Model-free reinforcement learning algorithms learn the policy directly by interacting with the environment without storing experience four-tuples or learning a model (i.e. without learning P and R). The best-known model-free algorithm is Q-learning, but researchers have also explored actor/critic and policy gradient algorithms that directly modify the control policy to improve its performance. (*See* **Reinforcement Learning: A Computational Perspective**)

In many control problems, the entire state of the environment cannot be observed at each time step. For example, when driving a car, the driver cannot simultaneously observe all of the other cars driving on the same street. Similarly, a robot controller can rarely observe the entire state of the world. The task of controlling such partially observable environments is known as a Partially Observable Markov Decision Problem (POMDP). As with MDPs, model-based and model-free methods have been developed.

Model-based methods for POMDPs must posit the existence of underlying (but unobservable states) in order to explain (and predict) the way that the observable parts of the state will change. (*See* **Markov Decision Processes, Learning of**)

SPEEDUP LEARNING

We now turn our attention to analytical learning. Because analytical learning does not involve interaction with an external source of data, analytical learning systems cannot learn knowledge with new empirical content. Instead, analytical learning focuses on improving the speed and reliability of the inferences and decisions that are performed by the computer. This is analogous in many ways to the process of skill acquisition in people.

Consider a computation that involves search. Examples include searching for good sequences of moves in chess, searching for good routes in a city, and searching for the right steps in a cooking recipe. The task of speedup learning is to remember and analyze past searches so that future problems can be solved more quickly and with little or no search.

The simplest form of speedup learning is called *caching* – replacing computation with memory. When the system performs a search, it stores the results of the search in memory. Later, it can retrieve information from memory rather than repeating the computation. For example, consider a person trying to bake a cake. There are many possible combinations of ingredients and many possible processing steps (e.g. stirring, sifting, cooking at various temperatures and for various amounts of time). A cook must search this space, trying various combinations, until a good cake is made. The cook can learn from this search by storing good combinations of ingredients and processing steps (e.g. in the form of a recipe written on a card). Then, when he or she needs to bake another cake, the recipe can be retrieved and followed.

Analogous methods have been applied to speed up computer game playing. Good sequences of moves can be found by searching through possible game situations. These sequences can then be stored and later retrieved to avoid repeating the search during future games. This search for good move sequences can be performed without playing any 'real' games against opponents.

A more interesting form of speedup learning is generalized caching – also known as *explanation-based learning*. Consider a cook who now wants to bake bread. Are there processing steps that were found during the search for a good cake recipe that can be re-used for a good bread recipe? The cook may have discovered that it is important to add the flour, sugar, and cocoa powder slowly when mixing it with the water, eggs, and vanilla extract. If the cook can identify an *explanation* for this part of the recipe, then it can be generalized. In this case,

the explanation is that when adding powdered ingredients (flour, sugar, cocoa) to a liquid batter (water, eggs, and vanilla extract), adding them slowly while stirring avoids creating lumps. This explanation supports the creation of a general rule: add powdered ingredients slowly to a liquid batter while stirring.

When baking bread, the cook can retrieve this rule and apply it, but this time the powdered ingredients are flour, salt, and dry yeast, and the liquid batter is water. Note that the explanation provides the useful abstractions (powdered ingredients, liquid batter) and also the justification for the rule. Explanation-based learning is a form of analytical learning, because it relies on the availability of background knowledge that is able to explain why particular steps succeed or fail.

Retrieving a rule is usually more difficult than retrieving an entire recipe. To retrieve an entire recipe, we just need to look up the name ('chocolate cake'). But to retrieve a rule, we must identify the relevant situation ('adding powdered ingredients to liquid batter'). Sometimes, the cost of evaluating the rule conditions is greater than the time saved by not searching. This is known as the *utility problem*. One solution to the utility problem is to restrict the expressive power of rule conditions so that they are guaranteed to be cheap to evaluate. Another solution is to approximate the rule conditions with different conditions that are easier to evaluate, even if this introduces some errors. This is known as *knowledge compilation*. Explanation-based learning mechanisms have been incorporated into cognitive architectures such as the Soar architecture of Newell, Rosenbloom, and Laird and the various ACT architectures of Anderson. (*See* **Soar**; **ACT**)

A third form of speedup learning is to learn search control heuristics. These heuristics typically take the form of evaluation functions, pruning rules, preference rules, or macros. An evaluation function assigns a numerical score to each situation (e.g. to each proposed cooking step). A pruning rule evaluates a proposed step and indicates whether it is likely to succeed. If not, the step can be pruned from the search. A preference rule compares two different proposed steps and indicates which is better. It can be applied to rank-order the proposed steps. A macro prescribes a *sequence* of steps to take when certain conditions are satisfied. All of these search control heuristics are typically learned by applying empirical learning methods.

Evaluation functions are frequently employed in game-playing programs. For example, the best computer backgammon program (Tesauro's TD-gammon) applies the empirical $TD(\lambda)$ reinforcement learning algorithm to learn an evaluation function for backgammon. (*See* **Samuel's Checkers Player**; **Reinforcement Learning: A Computational Perspective**)

Pruning rules can be learned as follows. Suppose our cook has kept records of all of the cooking experiments along with information about which experiments succeeded and which ones failed. We can consider each step in each recipe as a training example, and assign it a label of 'succeeds' or 'fails' depending on whether it was a good step to execute. Then supervised learning algorithms can be applied to learn a classifier for recipe steps. When developing a new recipe, this classifier can be applied to evaluate proposed steps and indicate which ones are likely to succeed – thus avoiding search.

Similarly, preference rules can also be learned by supervised learning. One training example is constructed for each *pair* of proposed actions (e.g. proposed cooking steps). The example is labeled as 'Better' if the first step is better than the second, and 'Worse' if the second step is better than the first. Then a supervised learning algorithm can learn a classifier for ranking the proposed actions.

Finally, macros can be learned in many different ways. One interesting method is known as the 'peak-to-peak' method. It can be applied to convert an imperfect evaluation function into a set of macros. A perfect evaluation function gives a high score to every good move from the starting state to the final goal (i.e. from the raw ingredients to the finished cake). An imperfect evaluation function will give high scores to some steps but then incorrectly give poor scores to a sequence of steps before again giving high scores. We can view this as a 'valley' between two peaks. The valley can be removed by introducing a macro that says when you reach the first peak, execute the *sequence* of steps that will lead to the next peak. By executing the macro as a single 'macro step', we are able to move right through the valley without becoming confused by the evaluation function errors.

Machine Translation

Intermediate article

Christian Boitet, Université Joseph Fourier, Grenoble, France

CONTENTS

Machine translation is the subset of automated translation which aims to build programs capable of taking over translation per se, whether fully automatically or with the assistance of monolingual users.

INTRODUCTION

Machine translation (MT) was the first non-numerical application of computers. After initially promising demonstrations in the US around 1954, it was realized that high quality, fully automatic machine translation (HQFAMT) would in general be impossible. Less ambitious tasks were then attacked by lowering one or more requirements. The result was several kinds of automated translation (AT) systems. There exist many LQFAMT (low quality…) systems, producing rough translations used for accessing information in foreign languages. HQFAMT systems for very restricted kinds of texts are less common, but do exist. There are also MT systems for restricted text types which are high quality but not fully automatic (HQMT); these produce raw translations good enough to be revised cost-efficiently by professional revisers. HQMT can also be obtained by asking end users to assist the system. Finally, translation aids (TA), combining on-line dictionaries, term banks, and translation memories, are used extensively by professionals.

It is important to realize that human translation is difficult and diverse, and that automation is needed not only by end users but also by translators and interpreters. Also, automation itself comes in many forms. After expanding upon these points, we will move on to survey various linguistic and computational aspects of automated translation. This survey will yield an array of criteria for categorizing existing AT systems and for evaluating the state of the art. Finally, we present perspectives of future research, development, and dissemination.

Misconceptions about Translation

Translation is more difficult than usually believed, because of conceptual, cultural, and structural differences between languages; unavoidable ambiguities on many levels; and the need for considerable contextual knowledge. Underestimates concerning the inherent difficulty can distort evaluations of automated translation.

Further, the term 'translation' is often used imprecisely, as translation directions and purposes can vary widely. (According to the situation, the required translation may be 1-to-1, that is, from one language into another one, e.g. Russian–English; or 1-to-N, M-to-1, or M-to-N. The purpose of a translation may be to disseminate technical knowledge, to provide access to general information, etc. The purposes of speech translation, or interpretation, are again quite different.) Misleading generalizations about human translation may again distort perceptions about the practicality or worth of MT.

Misconceptions about human translation quality and costs are also common. While it is often believed that perfect understanding is needed to produce high quality translations, perfect understanding is rare, especially in rapidly developing specialties. In reality, experienced translators can often produce imperfect but high quality translations with less than full understanding. In any case, 'raw' translations produced by junior translators must usually be revised by senior translators. Thus the quality of even human translation is often lower than commonly supposed. Similarly, the work of interpreters is often judged much more by its speed and regularity than by its exactitude and completeness. As for translation cost, it is often underestimated. If it is done in-house, essential costs for such requirements as training, meetings, and research may not be taken into account. If it is subcontracted, different departments often use different subcontractors, and these expenses are not consolidated.

Why Automation is Needed

While misconceptions about translation remain widespread, the automation of translation and interpretation has become increasingly necessary since the 1950s as new requirements have arisen.

First, there can never be enough translators to cover the perceived needs. For example, not even the US army could train enough translators to skim through all Soviet literature in the Cold War era. With increasing globalization and the growth of the Internet, the need for all kinds of translation, from rough to raw to refined, is growing. The European Community now has eleven official languages, but still about 1200 in-house translators, the same number it had in the 1970s, when there were only eight official languages.

Second, many translation tasks are so boring or stressful that translators want to escape them. Automation can thus be seen as a way to free translators from menial tasks and promote them to revisers and co-developers of the automated systems.

Third, there is also increasing need for interpretation, especially to assist travelers abroad. There are many situations where sufficient knowledge of a common language is lacking: visiting a doctor, booking tickets for travel or leisure, asking for help on the roadside, calling motels, etc.

AUTOMATED TRANSLATION TASKS

When a translation job is automated, several tasks or subtasks may be affected. Computers can help to prepare translation resources, such as aligned bilingual texts; they can aid in preparation of the source text, e.g. by segmenting it; they can carry out all or part of the actual translation; and they can assist revision of a target text draft.

Preparation of Resources

Computers may first help in preparing resources for translation: they can (1) help to build bilingual terminological lexicons; (2) help to discover similar texts or dialogs, if possible already translated; (3) supply *aligners*, in order to build *bitexts* (aligned bilingual texts) from translations; or (4) provide terminology extractors working on monolingual texts or bitexts.

Preparation of Source Texts

Computers may also be used to prepare the texts to be translated. This preparation may first include correcting the texts using spellcheckers and grammar checkers – a crucial step, since bad source text quality is a principal source of translation errors. Second, it is often useful to *normalize* the source text: style and terminology checkers can be applied; pronouns with distant referents can be replaced by their referents; and implicit elements, such as subjects or objects in Japanese sentences, can be inserted. Third, texts can be segmented into maximally homogenous translation units. For example, long and complex sentences, even if they are admissible in the genre at hand, may be broken into simpler ones to help translation. Finally, it is also possible to annotate the text by inserting tags to help the analyzer.

Translation Proper

Translation *per se*, i.e. the passage from one language to another, can be totally, partially, or 'only apparently' automated.

'Pure' machine translation operates fully automatically, and its result is used by the end user. As mentioned, high quality of raw output can be obtained only by tuning systems to a restricted domain or genre. More generally, in order to achieve professional quality output and to give feedback to the machine translation developers, human revision must be used. It may take anywhere from one minute per page for very restricted domains (METEO ((Chandioux, 1988), 1976–), ALT/Flash (NTT, 1999–)…) to 10–15 minutes for broader domains such as technical manuals or administrative documents (ENGSPAN & SPANAM ((Vasconcellos and León, 1988), 1980–), CATALYST ((Nyberg and Mitamura 1992), 1992–)…).

In semi-automatic translation, one or more humans help the system translate. There are several variants. The oldest methods (ITS (BYU, Provo, 1974–81), N-Trans (Whitelock *et al*., 1986)) are highly interactive: as soon as the system encounters a problem in a local context (e.g. ambiguity in analysis, synonymy in generation, or both in transfer), a question is issued, and the user must give an answer. This procedure can be annoyingly demanding, and costly if specialized human knowledge is required. More recent semi-automatic systems (such as JETS at IBM-Japan (Maruyama *et al*., 1990; see also Boitet and Blanchon, 1994; Wehrli, 1992)) avoid these problems by delaying questions until one or two specific points in the translation process.

We say translation is 'only apparently' automated when the automation consists only of retrieving past translations from a *translation*

memory. When an exact match is found, the system may propose not only one, but several translations, produced in different contexts. In principle, all of them are very good, being of professional quality. When a 'fuzzy' or partial match is found, however, translations of similar but different source language segments are proposed, all of them in principle inadequate and requiring editing by the translator to become correct. In typical situations with high redundancy, such as successive versions of the same set of manuals, one may find 20–30% exact matches and 40–60% partial matches.

These approaches may be combined, e.g. by providing translators with suggestions from a translation memory and from an MT system.

Revision

To assist the revision of a first translation draft, both standard and specialized tools can be used. Standard tools would include various kinds of checkers of the target language. Specialized aids include: (1) flagging by the MT system of dubious passages (for which no complete analysis has been found, or in which unreliable choices had to be made); (2) production of two or more alternate translations of ambiguous terms, with appropriate formatting; and (3) development of special macro commands in the text editor to automate the most frequent correction operations, such as the permutation of three not necessarily contiguous blocks of texts (…A…B…C… to …B…C…A…).

COMPUTATIONAL ASPECTS OF AUTOMATED TRANSLATION

We now examine several computational aspects of automated translation. We will discuss linguistic architectures; various approaches to analysis of the source text; the handling of ambiguities; the use of specialized software languages; and the acquisition of linguistic resources.

At the outset, we should emphasize that imitating humans is no more a viable approach for translation than for voice recognition or other complex mental processes such as chess playing, since today's computers have very little in common with human brains. However, observation of human practice and introspection are nevertheless very useful: *what* is done can be reproduced independently of *how* it is done, and translator rules of thumb can be more or less exactly formalized as heuristic rules.

Linguistic Architectures

The possible linguistic architectures of MT systems are best understood with the help of Vauquois' triangle (Figure 1).

The triangle represents translation as proceeding from left to right. Thus we can imagine source language structures on the left, and target language structures on the right. The arrows which traverse the triangle from left to right represent translation or *transfer* processes which receive source language structures as input, manipulate them, and produce target language structures as output. Notice, however, that such linguistic structures can be defined at various *levels of abstraction or depth*: they may be shallow structures near the broad base of the triangle; or they may be deeper (more abstract) structures nearer to the narrow peak.

Each level can have its own translation or transfer process, shown in the figure as a horizontal arrow. The figure also contains ascending and descending arrows, representing the possibility that the transfer process could yield a structure more, or less, abstract than the input structure.

Direct and statistical MT: lexical replacement plus 'massaging'

Historically, the first MT paradigm was based on the supposed similarity of translation and deciphering. In this approach, a Russian text is viewed as the result of some encoding of an original English text, using word replacement and permutations of groups of words. To translate it into English, then, one tries to find the best English equivalents for the Russian words or groups of words by looking at the context in the utterance, and 'massage' the result into a grammatical English utterance.

This technique does not work very well, but human readers can often compensate for mistranslation and agrammaticality in the output if they are reading for comprehension only. The deciphering, or *direct*, approach is still used in many systems today (the majority of Systran language pairs until very recently, along with GlobaLink, Webtranslator, and others).

'Pure' statistical MT is a modern version of the direct approach. The IBM group, which pioneered the successful use of statistical methods for speech recognition has pioneered in the statistical translation area as well. The idea is to learn correspondences between (groups of) words of two languages from a large set of aligned sentences, such as the Hansard bilingual transcriptions of the debates of the Canadian Parliament, and then use these learned correspondences to translate new

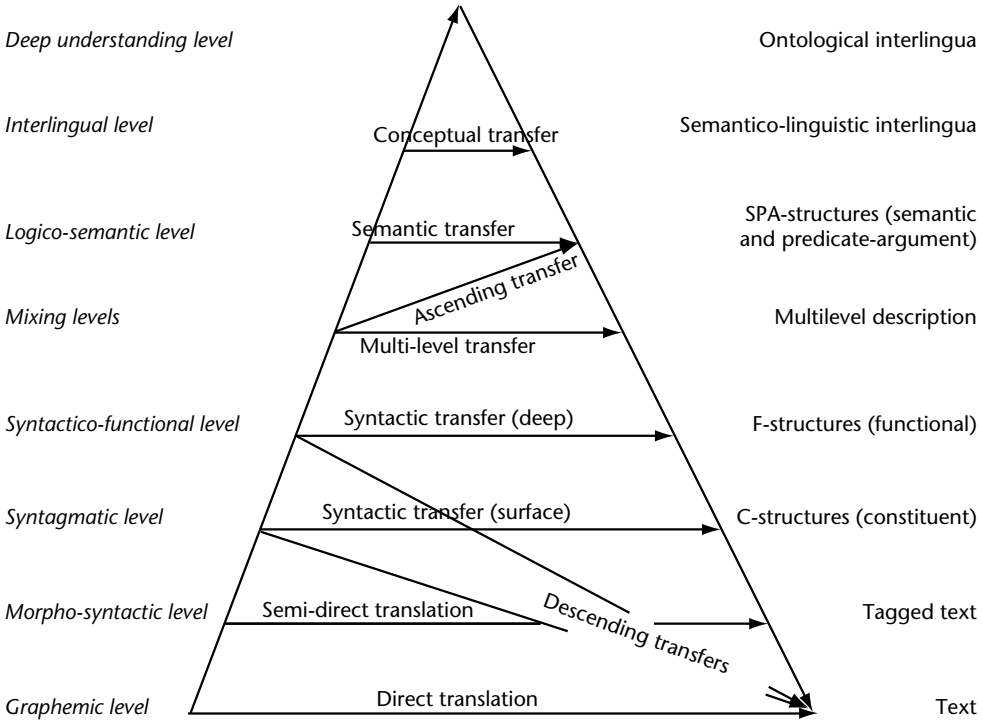

Figure 1. Vauquois' triangle.

sentences. Because of the huge number of possibilities to be examined (the combinatorial explosion), sentences used for training cannot be very long, and the word correspondences are usually limited to 1-1, 1-0, 0-1, and 1-N, although M-N (many-to-many) correspondences would be desirable.

Experiments have demonstrated that this statistical technique is inferior to the older handcrafted direct approach. But its proponents have been able to use the same ideas at higher levels of linguistic interpretation, this time with success (e.g. using 'stochastic grammars' at the syntagmatic, or syntactic, level, and more recently employing 'semantic grammars'), in effect moving from a semi-direct approach to a *transfer* or *pivot* approach.

Transfer approaches to MT

In the 'strict' transfer approach to MT, there are three steps: (1) a strictly monolingual analysis into a descriptive structure of the source language at some level L of linguistic interpretation; (2) a bilingual transfer (normally decomposed into a lexical and a structural phase) into a descriptive structure of the target language at the same level L; and (3) a monolingual generation process. One can distinguish between surface (e.g. TDMT (ATR)) and deep syntactic transfer (e.g. LMT (IBM)), semantic transfer (e.g. MU (University of Kyoto), and its successor MAJESTIC (JST)), and multi-level transfer (if the descriptive structure contains both syntactic and semantic information (e.g. GETA's Russian–French system (Boitet and Nédobejkine, 1981))). Whichever variant is used, the transfer-based translation technique makes it possible to reuse the analysis and generation steps in several language pairs (English–German and Russian–German).

Due to a lack of appropriate tools, some developers have started with the strict transfer approach in mind, but have not been able to develop the 'structural' part of a strict transfer process – that part which represents correspondences between arbitrarily complex source language and target language structures. The resulting systems (e.g. METAL (Slocum, 1985), Shalt-1 (IBM)) mix transfer and syntactic generation in one step, usually implemented by a recursive descent of the analysis tree structure, thus achieving a sort of 'descending' transfer, in which the transfer output is less abstract than the input.

By contrast, B. Vauquois introduced the technique of 'ascending' transfer, in which the transfer output is more abstract than the input. In this approach, the analysis produces a *multi-level structure* containing both semantic and syntactic structures. That is, the structures contain both a language-neutral level of logico-semantic interpretation and some information about surface levels,

such as syntagmatic categories (noun phrase, verb phrase, etc.) and syntactic functions (subject, direct object, etc.). During transfer, some surface-level information may be transferred from the source language structure to that of the target language; but, during generation, any remaining surface information is recomputed from the language-neutral semantic level. At this generation stage, the goal is to minimize the transfer of structural surface information – to rely as far as possible on the transfer of semantic information, so that the target language can express this semantic information idiomatically.

Pivot approaches to MT

Strictly speaking, the *pivot* approach simply consists in using some standard intermediate format to represent the information passed during translation from any language into any other language. But the nature of this pivot format may vary: it may be a natural language text, or it may be a structure describing the utterance being translated. In the latter case, the structure may or may not include language-specific information. Further, the intended coverage may be broad, ideally handling the relevant languages at large; or only restricted domains may be addressed.

Using natural language text as a pivot structure implies using the output of one MT process as the input for one or more later processes. Clearly, this approach is practical only if the output is of high quality and grammatically correct. But it always encounters the problem of the inherent ambiguity of the pivot language.

As mentioned, the next possibility is to use structural descriptors of a natural language L0 as pivotal elements, rather than normal text of L0. To translate between L0 and another language Lk, a standard transfer approach is employed, as explained above. However, to translate between two other languages Lj and Lk, one first analyzes Lj to obtain a structural description at some level; then performs a transfer to a corresponding structure of L0 (at the same level or a more abstract one); then performs a *second* transfer operation from the L0 structure to a structure of Lk; and finally generates target text from the Lk structure. If this procedure is followed, text of the intermediate language L0 need never be generated or analyzed, so any additional errors or ambiguity which might have been introduced during this generation or analysis can be avoided.

This structural pivot technique was initially proposed and tried by CETA in Grenoble (Vauquois, 1975) in the 1960s, under the name of *hybrid pivot*. It was then used successfully in the DLT project at BSO research between 1982 and 1988. The pivot language was Esperanto, and the pivot descriptors were Esperanto utterances augmented with structural and grammatical tags. The same technique is currently used by the IPPI team in Moscow (Boguslavskij *et al*.) to translate from UNL (see below) into Russian.

When the structural pivot approach is adopted, some means is needed to represent the lexical elements, or words, of the source and target structures. These *lexical units* can be dictionary forms (or *lemmas*) extracted from dictionaries of the relevant languages. Since natural language words generally have several meanings, it will in this case be necessary to specify the intended meaning, e.g. by using numerical indexes (so that *observe.1* indicates the watching meaning of this verb, and *observe.2* indicates the obeying meaning). Lexical units can also be derivational families, e.g. the unit 'OBSERVE-2' might contain the lemmas *observe, observable, observant, observance*.

However, it is also possible to create a language-neutral set of word meaning symbols (or *acceptions*). If such neutral symbols are used within structures which themselves are sufficiently abstract to contain no language-specific information, the result is a *linguistic interlingua*.

The best example today is UNL (the Universal Networking Language). The UNL project is concerned with multilingual communication over the Internet. It was initiated in 1996 by the University of the United Nations (based in Tokyo), and addressed fourteen languages as of 2000. The representation of an utterance is a hypergraph with a unique *entry node*, where normal nodes bear *Universal Words* (UWs, or interlingual word senses) with semantic attributes, and arcs bear semantic relations (deep cases, such as agt, obj, etc.).

Figure 2 gives an example of a UNL graph. The semantic attributes, marked by '@', represent phenomena like speech acts, modality, time, etc.

Finally, it is possible to develop purely semantic, task-oriented pivot representations within restricted domains such as transport and hotel reservation, schedule arrangement, etc. This approach has been taken in several speech translation projects such as CSTAR, which employs the Interface Format (IF) for intermediate representation. An utterance by a client such as *Hello Tom, how are you today?* may be represented by the IF expression 'C: greetings(time = morning, level = familiar)', which could then be re-expressed as *Good morning!*

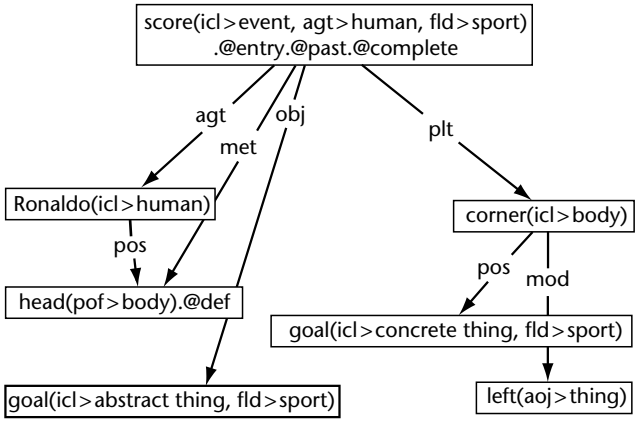

Figure 2. A simple UNL graph.

Analysis of Input: Symbolic, Numerical, and Hybrid Techniques

All operational MT systems use symbolic (rule- or procedure-based) techniques, sometimes enhanced with numerical (statistical) techniques. Their linguistic programs are thus based either on formal grammars or on automata.

The grammatical approach uses regular or context-free grammars, extended with attributes and abstract tree-building mechanisms, much as is done to build compilers.

Various sorts of *transducing* automata – abstract machines which incrementally transform input structures into output structures – are also used directly: (1) Finite State Transducers (FSTs) are extensively used for morphological and bounded syntactic processes. (2) In 1970, W. Woods introduced string-to-tree transducers called Augmented Transition Networks (ATNs) to build analyzers, and used them in the LUNAR project. ATN-based analyzers are used today in the Prompt (Softissimo), ENGSPAN/SPANAM (PAHO) and AS-TRANSAC (Toshiba) MT systems. (3) G. Stewart extended the model to Q-graphs transducers for the TAUM-Aviation project, but his remarkable REZO language has yet to find a successor. (4) Finally, various types of transducers for annotated trees (transformational systems) have been used for structural analysis, transfer, and generation. The first was built at CETA (Grenoble) between 1965 and 1966. Quite a few MT systems use some variants today, including ROBRA in GETA's Ariane-G5-based MT systems, L. C. Tong's GWR in Tapestry at KRDL in Singapore, Nakamura's GRADE in MU/Majestic in Japan, and HICATS of Hitachi.

