familiarity or activation is processed fairly directly, with accuracy and activation times reflecting item recency (the delay interval). Memory lists of different sizes reflect different mixtures of recency effects on both recognition time and accuracy (Figure 3(b)). In fact, under many conditions, retrieval of single items from working memory is achieved with the same time course regardless of the size of the working memory load or the study position of the item tested for recognition (Figure 3(c)). Information starts to become available at the same time and increases at the same rate independent of working memory load or temporal position (Dosher and McElree, 1992). The slower response times for larger working memory loads reflect lower memory strength for less recent items.

Simple, relatively rapid mnemonic evaluation of single items, independent of memory load, is a characteristic of item working memory. Item working memory tasks may exhibit parallel retrieval independent of the memory load. In contrast, the patterns of retrieval in relational working memory tasks exhibit substantial load effects and slower and load-dependent retrieval.

Relational Working Memory Tasks

Relational working memory tasks involve relational judgments, such as judgments of temporal or spatial order, over two or more items. These judgments place greater demands upon retrieval and rehearsal than do simple item tasks. For example, the relative order task (Figure 2(c)) requires the selection of the most recent of two test items. In comparison with the relatively rapid and load-independent retrieval exhibited for item tasks, processing of the relative temporal order (recency) is considerably slower than item retrieval, and is strongly dependent on the temporal positions of the items. The time course of judgments is rapid for memory probes including the most recent item, perhaps comparable to that of retrieval of single-item information. However, the time course of temporal order judgments is successively slower for probes with items experienced less recently, consistent with a sequential recovery of less recent items. Order judgments induce a more effortful, time-consuming, and serial process of retrieval (McElree and Dosher, 1993) (Figure 4).

Another form of relational, or order, working memory task that has been extensively studied is the *n*-back task (Figure 2(d)), which is a continuous performance task in which items repeated at a particular delay are detected. In a 1-back condition, immediate repetitions are detected, while in a 2-back condition, repetitions with one intervening item are detected (Cohen *et al*., 1997; McElree, 2001). In related tasks, a stream of successive items is inspected for a particular ordered sequence, such as '472'. Like other order judgment tasks, the *n*-back tasks require the maintenance, retrieval, and processing of order information as well as rehearsal and information manipulation to continuously update the task-relevant working memory set. The processing demands in these tasks have also been associated with attention (Engle *et al*., 1999). The *n*-back order tasks show load-dependent activity in functional brain activation, as studied by functional magnetic resonance imaging (fMRI) (Cohen *et al*., 1997), reflecting these higher retrieval and rehearsal demands.

In contrast to item working memory tasks, even the simplest relational or order tasks place increased demands on retrieval processes, with relational judgments often reflecting serial processing. More demanding forms of the relational or order tasks, such as the *n*-back tasks, also require extensive manipulation of the memory set ('relational plus' tasks), or a high demand on executive function.

Complex Working Memory Tasks

Complex working memory tasks involve sequences of responses. The complex tasks, like relational or order tasks, emphasize temporal order or spatial