Numerical, or statistical, techniques are increasingly used for source language analysis in speech translation. The end-to-end evaluation of the German VerbMobil project (1992–2000) has shown that, after comparable development efforts, they can lower the error rate to 30%, while the symbolic techniques produced errors in at least 60% of all cases. This advantage is due not only to the noisy nature of the input (a word lattice produced by the speech recognizer), but also to the fact that numerical techniques can 'learn' the weights of the transitions of a stochastic automaton far more complex than any automaton which could be built by hand.

Another promising avenue for source language analysis is the 'hybrid' approach, where symbolic and numerical techniques are mixed at different points. An exemplary case is the MT system developed by Microsoft (2000–01).

Handling Ambiguities

Traditionally, the goal of *source language analysis* is to produce one or several abstract representations (annotated or 'decorated' trees, feature structures, conceptual graphs, logical formulae, etc.), each of them *disambiguated*.

In the standard *combinatorial approach* to analysis, *all* possible analyses are computed. Subsequently, since a single best solution or small set of solutions is normally desired, filters, weights, or preferences are used. Filtering consists in applying increasingly stricter conditions of well-formedness until the set of solutions is satisfactorily reduced. Weights may be computed for solutions in a number of ways.

In the *heuristic approach*, by contrast, only *some* possible analyses are computed. The worst heuristic technique is to use a standard search algorithm (e.g. backtracking) and stop once the first solution is reached, because in this case potential ambiguities are simply ignored. A better technique is to use weights to guide the search and to seek more than one solution.

These two search techniques do not actually *handle* all candidate solutions; they are just ways to *eliminate* some solutions from further consideration. The use of preferences is more to the point: one tries to recognize the cause of ambiguity and choose among all candidates on some principled basis. But then all ambiguity cases and their solutions must be foreseen, a very difficult task. Also, principled selection of the best candidate based upon preferences is local, which makes it difficult to guarantee an overall best solution, and perhaps explains why other techniques often perform as well in practice. In practical working systems, the heuristic and the preferential approaches are combined.

The main problem with usual search techniques is that they produce a set, or a (weighted) list, of complete, fully disambiguated solutions, and *discard* all trace of the source of the ambiguities. B. Vauquois' solution to this problem of information loss was to produce abstract structures that *preserve certain internal ambiguities*, either directly, or through 'tactical' annotations. This technique enables a system to produce 'warnings' in the output which show the presence of ambiguities in a factorized way. However, ambiguities are coded in the same structures (annotated trees) used to describe disambiguated solutions, which leads to more complex transfers and generations.

Specialized Programming Languages

Specialized languages for linguistic programming (SLLPs, earlier called 'metalanguages') have been around since the 1960s, aiding in the production of MT dictionaries. Linguistic programming has often been done using classical programming languages (macroassembler and the C-macroprocessor for Systran, LISP for parts of METAL, etc.).

The idea is simply to define a symbolic language familiar to the linguist, and then to compile linguistic data or programs written in this SLLP into interpretable or directly executable binary code. The first complete SLLP was COMIT, developed at MIT in the 1960s. Later languages have been based upon theoretical models, or have emphasized powerful data structures and control structures.

Linguistic Resource Acquisition

Large-scale lexical acquisition has been a major problem since the beginnings of MT, in the 1960s. There are three main approaches, each with its context, methodology, and pros and cons. The first approach consists in working directly on dictionaries specialized for MT; the second in creating specialized lexical databases, generally asymmetrical and proprietary, and sometimes usable for applications different from MT; and the third in building lexical databases which can not only be used in multiple ways by both humans and machines, but are also intrinsically symmetrical, linguistically very detailed, potentially containing a great many entries and languages, and open. For the future, if MT systems are to cover all pairs of languages and all domains, it seems that the only approach which might circumvent prohibitive costs is that of Linux: a collaborative, Web-based approach to the creation and usage of lexical resources.

For any of these methods, it is necessary to use corpora to obtain primary information and to test refined information. In recent years, corpus linguistics has led to the development of very powerful automatic tools, based on low-level linguistic processing and sophisticated statistical techniques, which enormously help lexical acquisition. For example, there are now effective terminology extractors which work on monolingual documents and on bilingual aligned texts. However, their results must be refined by human labor: as many as 40% of the suggestions may be wrong, and information automatically obtained from the remaining 60% must still be revised.

The acquisition of syntactic and semantic knowledge remains mostly a human responsibility, reserved for specialists. However, in hybrid techniques, programs can to some degree be used to learn from examples, as at T. Matsumoto's lab at NAIST (Nara).

STATE OF THE ART

To assess current MT systems, it is useful to distinguish three main goals: MT aiming at rough translation of texts, MT aiming at quality translation of texts, and MT of speech.

Rough MT for Comprehension

Many MT systems are currently available, at low prices, for basic comprehension. The obtained translations are rough, but often adequate. They cannot practically be directly revised to obtain

quality translation, but readers understand the gist of the information, or at least its topics, and translators can use the result as a suggestion, just as they use suggestions from translation memories. The main uses for comprehension MT now are for surfing the Web and for seeking information, although military, economic, and scientific intelligence were early users, and demand continues in these areas. The number of available language pairs is in fact very low compared to the needs. For example, an official of the EU reported at LREC-2000 that EC-Systran had only nineteen pairs after 24 years of development, eight of them 'almost satisfactory'. However, there are 110 language pairs in the EC. In Japan (and similarly in China), very few language pairs are offered besides English ↔ Japanese and English ↔ Chinese. Russian is offered for two or three pairs, and Thai only for English ↔ Thai. Some websites claim to offer many language pairs by translating through English. Unfortunately, the results are usually terrible, for reasons explained above.

The identified obstacles here are:

- the cost of developing the first commercial version of a new language pair (at least 40 person-years according to the CEO of Softissimo).
- the direct approach, which makes it impossible to combine two systems without dramatically lowering the quality.
- the law of diminishing returns: each new language pair to be developed usually corresponds to a lesser need than the previous one, hence there are fewer users/buyers, all expecting to pay no more than the cost of already available language pairs.

Quality Raw MT for Dissemination of Information

We find here specialized systems for rare niches, such as METEO (Chandioux, 1988), ENGSPAN, SPANAM (Vasconcellos and León, 1988), METAL (Slocum, 1985), LMT (McCord, IBM), CATALYST (Caterpillar-CMU), perhaps some LOGOS systems, etc. In Japan, we might mention ALT/Flash (the NTT system for Nikkei stock market flash reports) and perhaps some specialized systems, mostly ENG-JAP, used internally for translating technical manuals (AS-Transac at Toshiba, ATLAS-II at Fujitsu, CrossRoad at NEC, SHALT at IBM, Pensée at OKI, etc.). In Europe, few such systems are now available, due to the relatively small market, and to the negative attitude of the EC and all governments towards funding quality MT.

Quality MT systems for information dissemination are very rare. However, these systems are indeed very good and very useful (30 Mwords/year for METEO, 75% English–French and 25% French–English, with 1mn revision per page, 0.15 cents/word for final output), because they are quite specialized.

It is extremely difficult to prepare comparative benchmarks for such systems because, like expert systems, they are very good in their domain, and fail miserably on other tasks. The best way to measure them is through some combined assessment of the sale, maintenance, and evolution prices, and through consideration of the human time needed to obtain a professional result.

Technically, these systems almost always have a separate analysis component, producing a syntactic or syntactico-semantic descriptor of the source unit of translation (usually an annotated tree). Almost all use some flavor of the transfer approach (even systems like ATLAS-II by Fujitsu or PIVOT-CROSSROAD by NEC). In most cases, there is no syntactico-semantic descriptor of the target unit of translation, transfer and generation being merged into a single phase using recursive descent of the analysis tree. Hence, changing the source language implies redoing all the work. (Compare the difficulties experienced by Siemens with METAL in the 1990s, which contributed to this company's exit from the scene.)

The identified obstacles here are:

- the cost of developing the first commercial version of a new language pair: at least 100 person-years according to H. Sakaki, the main author of KATE at KDD, and to Dr. Nagao, director of the MU project; and perhaps 300 person-years with large dictionaries, as H. Uchida estimated for ATLAS-II at Fujitsu.
- the impossibility of factorizing generation processes, when the situation changes from $1 \rightarrow N$ to $M \rightarrow N$.
- the apparent lack of demand for high quality translation for many language pairs, even though structural transfer systems could be combined, as explained above, to produce multiple pairs.

Speech Translation

Current commercially available technology makes speech translation already possible and usable for social interchanges such as chat. Such systems are usually built by combining speech recognition (SR), text MT, and speech synthesis. NEC demonstrated a system for JAP ↔ ENG at Telecom'99. Linguatec, a subsidiary of IBM, markets Talk & Translate (using IBM's Via Voice and Logic-Programming based Machine Translation (LMT) for ENG ↔ GER). The quality is of course not very high in all components, but this drawback is compensated for by the broad

coverage, by some feedback (e.g. editable output of SR and written reverse translation), and by human intelligence and desire to communicate.

At the research level, the aim is to obtain higher quality while allowing more spontaneous speech in task-oriented situations. The large German Verb-Mobil project (1992–2000) showed the feasibility of reaching these goals, and compared many alternative methods in the same task setting (Wahlster, 2000). The goals can also be reached in a multilingual setting, as demonstrated by the C-STAR II consortium in intercontinental public demonstrations with large media coverage in July 1999. C-STAR II used a kind of semantico-pragmatic pivot designed to represent the dialogue utterances of participants in a limited set of situations (e.g. getting tourism information, booking hotels or tickets for events and transports, etc.).

The identified obstacles here are:

- the great difficulty of developing an adequate pivot (such as the IF or Interface Format of CSTAR).
- the cost of building the necessary lexical resources, as for MT of texts.
- the difficulty of handling the context (pragmatic, discursive, linguistic, and lexical), and in particular of computing correctly the speech acts and the referents of anaphoras and elisions.

PERSPECTIVES: KEYS TO THE GENERALIZATION OF MT IN THE FUTURE

Despite considerable investment since the 1960s, only a few language pairs are covered by MT systems designed for information access, and even fewer are capable of quality translation or speech translation. To open the door towards MT of adequate quality for all languages (at least in principle), four keys are needed. On the technical side, one should (1) dramatically increase the use of learning techniques which have demonstrated their potential at the research level, and (2) use pivot architectures, the most universally usable pivot being UNL. On the organisational side, the keys are (3) the cooperative development of open source linguistic resources on the Web, and (4) the construction of systems where quality can be improved on demand by users, either a priori through interactive disambiguation, or a posteriori by correcting the pivot representation through any language, thereby unifying MT, computer-aided authoring, and multilingual generation.

CONTENTS

Markov models are probabilistic models of dynamical systems, which can be used to predict the future and the consequences of one's actions.

INTRODUCTION

The ability to predict the future is fundamental to probably all intelligent systems. Since in general we cannot hope to make perfect predictions, it makes sense to adopt a probabilistic approach. For example, although we may not be able to predict the exact price of a stock tomorrow, we may be able to predict its *expected* price; deviations around this mean will be modeled as 'noise', assumed to result from all the unknown factors that were omitted from the model. Similarly, although we may not be able to exactly predict the next word that someone will speak or type at a keyboard, we can predict a set of likely or probable words based on what we have heard or seen so far. (*See* **Reasoning under Uncertainty**)

It is standard to model the system to be predicted as a dynamical system. That is, the system is assumed to be in some state, $X_t \in \Omega$, at each time step t; the next state of the system is determined by the state transition function, $X_{t+1} = f(X_t)$. (In this article, we restrict our attention to discrete time dynamical systems.) Typically we do not know the exact dynamics of the system, so instead we consider a probabilistic state transition function: $P(X_{t+1}|X_t)$. Such a probabilistic formulation will be particularly useful when we try to *learn* the model from data, since although there may be no model that fits the data perfectly, some models might be more probable than others. The state space, Ω, might be discrete (finite) or continuous (infinite). For example, we might try to predict the probability that a stock goes up or down, in which case $\Omega\{\uparrow, \downarrow\}$, or we might try to predict its expected value, in which case $\Omega = \mathbb{R}$. Of course, the state X_t may also be vector-valued. (*See* **Dynamical Systems: Mathematics**)

A (first-order) Markov process is one such that $P(X_{t+h}|X_{1:t}) = P(X_{t+h}|X_t)$, where $X_{1:t} = X_1, \ldots, X_t$ is the past observation sequence and $h > 0$ is the amount of lookahead (the prediction horizon). This is often paraphrased as: the future X_{t+h} is independent of the past $X_{1:t-1}$ given the present X_t. A k'th order Markov process is such that $P(X_{t+h}|X_{1:t}) = P(X_{t+h}|X_{t-k+1:t})$. $X_{t-k+1:t}$ is called a sufficient statistic, since it can be used to predict the future with the same accuracy as would be obtained if we conditioned on the whole sequence of past observations. A k'th order Markov model can always be converted to a first-order Markov model by creating a 'mega variable' containing the last k observations (a sliding window). For example, if the system is second-order Markov, we can convert it to first-order by defining a new state space, $\tilde{X}_t = (X_t, X_{t-1})$, and set $P(\tilde{X}_t = (x_t, x_{t-1})|\tilde{X}_{t-1} = (x'_{t-1}, x_{t-2})) = \delta(x_{t-1}, x'_{t-1})\, P(x_t|x_{t-1}, x_{t-2})$. The δ function ensures that $\tilde{X}_t$ and $\tilde{X}_{t-1}$ assign the same value to the variables that they share (in this case, X_{t-1}).

Often a system has no finite (or reasonably small) sufficient statistic, which means we need to base our predictions on all the past data; this is clearly impractical, especially for high-dimensional data such as audio or video signals. However, we may posit the existence of a hidden or latent variable, which generates the observations at each step, and whose transition dynamics do satisfy the (first-order) Markov property. This is called a hidden Markov model (HMM) if the latent variable is discrete, or a state-space model if the latent variable is continuous. We will denote the hidden variable by X_t and the observed variable by Y_t. (Since the value of X_t is hidden, the model is called 'partially observed'.) In addition to the transition function $P(X_t|X_{t-1})$, we must now specify the observation function, $P(Y_t|X_t)$. We will explain this in more detail below.

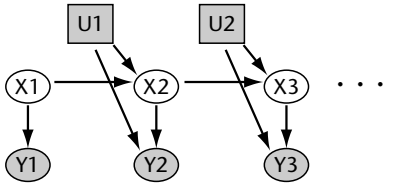

Figure 1. A generic discrete-time dynamical system represented as a dynamic Bayesian network (DBN). U_t is the input X_t is the hidden state, and Y_t is the output. Shaded nodes are observed, clear nodes are hidden. Square nodes are fixed inputs (controls), round nodes are random variables.

In addition to hidden and observed variables, we may have control or input variables, U_t. In this case, the transition function becomes $P(X_t|X_{t-1}, U_t)$ and the observation model becomes $P(Y_t|X_t, U_t)$. (Notice how what we see, Y_t, may depend on the actions that we take, U_t: this can be used to model active perception.) The resulting model can be represented as a Bayesian network, as shown in Figure 1. (*See* **Bayesian Belief Networks**)

In the following sections, we will explain how to learn Markov models from data. We start with the case where the system is fully observed, and then consider the harder case in which X_t is hidden, and we only get to observe Y_t, which is a probabilistic function of X_t.

FULLY OBSERVED MODELS

Discrete State Spaces: Markov Chains

In a finite state Markov chain, the system can be in one of S states, $X_t \in \Omega = \{1, 2, \ldots, S\}$; the probability of a transition from state i to state j is specified by a transition matrix, $A_t(i,j) \stackrel{\text{def}}{=} P(X_t = j|X_{t-1} = i)$. If A_t is independent of time, then this is called a homogeneous or stationary Markov chain; we shall assume this throughout. The initial state distribution is specified by $\pi(i) \stackrel{\text{def}}{=} P(X_1 = i)$. Since π is a probability distribution, it must satisfy the constraint that $\sum_{i=1}^{S} \pi(i) = 1$. Similarly, each row of A must satisfy $\sum_j A(i,j) = 1$; such a matrix is called stochastic.

A simple example of a finite state Markov chain is a bigram model, widely used in statistical approaches to natural language processing. In this case, Ω is the set of words, and the goal is to predict the next word given the previous. An n-gram model uses the last $n-1$ words to predict the next word, e.g. in a trigram model, the goal is to learn $P(X_t|X_{t-1}, X_{t-2})$ (see Model selection). (*See* **Natural Language Processing, Statistical Approaches to**)

Another example of a finite state Markov chain is a Markov decision process (MDP), widely used in reinforcement learning. In an MDP, the state transitions are 'triggered' by an input U_t. If we suppose the inputs are also discrete valued, we may write $P(X_t = j|X_{t-1} = i, U_{t-1} = k) = A_k(i,j)$; that is, the input just specifies which transition matrix to use. This can be represented as in Figure 1 by omitting the observation nodes Y_t (since we are assuming that we can directly observe X_t; if this were not the case, the model would be a *partially observed* MDP, or POMDP). (*See* **Reinforcement Learning: A Computational Perspective**)

Parameter estimation

Given a training set D of sequences, the goal of parameter learning (also known as system identification) is usually defined as finding the maximum likelihood estimate of the parameters: $\hat{\theta}_{ML} \stackrel{\text{def}}{=} \arg\max_\theta P(D|\theta)$, where $\theta = (\pi, A)$. If the training data contain N independent sequences, we can express the likelihood as $P(D|\theta) = \prod_{n=1}^{N} P(D^{(n)}|\theta)$. To compute the likelihood of an individual sequence, consider an example: $X_{1:4} = (1, 2, 1, 2)$. This has likelihood

$$\begin{aligned} P(X|\theta) &= P(X_1 = 1)P(X_2 = 2|X_1 = 1) \\ &\quad P(X_3 = 1|X_2 = 2)P(X_4 = 2|X_3 = 1) \\ &= \pi(1)A(1,2)A(2,1)A(1,2) \\ &= \pi(1)A(1,2)^2A(2,1)^1 \end{aligned}$$

In general, the likelihood is

$$P(D|\theta) = \prod_{i=1}^{S} \pi(i)^{\#1(i)} \prod_{i=1}^{S} \prod_{j=1}^{S} A(i,j)^{\#(i \to j)}$$

where $\#(i \to j)$ is the number of times an i to j state transition is observed in the whole training set:

$$\#(i \to j) \stackrel{\text{def}}{=} \sum_{n=1}^{N} \sum_{t=2}^{T_n} I(X_{t-1}^{(n)} = i, X_t^{(n)} = j)$$

Here, $I(e)$ is the indicator function that is 1 if event e occurs, and is 0 otherwise. $\#_1(i)$ is defined analogously to be the number of times the first state is observed to be i.

Maximizing the log-likelihood is equivalent to maximizing the likelihood (since log is a monotonic transformation), but is mathematically more convenient. The log-likelihood of a sequence is given by

$$\log P(D|\theta) = \sum_{i=1}^{S} \#_1(i) \log \pi(i) + \sum_{i=1}^{S} \sum_{j=1}^{S} \#_{i \to j} \log A(i,j)$$

To maximize the log-likelihood we must introduce Lagrange multipliers to enforce the sum-to-one constraints. Some simple calculus yields the intuitive results that the parameter estimates are just the normalized counts:

$$\hat{A}_{ML}(i,j) = \frac{\#(i \to j)}{\sum_k \#(i \to k)}$$

$$\hat{\pi}_{ML}(i) = \frac{\#_1(i)}{\sum_k \#_1(k)} = \frac{\#_1(i)}{N}$$

One problem with maximum likelihood (ML) estimation is that it assigns a probability of 0 to any event that was not seen in the training data; this is called the 'sparse data' problem. To see why this is a problem, consider the case of bigram models of language, where Ω is the set of all words. If the training corpus contains the phrase 'good dog' but not 'bad dog', the ML parameter estimates will assign a probability of 0 to any test sentence that contains 'bad dog', even though intuitively this ought to be as probable as a sentence that contains 'good dog'.

A simple and well principled solution to the sparse data problem is to compute the maximum a posteriori (MAP) estimate instead of the ML estimate: $\hat{\theta}_{MAP} \stackrel{\text{def}}{=} \arg\max_\theta P(\theta|D)$. By Bayes' rule

$$P(\theta|D) = \frac{P(D|\theta)P(\theta)}{P(D)}$$

or, in words,

$$\text{posterior} = \frac{\text{conditional likelihood} \times \text{prior}}{\text{likelihood}}$$

If we use a Dirichlet prior $P(\theta)$ (Heckerman, 1998), it can be shown that the MAP estimate of the transition matrix of a Markov chain is given by

$$\hat{A}_{MAP}(i,j) = \frac{\#(i \to j) + \alpha(i,j)}{\sum_k \#(i \to k) + \alpha(i,k)}$$

where the $\alpha(i,j)$ have an intuitive interpretation in terms of 'pseudo counts', i.e. $\alpha(i,j)$ is the number of times an $i \to j$ transition was observed in some prior 'virtual' training set. Using the uninformative prior $\alpha(i,j) = 1$ (also known as Laplace's prior) has the effect of preventing any 0s in the estimated parameters, but otherwise letting the data 'speak for itself'. (*See* **Reasoning under Uncertainty**)

We can estimate the parameters of a k'th order Markov model in a similar way. Unfortunately, the number of parameters that we need to specify $P(X_t|X_{t-k:t-1})$ is now $O(S^k)$, making the sparse data problem particularly severe. One solution is to approximate the conditional distribution $P(X_t|X_{t-k:t-1})$ as a mixture of k bigram models (Saul and Jordan, 1999). We can learn the parameters of such a mixture model using the EM algorithm (see The EM algorithm). Another solution is to use more complex parameter priors (MacKay and Peto, 1995), or to cluster words into similar categories; in this case, the category is a hidden variable, making the model partially observable.

Model selection

The problem of choosing the appropriate number of steps of history to maintain, k, is called *model order determination*, and is a simple example of *model selection*. Maximum likelihood is not an appropriate metric, since the model with the highest likelihood on the training set will always be the one with the largest possible value of k (since this has the largest number of parameters, and hence can fit the data the best: this is called overfitting). One approach to model selection is to use cross-validation, i.e. to choose k by measuring performance on a hold-out set (as opposed to the training set). Alternatively, we can can choose the model M that maximizes a penalized log-likelihood function: $M^* = \arg\max_M \log P(D|\hat{\theta}_M) - g(d_M)$, where $\hat{\theta}_M$ is the ML estimate of the parameters for model M, d_M is the number of parameters in M, and $g(d)$ is some complexity penalty that increases with d. Some popular choices for this penalty function are the Akaike information criterion (AIC), $g(d) = d$, the Bayesian information criterion (BIC), $g(d) = \frac{d}{2}\log N$, where N is the number of samples, and the minimum description length (MDL) criterion, which is the same as BIC (Heckerman, 1998).

Continuous State Spaces

The most common form for a Markov process with a continuous state space is $X_t = f(X_{t-1}, U_{t-1}) + W_t$ where f is some function, and W_t is a zero-mean random variable, representing noise.

Linear systems

A widely studied special case is when f is a *linear* function, and the noise is Gaussian, in which case we can write $X_t = AX_{t-1} + BU_{t-1} + W_t$ where $W_t \sim N(0, \sum)$. Equivalently, we may write

$$P(X_t = x_t|X_{t-1} = x, U_{t-1} = u) = N\left(x_t; Ax + Bu, \sum\right)$$

where the notation $N(x; \mu, \sum)$ means evaluating a normal (Gaussian) probability density function with means μ and covariance $\sum$ at the point (vector) x. The distribution of the initial state is $P(X_1 = x) = N(x; \mu_1, \sum_1)$. It is possible to estimate

the parameters of such a linear system using techniques based on linear regression (Ljung, 1987).

Nonlinear systems

The usual approach to learning nonlinear dynamical systems is to represent the f function using a feedforward neural network (also called a multilayer perceptron). We create a training set from the matrices

$$X = \begin{pmatrix} X_1' & U_1' \\ \vdots & \\ X_{T-1}' & U_{T-1}' \end{pmatrix}, \quad Y = \begin{pmatrix} X_2' \\ \vdots \\ X_T' \end{pmatrix}$$

where the t'th row of X is the t'th input vector, and the t'th row of Y is the corresponding output. (X_t' denotes the transpose of the vector X_t.) Now we use some nonlinear learning procedure, such as back propagation or a conjugate gradient method (Bishop, 1995), to estimate the parameters of the f function. The ML estimate of $\sum$ is the empirical covariance matrix of the residuals (i.e. the difference between the predicted output and the actual output). (*See* **Perceptron**)

Higher order models

It is easy to convert a k'th-order linear model to a first-order model. For example, consider the following autoregressive process of order 2:

$$X_t = A_1 X_{t-1} + A_2 X_{t-2}$$

(This is called autoregressive since X_t is computed by using linear regression applied to 'older' values of itself.) This can be represented as a first-order model as follows:

$$\tilde{X}_t \stackrel{\text{def}}{=} \begin{pmatrix} X_t \\ X_{t-1} \end{pmatrix} = \begin{pmatrix} A_1 & A_2 \\ I & 0 \end{pmatrix} \begin{pmatrix} X_{t-1} \\ X_{t-2} \end{pmatrix} \stackrel{\text{def}}{=} \tilde{A}\tilde{X}_{t-1}$$

Now we should estimate each block in $\tilde{A}$ separately. (Note that, in contrast to the case of discrete state spaces discussed in Model selection, the number of parameters increases *linearly* with k, not exponentially.) The most common way to choose k is to use the AIC scoring metric; this is built in to many software packages.

For a nonlinear model, we can use a tapped delay line, i.e. we feed a window of the last k time slices into f. (Note that this does not exploit the prior knowledge that successive input vectors (windows) are overlapping, and hence highly correlated.) In this case, k is usually chosen by cross-validation.

PARTIALLY OBSERVED MODELS

Consider trying to predict a speech signal, represented, for example, as an m-dimensional vector encoding the instantaneous power of the signal in m different frequency bands (typically $m \approx 20$). One approach would be to build a nonlinear model to directly predict Y_{t+1} as a function of Y_t, Y_{t-1}, etc. Such a model would probably need a very large number of parameters.

An alternative approach would be to try to infer the word that the person is saying, based on the acoustic evidence, then predict the next word that they are likely to say, and finally predict the corresponding sound. (In practice, it is more common to work with phonemes instead of words, since phonemes have less acoustic variability, and suffer less from the sparse data problems mentioned previously.) This is the basis of the hidden Markov model (HMM) approach to speech recognition (Rabiner, 1989; Jelinek, 1997), which has proved to be quite successful in practice. We will discuss how to learn such models later.