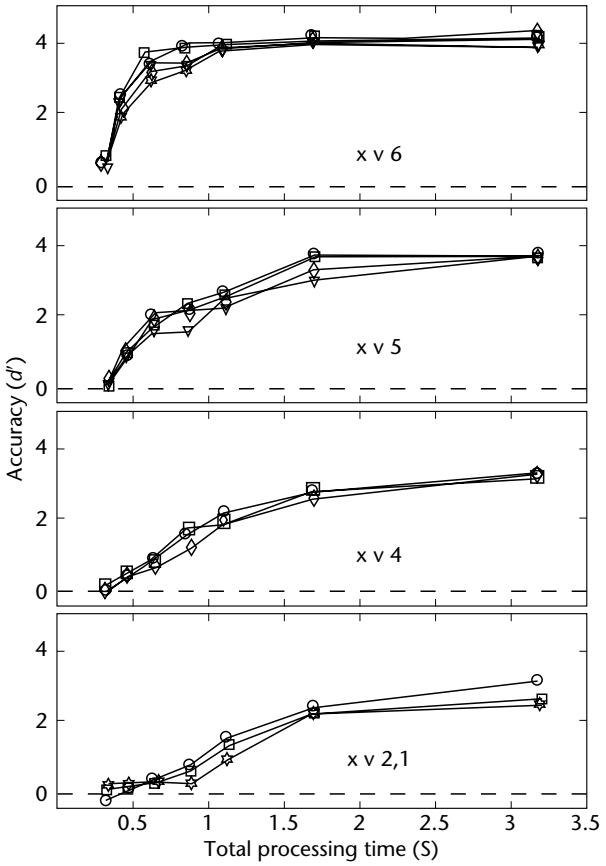

Figure 4. A relational task (judgment of recency) (Figure 2(c)) requires slow and serial processing. The task is to decide which of two item probes is the most recent in the working memory load of six items. Accuracy (d') is expressed as a function of processing time for conditions grouped by the most recent item. The time course of relational judgment depends on the recency of the most recent item, reflecting a serial retrieval process. The upper panel shows fast retrieval for all tests involving the last (sixth) item (1v6, 2v6, etc.). The other panels show successively slower retrieval for tests in which the second to last (fifth) item was most recent, and the middle (third) item was most recent (data from McElree and Dosher, 1993). Reproduced with permission of B. Dosher.

order of the memory set in the response sequence. Among the most classical working memory tasks is the span task (Figure 2(e)). In this task, a working memory load of digits, letters, or words is presented, usually in temporal sequence, and is then recalled under instructions to reproduce the list exactly (serial ordered recall). The more demanding form, known as 'running span', interleaves processing distraction with the input of the working memory set (Figure 2(f)).

As was mentioned earlier, the modular view of working memory was developed and tested using the ordered word span task. One key observation was that the time taken to pronounce words determined the number of words that were successfully recalled in the correct order (the word-length effect) (Baddeley *et al*., 1975). Based on these observations, the duration of working memory was estimated to be approximately 1.5–2 seconds – the time required to pronounce a list of span length (that length of list which is perfectly recalled on average half the time). The idea is that if (subvocal) rehearsal can be completed before item traces are lost from working memory, then the list could be perfectly maintained (Schweickert and Boruff, 1986). One problem with this account is that the actual time taken to recall a span-length list may be 5–8 seconds, which is two to three times the estimate of 1.5–2 seconds (Dosher and Ma, 1998). Either the verbal memory trace is maintained in a phonological loop over intervals of up to 8 seconds, or complex attention strategies maintain items in working memory during the extended act of recall. In common with the relational or order judgment tasks, the simple span tasks require the maintenance and retrieval of order information in working memory. In addition, these complex tasks require the coordination of a succession of recall products, and may involve complex rehearsal and information management.

Complex memory span (Figure 2(f)) makes the same demands as simple serial ordered recall, but each item in the working memory set is separated by a distracting task (Daneman and Carpenter, 1980). Perhaps because these tasks make extremely high demands on mental manipulation and transformation of information, they have been especially important in demonstrating the interrelationship between working memory capacity or efficiency in individuals and the general cognitive functioning of those individuals (Engle *et al*., 1999).

MODELS OF SERIAL MEMORY

Performance in serial memory tasks is characterized by a large and systematic set of phenomena. This does not just include the word-length effect (in which fewer longer words than shorter words can be remembered) and the reduction of successful recall under articulatory suppression (repetition of a distracting phrase) discussed in relation to the modular working memory framework (Baddeley, 1986). Additional phenomena include better memory for spoken than for written presentation, error rates that increase with serial position, and the dominance of transposition (order inversion) errors, as well as many others.

A number of precise computational models have been developed to account for performance in serial memory tasks. Different models are based, in some cases, on quite different principles and assumptions about representation, the causes of information loss, and information retrieval. Three examples of specific mechanistic accounts of working memory in sequential recall tasks are the feature model of Neath and Nairne (Neath, 1998), the primacy model of Page and Norris (1998), and the distributed associative memory model of Lewandowsky and Murdock (1989). This list is by no means exhaustive, but it is selected to illustrate the range of possible representations and processes in models of working memory. Future research must link these representational and process assumptions to the consequences of brain function and coding (for a network example, see O'Reilly *et al*., 1999).

In the feature model, items are represented by collections of modality-independent and modality-dependent features, with the items that are represented stored in order of input as a linked list. As each new item is stored, it over-writes similar features of the immediately previous item or items. In ordered recall, each item is recovered in order from an incomplete or noisy representation. Spoken presentation leads to the storage of a larger number of modality-specific features than visual presentation. Auditory similarity reduces memory due to over-writing of similar auditory features, while articulatory suppression over-writes verbal modality-specific features. Word length has an effect on performance because long words are stored in a sequence of syllabic structures. In contrast, in the primacy model, order is recoded as strength – items are stored in memory with higher activation strength for earlier list items. These strengths then undergo forgetting, or loss. At the time of recall, items are produced in the (noisy) order of strength. Rehearsal resets strength. Longer words take longer to produce or rehearse and experience more forgetting. Finally, in the associative model, individual items and associations between temporally adjacent items are stored in a single composite memory. Items, associations, and the composite memory are represented as a vector of feature values. Recall occurs by recovering successive items from the composite trace through chaining of recovered representations. Similarity between items may increase the error rates due to confusion between similar traces. Although each of the models fails to account for some aspect of the data, each of them also provides a good account of many of the phenomena in working memory that are exhibited in serial recall tasks.