Another reason to consider models with hidden variables is that often we are more interested in inferring the hidden causes of a signal than in predicting the signal itself. As in Bayesian networks, a good approach is to build a generative model of the observed signal (a mapping from X_t to Y_t) and then to apply Bayes' rule to 'invert the causal arrow', i.e. to infer $P(X_t|y_{1:t})$. We will discuss how to do this below. (*See* **Bayesian Belief Networks**)

The EM Algorithm

Parameter learning in the case of partially observed models is much harder than in the case of fully observed models because the likelihood surface can have multiple maxima. (A simple way to see this is that we can permute the labels of the hidden states without affecting the likelihood function.) One approach is to use gradient ascent (e.g. Binder *et al.*, 1997), but there is a simpler and often more effective algorithm called expectation maximization (EM) (Dempster *et al.*, 1977; Neal and Hinton, 1998). EM is guaranteed to converge to a local maximum of the likelihood (or MAP) surface, and works roughly as follows. We first perform probabilistic inference to try to estimate the hidden state given the observation sequence (this is the E step). We then use the estimated values of the hidden variables as if they were observed, in order to update the parameters using the techniques discussed for fully observed models (this is the M step). Since the inferred values depend on the parameter settings, we then need to re-estimate the hidden values, and then re-estimate the parameters, repeating this until convergence. We will explain the EM algorithm in more detail below.

(Note: when applied to HMMs, EM is also known as the Baum-Welch algorithm.)

Discrete State Spaces: Hidden Markov Models

A hidden Markov model (HMM) is a partially observed Markov process. The dynamics of the hidden variable X_t are modeled using a standard finite state Markov chain; the observed variable Y_t is some function of X_t. For example, in speech recognition, in which $Y_t \in \mathbb{R}^m$, we assume that the distribution of Y_t is Gaussian (or perhaps a mixture of Gaussians), whose parameters are determined by the hidden state X_t: $P(Y_t = y|X_t = i) = N(y; \mu_i, \sum_i)$. If Y_t is discrete, we specify the observation model using another matrix: $P(Y_t = j|X_t = i) = B(i,j)$.

The complete log-likelihood of a sequence is given by

$$\log P(X_{1:T}, Y_{1:T}) = \log P(X_1) + \sum_{t=1}^{T} \log P(Y_t|X_t) + \sum_{t=2}^{T} \log P(X_t|X_{t-1})$$

Using the trick discussed in Parameter estimation, we may rewrite the last term as

$$\sum_{t=2}^{T} \sum_{i=1}^{S} \sum_{j=1}^{S} I(X_{t-1} = i, X_t = j) \log A(i,j)$$

and similarly for the other terms.

We cannot maximize this directly, since X_t is hidden. Instead, we will try to maximize the expected complete-data log-likelihood. Taking expectations with respect to the hidden variables X_t, using the current parameter settings θ, we find

$$E\ \log P(X_{1:T}, Y_{1:T}) = \ldots + \sum_{i=1}^{S} \sum_{j=1}^{S} E\left[\sum_{t=2}^{T} I(X_{t-1} = i, X_t = j)\right] \log A(i,j)$$

where we have omitted terms not involving A for simplicity. The terms inside the square brackets are the expected number of times we see an $i \to j$ transition:

$$E(i,j) \stackrel{\text{def}}{=} E\left[\sum_{t=2}^{T} I(X_{t-1} = i, X_t = j)\right] = \sum_{t=2}^{T} P(X_{t-1} = i, X_t = j|y_{1:T})$$

If we could compute these expected sufficient statistics (ESS), we could update the parameters to

$$\hat{A}_{ML} = \frac{E(i,j)}{\sum_k E(i,k)}$$

by analogy with the fully observed case. We could then use the new parameters to recompute the ESS, and so on, until convergence.

The forwards-backwards algorithm

We will now explain how to compute $\gamma_t(i) \stackrel{\text{def}}{=} P(X_t = i|y_{1:T})$ and $\xi_t(i,j) \stackrel{\text{def}}{=} P(X_{t-1} = i, X_t = j|y_{1:T})$ in $O(TS^2)$ time and $O(TS)$ space using dynamic programming, where T is the length of the sequence and S is the number of states.

In the forwards pass, we compute

$$\begin{aligned}\alpha_t(j) &\stackrel{\text{def}}{=} P(X_t = j, y_{1:t}) \\ &= P(y_t|X_t = j, y_{1:t-1})\ P(X_t = j|y_{1:t-1}) \\ &= P(y_t|X_t = j) \sum_i P(X_t = j|X_{t-1} = i, y_{1:t-1}) \\ &\quad P(X_{t-1} = i|y_{1:t-1}) \\ &= P(y_t|X_t = j) \sum_i A(i,j)\, \alpha_{t-1}(i)\end{aligned}$$

Notice how this algorithm contains the two key steps of sequential Bayesian updating: predict (i.e. computing the one step-ahead prediction, $P(X_t|y_{1:t-1})$), and update (combining the prediction with the likelihood $P(y_t|X_t)$ to get the updated estimate $P(X_t|y_{1:t})$).

If we define a diagonal matrix B_t in which $B_t(j,j) \stackrel{\text{def}}{=} B(j, y_t)$, we may rewrite the above equation as a simple vector-matrix multiplication: $\alpha_t = B_t A' \alpha_{t-1}$.

In the backwards pass, we compute

$$\begin{aligned}\beta_t(i) &\stackrel{\text{def}}{=} P(y_{t+1:T}|X_t = i) \\ &= \sum_j P(X_{t+1} = j|X_t = i) \\ &\quad P(y_{t+1:T}|X_t = i, X_{t+1} = j) \\ &= \sum_j P(X_{t+1} = j|X_t = i)\, P(y_{t+1}|X_{t+1} = j) \\ &\quad P(y_{t+2:T}|X_{t+1} = j) \\ &= \sum_j A(i,j)\ P(y_{t+1}|X_{t+1} = j)\ \beta_{t+1}(j)\end{aligned}$$

Again, we may rewrite this as a simple vector-matrix multiplication: $\beta_t = AB_{t+1}\beta_{t+1}$.

Finally, we combine the results of the forwards and backwards steps to obtain

$$\gamma_t(i) \stackrel{\text{def}}{=} P(X_t = i|y_{1:T}) \propto P(y_{t+1:T}|X_t = i, y_{1:t})$$
$$P(X_t = i, y_{1:t}) = \beta_t(i)\ \alpha_t(i)$$

and

$$\xi_t\ (i,j) \stackrel{\text{def}}{=} P(X_{t-1} = i, X_t = j|y_{1:T})$$
$$\propto P(X_{t-1} = i|y_{1:t-1})\ P(X_t = j|X_{t-1} = i)$$
$$P(y_t|X_t = j)\ P(y_{t+1:T}|X_t = j)$$
$$= \alpha_{t-1}(i)\ A(i,j)\ B_t(j,j)\ \beta_t(j)$$

The ESS for A can be computed using $E(i,j) = \sum_{t=2}^{T} \xi_t(i,j)$, and similarly for the other parameters.

The Viterbi algorithm

A useful task in a variety of applications is to compute the most probable state sequence given the observations: $\arg\max_{x_{1:T}} P(x_{1:T}|y_{1:T})$. For example, in speech recognition, this might be the most likely sequence of words given the acoustic signal, and in biology, it might be the most likely alignment of a protein sequence to some model. This quantity can be computed using the Viterbi algorithm, which is like forwards-backwards except that we replace the $\sum$ operator with max in the forwards pass, and do pointer-following in the backwards pass: see Rabiner (1989) for details.

Classifying sequences using HMMs

The normalization constant used to compute $\gamma_t(i) = P(X_t = i|y_{1:T})$ is equal to the likelihood of the data:

$$P(y_{1:T}) = \sum_i P(y_{t+1:T}|X_t = i, y_{1:t})\ P(X_t = i, y_{1:t})$$

This is a useful quantity, because it can be used to classify a sequence. For example, suppose we train up 10 HMMs, one for each spoken digit 0 to 9; given a test sequence $y_{1:T}$, we compute the likelihood that HMM i generated $y_{1:T}$; we then classify $y_{1:T}$ as digit i if HMM i has higher likelihood than any of the rival models.

Factored state spaces

An HMM represents the state of the system using a single discrete random variable X_t. To represent k bits of information, we need to use 2^k values; this results in high computational complexity (i.e. inference using forwards-backwards is slow) and high sample complexity (i.e. the amount of data needed by EM is large). An alternative is to use a distributed representation of state, i.e. to use k binary variables. Such a model is called a factorial HMM (Ghahramani and Jordan, 1997), and is shown in Figure 2. This model has exponentially fewer parameters, and hence is easier to learn. Unfortunately, inference is still slow, because the k hidden random variables become correlated: intuitively, they 'compete' to 'explain' the observation, a phenomenon called 'explaining away' (Pearl, 1988). However, it is possible to exploit the structure of the model to enable efficient approximations.

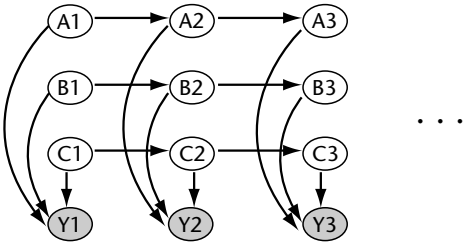

Figure 2. A factorial HMM. The hidden state is represented in a distributed fashion, in terms of three discrete random variables, $X_t = (A_t, B_t, C_t)$.

A factorial HMM is an example of a more general class of models called dynamic Bayesian networks (Dean and Wellman, 1991; Ghahramani, 1998; Murphy, 2002).

Continuous State Spaces

Linear systems and the Kalman filter

A linear dynamical system (LDS) has the generic form

$$X_t = AX_{t-1} + BU_{t-1} + W_t$$

$$Y_t = CX_t + DU_t + V_t$$

where $W_t \sim N(0, Q)$ and $V_t \sim N(0, R)$ are independent random variables representing Gaussian noise.

The Kalman filter is an algorithm to compute $P(X_t|y_{1:t}, u_{1:t})$ in an LDS. It is analogous to the forwards algorithm for HMMs (Minka, 1999). (In particular, it contains the same kind of predict-update cycle, which, it has been claimed (Rao, 1997), has analogs in the brain in terms of top-down and bottom-up visual processing.) For off-line learning, one can get better performance by estimating the hidden states based on 'future' data, as well as past, i.e. by using the 'smoothed' quantities $P(X_t|y_{1:T}, u_{1:T})$. The Rauch–Tung–Striebel (RTS) algorithm is a way to compute $P(X_t|y_{1:T}, u_{1:T})$ in an LDS, and is analogous to the forwards-backwards algorithm for HMMs. In the general case, the RTS algorithm takes $O(Tm^3)$ time and $O(Tn^2)$ space, where $Y_t \in \mathbb{R}^m$ and $X_t \in \mathbb{R}^n$, because at each step, the algorithm must invert an $m \times m$ matrix and must store an $n \times n$ covariance matrix. To do

parameter estimation in an LDS, we can use the EM algorithm, using the RTS algorithm as a subroutine to compute the required expected sufficient statistics (Roweis and Ghahramani, 1999).

Nonlinear systems

Inference, and therefore learning, is much harder in systems which are nonlinear and/or have non-Gaussian noise, and one typically has to resort to approximate methods. A popular method for computing $P(X_t|y_{1:t})$ is particle filtering (Doucet *et al*., 2001) or the extended Kalman filter (Bar-Shalom and Fortmann, 1988); for off-line computation of $P(X_t|y_{1:T})$, one can use Gibbs sampling (Gilks *et al*., 1996) or the extended Kalman smoother (Roweis and Ghahramani, 2001). These inference routines can be used as subroutines for the E step of EM.

Means–Ends Analysis

Introductory article

Wayne Iba, Kanisa Inc., Cupertino, California, USA

CONTENTS

Means–ends analysis is a simple, yet powerful, approach to problem-solving whereby progress towards a goal or solution is achieved by incrementally searching a state space.

DIFFERENCE REDUCTION IN A STATE SPACE

The basic idea of means–ends analysis (MEA) relies on two notions. First, the problem solving domain may be represented and explored as a state space. Specifically, the state of the world at the start of the problem-solving exercise, the goal state in which the problem has been 'solved', and any intermediate states, can all be represented within a state space. Second, MEA takes advantage of a correspondence between the state space representation and the definitions of the operators that transform the world from one state to another.

Representing the World

In many domains, one can solve problems by representing the world as a state consisting of propositions and relations. That is, the important aspects of the world – those that are relevant to the problem at hand – can be captured as a set of objects, predicates describing these objects' characteristics, and relations that exist between these objects.

For example, in the context of a world where structures such as towers and arches must be constructed from toy building blocks, one particular state of the world could be captured as: `((block A) (block B)(block C)(on-table A) (on-table C)(on B C))`. This state description ignores characteristics such as color and size, but captures the notion that there are three blocks, *A*, *B*, and *C*, that blocks *A* and *C* are on the table, and that block *B* is stacked on top of block *C*.

However, representing the state of the world is only the first step in establishing a state space. We also need to represent the operators that transform one state into another. In traditional state space representations for MEA, operators are represented as a set of preconditions and consequences. The preconditions specify properties and relationships that must be true in a state in order to apply the given operator. The consequences specify the properties and relationships that become true and are added to the state, as well as those that are no longer true and are deleted from the state, when the operator is applied.

For a given representation language and a finite set of objects, we can imagine the set of all possible state descriptions. Then, for a finite set of operators, we can construct directed links between pairs of states, according to whether the preconditions of the operator are true in the initial state and the differences between the initial state and the resulting state correspond to the consequences of the operator.

Goals and Sub-goals

Given a state space description of a problem-solving domain, a specific problem to solve can be thought of as a pair of states: the current state of the world, and the desired, or goal state. Stages of solving the problem can be thought of as sub-goals. For example, if your goal is to buy a car, one solution might be to get some money, go to the car showroom, and drive home in a car. Your initial state is without car and your goal state is with car. A sub-goal is to get some money, which might involve activities like getting a job and saving your earnings. Each of these may also involve sub-goals such as applying for and securing a well-paid job and opening a bank account. Sub-goal formation is guided by the preconditions of higher-level goals. For example, a precondition of getting a well-paid job may be having a good education, so getting a good education may become a new sub-goal.

At the end of a problem-solving activity, the result is a path from state to state through the state space. This path corresponds to a sequence of actions each of which accomplishes the transformation of one state into the next. Any state in this path may be thought of as both a sub-goal and as the initial state for some other sub-goal.

FORWARD AND BACKWARD REASONING

Searching for Solutions

Having described world states, operators, state spaces, and solutions, we now turn to the task of finding a solution (i.e. a path through the state space from the initial problem state to the goal state). This task is best thought of as a search problem. Techniques such as 'breadth-first' and 'depth-first' search exhaustively explore a search space until the goal is found. In the context of problem-solving this amounts to a search through the space of paths, where the desired item is a path that starts at our initial state and ends at the goal state. Unfortunately, itemizing and organizing the space of all paths through the state space is prohibitively expensive; thus, short cuts are needed.

Typically, a search scheme will construct a path incrementally by starting at the initial state, considering states reachable from the current one, and repeating this process until the goal state is found. This approach is known as forward search, and more generally 'forward reasoning'. Alternatively, 'backward reasoning' employs a scheme that starts at the goal state, considers all possible states that can reach the goal state in question, and repeats this process until the problem's initial state is found. Regardless of the direction of search, the biggest limitation for solving problems of any significant complexity is the size of such a search, which increases exponentially. For example, if there are just 10 reachable states from each state, there are 10^{10} (10 billion) paths of length 10. Both the branching factor and the length of solution are often much larger than 10: in fact, it is not uncommon to search a space that contains more states than the number of elementary particles in the universe. Thus, problem-solving schemes must employ heuristics, or rules of thumb, which selectively guide the consideration of states.

Search Strategies

Typical search strategies prioritize the consideration of possibilities by their cost or by their effectiveness. Usually, the cost of an action is known directly, but the effectiveness of an action, with respect to progress towards the goal, must be estimated by heuristics.

MEA integrates forward and backward search, and estimates of operator effectiveness, by selecting operators based on the differences that the operators reduce. Differences exist between two states when a predicate or relation between objects is true in one state but not the other. When the current state has been transformed into a state that has no differences from the goal state, the search has found a solution. For example, suppose there are 20 possible actions that can be executed in a current state, but the consequences of only one of them changes the state in a way that reduces the differences between the current state and the goal state. It makes sense to consider this action first before any of the others. Of course, it is not guaranteed that this action will actually participate in an eventual solution: one of the other operators may establish a precondition for some other action that makes more effective progress towards the goal. In MEA, when the strategy fails to yield progress, the search reverts to 'weak methods', which require no domain-specific knowledge.

MEA's search scheme is neither forward nor backward, but rather a blend of both. Based on differences, a selected action might transform the current state or reach the goal state. Alternatively, however, it might 'float' somewhere in the middle, creating a new sub-goal determined by the action's preconditions and a new initial state determined by the action's consequences. In this case, MEA then tackles two smaller problems: find a path from the initial state to the preconditions of the selected action, and find a path from the consequences of the action to the goal state. Finally, these two solutions can be joined by the originally selected action, thus yielding a complete solution to the problem.

OPERATOR–DIFFERENCE CORRESPONDENCE

MEA works by establishing a correspondence between an operator's consequences and state-pair differences. When the preconditions and consequences of operators are explicitly defined by their state features, it is straightforward to establish this correspondence: the state-pair's differences (predicates and relations that must hold in the goal state but that do not hold in the initial state) can be compared to the operator's consequences (also described as predicates and relations); and the operator that resolves the most differences is selected.

If instead the actions are not directly inspectable, background domain knowledge must be provided in the form of an operator–difference table. For each operator, this table specifies the differences it reduces. Now instead of comparing an action's consequences to a set of differences, the differences are used directly to look up actions in the table.

Sometimes, it is also desirable to specify preferences among differences or to attach relative importance to particular differences. For example, in a problem-solving domain such as our earlier car-buying scenario, first reducing differences in resource availability (bank account balance) may more effectively guide the search for a solution than focusing initially on differences such as being at a dealer, or deciding on a model or color. This kind of domain-specific knowledge can be conveniently included in the operator–difference table.

RELATION TO OTHER SEARCH TECHNIQUES

Heuristic Search

The idea of heuristic search is to focus exploration of the state space in a particular direction. Often, the heuristic avoids exponential search sizes by estimating the total cost of a solution based on the actual cost of the partial solution found thus far combined with the expected cost for completing the partial solution. The primary heuristic in MEA is using differences to guide search: instead of estimating the cost of a solution, the operator–difference heuristic estimates which solutions would be found more quickly, by reducing the biggest differences first. Thus, MEA is an instance of a particular type of heuristic search known as 'greedy' search.

Exhaustive Search

Heuristic search is not guaranteed to generate an efficient solution, nor even to find an inefficient solution quickly. However, because of MEA's ability to fall back on weak methods, it is guaranteed to find a solution eventually if one exists. Thus, MEA may be thought of as an exhaustive search where the order in which operators are considered is dynamically determined.

MEANS–ENDS ANALYSIS IN HUMAN REASONING

The MEA approach was developed to model and study human problem-solving. The working hypothesis was that humans solve problems using the operator–difference heuristic. To validate this hypothesis, the technique of 'protocol analysis' has been employed to observe and record the reasoning behavior of a human in the process of solving a problem. In this manner, mental problem-solving can be inspected and a virtual search trace can be extracted; this search trace can be compared with that generated by MEA. The stronger the correspondence between the two search traces, the more confident we are that the working hypothesis is correct. In experiments, the fit between protocol analyses and means–ends traces has been compelling, particularly in puzzles such as 'missionaries and cannibals', the Tower of Hanoi, and various water jug problems. These puzzles, for which this correspondence has been demonstrated, are difficult for people because their solutions can be a lengthy sequence of operators but are also tractable for protocol analysis because they inhabit a narrowly constrained state space.

SYSTEMS

GPS

The 'general problem-solver' (GPS) contained the first implementation of means–ends analysis and was designed as a theory of human problem-solving. It was intended to work on any problem that could be expressed using a state space and a set of operators. However, in order to move beyond very simple problems it relied on an operator–difference correspondence table for each problem. GPS exerted a strong influence on both cognitive science and artificial intelligence planning and problem-solving systems. It was also, in a sense, a precursor to Soar, both because of its conceptual framework and because of the influence and involvement of Allen Newell.

Prodigy

The Prodigy framework is a GPS-like system that integrates several machine learning methods. Prodigy's architecture encompasses problem-solving, planning, and learning. Several learning methods are included, such as explanation-based generalization, abstraction learning, and derivational analogy. When Prodigy has solved a particular problem, it might decide to store the solution trace, depending on how 'interesting' the system considers the solution to be. If the built-in heuristics predict that the solution will be useful in solving similar problems, and the solution is sufficiently

distinct from others that have already been stored, the trace will be saved for possible application during future problem-solving. Given a new problem to solve, if the initial and goal conditions are sufficiently similar to those of a saved trace, then the saved solution can be used as if it were a single operator with its own preconditions and consequences.

ICARUS

The ICARUS architecture also incorporates a general problem solver and learning, with many of the strengths of GPS and of Prodigy. The goal of ICARUS was to reduce the amount of domain-specific knowledge required, such as the operator–difference correspondence table. Instead of combining several learning methods to obtain flexible improvements in performance, ICARUS includes a single architectural learning method: probabilistic hierarchical concept formation. As with GPS and Prodigy, means–ends analysis serves as the basic problem-solving method. However, instead of relying on domain-specific knowledge, such as an operator–difference table, ICARUS learns the relevant knowledge through experience. Instead of providing derivational analogy or other special-purpose mechanisms, this architecture relies on the combination of its hierarchical memory organization and its memory retrieval mechanism to get analogical reasoning and other behaviors to emerge from the system's innate behavior.

Modeling Coordinate Transformations

Introductory article

Alexandre Pouget, University of Rochester, Rochester, New York, USA
Lawrence H Snyder, Washington University, St Louis, Missouri, USA

CONTENTS

Sensorimotor transformations can often be decomposed into a series of intermediate coordinate transforms. These may be modeled using units computing a product of sigmoidal tuning curves to sensory and posture signals.

INTRODUCTION

Coordinate transforms occur mostly in the context of sensorimotor transformations; i.e. the transformation of sensory signals into motor commands. For instance, to reach for an object in view, the brain needs to compute the changes in angles of the joints of the arm that bring the hand to the location of the object. This change of joint angles is obtained by computing the difference between two vectors: the current and the desired position of the hand, both expressed in terms of joint angles; i.e. in joint-centered coordinates. The current position of the hand is provided by visual and proprioceptive signals, but the desired position can be computed only by combining the information provided by the visual system – the retinal, or eye-centered, coordinates of the object – with posture signals, such as the position of the eyes in the head (eye position for short) and the position of the head with respect to the trunk (head position for short). Therefore, reaching requires a transform from eye-centered to joint-centered coordinates. Similar coordinate transforms take place in all other sensorimotor transformations.

LINEAR COORDINATE TRANSFORMS

In many cases, sensorimotor transformations can be decomposed into a series of intermediate coordinate transforms. For instance, instead of directly computing the change in joint-centered coordinates required to reach an object from its eye-centered coordinates, one can first compute the head-centered coordinates of the target, then the body-centered coordinates, and finally the joint-centered coordinates (Figure 1(a)). In this example, many of these transformations are linear (Figure 2): they simply involve summation of the signals involved. For example, the transformation from eye-centered to head-centered is (approximately) linear because the head-centered location of an object ($\mathbf{H}$) is approximately equal to the sum of the eye-centered location ($\mathbf{V}$) of the object and the current eye position ($\mathbf{E}$): $\mathbf{H} = \mathbf{V} + \mathbf{E}$ (we use bold type to denote vectors).

For these transformations we may consider a linear representational scheme which involves the coding of each vector, such as $\mathbf{V}$ and $\mathbf{E}$, through the activity of N units, where each unit computes a dot product between the unit's preferred direction ($\mathbf{V}_i$) and the vector to be encoded ($\mathbf{V}$) – see eqn [1] for the definition of a dot product. For instance, in the case of the two-dimensional retinal location of an object (we ignore the position of the object in depth and consider only the horizontal and vertical position, noted respectively, v^x and v^y, for vector $\mathbf{V}$), the activity (a) of the ith unit takes the form

$$\begin{aligned} a_i &= \mathbf{V}_i \cdot \mathbf{V} \\ &= v_i^x v^x + v_i^y v^y \\ &= \|\mathbf{V}_i\| \|\mathbf{V}\| \cos(\theta_i - \theta) \end{aligned} \quad (1)$$

where $\|\mathbf{V}\|$ is the Euclidean norm, or length, of $\mathbf{V}$, θ is the angle of the retinal vector, and θ_i is the preferred retinal direction for neuron i. The second line uses cartesian coordinates, while the third line uses polar coordinates. Redish and Toureztky call this representation a *sinusoidal array* to refer to the cosine tuning of the units (as can be seen

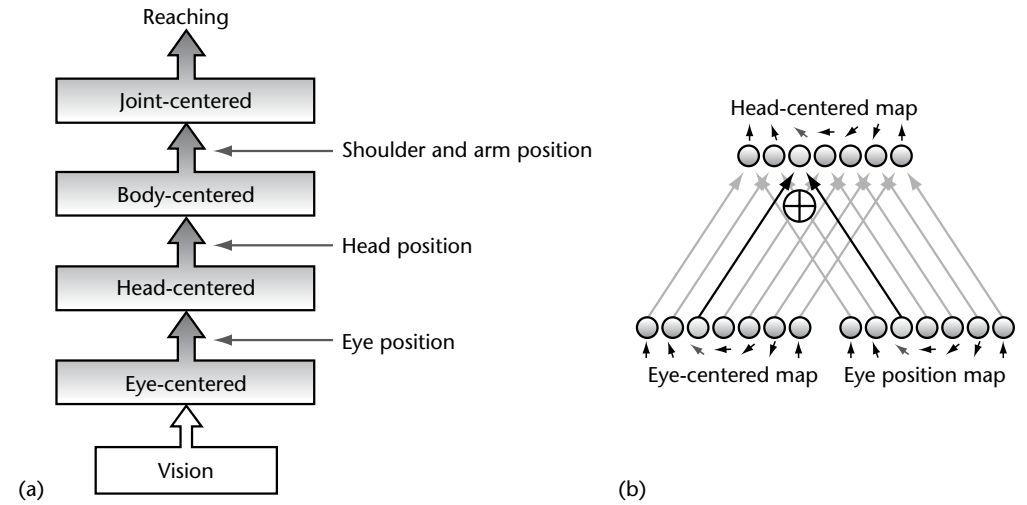

Figure 1. (a) During the process of reaching for an object, the cortex must transform the eye-centered coordinates of the object into the change of joint angle of the arm (joint-centered coordinates). This transformation can be decomposed into a series of coordinate transforms in which the position of the object is successively recoded into a set of intermediate frames of reference. Some of these transformations are linear in the sense that they require only a sum of the signals involved. For example, the head-centered location of an object is simply equal to the sum of the eye-centered and eye position signals. (b) A network implementation of the linear transformation from eye-centered to head-centered. Each vector is encoded with a sinusoidal array. For instance, the current eye-centered location of the object is encoded through the activity of N units. Each unit has a cosine tuning to the eye-centered location of the object and is characterized by a preferred direction (indicated by the small arrows). The preferred directions are uniformly distributed along a circle. When the units are activated with the current eye-centered position of the object, the pattern of activity across the neuronal array follows a cosine profile due to cosine tuning curves. The amplitude of this cosine pattern of activity encodes the eye-centered eccentricity of the stimulus, $\|\mathbf{V}\|$, while the phase encodes the angle of the eye-centered vector, θ. This representation is quite compact since it manages to encode a two-dimensional vector, $\mathbf{V}$, with a single-dimensional array. A similar code is used in the other maps. Each unit in the head-centered map takes the sum of two units with the identical preferred direction in the eye-centered and eye position maps (an example of which is shown in darker shading). This connectivity ensures that the network performs a vector addition.

on the last line of eqn [1]). Note that if we sum the activities of two neurons, one tuned to $\mathbf{V}$ and the other tuned to $\mathbf{E}$ with identical preferred directions ($\mathbf{V}_i = \mathbf{E}_i = \mathbf{H}_i$), we obtain a neuron tuned to $\mathbf{H}$ with the same preferred direction $\mathbf{H}_i$

$$\begin{aligned} a_i &= a_i^V + a_i^E \\ &= \mathbf{H}_i \cdot \mathbf{V} + \mathbf{H}_i \cdot \mathbf{E} \\ &= \mathbf{H}_i \cdot (\mathbf{V} + \mathbf{E}) \\ &= \mathbf{H}_i \cdot \mathbf{H} \end{aligned} \qquad (2)$$

Therefore, linear coordinate transforms can be performed with simple addition of activities (Figure 1(b)). Whether the brain uses a similar scheme remains controversial. A key piece of information, currently lacking, is whether individual neurons in areas such as the posterior parietal cortex have retinal and postural signals tuned to the same preferred directions. Colinear tuning would be an essential ingredient of a coding scheme in which transformations were performed by summing the activities of the neurons (eqn [2]), but to date no evidence has been obtained for such colinearity in cortical neurons.