As is evident, each of these models assumes a quite different form of representation and makes quite different assumptions about the nature of memory. Yet each of the models incorporates a mechanism for sequential readout of items from memory, and a mechanism of over-writing or interference to account for forgetting. As these and other quantitative models are developed further, they should provide an increasingly accurate explanation of the maintenance functions of working memory. Precise structural and functional descriptions will complement information about biological implementation.

BIOLOGICAL SUBSTRATES OF WORKING MEMORY

Working memory functions are now thought to reflect activity in a network of brain regions, including regions of the prefrontal cortex and more posterior regions in association cortex (Petrides, 1994). Important brain regions have been identified using a range of methods. Cellular recording of activity in non-human primates during various delayed response tasks has identified the continued activation during the delay (retention) period in certain prefrontal areas with storage of that information (Fuster, 1973). The time course of the delay activity has been shown to depend upon both response accuracy and the duration of the retention interval. Although initial demonstrations demanded spatial memory in responses, delay-period activity in the prefrontal cortex has also been demonstrated in a variety of nonspatial working memory tasks.

Regions of the prefrontal cortex have also been identified in a variety of brain imaging studies in humans (Cohen *et al*., 1997). However, the majority of these studies involved more complex forms of working memory tasks, such as the *n*-back tasks, which make extensive demands upon manipulation and transformation of the information to be remembered – executive function or control architectures. Some researchers have argued that activation in the dorsolateral prefrontal cortex reflects manipulation and transformation, rather than storage or retention (Owen *et al*., 1998). Some evidence from early lesion studies of patients with specific disorders of working memory and also from imaging studies has identified regions of posterior parietal cortex with simple registration and storage. The registration, storage, retrieval, and manipulation functions have yet to be segregated in analyses of working memory function as measured by brain imaging in humans. This will require the

measurement of brain activation with reasonable temporal resolution. In particular, this will necessitate the examination of tasks with clearly temporally segregated retention periods, and the comparison of different tasks with different demands for information manipulation. It will also require the measurement of brain activity in each of the major classes of working memory tasks (Figure 2). Critical new evidence segregating the activation patterns of these brain regions during specific time intervals, isolating storage, manipulation and retrieval in each of these task types, should be available within the next few years with improved methods and technology.

WORKING MEMORY, SHORT-TERM MEMORY, ATTENTION, AND EXECUTIVE FUNCTION

Understanding the functions and interrelationships between modules in working memory is necessary to a full understanding of the brain mechanisms involved, and to the construction of a complete information-processing model. Some theorists (Cowan, 1995) define working memory as the functional interrelationship between short-term memory, processes of attention that reactivate the short-term memory set, and executive function related to transformation, manipulation, and strategy selection. A substantive task analysis is necessary for the segregation of these functions in behavioral analysis as well as in the analysis of brain activation. Future research instantiating working memory tasks within models of perceptual motor limitations, memory stores, and executive function (O'Reilly *et al*., 1999) may provide a precise theoretical structure for distinguishing these subfunctions of working memory.

WORKING MEMORY AND GENERAL COGNITIVE PERFORMANCE

The importance of working memory in general cognitive function is directly supported by the relationship between measures of working memory and performance in a variety of cognitive tasks (Baddeley, 1986). Measures of working memory retrieval time (Figure 3) have been correlated with general cognitive indices such as aptitude scores (Engle *et al*., 1999), and have been shown to differ for different developmental and other populations (Sternberg, 1975). The simpler modules of working memory, such as the phonological loop, appear to play a vital and quite specific role in developmental functions such as language learning (Baddeley *et al*., 1998), where the ability to repeat and maintain a phonological representation may be especially important in learning new words during development, or in learning new languages when supportive semantic information may be unavailable. Performance on working memory tasks, especially complex working memory tasks such as running span, with high demands on executive function (Figure 2(f)), is also correlated with performance on a wide range of other tasks, such as reading or problem solving. Thus, executive functions of working memory may be especially relevant for general cognitive function.

Working memory serves a basic human intellectual function. Elucidating the behavioral function of working memory, the brain activity that supports working memory function, and its relationship to general cognitive function represents a central component of understanding intelligent human activity.