It has been argued that the primary motor cortex uses sinusoidal arrays to encode the direction of hand movements, but this has never been thoroughly tested. Thus, Sanger has pointed out that the statistical test used by Georgopoulos *et al.* cannot distinguish between cosine tuning curves and almost any other alternative tuning curves. The evidence for cosine tuning functions is more convincing in the nervous systems of leeches and crickets, suggesting that sinusoidal arrays might provide a good conceptual framework for sensorimotor transformations in invertebrates.

NONLINEAR COORDINATE TRANSFORMS

Although some of the intermediate transforms involved in computing the change in joint angles of the arm are linear, this is not true for all sensorimotor transformations. In particular the

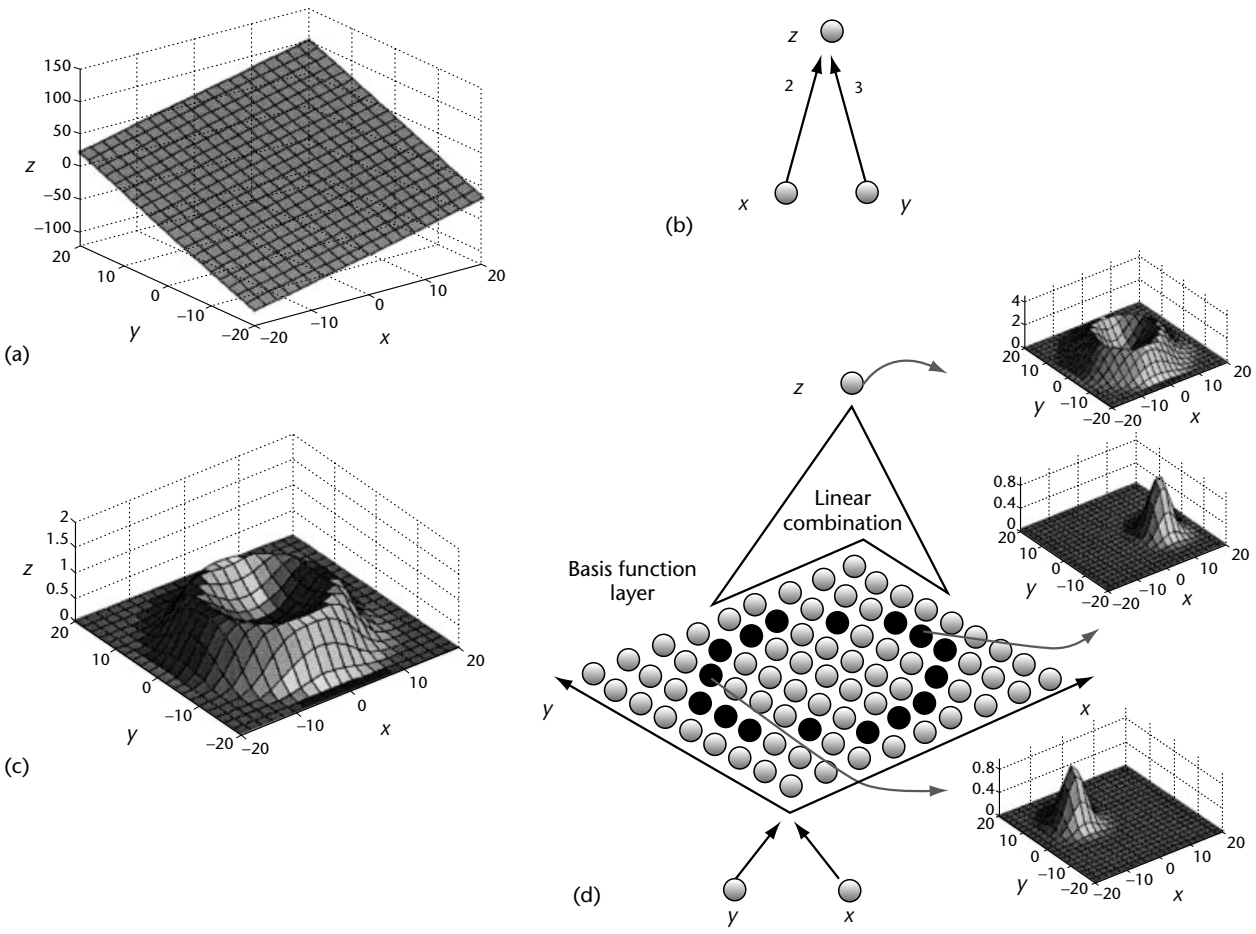

Figure 2. Linear versus nonlinear functions. (a) A function is said to be linear if it can be written as a weighted sum of its input variables plus a constant. All other functions are called nonlinear. For instance, $z = 2x + 3y$ is a linear function of x and y. This linear function forms a planar surface (as do all other linear functions). (b) Linear functions can be implemented in two-layer networks. The network shown corresponds to the linear function in (a). The output unit simply takes the sum of the input unit activity weighted by the coefficient indicated next to the connections. (c) A plot of the nonlinear function $z = \exp(-(x^2 + y^2 - 100)^2/1000)$. Nonlinear functions can take arbitrary shapes, in this case a circular ridge. (d) A neural network implementation of the nonlinear function shown in (c) using Gaussian basis functions in the intermediate representation. The basis function units are organized to form a map in the x–y plane. Two representative response functions of these basis function units are shown on the right (middle and bottom). The activity of the output unit is obtained by taking a linear sum of the basis function units. In this example, the weights of the black units onto the output unit are set to 1, while all the other units have a weight of 0. As a result, the output unit adds a set of Gaussian functions arranged along a circle in the x–y plane. This leads to the response function illustrated on the right (top), which is similar to the circular ridge shown in (c). The same idea can be applied to sensorimotor transformations. Unlike the examples above, sensorimotor transformations involve more than two input variables (e.g., x and y retinal position from each retina, plus many postural signals). Similarly, the output is also multidimensional. Yet, these high-dimensional transformations can be computed in a way exactly analogous to the low-dimensional computation illustrated here. One advantage of the basis function layer is that it can be used to control, and coordinate, several behaviors aiming at the same object. Indeed, motor commands are nonlinear functions of the sensory inputs and, as such, any motor command can be obtained by a linear combination of the basis functions.

transformation from body-centered coordinates to the required change in joint angles is nonlinear because it cannot be written as a weighted sum of the body-centered position and the current arm position. The exact equation involved in this case is complicated but the details do not matter for the theory we are about to develop. The critical point is that the transformation involves more than just simple summation. As a result, the overall transformation from eye-centered to joint-centered coordinates is also a nonlinear transformation. One way to approach nonlinear transformations is to

consider them in the general framework of nonlinear function approximation. Indeed, the coordinate transforms required for reaching are equivalent to the computation of a mathematical function which takes as input the visual position of the object and the posture signals, and produces as output the joint-centered coordinates of the object. Using the notation **V**, **P**, and **J** to refer to the visual position of the object, the posture signals and the change in joint angles, the coordinate transform can be expressed as a function f mapping **V** and **P** into **J**

$$\mathbf{J} = f(\mathbf{V}, \mathbf{P}) \tag{3}$$

Unlike linear functions, a nonlinear function cannot be implemented in two-layer networks. One needs at least one intermediate layer (or 'hidden' layer) to recode the sensory inputs before they can be transformed into motor commands (Figure 2(c) and (d)). One solution involves using intermediate units which compute basis functions. By definition, most functions of interest can be approximated using a linear combination of the functions from a basis set. The classic example of a basis set is all possible cosine and sine functions. This is the principle behind the Fourier transform: any function can be expressed as the sum of a series of cosine and sine functions with all possible amplitudes and frequencies. This result is not restricted to sine and cosine functions. Other families of functions such as Gaussian and sigmoid functions also form basis sets (Figure 2(d)).

When applied to sensorimotor transformations, and in particular to the example of reaching toward a visual target, the idea is as follows: the reaching motor command **J** can be obtained by a weighted sum of basis functions $\{B_i(\mathbf{V}, \mathbf{P})\}_{i=1}^{N}$ of the visual and posture signals, **V** and **P**

$$\mathbf{J} = \sum_{i=1}^{N} w_i B_i(\mathbf{V}, \mathbf{P}) \tag{4}$$

The set of weights, $\{w_i\}_{i=1}^{N}$, is specific to the reaching motor command being computed and, as we will see later, can be determined using simple learning rules.

Many choices are available for the basis functions. For instance, one can use the set of all Gaussian functions of **V** and **P**, which are a subset of a larger family known as radial basis functions (Figure 2(d)). An alternative choice for a basis set is the product of a Gaussian function of **V** and a sigmoid function of **P**. Figure 3(a) illustrates the response of an idealized neuron whose response function follows a Gaussian function of the eye-centered position of an object multiplied by a sigmoid function of eye position. Figure 3(b) shows a mapping of the receptive field of such a neuron for three different positions of the eyes. The receptive field is eye-centered; i.e. it remains at the same eye-centered location regardless of the position of the eye; however, the gain (or amplitude) of the response changes with the position of the eyes.

One of the problems from a biological point of view with eqn [4] is the format of the input and output vectors involved. For instance, we used a vector **V** which stores the three-dimensional polar coordinates of the object, yet no such explicit vector exists in the cortex. Instead, the visual position of objects is encoded by the activity of a large number of binocular neurons forming the retinotopic (or eye-centered) maps in the early visual areas. This does not mean that we cannot use the basis function framework; one simply needs to replace the vector **V** with a new vector, $\mathbf{V}^{\mathrm{A}}$, whose components are the activities (e.g. firing rates) of the neurons in response to the image of the object. This new vector has as many dimensions as there are neurons in the retinotopic maps – instead of three dimensions for **V**. Likewise, the vectors **P** and **J** can be replaced by the corresponding neuronal patterns of activities, $\mathbf{P}^{\mathrm{A}}$ and $\mathbf{J}^{\mathrm{A}}$. The function to be computed is now from $\mathbf{V}^{\mathrm{A}}$ and $\mathbf{P}^{\mathrm{A}}$ onto $\mathbf{J}^{\mathrm{A}}$. When this function is nonlinear, which it is in this particular case, we can once again use the basis function approach. Figure 3(c) illustrates a basis function network which uses map-like representations, $\mathbf{V}^{\mathrm{A}}$, $\mathbf{P}^{\mathrm{A}}$, and $\mathbf{J}^{\mathrm{A}}$. Many neural network models of sensory motor transformations rely on such basis function representations in their intermediate layer.

Basis functions of $\mathbf{V}^{\mathrm{A}}$ and $\mathbf{P}^{\mathrm{A}}$ can be used to compute $\mathbf{J}^{\mathrm{A}}$ as well as any other motor command (i.e. function) depending on $\mathbf{V}^{\mathrm{A}}$ and $\mathbf{P}^{\mathrm{A}}$. One simply needs to adjust (or learn, see below) the weights $\{w_i\}$ in eqn [4] for the desired motor command. This means that basis function neurons are ideally placed to coordinate different behaviors depending on the same set of variables, such as moving the eyes and hand to the same object, despite the fact that these movements must be programmed using distinct coordinates.

Biological Plausibility of the Basis Function Approach

The basis function approach requires that the tuning curves of neurons in intermediate stages of computation provide a basis function set. Neurons whose response can be described by a Gaussian function of retinal location multiplied by

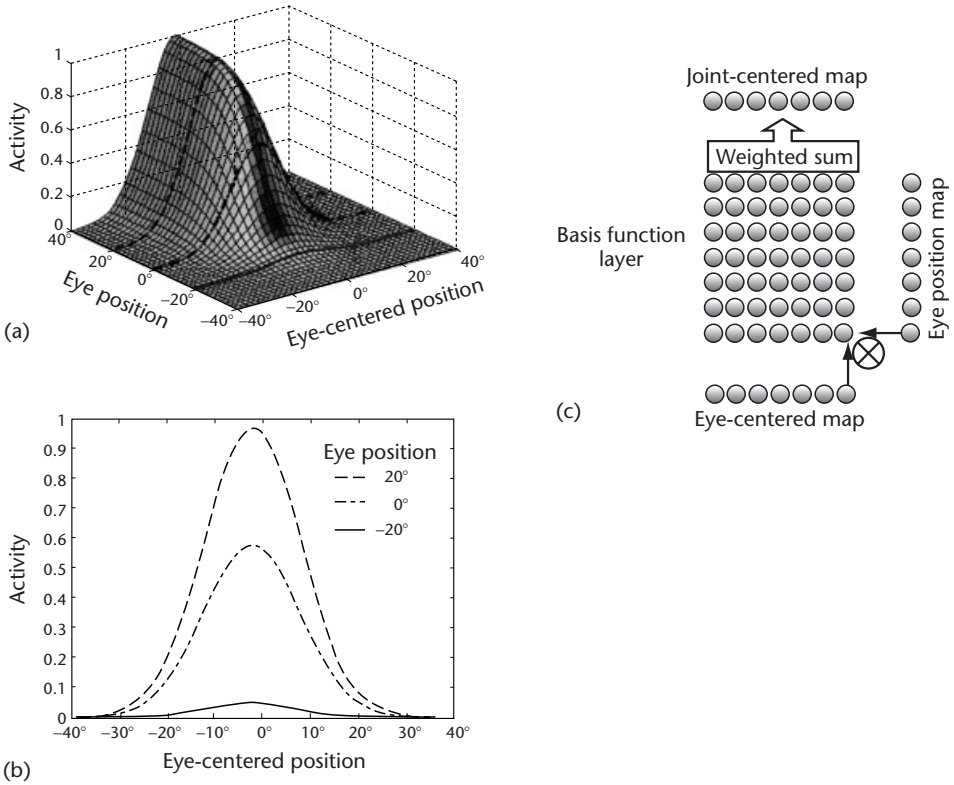

Figure 3. Basis function units. (a) The response function of a basis function unit computing a product of a Gaussian function of retinal location multiplied by a sigmoidal function of the position of the eyes. (b) A mapping of the retinotopic receptive field derived from a unit with the properties shown in (a) for three different eye positions. The bold lines in (a) correspond to the three curves shown here. The receptive field always peaks at the same retinal location but the gain (or amplitude) of the response varies with eye position. Gain modulations similar to this are found in numerous cortical areas, from V1 to the premotor cortex. (c) A neural network model for nonlinear sensorimotor transformations using basis functions. The input layer encodes the retinal location of an object and the current eye position while the output layer encodes the change in joint angles of the arm. The tuning curve of the eye-centered and eye position units are assumed to follow Gaussian and sigmoid functions, respectively. This nonlinear sensorimotor transformation requires an intermediate layer. In the case illustrated here, the intermediate layer uses basis function units. Each unit computes the product of the activity of one input unit from the eye-centered map and one input unit from the eye position map. As a result, the response of the basis function units is as shown in (a) and (b). The transformation from the basis function to the output units involves a simple linear transformation, namely a weighted sum of the activity of the basis functions units. This is the main advantage of this approach: once the basis functions are computed, nonlinear transformations become linear.

a sigmoidal function of eye position would qualify (see Figure 3(a) and (b)). Such gain-modulated neurons have been reported in large numbers in several cortical areas within the parietal lobe. Gain modulations between sensory and posture signals have been also reported in occipital and premotor cortices, suggesting that basis function representations may be used throughout the cortex.

In early studies gain modulation by posture signals was reported to be linear, not sigmoidal. Linear gain modulation is incompatible with the basis function hypothesis because it does not result in a basis set. These experiments, however, were designed to detect an effect, not to distinguish the precise form of the gain field. A linear model of gain fields was simple and lent itself most easily to statistical testing. However, more recent experiments and new analyses have revealed significant nonlinearities consistent with sigmoidal modulation.

LEARNING SENSORIMOTOR TRANSFORMATIONS

It is conceivable that a few sensorimotor transformations are already wired at birth and require little training (such as the eye blink reflex). In most cases, however, the mapping from sensory to motor coordinates must be learned and updated through life

as the eyes, arms, and body parts change in size and weight.

The goal of learning is to find out how to generate the proper motor commands in response to a desired sensory state. How do we learn to map the sensory coordinates of objects into motor coordinates? Piaget proposed that babies learn the appropriate mapping by associating spontaneous motor commands with the sensory consequences of those spontaneous actions. Consider how this would work in a two-layer network trained to control arm movements. We assume that the input layer encodes the visual location of the hand, while the output layer represents reaching motor commands in joint-centered coordinates. Note that we now define the motor command as the position of the arm expressed in joint-centered coordinates, as opposed to the changes in joint angles of the arm required to reach the target. We do so because learning is easier to explain with this new definition, but the points we make apply just as well to our previous definition. On each trial the network generates a spontaneous pattern of activity in the motor layer. This pattern is fed to the arm which moves accordingly. The network receives visual feedback regarding the position of the hand as a result of this movement. At this point, the system can learn the association between patterns in the sensory and output layers. In particular, the Hebb rule can be used to increase the weights between sensory and motor units that are coactive.

One can even use the current weights between the sensory and motor layers to compute the reaching motor command that the system would generate in response to the observed visual position of the hand. We will refer to this command as the predicted reaching command. If the predicted and spontaneous motor commands are the same, the network can already accurately bring the hand to the desired location and no learning is required. If the two commands differ, the difference between the two can be used as an error signal to adjust the weights (Figure 4(a)). For instance, one could use a learning rule known as the *delta rule*, which takes the form

$$\delta w_{ij} = \alpha\, a_i(a_j^* - a_j) \tag{5}$$

where δw_{ij} is the change in the weight between the

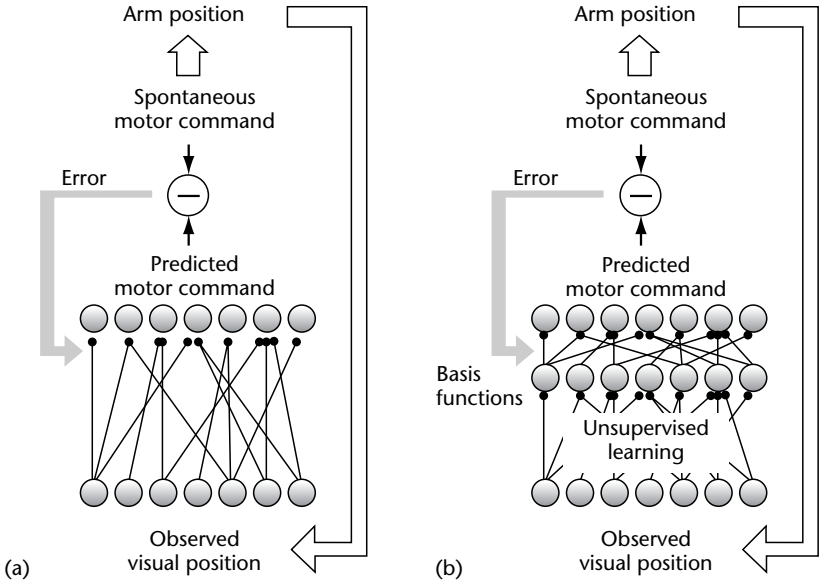

Figure 4. Learning sensorimotor transformations in neural networks. (a) Learning motor commands with spontaneous movements. The motor layer generates a spontaneous pattern of activity; this activity is fed into the arm, resulting in a new arm position, which is observed in the input sensory layer. The sensory activity is passed through the weights to compute a predicted motor command. The weights can then be adjusted according to an error signal obtained by computing the difference between the spontaneous and predicted motor command. By repeating this procedure many times, one can learn the appropriate sensorimotor mapping. (b) When the transformation is nonlinear, as is the case for arm movements, an intermediate layer of units is required. If basis functions are used in the intermediate layer, learning can be done in two stages. The weights to the basis function can be learned with an unsupervised or self-organizing rule because the basis functions depend only on the input, not on the motor command computed in the output layer. The weights to the output layer are equivalent to the ones in the network shown in (a) and can be learned using the same error signal.

presynaptic sensory unit i and postsynaptic motor unit j, α is a learning rate, a_i is the activity of the presynaptic unit, a_j^* is the spontaneous postsynaptic motor activity, and a_j is the predicted postsynaptic motor activity.

This strategy works well if the sensorimotor transformation is linear (that is, it can be implemented in a two-layer network), such as learning to make an eye movement to a visual target. Indeed, the retinal location of a target and the saccade vector required to obtain that target are identical. The transformation from a sensory map (e.g. cortical area V1) to a motor map (e.g. the superior colliculus) is therefore an identity mapping, which is a linear transformation.

Unfortunately, however, most sensorimotor transformations are nonlinear, and the networks that compute them require at least one intermediate layer. We have seen in the first section that a good choice for the intermediate representation is to use basis functions. This turns out to be a good choice for learning as well. Indeed, with basis functions, we can decompose learning into two independent stages:

- learning the basis functions
- learning the transformation from basis functions to motor commands (Figure 4(b)).

To learn the basis functions, one can use a purely unsupervised learning rule; that is to say, the basis functions can be learned without regard to the motor commands being computed – before the baby even starts to move his arm. Indeed, since by definition any basis function set can be used to construct any and all motor commands (eqn [4]), the choice of the basis set is independent of the exact set of motor commands that will eventually be learned. The choice, however, is constrained by general properties of motor commands: for example, motor commands tend to be smooth functions in the sense that similar sensory inputs usually lead to similar motor commands. It is therefore helpful to use smooth basis functions, such as Gaussian functions, which provide smooth interpolation between training samples. Learning constraints can also play a part. Hence, learning the transformation from the basis functions to the motor command is easier when the basis functions are local; i.e. when the functions are nonzero over a limited range of inputs, like Gaussian functions (a counterexample would be polynomial functions like x^2). Indeed, changing the weight of a local basis function affects the motor command only over the range of inputs that activates the basis function, while leaving intact what has already been learned for other sensory inputs, leading to a modular form of learning. Finally, some choices are more consistent with what we know of neuronal responses; this is true in particular of Gaussian and sigmoid functions which fit quite well the tuning responses of many neurons in the cortex. Several biologically plausible self-organizing rules are available for learning such basis functions.

Learning the transformation from basis functions to motor commands is easy, since motor commands are linear combinations of basis functions (see Figure 3(c)). We need to learn only the linear weights in eqn [4] which can be done as outlined above with a simple delta rule (Figure 4(b)). Other problems arise during learning when the nonlinear sensorimotor transformation is a one-to-many mapping, but these issues lie beyond the scope of this article.

CONCLUSION

Coordinate transforms for sensory motor transformations fall into two broad classes, linear and nonlinear. The linear transformations can be performed by networks of units computing simple dot products. The computation of the dot product leads to cosine tuning curves consistent with what has been reported in sensory and motor neurons of invertebrates. Most transformations, however, are nonlinear and require multilayer networks with intermediate representations. Several choices are available for these intermediate representations, but an efficient way to proceed is to use units computing a product of bell-shaped, or sigmoidal, tuning curves to sensory and posture signals. The key property is that units with bell-shaped tuning curves provide basis functions which, when combined linearly, make it easy to compute and learn nonlinear mappings. This solution also has the advantage of being biologically plausible since basis function units show a gain modulation of sensory evoked activity by posture signals, similar to what has been reported for many neurons in the prestriate, parietal, and premotor cortices. This tight link between the observed neurophysiological responses and the theory makes the issue of coordinate transforms one of the best-understood problems in computational neuroscience.

Clearly, basis function networks are only the beginning of the story. Unresolved issues abound, starting with the fact that basis function representations are subject to combinatorial explosion; i.e. the number of neurons required increases exponentially with the number of signals being integrated. One solution to this problem is to use multiple modules of basis functions. It is clear that the brain is indeed using multiple cortical modules

for sensorimotor transformations and it will be interesting to identify the computational principles underlying this modular architecture.

Modeling Individual Neurons and Small Neural Networks

Intermediate article

Elizabeth Thomas, Research Centre for Cellular and Molecular Neurobiology, Liège, Belgium

CONTENTS

Realistic models of neurons range in complexity from the perfect integrate-and-fire model to conductance models in which the ionic currents are computed from the kinetics of the underlying gating particles.

INTRODUCTION

This section outlines the construction of neuronal models which describe in more detail their intrinsic properties as well as their interactions with neighboring neurons. It starts with the integrate-and-fire neuron as a model at the less detailed end of the spectrum, and concludes with models in which the ionic currents emerge from the kinetics of the underlying gating particles. The complexity of the model that is chosen for a particular study would largely depend on the type of question being investigated. For example, one cannot fully investigate the effects of many drugs on a neuronal network without using the Hodgkin–Huxley model, the reason being that in many cases the effect of the drug is known in some detail. For example, benzodiazepines mainly affect the decay of γ-aminobutyric acid A ($GABA_A$)-mediated postsynaptic potentials and not the maximum conductance (Otis and Mody, 1992). On the other hand, if one is investigating auditory processing, much is still unknown about the manner in which information is encoded in a simple network, and constructing a complicated conductance model only serves to confound the problem. The extra details may also be irrelevant to the questions that are being addressed.

In describing various 'realistic' neuronal models by starting out with the simplest, this article begins with the integrate-and-fire model, before moving on to the leaky integrate-and-fire model, the rate model of a neuron, and finally conductance models. The conductance models can be constructed either with macroscopic descriptions of ionic currents or with more detailed models that outline the kinetics of each of the particles gating the channel. A study of network interactions requires models of synaptic activity. The article therefore describes two commonly used synaptic models, namely those with prefixed functions of postsynaptic activity and kinetic models. Finally, since phenomena such as learning and memory require the investigation of neuronal plasticity, the article describes biological models of both short- and long-term plasticity.

INTEGRATE-AND-FIRE MODEL

The integrate-and-fire model of neurons does not include any detailed information on the intrinsic properties of the neuron. Input to the neuron is integrated, and a spike or action potential is generated once a fixed threshold has been reached. The spiking property of the neurons allows the study of the role of factors such as spike timing and spike synchrony in network activity. Some recent connectionist models incorporating the spiking activity of neurons have been found to yield certain advantages over a network of non-spiking neurons (Sougné, 1998). The integrate-and-fire neuronal model is described by the following type of equation:

$$C_m \frac{dV_m}{dt} = I(t) \qquad (1)$$

where C_m is the capacitance of the neuron, V_m is the membrane potential and $I(t)$ is the summated input

current due to synaptic input from neighboring neurons as well as any external current source such as an electrode. The neuron fires a fixed action potential when a threshold is reached. The membrane potential is then set to a prefixed value after the spike. Implicit in such a model is the idea that the timing of a spike, and not its form, is important in carrying information about the system.

The simplest way of representing a spike from the neuron is a simple delta function $\delta(t - \tau_k)$ for a neuron which fires at time τ_k. Although this is the simplest representation that can be used, various complications can be added to the model in order to characterize more realistically the neuronal spike and, more importantly, its activity immediately afterwards. Perhaps the most important of these is the refractory period immediately after an action potential. During this period no stimulus is able to elicit a second action potential from the neuron. The refractory period is due to the fact that the sodium channels which are largely responsible for generating a spike are in an inactivated state. The presence of this constraint places an upper limit on the frequencies at which a neuron may fire an action potential. If the refractory period is t_{ref}, the maximum firing frequency of the neuron, $f_{\max}$, is $1/t_{\text{ref}}$. The neuronal model may also include a relative refractory period immediately after the refractory period, during which the threshold for evoking a spike is increased.

LEAKY INTEGRATE-AND-FIRE MODEL

These models add a new level of complexity to the behavior of a neuronal model by including a leak current. The neuronal membrane in this instance can be represented by the equivalent circuit shown in Figure 1. The current flowing across the resistance of the circuit represents the leak current. The total current I_m flowing across the neuronal membrane is the sum of the capacitance current I_C and the leak current I_l:

$$I_m = C_m \frac{dV_m}{dt} + \frac{V_m}{R_m} \tag{2}$$

The simple integrate-and-fire model would linearly integrate two temporally separated inputs provided that their sum does not exceed threshold. However, the presence of a leak introduces a more realistic behavior in which the occurrence of an input is gradually forgotten over time. The earlier occurring input therefore makes a less important contribution to the summated neuronal response at a later time.

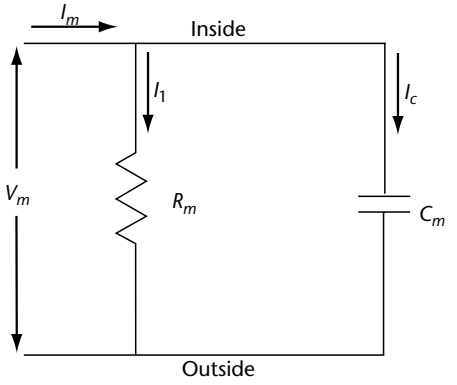

Figure 1. Equivalent circuit for leaky integrate-and-fire model of neuron.

In the presence of a leak term, the membrane potential in the absence of any input current will gradually decay to its initial value. In response to a constant current pulse I_m, the leaky integrate-and-fire model would attain the steady-state value $V_m(\infty) = I_m R_m$. However, the value of the membrane potential before this steady state is reached is given by:

$$V_m(t) = I_m R_m (1 - e^{-t/\tau_m}) \tag{3}$$

where $\tau_m = R_m C_m$ and is the membrane time constant representing the time taken for V_m to reach 63% of its final value.

RATE MODEL

In many models of large networks, the neuronal output is not represented in the form of individual spikes. Instead, the information that is taken into account is the firing rate of a neuron. In this case, the neuronal output is computed from a sigmoidal function relating membrane potential to the neuronal firing rate. The instantaneous firing rate $z_i(t)$ of a neuron is usually obtained from the neuronal membrane potential $V_m(t)$ with the use of a sigmoid function:

$$z_i(t) = \frac{z_{\max}}{1 + e^{-b(V_m(t) - \theta)}} \tag{4}$$

The use of this function allows for two factors contributing to nonlinearities in the neuronal output. Due to the refractory period, there is a maximal rate at which the neurons can fire, $z_{\max}$. The second factor is a threshold to reflect the fact that a minimum level of excitation is required for the neuron to begin firing. The factors b and θ contribute to setting the threshold of excitation and also the rate at which the firing increases with membrane potential.

Of course, the use of a rate model does not allow for the use of information that might be represented in the timing of neuronal firings or the correlation of firing times between neurons. The question of whether a rate code or temporal code is used for information coding in the nervous system has been much debated during the last few years. The investigators who have presented evidence for the representation of stimulus information in the temporal modulation of the neuronal spike train have included Bialek *et al*. (1991), who worked on the fly visual system, and Richmond *et al*. (1987), who investigated the inferior temporal cortex. The view that spike timing in neuronal firing is not very important has been taken by investigators such as Shadlen and Newsome (1998) and Thomas *et al*. (2000). The latter investigators have presented evidence to demonstrate that a good level of category information can be represented in the inferior temporal cortex without information on spike timing.

SYNAPTIC INPUT TO THE INTEGRATE-AND-FIRE NEURON

When they are present in a network, the neurons receive input from the surrounding neurons. At a given timestep, all of the input from the surrounding neurons is summed linearly to give the resulting activity V_i of a neuron i:

$$C_m \frac{dV_i}{dt} = \frac{V_i}{R_m} + \sum_j \sum_k \omega_{ij} g_{ij}(t - \tau_k)\delta_j(t - \tau_k)[V_i - V_{eq}] \tag{5}$$

The double summation is to take into account not only the input from all of the presynaptic neurons j, but also to sum over each incidence k of a presynaptic neuron firing. The term ω_{ij} is the sign and the strength of connections between neurons i and j. The function $g_{ij}(t - t_0)$ usually takes the form of an alpha function:

$$g_{ij}(t - t_0) = \frac{(t - t_0)}{\tau} e^{-(t-t_0)/\tau} \tag{6}$$

where t_0 is the time of transmitter release. The function $g_{ij}(t - t_0)$ decays with a time constant τ after reaching a peak. The values of τ are chosen to reflect the various fast and slow excitatory and inhibitory synapses that are seen in the nervous system. In many realistic network models these include the fast inhibitory synapse $GABA_A$, the slow inhibitory synapse $GABA_B$, fast excitation mediated by alpha-amino-3-hydroxy-5-methylisoxazole 4-proprionic acid (AMPA) receptors, and a slow excitation mediated by *N*-methyl-D-aspartate (NMDA) receptors. Each synapse also has its own characteristic value of V_{eq}, where $(V - V_{eq})$ represents the driving force on each synaptic current.

CONDUCTANCE MODELS

Many studies in neuroscience involve investigation of the neuronal ionic channels. The effects of various drugs on neurons are understood in terms of their actions on these ionic channels. The framework that is most widely used to describe these channels is the Hodgkin–Huxley model for action potentials (Hodgkin and Huxley, 1952). One of the main advantages of using this model is the availability of a large number of the required parameters from the experimental literature, as many of the experimental investigations themselves are conducted using the Hodgkin–Huxley framework. Some of the disadvantages of using the model include the large number of parameters that are required to characterize the system, and the long computer run times that are required to treat such unwieldy systems.

Ionic channels in the Hodgkin–Huxley model are represented as resistances (or conductances) arranged in parallel (Figure 2). The equivalent circuit for such a system is an elaboration of what has already been presented in Figure 1. In this case, additional resistances are added to simulate the other currents in the neuronal membrane in addition to the leak current. The circuit in Figure 2 denotes the currents that are typically represented in models of thalamocortical (TC) cells (Lytton and Thomas, 1997; Thomas and Lytton, 1997; Thomas and Grisar, 2000). The following equation describes such a circuit:

$$C_m \frac{dV}{dt} = -I_T - I_h - I_{Na} - I_K - I_l - I_{GABA_A} - I_{GABA_B} \tag{7}$$

The currents I_T, I_h, I_{Na}, I_K, and I_l are intrinsic currents, while I_{GABA_A} and I_{GABA_B} are synaptic currents. The values of these ionic currents are obtained from Ohm's law:

$$I = g\bar{g}(V - E_{eq}) \tag{8}$$

where E_{eq} is the reversal potential of the channel and $\bar{g}$ is the maximum conductance of a channel. Both of these values are fixed. However, the value of g, the channel conductance, is frequently dependent on factors such as the membrane potential,

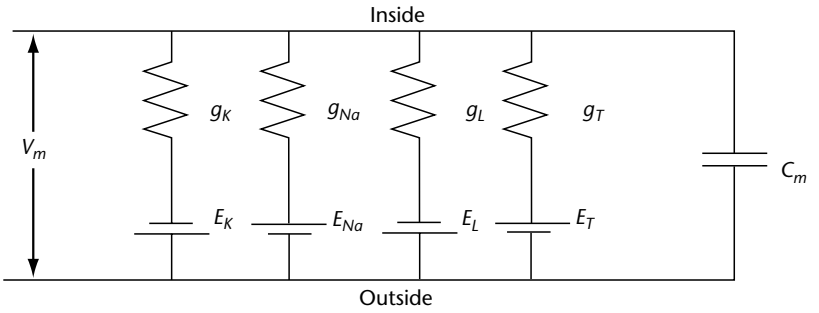

Figure 2. Equivalent circuit for conductance model of thalamocortical neuron.

time, or the internal calcium concentration, and has to be generally computed for each channel at each timestep. The leak current is usually an exception to this.

In the case of the intrinsic channels in which g changes, the value of g depends on the state of the gating particles m and h. While m is an activation gate, h is an inactivation gate. If N is the number of activation gates:

$$g = m^N h \tag{9}$$

The state of the gating particles (m or h) is a function of membrane potential as well as of time. At any time t, its value can be computed from the following equation:

$$gate_t = gate_\infty - (gate_\infty - gate_{t-1})\exp\left[\frac{-\Delta t}{\tau_{gate}}\right] \tag{10}$$

The values $gate_\infty$ and τ_{gate} depend on the membrane potential. In the case of many channels, their values as a function of membrane potential are directly available from the experimental literature.

In other cases they have to be computed from α and β, the rate constants for the reaction between open and closed states for gating particles:

$$gate_{open} \underset{\beta}{\overset{\alpha}{\rightleftarrows}} gate_{closed} \tag{11}$$

In this case:

$$gate_\infty(V) = \frac{\alpha(V)}{\alpha(V) + \beta(V)} \tag{12}$$

$$\tau_{gate}(V) = \frac{1}{\alpha(V) + \beta(V)} \tag{13}$$

As indicated by the name, the value $gate_\infty$ determines the magnitude of gate opening when the membrane potential is held at a particular value for time infinity. The value of τ_{gate} determines the amount of time required for the gate opening.

KINETIC MODELS OF IONIC CHANNELS

The Hodgkin–Huxley representation of ionic currents is at a macroscopic level. Many models also portray the currents at a more detailed level by describing the ionic channel based on the state transitions of each of the gating particles that constitute the channel. The value of an ionic current therefore emerges from the underlying dynamics of the system. There are two key assumptions that underlie classical kinetic theory which is used to describe the state transitions of the gating particles. First, gating is a Markov process – the rate constants of the transition of a gating particle from one state to the other (e.g. open to closed) are independent of the previous history of the system. Secondly, the transitions can be described by first-order differential equations with a single time constant.

A construction of such models can be illustrated by the model of a potassium (K^+) channel previously described by Hodgkin and Huxley. The channel is composed of four n gates. Each of these gates can be in either an open (1) or closed (0) state. The channel is conducting only if all four n gates are in an open state (1111). Starting from the condition where all of the gates are closed (0000), the system can therefore go through 14 intermediate closed states before it finally becomes open (1111) (Figure 3). By making the assumption that the four gates are independent and kinetically identical, the web of equations that lead from the nonconducting to the conducting state of the K^+ ionic channel can be very much reduced. For example, all states with the same number of closed gates are kinetically identical and can therefore be treated together. Using such assumptions, the entire tree of reactions can be collapsed to the transitions between five major states, with state 4 being the only conducting state. The values 4α, 3α, 2α, and α are the rate constants for all of the forward reactions

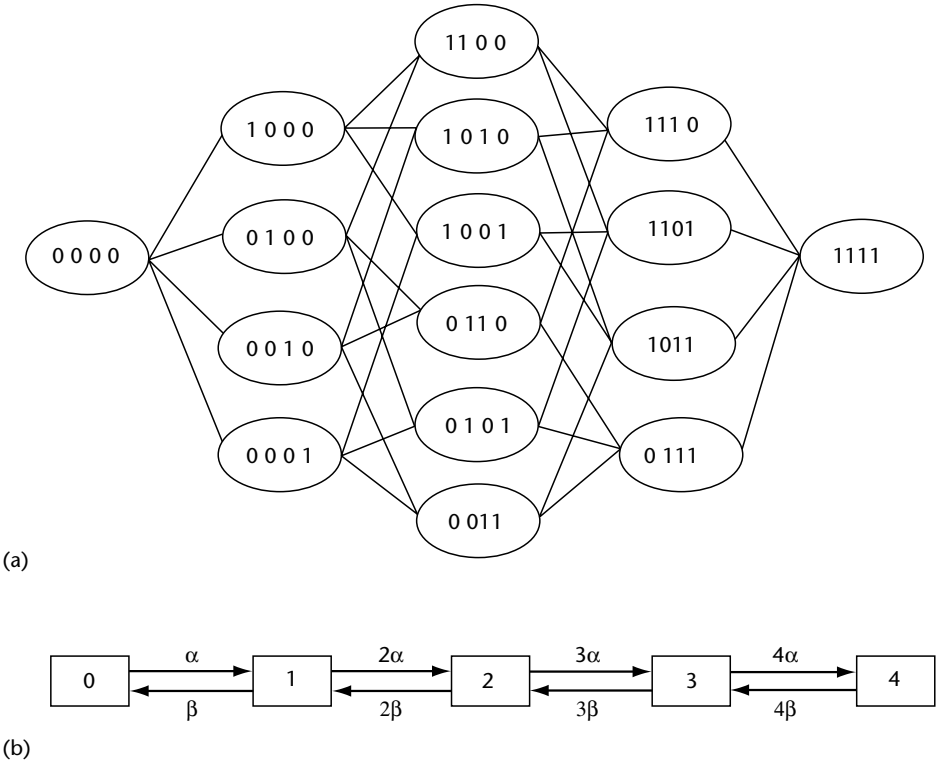

Figure 3. (a) The K^+ channel consisting of four n particles can go from the closed state (0000) to the only open state (1111) via 14 intermediate states which are all closed. (b) By pooling together states which are kinetically identical, the complex state diagram in (a) can be reduced to five states (Hille, 1991).

leading to state 4, while 4β, 3β, 2β, and β are the rate constants for the backward reactions leading from open state 4 to the closed state 0.

SYNAPTIC INPUT TO CONDUCTANCE MODELS

Synaptic input in many conductance models is represented in the form of the alpha function introduced in the earlier section on synaptic input to the integrate-and-fire neuron. As mentioned earlier, one of the problems with using this model is the fact that the time of occurrence of each spike has to be stored in a queue, and the corresponding exponentials have to be calculated for each time-step. Another criticism of these models is that although they imitate the observed time course of postsynaptic potentials in electrophysiological recordings, they are not based on any of the underlying mechanisms in the process. Furthermore, these models do not naturally provide for a saturation that could occur at the synapse.

A kinetic model of receptor binding described by Destexhe *et al*. (1994a) is able to resolve many of these problems. In a two-state kinetic model, neurotransmitter molecules T bind to the postsynaptic receptor R according to the following first-order scheme:

$$R + T \underset{\beta}{\overset{\alpha}{\rightleftarrows}} TR^* \tag{14}$$

If r is the fraction of bound receptors, then:

$$\frac{dr}{dt} = \alpha[T](1 - r) - \beta r \tag{15}$$

If $[T]$ occurs as a pulse, the above equation can be solved to obtain the following expression for the value of r during the pulse ($t_0 < t < t_1$) and for the period following the pulse ($t > t_1$).

During the pulse:

$$r(t - t_0) = r_\infty + (r(t_0) - r_\infty)\exp\left[\frac{-(t - t_0)}{\tau_r}\right] \quad (t_0 < t < t_1) \tag{16}$$

After the pulse:

$$r(t - t_1) = r(t_1)\exp[-\beta(t - t_1)] \quad (t > t_1) \tag{17}$$

where both r_∞ and τ_r are functions of the rate constants α and β in eqn [14].

The value of r is then used to calculate the synaptic current in the same manner as an intrinsic current:

$$I_{syn}(t) = \overline{g}_{syn} r(t)\left[V_{syn}(t) - E_{syn}\right] \tag{18}$$

Although these two state models capture many of the important characteristics of postsynaptic potentials, a larger number of states can be used to model them more accurately (Destexhe *et al*., 1994b).

MODELS OF SYNAPTIC MODIFICATION

The efficacy of connections between the neurons of the nervous system has been found to be a parameter that is not constant but which fluctuates according to the dynamics of the network. These changes can be both long- and short-term, and can cause synaptic efficacy to increase or decrease. While the short-term changes last for the order of seconds to minutes, the long-term changes may persist for an hour or more.

A model for short-term synaptic facilitation and depression has been provided by Abbott *et al*. (1997). In this model, the amplitude of neuronal response K_1 is adjusted by a factor $A(t_i)$. If R is the response of a neuron to a train of spikes:

$$R(t) = \sum A(t_1) K_1(t - t_i) \tag{19}$$

If there was an isolated spike, and previous spikes did not have an influence on the postsynaptic response, A would have a value of 1. However, as a result of a presynaptic spike, A would either increase in the case of facilitation or decrease in the case of depression. This could take place in either an additive or a multiplicative fashion. The value of A would change according to $A \rightarrow fA$ in the multiplicative case, or according to $A \rightarrow A + (f-1)$ in the additive case. A value of $f > 1$ would correspond to facilitation, while a value of $f < 1$ would lead to depression. In order to produce biologically realistic behavior, Abbott recommends the usage of a multiplicative expression for depression ($f < 1$) and an additive description for facilitation ($f > 1$).

Another model of short-term depression is that of Markram *et al*. (1998). This model aims to explain the frequency dependence of synaptic transmission. Both Markram and Abbott have suggested that these changes in synaptic strength have implications for the type of encoding that is used by the nervous system. A rate code is favored when depression is slow and a temporal code is favored when depression is fast. A neuron which was initially sensitive to the firing rate of a rapidly firing presynaptic terminal, as a result of synaptic depression, now reaches a steady state which is no longer a function of the presynaptic firing rate. However, several depressed excitatory postsynaptic potentials (EPSPs) are generated before this steady state is reached. During this period, the neuron shows an increased sensitivity to temporal coherence in the presynaptic input (Abbott *et al*., 1997; Tsodyks and Markram, 1997).

The long-term changes that are observed in the strengths of synaptic connectivity are long-term potentiation (LTP) and long-term depression (LTD). The experimental paradigm that is usually used to produce LTP is a train of high-frequency stimulation, while LTD is produced by a train of low-frequency stimuli. LTP has been found to be mediated by both NMDA and non-NMDA synapses. Long-term potentiation mediated by NMDA synapses generally obeys Hebbian rules for induction. The Hebbian rule was proposed by Donald Hebb as a mechanism for learning. He suggested that the concurrent excitation of pre- and postsynaptic elements would result in an increase in synaptic efficacy. In the NMDA synapse the requirement for concurrence arises because the postsynaptic terminal has to be depolarized in order to remove an Mg^{2+} block. The presynaptic terminal has to be depolarized for the release of neurotransmitter. Realistic models of the NMDA synapse must therefore take into account the concentration of Mg^{2+} ions. The following is an example of an equation for an NMDA-mediated current in a model of working memory in the cortical network (Wang, 1999):

$$I_{NMDA} = \frac{g_{NMDA}(V_m - V_E)}{(1 + [Mg^{2+}]e^{-kV_m})} \tag{20}$$

More recent experimental research has revealed more details of the way in which the relative timing of pre- and postsynaptic firing can change the sign as well as the strength of synaptic modification. If the presynaptic action potential precedes postsynaptic firing by no more than about 50 ms, then an increase in synaptic strength occurs. The smaller the temporal separation between the presynaptic firing and the postsynaptic action potential, the larger is the increase in synaptic strength. On the other hand, presynaptic action potentials that follow postsynaptic spikes lead to a depression in synaptic strength. Models of this type of spike-timing-dependent plasticity have been developed by Song *et al*. (2000).

MULTICOMPARTMENTAL MODELS

The highly branched dendritic trees of a neuron confer highly complex spatial structures on the neuron. Neuronal models which attempt to understand the role of these structures make use of multicompartments (Figure 4). The compartmental approach to study of the flow of ionic currents in dendritic trees was pioneered by Rall (1964), who modeled the dendritic tree by using cable equations. These equations could be solved analytically under extremely limited circumstances. This approach became difficult and sometimes impossible when most realistic dendritic structures were taken into account. Membrane properties that are voltage dependent and which generate action potentials are also problematic. Rall had pointed out that in such cases compartmental models should be used. A good description of such models can be found in Segev and Burke (1999). In this instance each neuron is composed of a number of compartments. Each compartment is considered to be isopotential and its properties are considered to be uniform. For such models, the property of each compartment is not only the consequence of currents intrinsic to the compartment, but also depends on currents which enter and leave from adjacent compartments.

The membrane potential for a neuronal compartment k with adjacent compartments $k+1$ and $k-1$ is then computed as follows:

$$C_m \frac{dV_k}{dt} + I_{ion} = \frac{V_{k-1} - V_k}{r_{k-1,k}} - \frac{V_k - V_{k+1}}{r_{k,k+1}} \qquad (21)$$

Although in many instances unicompartment models are sufficient to generate the activity of interest, in some situations they fail. An example of this is provided by a study described by Abbott and Marder (1998). These researchers demonstrated how in some bursting cells in the somatogastric ganglion of certain invertebrates it is important to isolate the primary neurite from the spike initiation zone on the axon. If this is not done, the slow oscillating potentials that are generated in the primary neurite can prevent the de-inactivation of the fast Na^+ conductance which terminates the action potential in the spike initiation zone. However, once these two areas are electrotonically separated the problem is resolved.

Motor Control: Models

Advanced article

Liana E Brown, Pennsylvania State University, University Park, Pennsylvania, USA
David A Rosenbaum, Pennsylvania State University, University Park, Pennsylvania, USA

CONTENTS

The term 'motor control' refers to the ability of biological and artificial systems to plan, initiate, maintain, monitor, and correct movements to attain physically realizable goals. A 'model' is a system or process that permits predictions.

INTRODUCTION

As in most areas of cognitive science, models play an important role in motor control research. This is fitting because motor control itself relies on models which predict the outcomes of actions. This article reviews the main challenges faced by motor control systems, and various conceptions of how these challenges might be met.

DEFINITIONS AND CHALLENGES

The term 'motor control' refers to the ability of biological and artificial systems to plan, initiate, maintain, monitor, and correct movements to attain physically realizable goals. The term 'model' refers to a description of a system or process that permits predictions. Models relevant to motor control permit predictions, for example, of the mechanical effects on the forearm of contracting the biceps muscles, of the optical effects on the retina of rotating the eye, and of the haptic effects of gripping a cup of tea. As these examples show, models apply over a wide variety of events.

In motor control research, it is typically assumed that the actor has some goal that can be satisfied physically. Selection of the goal is usually considered a motivational rather than a motor-control problem. The choice of goal may depend, however, on knowledge of what the actor can achieve motorically.

When a goal has been specified, the nature of the action to be carried out is usually not fully determined. If an apple is in reach, for example, there may be an infinite number of movements that allow it to be obtained. One challenge for motor control research is to explain how one movement is chosen from the plethora that are possible. This is an example of the redundancy problem. Redundancy is present at all levels of the motor control system. The redundancy problem (the problem of finding one motor solution when more than one is possible) can be approached by considering body positions while ignoring the forces behind them (kinematics), or by considering the forces involved (dynamics). Considering kinematics alone may be acceptable in computer animations or in abstract computational models. Dynamics may be considered without regard to the underlying muscle recruitment patterns, or, for even more physiological realism, with regard to how muscles are recruited and even how neurons fire.

A second challenge in motor control is learning. The learning problem is how to model relations between movements and their effects. Some learned models are 'forward' (e.g. 'What happens to my elbow if my biceps muscle contracts?'); others are 'inverse' (e.g. 'What muscle events caused my elbow to flex?').

A third challenge in motor control is perceptual–motor integration. It is important to understand how feedback (information about past performance) is used to correct errors, and also how feedforward (information about forthcoming performance) is used to prevent errors. Note that feedback control and feedforward control may each rely on either forward or inverse models.

A fourth challenge in motor control is movement sequencing. This is often called the serial order problem. This problem has been studied mainly in connection with such tasks as walking, speaking, typewriting, and drawing. Because the serial order of motor acts is implied by their timing, the problem of timing is closely related to the problem of

serial order. These two problems will be treated together in this article.

MODELS FOR REDUNDANCY

There are many ways to carry out elementary actions. Consider the task of reaching for an apple. The apple can be grasped in many ways, because more degrees of freedom characterize the state of the limb than the state of the apple. The components needed to characterize the position of the apple are six: the apple's position on the horizontal, vertical, and depth axes, and its pitch, roll, and yaw. But the apple can be grasped in infinitely many ways because the body has more than six mechanical degrees of freedom. The arm has more than six degrees of freedom because the shoulder can rotate in three spatial dimensions, the elbow can rotate in two, and the wrist can also rotate in two. Taking into account the fact that the fingers and trunk add their own degrees of freedom, it is apparent that there is much redundancy in the apple-grasping task. Thus, the question arises of how one particular grasping motion is chosen out of the infinite number that are possible in principle.

Models that have addressed this problem have been of four main types: models that emphasize properties of the peripheral neuromotor system; models that emphasize effector interactions; models that emphasize geometric restrictions; and models that emphasize cost reduction. Each will now be considered in turn.

Models Based on the Peripheral Neuromotor System

Models of the first type recognize that muscles and reflexes have properties that allow effectors to be treated as mass–spring systems with adjustable equilibria (Bizzi *et al*., 1992; Feldman, 1986). In this approach, desired positions are represented as modifiable equilibrium positions to which the body is drawn. There is controversy about how equilibria are represented. One view is that viscoelastic properties of muscle are set through feedforward control (Bizzi *et al*., 1992). Another view is that feedback properties of neuromuscular reflexes are changed to allow effectors to alter their resting states (Feldman, 1986). In any case, evidence exists for the general proposition that terminal positions are planned as goals rather than as mere consequences of movements. Firstly, limbs can reach terminal positions despite perturbations, even when feedback is removed (Polit and Bizzi, 1978). Secondly, position variability increases during movement but then decreases near terminal positions (Harris and Wolpert, 1998; Rosenbaum *et al*., 2001). Thirdly, memory for final positions is more long-lasting and more accurate than memory for movements to those final positions (Marteniuk and Roy, 1972).

Models Based on Effector Interactions

The second class of models that addresses the redundancy problem emphasizes effector interactions (Bernstein, 1967). These models assert that dependencies between limb segments limit action possibilities. For example, within one arm it is more difficult to steadily coordinate extension of the wrist with flexion of the elbow than to steadily coordinate extension of the wrist with extension of the elbow. Similarly, people find it difficult to draw a circle with one hand while drawing a rectangle with the other. Interestingly, callosotomy (split-brain) patients show no such spatial coupling (Franz *et al*., 1996). Some effector interactions are dependent on the perceptual feedback provided. Thus, neurologically normal individuals can produce bimanual movement patterns that are otherwise difficult if special visuo-motor displays are used (Mechsner *et al*., 2001).

Other interactions are task-dependent. If a downward force is lightly applied to the lower lip as it ascends during simple utterances such as 'aba, aba, aba', the upper lip descends more than usual, and with remarkably short latencies, to complete the lip closure (Abbs *et al*., 1984). By contrast, if the same light downward force is applied to the lower lip as it ascends during simple utterances such as 'ala, ala, ala', the upper lip does not descend more than usual. In saying 'ala, ala, ala', bilabial closure (bringing the lips together) is unnecessary. This demonstrates that coupling of effectors depends on the task being performed. Sophisticated neural control mechanisms must exist to permit such functionally adaptive coupling.

Models Based on Geometric Restrictions

The third class of models that addresses the redundancy problem emphasizes geometric restrictions. Models in this class focus on the observation that the range of adopted postures is less than the range of postures that are possible. When the eyes rotate to gaze at objects in different locations, for example, they do not adopt all possible ocular positions (Tweed and Vilis, 1990, 1992). Although in principle

the eyes can rotate freely about their vertical, horizontal, and torsional (depth) axes, eye movements conform to 'Listing's law': the axes of rotation actually used by the eyes tend to lie in a plane. When the upper arm rotates about the shoulder, the positions it adopts are similarly restricted (Gielen *et al*., 1997). Geometric restrictions may reflect a control strategy for dealing with motor redundancy.

Models Based on Cost Reduction

The fourth class of models that address the motor redundancy problem emphasizes cost containment. Much of the work illustrating this approach has focused on hand movements. Because such movements tend to be smooth, investigators have suggested that they implicitly satisfy a smoothness constraint such as minimization of the mean rate of change of acceleration (Flash and Hogan, 1985) or minimization of the mean rate of change of torque (Uno *et al*., 1989).

Much as effector interactions may be task-dependent, smoothness constraints may also be elective or 'soft' rather than physically necessary or 'hard'. This view is supported by the fact that skilled actors may intentionally switch between smooth and jerky movements. For example, a violinist may switch between bowing in a staccato or legato fashion. Recent models have emphasized flexible adjustment of movement properties (Rosenbaum *et al*., 2001). Such models rely on multiple constraints whose priorities can be changed according to task demands.

MODELS FOR LEARNING

As stated earlier, motor learning may use forward and inverse models. Acquisition of forward models is generally more straightforward than acquisition of inverse models. Acquiring a forward model entails predicting sensory outcomes of motor commands, comparing those outcomes to obtained feedback, and using error signals to alter the forward model (see Figure 1). By contrast, acquiring an inverse model entails predicting what change in motor commands will correct a mismatch between intended and obtained results. Only when the correct inverse model is available will the prediction be consistently correct. Because of the significant nonlinearities of the system, finding the correct inverse model may be difficult (Wolpert and Kawato, 1998).

Regardless of how models are learned and used, one fact that has clearly emerged from recent research on motor learning is that actors do indeed learn 'smart' functions relating performance to perception. In a demonstration of this capability, participants made point-to-point hand movements in artificial force fields (Conditt *et al*., 1997). Initially the participants' hand paths were curved, but soon they became essentially as straight as observed in normal circumstances. Even when the participants had to generate hand translations in new parts of the workspace, they could immediately produce straight movements, provided they had learned to compensate for the force field in the originally trained part of the workspace. This shows that the motor system does not learn the dynamics of the arm by rote memorization of past experience. Instead, it learns models that allow for transfer to new situations. Such models are needed not only for adaptation to artificial force fields but also for adaptive performance in the everyday environment. To maximize the effectiveness of models (forward and inverse), one approach has been to allow for the operation of many internal models, each of which may contribute to the planned movement in proportion to how well the current environment fits the environment for which it was developed. In this approach, the multiple internal models allow the system to respond appropriately in many different contexts (Wolpert and Ghahramani, 2000).

MODELS FOR PERCEPTUAL–MOTOR INTEGRATION

Moving skillfully requires anticipation of the perceptual consequences of one's own actions (feedforward), and rapid correction for perceived errors (feedback). These two forms of discrimination are considered below.

Feedforward

Anticipating the perceptual consequences of one's own actions (feedforward) is a prerequisite for effective motor control. That this capability is fundamental is shown by the fact that even insects benefit from it. This was discovered through an ingenious experiment that involved turning a fly's head so that the top of the fly's head was on the bottom and the bottom of its head was on the top, gluing the rotated head against the fly's thorax, and then observing the fly's behavior (von Holst and Mittelstaedt, 1950). When the fly's head was flipped, it walked haltingly, if at all, when it was in lit surroundings, though it could walk perfectly well in darkness. Why did the fly not walk in its normal way when the lights were on? The explanation was

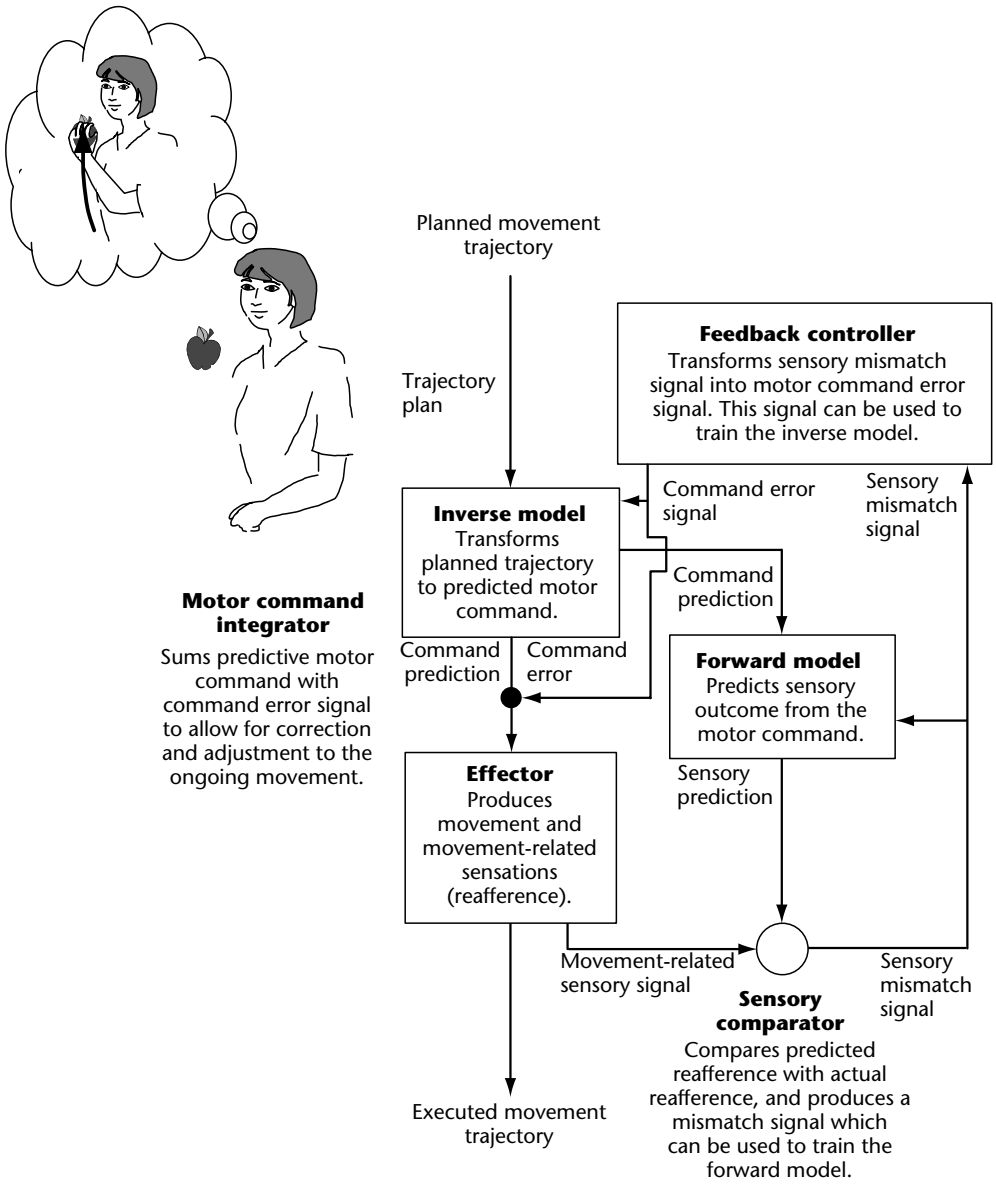

Figure 1. An example movement control system in which an inverse internal model and a forward internal model cooperate for movement control and learning. The inverse and forward models provide feedforward control by producing the predicted motor command and sensory consequences, respectively. The command signal is transmitted both to the forward model ('efference copy') and to the effector. The forward model uses the command signal to predict movement-related sensory feedback ('reafference') for the planned trajectory. The effector produces the trajectory and movement-related reafference. Predicted and actual reafference are compared and movement error is coded as a sensory mismatch signal. The sensory mismatch signal provides feedback control to the ongoing movement and is used to train the forward and inverse models. The forward model is trained directly on the basis of the sensory mismatch signal. The inverse model is trained after the sensory error signal is transformed to a motor command error signal, which is equivalent to the command that would correct for error in the executed movement trajectory. Adapted from Wolpert *et al*. (1998) and Wolpert and Kawato (1998).

that the fly expected visual shifts opposite to its own displacement. When the obtained visual shifts were in the same direction as the fly's movement, they signaled to the fly that the world was moving, which in turn caused the fly to behave conservatively – standing still rather than walking. In other words, the fly anticipated what it would see when it prepared to move.

Such anticipation also occurs in higher animals. Pushing gently on one's eyeball causes the seen

world to move even when it is stationary. In this situation, the normal commands for moving the eyes are absent and the induced retinal shift is interpreted as resulting from external motion. By implication, when the eyes are controlled by normal oculomotor commands, the seen stable world appears stationary because the oculomotor commands give rise to anticipated visual shifts. Brain changes reflecting such anticipations have been recorded neurophysiologically (Duhamel *et al*., 1992). Such data, coupled with behavioral results like the ones just reviewed, indicate that motor control is accompanied by anticipated perceptual changes.

Recent research shows that it is possible to anticipate not only what motor-related perceptual changes will occur, but also when they will occur. The capacity for time-related anticipation is important because long feedback delays can make it difficult to correct for errors. Feedback delays for normal eye–hand coordination usually range from 100 to 250 milliseconds, though in some circumstances the delays can be much longer (e.g., while interacting with a slow computer). One method for dealing with such temporal alignment problems is to use a model that estimates the delay of the feedback – a so-called 'Smith predictor' (Miall *et al*., 1993). Here a controller not only sends signals to the muscles to bring about immediate perceptual changes; it also preserves a copy of the expected perceptual changes and compares them with actual feedback signals when they arrive. Simulation results and behavioral data support the biological reality of this method. Miall *et al*. hypothesized that the cerebellum may play a central role in such prediction.

Feedback

Even when prediction works well, it rarely works perfectly. For a task as simple as moving a stylus to a target, the movement time M to get the stylus to the target increases as the distance D to be covered increases and as the width W of the target narrows. A quantitative relation among these variables was formulated by Paul Fitts (1954) and proved to be so reliable that it came to be called Fitts' law:

$$M = a + b\log(D/W) \quad (1)$$

The functional mechanisms underlying Fitts' law awaited explication by later investigators (Meyer *et al*., 1990), who noted that the higher the velocity of movement (and, in turn, the greater the forces generated), the greater the variability of the endpoints that are reached. Performers confronted with this velocity–variability trade-off must find a minimum time that allows D to be covered with an acceptable range of endpoints. Meyer *et al*. showed that Fitts' law represents an optimal trade-off between distance and time when increases in velocity, D/M, cause proportional increases in endpoint distributions. The argument presented by Meyer *et al*. emphasizes the inherent variability of motor control and the importance of developing internal models that optimally compensate for this variability. A similar view has been advanced by Harris and Wolpert (1998).

MODELS FOR SERIAL ORDER AND TIMING

One domain where understanding of variability has yielded good results is in models of the control of serial order and timing. Early in the study of movement sequencing it was suggested that movements are simply triggered by feedback from earlier movements. This view was rejected when it was found that interruption of feedback does not prevent movements from unfolding normally (Lashley, 1951). Another finding that dispelled the hypothesis was that early aspects of movement sequences often reflect later aspects, indicating that plans are established for forthcoming behavior.

Three sources of behavioral evidence for advance planning have been adduced. Firstly, the time to initiate a series of motor responses (e.g. keystrokes in typewriting) increases with the number of responses to be produced (up to a limit of about seven), provided the response rate is high (Sternberg *et al*., 1978). Secondly, performance errors (e.g. slips of the tongue) reveal implicit knowledge of what will be said or done (Lashley, 1951; Norman, 1981). Thirdly, the properties of correct actions reflect advance information of what will be done later. For example, the way an object is picked up changes as a function of where it will be placed (Rosenbaum *et al*., 1993). Detailed analyses of such effects have led to hierarchical models of motor plans. According to such models, serial ordering of behavior is achieved by the unfolding of high-level goals into lower-level constituents (e.g., MacKay, 1987). This general conception has been supported by studies of brain activity prior to movement (Gazzaniga *et al*., 1998).

Studies of timing likewise suggest hierarchical levels of organization. One of the most influential models of motor timing assumes two levels for timing control: a time-interval or 'clock' level, and a motor-execution level (Wing and Kristofferson,

1973). Patterns of timing variability from tasks where subjects try to generate responses at fixed rates (e.g. steady finger tapping) generally confirm predictions based on this two-tier model. More complex models that permit hierarchically nested timing relations have also been adduced to explain production of complex rhythmic sequences (Vorberg and Wing, 1996).

The fact that hierarchical models apply to timing as well as to serial ordering of behavior fits with the view that timing is essential for perceptual–motor integration, as mentioned above in connection with the Smith predictor. Further studies using brain-imaging and other psychophysical techniques have shown that predictive capabilities make it possible to engage in remarkably vivid motor imagery (Jeannerod, 1994). Such imagery can be useful for modeling one's own performance in tasks calling for critical action decisions (e.g., deciding where to grab an outcropping on a cliff while scaling it) and for improving one's perceptual–motor skills when it is impossible to practice those skills physically (see Schmidt and Lee (1999) for a review).

Natural Language Processing: Models of Roger Schank and his Students

Intermediate article

Roger C Schank, Northwestern University, Evanston, Illinois, USA
David B Leake, Indiana University, Bloomington, Indiana, USA

CONTENTS

Over many years, Roger Schank and his students developed a series of theories and computer models of natural language processing, guided by two main tenets: that natural language processing cannot be studied in isolation from the purposes for which language is used, and that meaning and world knowledge may be crucial at even the earliest points in the understanding process. Through an interplay between study of human reasoning, development of theories, and experiments with computer models, this work has identified important research questions and shed light not only on natural language processing but on a broad range of cognitive processes such as planning, learning, explanation, and even creativity.

INTRODUCTION

A central question in the study of natural language processing (NLP) is what the relationship is between NLP and of other aspects of cognition. One possibility, pursued in a substantial body of research, is to consider NLP to be a fairly independent area, concerned primarily with linguistic issues that can be studied independently from questions of how people use the content of that language – how they understand, remember, learn, and achieve their goals in the world. Over several decades, Roger Schank's research group has developed a succession of theories guided by the opposite viewpoint: that language and thought are inextricably connected. In this view, communication is at the heart of language; the goal of NLP is to understand how people extract and generate the content of communication. This, in turn, requires addressing a wide range of general issues beyond language *per se*. For example, the group has studied questions such as how conceptual expectations guide understanding, the role of inference in the understanding process, the knowledge structures into which new information is placed, how knowledge is organized, how it is learned, and how it is brought to bear on future understanding. The group's methodology combines artificial intelligence, cognitive science, and psychology. Theory building and testing are guided by a continual interplay between psychological data and experiments with computer models.

This article describes some of the major milestones of the group's models of parsing, inferencing, understanding, learning, memory, and explanation, and explains the tenets of their work. This succession of projects has both answered questions, and, equally importantly, raised important new questions. This process has not only sharpened our understanding of NLP, but also provided theories of basic processes of thought.

THE INTEGRATED PROCESSING HYPOTHESIS

In the 1950s and 1960s, the availability of computers stimulated attempts to develop machine translation systems. However, the early attempts could not handle problems such as ambiguity and implicit content. As it became clear that a theoretical foundation was needed, in the mid-1960s many researchers turned to linguistics and theories of syntax, developing approaches with varying degrees of separation between syntax and semantics. At one extreme were theories of autonomous

syntax, which treated the extraction of syntactic structure as an autonomous process that preceded, and provided input for, later semantic processing. Other approaches treated syntax and semantics as largely 'decomposable', with processing controlled by syntax but syntactic processing occasionally querying a semantic component; or as following separate, but more cooperative processes.

It seems clear that semantic and pragmatic knowledge (which we will call conceptual knowledge) play an important role during human language processing. For example, someone with a limited grasp of a foreign language can often make sense of magazine articles in that language, and finds it much easier to do so than to paraphrase the article in the foreign language: knowledge of the domain can guide understanding, even when syntactic knowledge is weak. Likewise, there is strong evidence that humans generate conceptual expectations as they understand. For example, most people who read 'the old man's glasses were filled with sherry' are surprised by the last word: their knowledge of old age makes eyeglasses the expected meaning for 'glasses', before the conclusion of the sentence is read. Such observations shaped the 'integrated processing hypothesis' that has guided the work of Schank's group: 'meaning and world knowledge are often crucial at even the earliest points in the process of understanding language' (Schank and Birnbaum, 1984, p. 212). Contrary to some misunderstandings of their work, this hypothesis does not reject the use of syntactic knowledge, nor does it claim that early processing is purely semantically based. It means that understanders use whichever available knowledge is most useful and apply it in a unified way, with a single mechanism controlling the application of both types of knowledge. We describe below a series of projects exploring this hypothesis in a series of computer models with increasing levels of integration, guided by increasingly sophisticated theories of the knowledge that guides understanding and how it is applied.

CONCEPTUAL DEPENDENCY THEORY

Modeling the role of language as communication requires theories of how to represent the content of language, as well as theories of the processes used to map language to and from that representation. Conceptual dependency (CD) theory, one of the first theories developed by Schank's group, is often thought of as the theory of a specific set of primitives for knowledge representation, but in fact it is more: it is a theory of how knowledge drives the understanding process.

CD theory has four main tenets (Schank and Riesbeck, 1981, p. 13):

1. The representation of events is done apart from the words used to encode those events.
2. The task of the understander is to represent the underlying events, rather than to represent the sentences themselves.
3. Such representations are governed by a set of rules regarding the fitting of inputs into a predefined representation scheme.
4. The rules for 'filling in the slots' of those representations are the rules that are the basis of language understanding.

CD represented the meaning elements necessary to represent actions, causal relations, states and state changes, in a language-independent form. The initial set of primitive acts included 11 acts, such as:

- PTRANS: to change the location of an object.
- MTRANS: to transfer information, either within memory or between people.
- PROPEL: to apply a force to an object, in a given direction.
- INGEST: to take something inside an animate object.

In CD, similar events are represented in similar ways, regardless of differences in the sentences used to express them. For example, because both reading a newspaper and watching the news on television involve transmission of information, their CD representations both use MTRANS. Consistently with the aim of CD to represent the underlying events, rather than the sentences themselves, a single CD primitive may be used to represent a wide range of verbs (for example, PTRANS can represent the events underlying verbs such as 'go', 'drive', 'fly', or 'carry' a cargo to a destination). Each primitive licenses certain inferences, and the meaning of each primitive may be seen as coming from what a reasoner may infer from the act (e.g., that PTRANS involves a change of state from one location to another).

Each primitive act has associated conceptual cases which modify the action. PTRANS has five cases: the 'objective' case (the object whose location is being changed), the 'directive' cases TO and FROM (describing the change in location), the 'actor' (who effects the change), and the 'instrumental' case (how the change is effected, e.g., an object might be moved by the actor PROPELing it).

The MARGIE system (Schank, 1975) was developed to test the usefulness of CD and to

demonstrate the ability of an understanding system to successfully map natural language to – and back from – an independent conceptual representation. In performing this process, MARGIE could perform machine translation, but the fundamental research focus was on modeling understanding. The system was composed of three modules: a parser, Christopher Riesbeck's ELI, which performed conceptual analysis, taking natural language input and using the low-level semantic expectations from CD structures to generate a representation in CD; a memory module, Charles Rieger's MEMORY, to make plausible inferences from the CD representation; and Neil Goldman's natural language generator BABEL, which took CD input from either of these modules to produce either paraphrases of the input or sentences expressing the inferences in a variety of natural languages.

CONCEPTUAL ANALYSIS

In conceptual analysis, the task of parsing is seen primarily as connecting concepts referenced in a sentence and selecting appropriate meanings to resolve potential ambiguities. In this process, as explored in ELI and later in Larry Birnbaum and Mallory Selfridges's CA (Schank and Riesbeck, 1981, pp. 318–353), the conceptual cases from incomplete CD representations provide expectations that are used to extract meaning from sentences and resolve potential ambiguities. For example, consider the conceptual analysis process for the sentence 'Mary ate a macintosh'. When the conceptual analyzer encounters the word 'ate' it maps that word to the conceptualization INGEST, which provides the expectation that its object will be a food. Because the food sense of 'macintosh' (a type of apple) satisfies the expectation, that meaning is selected instead of alternatives that are unlikely in context, such as a type of raincoat or computer.

Conceptual analysis provided a first, partial step towards realizing the integrated processing hypothesis. Although it did not yet bring higher-level knowledge to bear, it constructed a conceptual representation using a unified control structure to apply conceptual knowledge throughout its parsing process, without requiring an independent syntactic analysis phase (Schank and Birnbaum, 1984).

CAUSAL COHERENCE AND INFERENTIAL MEMORY

Extracting the meaning of individual sentences is only part of understanding: understanding their connections and ramifications is just as important. For example, a person would not be said to understand 'John won a million dollars and took a trip around the world', without also understanding that John's new wealth enabled the trip; or to understand 'John bought a book', without knowing that it is likely that he wants to read it; or to understand 'Mary sold a car' without knowing that she no longer has the car, and that someone else does. MARGIE's memory module generated plausible inferences from CD representations generated by ELI, in a spontaneous inference process. For example, given the input 'John gave Mary an aspirin', it generated inferences such as 'John believes that Mary wants an aspirin', 'Mary is sick', 'Mary wants to feel better', and 'Mary will ingest the aspirin'. This process identified the connections between new information and information in memory, in order to establish coherence.

MARGIE succeeded in bringing inferential memory to bear on understanding, but also demonstrated important limitations of general-purpose inference chaining models. First, despite the usefulness of general-purpose knowledge, such knowledge is not sufficient in itself: some inferences depend on highly context-specific knowledge. For example, a program (or person) with no knowledge of Japanese culture will be unable to infer why customers remove their shoes when entering a Japanese restaurant. Secondly, MARGIE's memory module identified a serious processing issue: that unguided inferencing is computationally infeasible. As inferences are drawn from an input, and then from those inferences, and so on through many inference levels, the rapid increase in the number of possible inferences will soon overwhelm any reasoning system. This limitation suggested that a new theory was needed to account for the ease of human inferencing.

SCRIPTS, PLANS, AND GOALS

The theory of scripts (Schank and Abelson, 1977) was developed as a solution to the problems of controlling inference cost and providing context-specific guidance. A script is a stereotyped sequence of events that take place in a particular context, such as the events involved in going to a restaurant (wait for a table, sit down, order, etc.). The theory of scripts proposed that in familiar situations, people rely on scripts to provide overall structure and context-relevant expectations for what will happen next.

Scripts distinguish normative features (e.g. that restaurant visits normally include ordering), from

unique features of a given instantiation (e.g. what was ordered on a given restaurant visit). This knowledge provides a basis for summarization of stories: in good summaries, the noteworthy points of a story are described, and events that can be routinely filled in are left unstated.

The application of script theory to understanding was demonstrated in Richard Cullingford's program SAM (Schank and Riesbeck, 1981, pp. 75–119). The system used ELI to generate a conceptual representation of sentences, to which scripts were then applied. The system could read newspaper articles and summarize them in a number of languages. In addition, the question-answering system QUALM, developed by Wendy Lehnert, could use high-level, script-based knowledge to fill in missing information in a focused way, and to answer questions going far beyond information contained explicitly in the texts it processed, even to the extent of understanding and answering questions about what did not happen in the stories. For example, if John ordered a hamburger, but left because it was burnt, SAM could use its knowledge of normative events to correctly answer the question: 'Why didn't John eat the hamburger?'

Script theory provides a model of understanding for routine, stereotyped events, and experiments by Bower *et al* (1979) provided psychological support for the existence of scripts as culturally shared human knowledge structures. However, script theory does not attempt to account for understanding the more interesting stories that concern novel situations. Understanding such stories requires being able to understand their characters' motivations: their plans and goals. This led Schank's group to develop a theory of the requirements for understanding goal-based behaviors: of plans and goals, and of themes, which provide background knowledge about why people have particular goals (for example, role themes provide expectations for the goals of actors in certain societal roles, such as waiters, doctors, or police). In conjunction with the study of plans, goals, and themes, the group developed theories of the processes involved in understanding plan-based stories, as demonstrated in Robert Wilensky's PAM (Schank and Riesbeck, 1981, pp. 136–179).

Study of scripts, plans, and goals increased our understanding of the high-level knowledge needed in understanding; the next step was to develop models of how this knowledge could be brought to bear at the first phases of the understanding process. The group's first attempt to integrate high-level knowledge into early understanding was Gerald DeJong's program FRUMP (Schank and Abelson, 1977, pp. 204–210). FRUMP used its scripts directly to guide processing of stories, skimming their texts for script-relevant content. This strongly expectation-based system was sufficiently fast and robust to process and summarize news stories directly from the newswire, in real time.

DYNAMIC MEMORY THEORY

People learn from what they read, and what they learn colors their interpretations of later experiences. SAM, PAM, and FRUMP, however, did not learn: no matter how many times they processed a particular story, they processed it in exactly the same way. The next major effort of Schank's group was to model the relationship between understanding, learning, and memory. One of the findings they sought to address was a surprising result from the experiments of Bower *et al* that people who read script-based stories with similar components may confuse their components when asked to recall events. For example, if a story involves visits to both a dentist and a doctor, picking up a magazine in one waiting room might be remembered as taking place in the other. This result suggested that when events are stored in human memory, they are not associated with independent scripts, but instead with knowledge structures that share components.

This insight led to the development of the theory of memory organization packets (MOPs) (Schank, 1982). Like scripts, MOPs characterize event sequences; unlike scripts, they allow a sequence to be composed of a number of lower-level components which can be shared by a number of MOPs. The basic components, which are called scenes, normally describe events that take place in a single location, with a single purpose, and in a single time interval. For example, the MOP for professional office visits contains steps that take place in the office, such as waiting in the waiting room, receiving the service, and paying the bill. Scenes such as waiting in the waiting room are specific to professional office visits, and are directly associated with that MOP; other steps in the sequence, such as receiving the service, are filled in by other MOPs or by scenes from other MOPs that are simultaneously active. For example, the 'get service' step for a doctor's visit is provided by the MOP `M-Doctor-Service`, and the 'pay' scene is supplied by `M-Contract`.

MOPs are organized hierarchically, inheriting properties of more abstract MOPs: `M-Doctor-Service` is itself a specification of the general

MOP `M-Use-Service`. MOPs also organize information about initiating and follow-up steps – for example, how to get to the appointment – which may also be filled in by other MOPs. Figure 1 illustrates the MOP and scene organization for some of the components required to process a visit to a doctor's office.

The act of payment after a professional office visit is usually standard regardless of the particular profession involved. Although `M-Doctor-Visit` and `M-Dentist-Visit` are distinct MOPs, both share the same `Pay` scene. When these MOPs are applied during understanding, their details are reassembled by combining their constituent scenes. This principle of sharing structures has a significant functional benefit: it enables cross-contextual learning. Once learning in one context has changed a scene, that learning is automatically reflected in all MOPs using that scene.

MOPs are not only a processing structure, but also a memory structure. Events are organized in memory under the scenes used to process them, and an instantiation of a MOP is retrieved by reassembling it from its constituent scenes. When those scenes are shared across different MOPs, events that occurred in one MOP may be remembered as occurring in another, explaining the observed recall confusions. Thus MOP theory explains both the cross-contextual learning capabilities and script confusions exhibited by people: both are consequences of a dynamic memory.

MOP theory is intimately related to how remindings occur. When people encounter new situations, they often find that other similar situations spontaneously come to mind. Because events are stored in memory under the scenes used to process them, when a MOP is used to understand a new situation, records of those events may become available. This is especially useful in helping us to understand expectation failures, when a new event deviates from a MOP's expectations and the understander is reminded of a previous event that deviated in a similar way. Remembering a past failure and its repair, for example, may suggest a way to repart a new failure.

MOP theory and memory organization were studied in Janet Kolodner's CYRUS (Schank, 1982, pp. 207–218), a system that studied the use of memory to answer questions after understanding. In addition to modeling how new MOPs are built and organized in memory, the system examined the process of memory search in which questions are generated, refined, and elaborated to answer questions in flexible ways. Michael Lebowitz's system IPP modeled MOP-based learning in an integrated understander (Schank, 1982, pp. 197–207). Rather than relying on static knowledge structures, IPP formed inductive generalizations from events it read about to build new MOPs, which it then used to interpret later stories. This enabled it to recognize routine events and to point out potentially interesting deviations. As an example of its processing, consider the following story from the *New York Times*:

> An Arabic speaking gunman shot his way into the Iraqi Embassy here [Paris] yesterday morning, held hostages through most of the day before surrendering to French policemen, and then was shot by Iraqi security officials as he was led away by French officers.

IPP's language processing was guided directly by its MOPs. Consequently, it could ignore words without significant conceptual content (e.g., the word 'way' in 'shot his way'), and could immediately process significant words to generate high-level expectations to guide future processing (e.g., processing the word 'hostages' activated a MOP for terrorist acts).

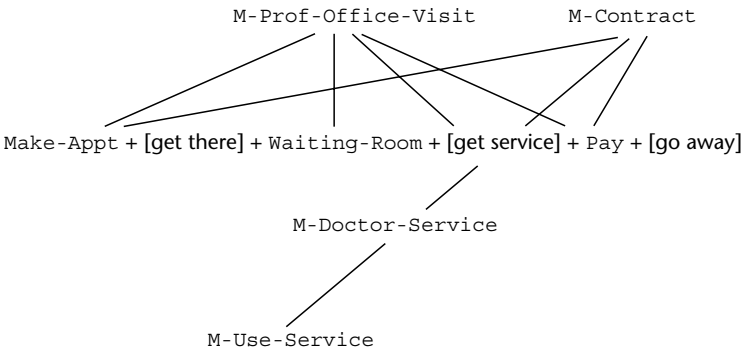

Figure 1. Some of the MOPs and scenes involved in understanding a visit to a doctor's office (Adapted from Schank and Birnbaum, 1984).

The beginning of this story is a fairly routine story of terrorism, but it is startling that the Iraqi officials shot the gunman after he had surrendered. IPP could recognize from experience that this shooting was exceptional, but could not reconcile the novel event with its other knowledge by explaining why it took place. How to model this aspect of understanding became the next research focus of Schank's group.

EXPLANATION PATTERNS AND CREATIVITY

When surprising things happen, people try to understand them by generating explanations. These explanations can in turn help guide the generation of new knowledge structures, the revision of existing knowledge, or the re-indexing of knowledge in memory. Work on explanation patterns, begun in the mid-1980s, combines the study of how to detect anomalies, how to generate new explanations, and how to adapt prior knowledge in novel ways – a form of creativity.

Building explanations from scratch is computationally intractable: it involves searching an enormous space of alternatives, often with very limited information to help narrow the set of possibilities. Thus it is a difficult question how to account for human facility at generating plausible explanations. In the SWALE project, the group investigated explanation using case-based reasoning: building new explanations by retrieving and adapting prior explanations (Schank, 1986; Schank and Leake, 1989). The SWALE system, developed by Alex Kass, David Leake and Chris Owens, was a story understanding system that used MOP-based understanding to account for routine situations and case-based explanation to explain novel events when its MOP-based understanding failed.

SWALE's namesake example was the story of a 3-year-old racehorse named Swale. Swale was in peak form, and had recently won two major victories, when a shocking headline appeared on the front page of the *New York Times*: Swale was dead. The death attracted much interest, both within and outside the racing community. A vast range of possible causes could be hypothesized for Swale's death, and little information was available to constrain the alternatives. Nevertheless, human explainers had little trouble generating plausible hypotheses, and prior experiences were often cited as the reasons for the hypotheses proposed. For example, one veterinarian's immediate reaction to the news was: 'This sounds like an aneurysm. I've seen this sort of thing before.' Swale's death reminded a Yale student of the death of the runner Jim Fixx, who died when the exertion of recreational jogging overtaxed a hereditary heart defect; the student therefore hypothesized that Swale's death was also caused by a heart attack. The explanation for Fixx's death does not apply directly – Swale was unlikely to do recreational jogging – but a minor adaptation of the explanation, substituting horse racing for jogging, produces the plausible explanation that the stress of running in a race overtaxed a hereditary heart defect. This process of retrieving and adapting prior explanations is at the heart of SWALE's understanding process. Later experiments by Read and Cesa (1991) provided psychological support for a human tendency to favor explanations supported by prior cases.

With sufficiently flexible retrieval and adaptation, the case-based explanation process also models a form of creativity. For example, Swale's death reminded one student of the death of Janis Joplin. Joplin was driven to recreational drug use by the stress of fame, and died from accidentally taking an overdose of recreational drugs. Little of that explanation applies to Swale: racehorses do not take recreational drugs. However, an essential part of the explanation is applicable: that Swale might have died of a drug overdose. By searching through its world knowledge to find potential supports, SWALE generates the hypothesis that Swale died of an overdose of performance-enhancing drugs administered by a trainer.

LATER MODELS

We have described a few landmark steps in the development of these theories of understanding, but many other models have been developed, and continue to be developed, by Schank, his students, and their own students. Charles Martin and Christopher Riesbeck's 'direct memory access parsing' (DMAP) (Riesbeck and Schank, 1999, pp. 319–352), for example, fully integrates parsing and understanding. In the DMAP model, expectations from a MOP-based memory are applied by a single, uniform parallel process. In this model, the goal of parsing is to interpret and impose structure – summarization is replaced with the formation of opinions – and the result of parsing is a new state of memory.

As the theories described above go beyond language *per se*, their ramifications also go beyond language. For example, the work on reminding and memory provided a foundation for research in case-based reasoning, which has had extensive influence beyond language processing for tasks

such as planning, design, and interpretation (Riesbeck and Schank, 1999; Kolodner, 1993; Leake, 1996). Looking at how people communicate led the group to study stories and storytelling: why people tell stories, how stories are indexed in memory, how they are understood, and the relationship between stories and intelligence (Schank, 1990). (*See* **Learning through Case Analysis**)

Recently the group has applied theories of human learning to education. This has led to the development of educational systems that support students' case acquisition by learning by doing in goal-based scenarios. Goal-based scenarios provide rich learning environments in which students learn skills and conceptual knowledge by performing activities in pursuit of compelling goals (Schank, 1998). Will Fitzgerald's research on indexed concept parsing has developed methods for robust, practical conceptual parsers to enable students to communicate with these educational systems.

CONCLUSION

Over many years, the work of Roger Schank and his students on natural language processing has been driven by the view that a theory of NLP must be a theory of how language is used to communicate information, which in turn requires addressing the cognitive processes underlying understanding, memory, and learning. Hence, in their view, the essential issues of natural language processing include issues such as the types of knowledge structures memory contains, how they are brought to bear, and how they change with experience.

The work on CD, scripts, plans, goals, and MOPs has all been aimed at understanding the knowledge structures that enable people to understand the world that language describes, and the processes by which these knowledge structures are applied and refined. This research has contributed both to artificial intelligence, by advancing the performance of computer systems, and to the understanding of human reasoning and learning. These models have generated a succession of research questions as they have identified issues that are central not only to NLP, but also to human cognition in general. These questions continue to drive research.

Natural Language Processing, Disambiguation in

Intermediate article

Graeme Hirst, University of Toronto, Toronto, Ontario, Canada

CONTENTS

Ambiguity pervades all levels of language. Any computer system that uses the meaning of natural language must disambiguate its input.

INTRODUCTION

Language is rife with ambiguity: a single utterance can, in principle, have many different interpretations or meanings. Usually, however, the speaker or writer intends just one of these meanings – usually, only one of them will make sense – and humans are adept at rapidly determining which one was intended, not even consciously noticing the others. Computer language-processing systems that use the meaning of an utterance in their task must therefore, like people, disambiguate their input. (*See* **Natural Language Processing**)

For example, an English-to-French machine translation system must decide whether to translate the word *duty* as *douane* or *devoir*, depending on whether its meaning in the utterance relates to an import tax or to a moral or legal obligation. A speech recognition system that hears [djuti] must decide whether it should be rendered as *duty* or *due tea*. Suppose a text interpretation system comes across this excerpt (from Jane Austen's *Persuasion*):

> The Admiral, after taking two or three refreshing turns about the room with his hands behind him, …

It must then decide whether the prepositional phrase *with his hands behind him* describes the room or the Admiral's manner of taking refreshing turns. And in either case, it must also decide exactly whose hands are behind whom. (*See* **Machine Translation**)

As these examples show, ambiguity can occur in many ways and at all levels of language. This article will cover ambiguities of syntax and of word senses, including the special case of pronouns. Most of the article applies to both spoken and written text, and the terms *speaker* and *writer* will be used interchangeably. Ambiguity can be treated more specifically at the phonetic level and at the morphological level. (*See* **Speech Perception and Recognition, Theories and Models of**; **Morphological Processing**)

LEXICAL DISAMBIGUATION

There are two kinds of lexical ambiguity – that is, of ambiguity of words. The first is ambiguity as to the syntactic category, or part of speech, of a word in an utterance: for example, the word *flies* can be used as either a verb or a noun. While only about 12 percent of the word types of English are ambiguous as to category, they tend to be the more common words, representing about 40 percent of the word tokens that are uttered (DeRose, 1988). The second kind of lexical ambiguity is ambiguity of meaning even after the part of speech is determined. (*See* **Lexical Ambiguity Resolution**)

Part-of-speech Tagging

Ambiguities of syntactic category are resolved as part of the process of 'part-of-speech tagging' – labeling each word in an input sentence with its category – which is the first stage of processing in many applications of natural language processing. The rules of grammar constrain the allowable sequences of syntactic categories – in English, for example, the base form of a verb may not immediately follow the definite article *the* – and about 60 percent of word tokens are not ambiguous as to category (including, in English, the articles *the* and *a*). Consequently, the category of a word can be resolved with a high degree of accuracy, 97 percent or better, just by looking at the categories of a few preceding words. It is easy to construct examples in which a much greater number is required, but such cases are rare in practice. Part-of-speech tagging is usually regarded as a probabilistic process in

which the most likely category is chosen in light of the two preceding words and the potential categories of the word under consideration. Two sources of information are thus required: a lexicon of words, listing the allowable categories of each, and knowledge of allowable sequences of categories along with their probabilities of occurrence. (*See* **Natural Language Processing, Statistical Approaches to**; **Lexicon**; **Lexicon, Computational Models of**)

The Nature of Word Senses

A glance at a page of a dictionary reminds us that it is only a small minority of words – mostly technical terms – that have only a single sense. When the senses of a word are closely related, the word is said to be polysemous. For example, *window* can mean either an opening in a wall (*crawled through the window*) or the glass that fits in the opening (*broke the window*). When the senses are completely different, the word is said to be homonymous. For example, *ash* can mean either a tree or the residue from combustion. A single word may be both homonymous and polysemous: *bank* is homonymous in its senses relating to financial institutions and to the edge of a watercourse; but, when pertaining to a financial institution, it is polysemous in that it can denote both the institution and the building in which the institution does business. In speech recognition, word sense ambiguity arises from similarity of sound rather than spelling; thus disambiguation is required between *see* and *sea*.

The conventional view of word senses assumes that for each word there is a fixed inventory of senses to decide among, and that for any particular utterance, to disambiguate is to choose exactly one of these senses as 'correct'. The assumption of a fixed inventory of senses has been challenged by many researchers (e.g. Kilgarriff, 1997), who point to the wide disparities in treatments of the same word by different lexicographers in different dictionaries, especially with regard to fine-grained distinctions between polysemous senses: what is one sense for one lexicographer might be two or three for another. And people often find it hard to decide which fine-grained dictionary sense best represents the meaning of a word in its context (Kilgarriff, 1992); often, they will say that a word is being used in two senses at once. For example, *Nadia visited the bank to get some money* seems to invoke *bank* as both building and institution simultaneously. Can we reasonably expect or require a computer to be more precise or decisive about word senses than people are? Often, it doesn't matter: in many applications of natural language processing, very fine-grained word sense disambiguation is unnecessary, and it suffices to resolve homonymy and perhaps coarse-grained polysemy at a level where there is reasonable agreement as to the inventory of senses. For example, a program that translates English to French needs to know whether an occurrence of *bank* is used in a financial or river-related sense in order to choose the correct translation; but, if it is used in a financial sense, the program need not decide between the institution and the building as the translation is the same in either case. (*See* **Word Meaning, Psychology of**; **Word Recognition**)

Methods of Word Sense Disambiguation

When an ambiguous word is a member of more than one syntactic category, part-of-speech tagging allows senses not associated with the category in which the word is being used to be eliminated from consideration; occasionally this yields a unique sense. A unique sense can also be assigned if the word is recognized as part of an unambiguous lexicalized compound; for example, if *private school* is listed as a phrase with its own meaning, there is no need to choose among the different senses of *private* and of *school*. But usually more sophisticated methods are required.

Many such methods are based on selectional restriction, relationship to the topic of the text, or both. In addition, the relative frequency of two different senses may be used to break a tie between them when other methods are unable to choose. In particular, when one or more of a word's senses are relatively rare, they may be eliminated from consideration unless there is positive evidence for them: for example, the noun *email* in its now-rare sense of enamel should be ruled out in favor of the electronic mail sense unless there is some particular reason to suppose that enamel is intended. Data on how frequent each sense of a word is can be derived from large corpora of text that have been disambiguated by humans or by semi-automatic methods with human verification. The accumulation of sufficient sense frequency data to adequately cover a language is an enormous task, however, and so far only relatively small sense-tagged corpora exist for English (Resnik and Yarowsky, 1999). Like relative frequency, the 'one sense per discourse' heuristic (Yarowsky, 1995) can serve as an adjunct to any other method. This heuristic relies on the fact that it is rare in practice for a homonym to be used in more than one sense within

the same text or discourse; so if, for example, the word *crane* occurs five times in a text and some disambiguation method deems it to be a bird in four instances and construction equipment in the other, then the latter is almost certainly wrong and should be corrected to the majority vote.

Selectional restrictions are the semantic constraints that a word sense may place on the senses of other words that combine with it. For example, the verb *eat* requires in literal language that its subject be an animate being and its object be something edible; so in *the mouse ate the corn*, we favor *mouse* as rodent rather than computer equipment and *corn* as cereal rather than callus. Metaphor and other kinds of nonliteral language can violate selectional restrictions (*the photocopier ate my report*), so such restrictions are helpful but not absolute constraints. Selectional restrictions vary in their degree of specificity: *elapse* accepts only time or a unit of time as its subject, whereas many different kinds of things can *grow*.

For a natural language processing system to use selectional restrictions, it first needs a knowledge base of the restrictions pertaining to each word sense, but no such knowledge base yet exists, and the creation of such a resource would be a large and poorly defined lexicographical task (the FrameNet project (Johnson and Fillmore, 2000) is a step in this direction). Resnik (1998) has proposed a process that can construct such a knowledge base automatically from a parsed corpus and an online hierarchical thesaurus such as WordNet (Fellbaum, 1998). For example, if the corpus contains examples of forms of the verb *drink* with objects such as *coffee, wine*, and *water*, the process can learn, by looking up these words in the thesaurus, that *drink* tends to select objects that are beverages or liquids. Resnik's experiments with the process showed that the information it derived was helpful, but of course not by itself sufficient for reliable disambiguation of word senses.

Many methods of word sense disambiguation have tried to capture the intuition that a good disambiguation cue, especially for homonyms, is the existence of a general semantic relationship between one of the candidate senses and those of nearby words in the text. For example, in proximity to the words *garden* and *pest*, the word *mole* is much more likely to refer to a mammal than to a skin blemish or a chocolate sauce. More generally, the topic of the text as a whole can be a helpful cue. The problem is how to make this idea precise and determine the semantic relationships.

Lesk (1986) proposed that dictionary definitions could be used for this. From an online dictionary, the definitions of all content words within, say, 100 words of the target word are found. Regarding this set of definitions as nothing more than a 'bag of words', with no consideration of the structure of the sentences or even the order of the words, the candidate sense of the target word is chosen that contains in its own definition more of the words in the bag than any of the other candidates. For a simplified example with just one word of context, consider the word *keyboard* in the phrase *the keyboard of the terminal*: its dictionary definition includes, in one of its senses, the word *computer*, as does one of the senses of *terminal*; accordingly, this sense of *keyboard* is chosen. Observe that *terminal* is similarly disambiguated. Lesk's method is surprisingly effective given its simplicity, and serves as the baseline against which more complex methods are compared (Kilgarriff and Palmer, 2000).

An example of a more complex method is the use of naive Bayesian classification to classify words according to which sense of each ambiguous word they tend to be associated with. For example, *money* tends to be associated with the financial sense of *bank*, and so do the words *loan* and *mortgage*, but *time* does not and *grass* is probably a contraindication. By looking at a very large corpus of text in which each word is tagged with its correct sense, and counting the number of times that each sense occurs with various other words in its proximity, we can compute the probability of any given word occurring in the proximity of each sense. Then, when disambiguation is necessary, the probability of each sense can be computed in the context of the nearby words, even if those words do not all indicate the same sense, and the sense with the greatest probability can be chosen. This method assumes that all the words in the context are conditionally independent of one another: the probability of seeing one word in context is independent of seeing any other word in the same context. Obviously, this is not true in practice, almost for the very reason that we want to use this method: words of related meaning tend to cluster. None the less, the method gives reasonable results. (*See* **Machine Learning**; **Natural Language Processing, Statistical Approaches to**)

However, this method is limited by the need for sense-tagged corpora as training data. Sufficient data do not exist to cover English, let alone less studied languages. Researchers have sought methods of circumventing this limitation. Yarowsky (1992) proposed that naive Bayesian classification could be used if the goal is not to determine the fine-grained sense of an ambiguous

word but merely an indication of the topic with which it is associated: in effect, resolution of homonyms, which, while coarse-grained, is none the less useful in many applications such as information retrieval. For example, instead of having to determine separately the probability that the word *money* indicates a certain sense of *bank* and so do *deposit* and *account* and *river* and *canal* and *creek*, we instead determine that any word related to finance indicates one sense of *bank* (or one group of senses) and any word related to watercourses indicates another. Yarowsky used the categories of *Roget's Thesaurus* as his set of topics. In an experiment on 12 ambiguous words that appeared in a total of 39 thesaurus categories, he determined, from a corpus of 10 million words, what other words were both frequent and salient as indicators of each of the thesaurus categories in which those words appeared; he then used these words in a naive Bayesian process to classify occurrences of the same 12 words in a test corpus. The results were very good for words such as *mole*, whose senses are generally topic-specific, but not for words such as *interest*, whose senses tend to cut across topics.

But while this method avoids the need for a sense-tagged corpus, it still requires supervised training – that is, its learning phase is still based on some predefined knowledge source, in this case the thesaurus. Yarowsky (1995) has also proposed a method by which decision lists for disambiguation can be learned by unsupervised training. A decision list is an ordered sequence of very specific conditions for classifying a word by meaning: for example, a decision list for the word *bass* might include the conditions 'if the next word is *player*, the topic is music' and 'if the next word is *are*, the topic is fish'. The list is derived from an extremely large corpus, along with a 'seed' – an extremely strong cue – for each sense of the ambiguous word (*bird* and *construction* could be seeds for *crane*). Because the corpus is so large – 460 million words in Yarowsky's experiments – the seeds are sufficient to indicate a number of definite occurrences of each sense, whose context words, in turn, suggest additional cues to each sense. When some of the data have been thus tagged, a classification algorithm is used to find additional rules. The process then iterates, alternating with the 'one sense per discourse' heuristic, until most or all occurrences of the ambiguous word in the corpus have been tagged. The resulting decision lists give a disambiguation accuracy similar to that of the thesaurus-based method.

Both of Yarowsky's methods require separate training for each ambiguous word, so in practice they have been tried only on a few test words. The task of using these methods to cover all ambiguous words of a language remains a daunting one.

STRUCTURAL DISAMBIGUATION

Structural ambiguity is ambiguity of the structure of the utterance itself, as seen in the 'Admiral' example above, in which the prepositional phrase *with his hands behind his back* could be a modifier of *taking*, describing the manner in which the turns around the room were taken, or of *room*, describing the room. The ambiguity in this example is often referred to as one of 'prepositional phrase attachment', as the problem is determining which node in the parse tree of the sentence the prepositional phrase should be attached to. There are many kinds of structural ambiguity (the attachment point of relative clauses is another important one) but prepositional phrase attachment in English has received the most study and will be the example used here. (*See* **Sentence Processing**; **Sentence Processing: Mechanisms**)

Because the ambiguity is reflected in the parse tree of the sentence, its resolution is part of the process of syntactic analysis of the sentence, or parsing. A common way to conceive of the problem is that the parser determines, from the rules of syntax of the language, what the possible attachment points are, and then asks some other process to determine which is most likely to be correct in context (Hirst, 1987). (However, in the case of lexically conditioned statistical parsers, such as that of Collins (1996), no distinction is made between attachment decisions that are mandated by the grammar of the language and those, the kind that are of interest here, that are 'discretionary'; in both cases, the decisions are based on the probabilities of syntactic dependencies between the particular words.) Structural ambiguity and lexical ambiguity are independent phenomena, but clearly resolution of either one interacts with resolution of the other: the best attachment point might depend on the meaning of a word, and the most likely meaning of a word might depend on a structural decision. In practice, however, the two ambiguities are usually considered separately. (*See* **Parsing**)

Prepositional phrase attachment ambiguity, in its simplest form, has three or four elements: a verb (e.g. *await*), the head noun of its object (e.g. *approval*), the preposition (e.g. *from*), and, in some methods, the head noun of the prepositional phrase (e.g. *government*). The disambiguation process must choose between the verb and the object head noun as the attachment point. Recent approaches have

tried, in various ways, to use the relative frequency of each attachment, as determined by statistics gathered from a large corpus of sentences. Because manual annotation of the corpus is not required, more data are available for this than for the analogous problem in lexical disambiguation. However, the problem is harder because even in very large corpora, most combinations of three elements occur rarely if at all; using four elements instead of three increases the potential accuracy of the method at the expense of exacerbating the sparseness of the data.

Taking the three-element problem, Hindle and Rooth (1993) achieved about 80 percent accuracy with an unsupervised training method based on the attachment probabilities that were observed in a 13-million-word corpus of newswire text. The corpus had been almost fully parsed but lacked resolution of its ambiguous prepositional phrase attachment points. The method computed 'lexical association (LA) scores', defined as the logarithm (base 2) of the relative likelihood of verb and noun attachment for triples: for example, LA(*send*, *soldier*, *into*) was found to be approximately 5.81, meaning that verb attachment is 56 (i.e. $2^{5.81}$) times more likely than noun attachment in the sentence *Moscow sent more soldiers into Afghanistan*. These scores were determined by first gathering data from cases of unambiguous prepositional phrase attachment in the corpus (such as attachments to subjects of sentences and attachments to verbs without objects) and then, where strong lexical associations were found, using these data to resolve ambiguous cases; the procedure iterated until as many scores as possible were computed. Ratnaparkhi (1998) subsequently obtained similar results from an unsupervised method that required only part-of-speech tagging of the corpus, not parsing, by improving the heuristics by which the unambiguous training cases could be identified in the corpus.

Taking the four-element form of the problem, Brill and Resnik (1994) also obtained about 80 percent accuracy with a set of disambiguation rules that were derived from a corpus by means of the same supervised transformation-based learning method that Brill had earlier used for part-of-speech tagging. The rules state conditions under which a particular attachment is more likely: for example, 'the attachment point is the verb if the preposition is *in* and the noun of the prepositional phrase is a measure, quantity, or amount' or 'the attachment point is the object noun if the verb is a form of *to be*'. The semantic categorization of words for the rules (for example, characterizing a word as a measure, quantity, or amount for the rule mentioned above) is based on the WordNet electronic thesaurus (Fellbaum, 1998). Disambiguation initially assumes that the attachment is to the object noun. The rules are then applied, in a sequence of increasing specificity, to possibly change that; the provisional choice of attachment point might alternate several times as the rules are applied.

PRONOUN RESOLUTION

The ambiguity of pronouns (and anaphora in general) is different from the word sense ambiguity treated above in that there is no fixed inventory of candidate senses. Rather, the pronoun has an antecedent in the text with which it corefers; to disambiguate the pronoun is to find its antecedent, and the candidates are those elements of the preceding text that are 'available' for pronominal reference (in a sense that we will make more precise below). (*See* **Anaphora**; **Anaphora, Processing of**)

The antecedent of a pronoun is distinguished from its referent in that the antecedent is an element of text and the referent is an object in the world. Consider the following text from Charles Dickens's *Our Mutual Friend*:

> 'Let me', says the large man, trying to attract the attention of his wife in the distance, 'have the pleasure of presenting Mrs Podsnap to her host.'

The antecedent of *his* is the noun phrase *the large man*, and the referent of both is Mr Podsnap. The antecedent of a pronoun may be another pronoun; thus a text of the form *Mr Podsnap … He … He … He* (all about Mr Podsnap) creates a 'chain' of coreference, with the second and third pronouns each having the previous pronoun as its antecedent. Although one might have instead said that *Mr Podsnap* is independently the antecedent of all three pronouns, viewing antecedence as a chain appeals to our intuition that the antecedent of a pronoun must be recent within the text. (*See* **Story Understanding**)

The resolution of a pronoun is thus a two-stage process: determining the candidate antecedents, and then, if there is more than one, choosing among them. We will consider each stage in turn.

Candidates for Antecedence

While textual recency is a criterion for antecedence, it is neither necessary nor sufficient; indeed, there need be no single explicit textual antecedent. What matters most is that the referent be in the 'focus of attention' at the point at which the pronoun is uttered. That the antecedent need not be recent

was shown by Grosz (1977) in her studies of people engaged in task-oriented dialogues, such as an instructor guiding an apprentice. Grosz found that when a partially completed task was resumed after a long intervening subtask, the speakers would often refer by pronouns to antecedents in the earlier discourse about the task; what mattered was that the particular task was again in the speakers' attention. That recency is not sufficient for an element to be available as an antecedent can be seen in this text:

> John put the wine on the table. It was brown and round.

Readers generally find this text to be somewhat odd, with the antecedent of *it* seeming to be *the wine*, even though *the table* is more recent and a table is more likely than wine to be brown and round. (In the terminology of centering theory, to be introduced below, this text is an example of a 'rough shift'.) That there need not be a single explicit antecedent can be seen in this text from Charles Dickens's *Our Mutual Friend*:

> Mrs Lammle bestowed a sweet and loving smile upon her friend, which Miss Podsnap returned as she best could. They sat at lunch in Mrs Lammle's own boudoir.

The antecedent of *they* is *Mrs Lammle* and *Miss Podsnap* together – a set that the reader must construct from separate elements of the text.

Choosing from Multiple Candidates

When there is more than one candidate antecedent, the choice among them is based on linguistic constraints and preferences and on common-sense knowledge of the world.

In most languages, pronouns are marked for gender, number, or both, and candidates that do not match these features are therefore immediately ruled out by these constraints; in English, a reference to a person can be eliminated as a possible antecedent for the pronoun *it*. Syntax also puts various restrictions on antecedence. For example, in English syntactic structures, if a nonreflexive pronoun functions as a complete noun phrase, its antecedent cannot be any node of the parse tree that is immediately dominated by another node that also dominates the pronoun. It is this rule that precludes *Nadia* being the antecedent of *her* in *Nadia baked her a cake*.

Syntactic structure can also determine a preference for one candidate over another. For example, a candidate antecedent that plays the same syntactic role as the pronoun is preferred over one that doesn't, especially if the sentences in which they occur exhibit 'syntactic parallelism'. For example, in *Nadia waved at Emily and then she shouted at her*, the preferred interpretation is that *she* is *Nadia* (both are subjects of their verb) and *her* is *Emily* (both are objects of their verb). Notice that if the pronouns are stressed heavily, the pattern is reversed; stress on a pronoun generally indicates that its antecedent is not the one that would normally be preferred (Kameyama, 1999).

One particularly influential theory of antecedence preference is centering theory (Walker *et al*., 1998). Centering theory relates the form chosen for a referring expression – such as the speaker's choice of whether or not to use a pronoun – to the focus of attention within the discourse, the syntactic structure of the text, and the difficulty of interpretation of the utterance. In the theory, each sentence within a discourse is said to have a 'center', which is, roughly, its topic or its most salient element; and each sentence of the discourse makes elements available, including its center, that could become the center of the subsequent sentence. These potential centers are ranked by their syntactic position – subject is ranked highest, then object, then other positions – and if any of these potential centers are indeed mentioned in the subsequent sentence, then the one that ranks highest in the first sentence is the actual center of the second sentence, regardless of its position in that sentence. Now, the center must always be pronominalized if any other element of the sentence is; thus, if a sentence contains just one pronoun and its antecedent cannot be found in the same sentence, that pronoun must be the center, and so its antecedent is therefore the highest-ranking potential center from the previous sentence. The following example is simplified from Thomas Bulfinch's *The Age of Fable*:

> Orpheus was presented by Apollo with a lyre and taught to play upon it. He did so to such perfection that nothing could withstand the charm of the music.

He is the only pronoun in the second sentence, so it must be the center, and its antecedent is *Orpheus*, which as subject of the first sentence outranks *Apollo*. This rule also explains the problem of the 'brown and round' example earlier; *it* is the only pronoun in the second sentence, and in the first sentence, *the wine* outranks *the table* as a potential center. Transitions like this, to a new center that is neither the center of the previous sentence nor its highest-ranking potential center, are very rare in naturally occurring text (Di Eugenio, 1998).

In observations such as these, centering theory thus provides a set of preferences that can be

employed in pronoun resolution and an explanation of the difficulty that people experience when the expectations that these preferences entail are not fulfilled (Hudson-D'Zmura and Tanenhaus, 1998).

By applying constraints and preferences such those just described, a natural language system can often determine a unique antecedent for a pronoun. Systems differ in the exact rules that they apply, the order in which they apply them, and how they trade off conflicting constraints and preferences. The system developed by Lappin and Leass (1994), for example, achieved an overall success rate of 89 percent on within-sentence antecedence and 74 percent on cross-sentence antecedence; since within-sentence antecedence is more common, the overall success rate was 86 percent. But an error rate of 14 percent is still too high for most practical uses.

It is not surprising that a system using only syntactic constraints and preferences will make mistakes relatively often, as knowledge of what 'makes sense' is often required to choose the correct antecedent of a pronoun. Lappin and Leass give this example (from a computer manual):

> This green indicator is lit when the controller is on. It shows that the DC power supply voltages are at the correct level.

Their system incorrectly chooses *controller* over *green indicator* for *it*; the two alternatives are rated equally in all respects (each is the subject of its verb) except for recency, which favors *controller*. Clearly, *indicator* is, in general, a 'better' subject for the verb *show* than *controller* is; this suggests the use of selectional restrictions, as used for lexical ambiguity, as an additional constraint. An approximation to this, frequency of co-occurrence, is proposed by Dagan and Itai (1990): statistics gathered from a large corpus would be used to give preference to the candidate antecedent that occurs more frequently as the subject of the verb *show*. Incorporating this and other heuristics into a single process, Mitkov (1998) has achieved anaphor resolution accuracy approaching 90 percent.

CONTENTS

Statistical approaches to natural language processing use large text corpora to allow rapid, robust, and accurate handling of the ambiguities in human languages.

INTRODUCTION

In a statistical approach to natural language processing (NLP), the operations of the system are based in some way on counts that have been made over a text corpus. Such a collection of texts is usually large, so that accurate estimates can be made from it. It may just contain normal sentences, or it may be text that has already been annotated with linguistic information, such as information about parts of speech, syntactic structure, or coreference.

What is counted depends on the particular model being used, and can range from simple word adjacency to sophisticated grammatical relationships – for example, how often a prepositional phrase modifies a noun phrase when the noun phrase contains a superlative adjective. Almost any theoretical model of natural language processing can be enriched with such counts, which provide the additional information of how often the various structures licensed by the theory occur.

These counts are normally used to set the parameters of a specific probabilistic model of language. Such a model can be of two types. Most research has used generative models, which place a probability mass function over the structural descriptions of a language that are allowed by the model. Other research, focusing on particular decisions (such as deciding the part of speech of a word) has used discriminative models, which simply learn to distinguish between the different parts of speech of a word. (*See* **Natural Language Processing**)

REASONS FOR ADOPTING A STATISTICAL APPROACH

Statistical approaches have transformed the field of NLP. Rather than hand-building categorical grammar-based models, much work now involves the induction of linguistic knowledge based on evidence from corpora. Even strongly grammar-based work is increasingly making use of corpus frequencies to encode preferences.

The widespread adoption of statistical methods in the 1990s coincided with broader trends in artificial intelligence and cognitive science towards the use of probability distributions to represent knowledge, and conditional distributions to infer knowledge. Computing power and online textual resources had grown sufficiently for statistical approaches to be feasible and successful. (*See* **Reasoning under Uncertainty**)

Such methods are very suitable for NLP because sentences of human languages are highly ambiguous: most words have various possible meanings and parts of speech, and often sentence structures are ambiguous as to how one part of a sentence relates to another. Thus the process of language understanding (and, indeed, also language generation and acquisition) frequently involves integrating and reasoning from incomplete and uncertain information, using not just the actual words uttered but also the prior discourse context and world knowledge. Probabilistic methods are a powerful approach to incorporating such diverse knowledge sources, and have been much more successful in practice than the heuristics, ad hoc algorithms, and grammatical approaches that were widely used previously. Moreover, rather than simply giving a structure to sentences, they provide a probability mass over sentence structures, representing how likely various structures are. This information has

proven vital in applications ranging from speech recognition to sense and sentence structure disambiguation. For instance, a speech recognition system will choose between several word sequence hypotheses (that sound similar to the acoustic signal being processed) based on which word sequence is more likely to occur in the language being recognized. (*See* **Natural Language Processing, Disambiguation in**)

HIDDEN MARKOV MODELS FOR ASSIGNING SYNTACTIC CATEGORIES

For many purposes, such as terminology extraction, partial parsing, lexical acquisition, and linguistically informed text searching, a useful level of linguistic analysis is to assign parts of speech (that is, syntactic categories like 'noun', 'verb', etc.) to each word in a text. This operation is generally referred to as 'tagging'. Tagging is a straightforward classification problem for which there is abundant training data available, and almost every machine learning method has been applied to the tagging task (Van Halteren, 1999). Hidden Markov models provide a natural generative probabilistic model for this problem (Bahl and Mercer, 1976), and have become the standard approach, though in general their performance is not significantly better than that of various other machine learning methods.

Consider the task of assigning parts of speech to the (*New York Times*) headline *Fed raises interest rates 0.5% in effort to control inflation*. Many of these words can have multiple parts of speech: *raises*, *interest*, and *rates* can be nouns or verbs, *to* can be a preposition or the infinitive marker, *in* is usually a preposition but has rare adjectival (*the in crowd*) and nominal (*he had some sort of in with the boss*) uses.

The two obvious sources of information to exploit in disambiguating such tokens are facts about the *a priori* distribution of the words (*raises* is used as a verb 9 times out of 10), and information about tag sequences ('determiner–noun' is a common sequence, while 'determiner–verb' is not). While the second of these sources of information may seem most obvious to a linguist, it turns out to be of limited use (for example, in the sentence above, *raises*, *interest*, and *rates* can all be either nouns or verbs, and either part of speech can follow another noun). The first source of information – which has no value as a categorical constraint, but only as a statistical constraint – turns out to have greater value (Charniak *et al*., 1993).

A hidden Markov model combines these two sources of information, as illustrated in Figure 1. When tagging, we wish to find the most likely tag sequence $t_1, \ldots, t_n$ for a sequence of words $w_1, \ldots, w_n$, which we assume to have been generated from an underlying (hidden) Markov process, where the states of the Markov model are taken to represent part-of-speech tags.

Using Bayes' rule, and the Markov assumption, we obtain:

$$\begin{aligned}
&\arg\max_{t_1,\ldots,t_n} P(t_1, \ldots, t_n | w_1, \ldots, w_n) \\
&\quad = \arg\max_{t_1,\ldots,t_n} P(w_1, \ldots, w_n | t_1, \ldots, t_n) P(t_1, \ldots, t_n) \\
&\quad = \arg\max_{t_1,\ldots,t_n} \prod_{i=1}^{n} [P(w_i|t_i) P(t_i|t_{i-1})]
\end{aligned}$$

The parameters of such a model can be easily estimated from a corpus of text that has been tagged by hand, although careful probability smoothing and estimation is necessary to deal with rare uses and previously unseen words. The most likely tag sequence for a new sentence can then be determined, on the basis of the above equations, by an efficient dynamic programming algorithm known as the *Viterbi algorithm*. When trained and tested on homogeneous corpora, modern taggers commonly get over 95% of part-of-speech tags right. However, performance can be considerably worse when the training and testing text differ in style or subject matter. (*See* **Statistical Methods**)

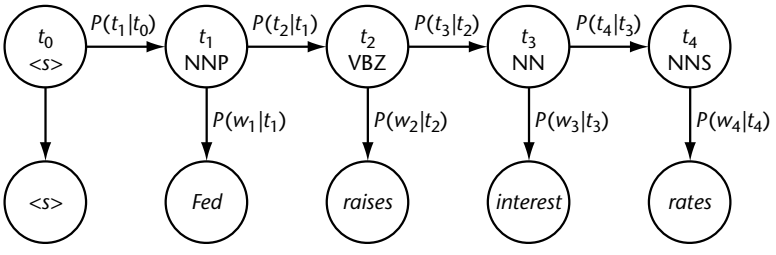

Figure 1. A hidden Markov model applied to tagging the sentence *Fed raises interest rates*. Arrows show direct probabilistic dependencies between part-of-speech states and words.

STATISTICAL PARSING

Parsing is the process of determining the correct structure for a sentence within the terms of a grammatical theory. Commonly, this involves a phrase structure tree representation. Because sentences' structures are highly ambiguous, a grammar that covers a fair proportion of general English (such as that found in newspapers) will typically produce dozens or even hundreds of possible parses for moderately long sentences. For example, in a sentence like *The board approved the acquisition [of the stores] [in Toronto] [at its monthly meeting]*, each of the three prepositional phrases at the end of the sentence is syntactically allowed to modify the verb or any preceding noun, so there are many possible structures. Whereas traditional parsers find all such structures, and then (sometimes) attempt to disambiguate on the basis of preferences or categorical selectional restrictions, statistical parsers attempt to chose the most likely parse for a sentence, by making use of statistics on how likely different words and phrases are to combine together in a sentence.

In the 1990s, new statistical parsers capable of successful, robust, rapid, broad-coverage parsing were developed (Charniak, 1997; Collins, 1997). The improvements were of three kinds. Firstly, since probabilistic language models use measures of likelihood instead of hard grammar rules, such parsers will find *some* analysis for any sentence. They will not fail to parse a sentence because of limitations of the grammar, or because it falls outside some narrow conception of grammaticality. Secondly, these parsers can work quickly. Traditional parsers exhaustively find all possible analyses for a string, but statistical parsers keep track of the most likely partial parses and expand just those. This generally involves orders of magnitude less work. Indeed, by using various methods to prune the search space, several modern probabilistic parsers parse in time linear in the sentence length (categorical parsers are typically cubic or worse).

The third and most important improvement was in accuracy. Statistical parsers use facts about word relationships to resolve ambiguities as to which parse structure to assign. The central statistics used in most current parsers are 'bilexical head dependencies', which are commonly collected from 'treebanks' of hand-parsed sentences. For example, if we are considering how to parse *Fed raises interest rates*, then on the hypothesis that *raises* is a verb, we would consider how frequently the subject relationship [*Fed, raises*] and the object head relationship [*raises, rates*] occur, whereas on the hypothesis that *interest* is the main verb, we would ask how likely it is that *raises* is the subject of *interest* and *rates* is the object.

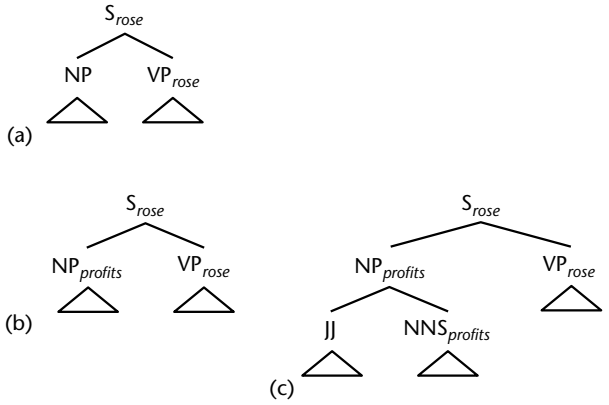

Figure 2. In the lexicalized probabilistic context-free grammar model of Charniak (1997), the generative model proceeds from a state such as that shown in diagram (a). It then determines the head $h =$ 'profits' of a non-head child given its category $c =$ NP and the head $h_P =$ 'rose' and category $c_P =$ S of the parent, using the probability function $P(h|h_P, c, c_P)$, to give diagram (b). Then it determines a rule r to expand this child using the probability function $P(r|h, c, c_P)$, to give diagram (c). This strategy is then iterated recursively.

Evaluation of these dependencies is generally achieved by lexicalizing a context-free grammar, so that the head word of each phrase is annotated on the parent node. Bilexical head relationships are then parent–child relationships. An example is [*profits, rose*] in Figure 2 (which follows the approach of Charniak (1997)). A generative probabilistic model predicts how likely nodes are to be headed and expanded in different ways. Although the probabilistic model uses top-down probabilistic conditioning, the actual computation is done using a bottom-up chart parser, which makes extensive use of search space pruning. Because of the extreme sparsity of bilexical head pairs, a lot of work goes into robust statistical estimation of the probability distributions shown in the figure, commonly via various forms of clustering and back-off. On newswire sentences (with an average length around 25 words), the best versions of such statistical parsers get about 90% of the postulated nodes in the parse tree right; and they get the overall constituency structure of the whole sentence right about 70% of the time (Charniak, 2000).

STATISTICAL EXTRACTION OF LEXICAL SEMANTICS FROM CORPORA

While knowing parts of speech and syntactic structures is helpful to human language interpretation,

most people apart from linguists are mainly concerned to understand not the structure but the meaning of human language sentences. In order to approach this goal, there has recently been a lot of interesting work on learning knowledge, in particular lexical semantic knowledge about word meanings, from large corpora. The idea is that a computer program, rather than having to have facts about word meanings encoded into it, can learn them by 'reading' a large corpus. For example, it can learn that a 'durian' is a kind of fruit, that 'image' and 'picture' mean roughly the same thing, or that people frequently 'repeat' a 'comment' but not typically an 'article'. All statistical NLP models need a large amount of information about individual words, many of which are quite rare, and whose meaning and manner of use varies between different genres or time periods.

Many approaches to this task have been explored. Some methods are similar to information extraction, where particular textual patterns that mark certain semantic relationships are detected. For example, Hearst (1992) used such methods to learn the hyponym ('is a kind of') relationships of a semantic hierarchy by matching frames such as '[*X*], a kind of [*Y*] …' in text corpora.

Other researchers have followed statistical approaches. Context vectors, which are counts of the words around instances of particular words, can be used with some success as a surrogate representation for the meaning of a word (Schütze, 1997). Richer syntactic relationships can be used to represent finer-grained semantic relationships. For example, clustering nouns based on just their modifiers can be an effective way to group nouns that share the same essential properties (Grefenstette, 1996); and clustering between pairs of verbs and the head noun of their object can pick out semantic classes of verbs, such as verbs of scalar motion or verbs of disposition (Rooth *et al*., 1999).

While all of these methods have had some success at learning partial semantic representations from large quantities of unannotated text, their success has so far been limited, both in terms of accuracy and in terms of the richness of the semantic information acquired. Finding effective methods for acquiring semantic information from large unannotated text corpora remains one of the central challenges for future NLP work. (*See* **Statistical Methods**)

Natural Language Processing

Introductory article

James F Allen, University of Rochester, Rochester, New York, USA

CONTENTS

Natural language processing is a field that explores computational methods for interpreting and processing natural language, in either textual or spoken form.

INTRODUCTION

Computers that can speak and understand natural language have long been a key component in science fiction. Actually building machines that can understand and produce speech, however, has proven to be exceptionally difficult. While research started in the first days of functional computers in the 1950s, the complexity of the problem thwarted researchers for decades. Recently, however, significant progress has been made and, while machines are far from understanding language like humans do, useful applications involving language are now possible. We see dictation systems that allow someone to dictate a letter to a computer, internet search engines that look for pages with certain content, automated telephone systems that allow you to dial numbers and make collect calls just by speaking, and systems that can answer simple questions about the weather, traffic or stock quotes over the telephone. In addition, more sophisticated language processing systems are currently under development and will become usable in the next few years.

It is important to realize that there are several different motivations for work in natural language processing. On one side, there are engineering goals, where one is interested in finding techniques that allow computers to perform practical tasks. On the other are the cognitive science goals, where one is interested in the insight that computational models can provide for understanding human language processing. While there is overlap in research towards these goals, this article will focus mainly on issues of relevance to the cognitive science goals.

INTRODUCTION TO RELEVANT LINGUISTIC NOTIONS

The principal difficulty in processing natural language is the pervasive ambiguity that is present. Ambiguity is found at all levels of the problem. For example, all natural languages involve:

- acoustic ambiguity (given a speech signal, what words were actually spoken?);
- lexical ambiguity (e.g. 'duck' can be a noun (the animal or the cloth) or a verb (to avoid something thrown));
- structural or syntactic ambiguity (e.g. in 'I saw the man with a telescope', the telescope might be used for the viewing or might be held by the man being observed);
- semantic ambiguity (e.g. 'go' as a verb has well over ten distinct meanings in any dictionary);
- pragmatic ambiguity (e.g. 'Can you lift that rock?' may be a yes/no question or a request to lift the rock); and
- referential ambiguity (e.g. in 'Jack met Sam at the station. He was feeling ill…' it is not clear who is ill, although the remainder of the sentence might suggest a preferred interpretation).

All these forms of ambiguity may interact, producing an extremely complex interpretation process. It is the prevalence of ambiguity that distinguishes natural languages from precisely defined artificial languages such as logic and programming languages. It also makes most of the techniques developed in programming language grammars, parsing and semantics, ineffective unless significantly modified.

It will help to break apart language processing into different phases as shown in Figure 1. One side involves the understanding processes, in which we move from speech to intentions. The other side involves generation, moving from intentions to speech. The stages of understanding language consist of transforming sound into words (speech recognition), words into meaning (understanding), and meaning into knowledge, intention, and action

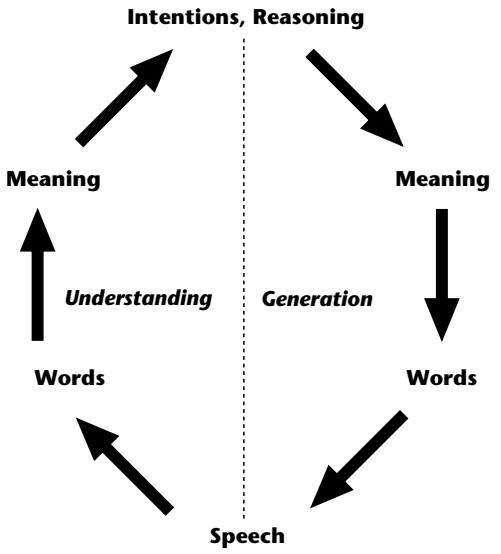

Figure 1. The stages of natural language processing.

(pragmatics and reasoning). For instance, say someone comes up and speaks to you. Using speech recognition you identify the words as *Do you know the time?* Using understanding techniques, you identify the meaning as a question about whether you know the time. Finally, using pragmatics and reasoning you decide that the stranger wants you to tell him the time and decide to answer the question. The stages of language generation account for the opposite process of generating a response. You decide to respond and form an intention to tell him the time, this is mapped into a meaning (content planning), then meaning to words, say, 'It's three p.m.' (generation), and finally words to sound (speech synthesis).

Each of these steps will be considered below. For many applications, we need only one or two stages. For instance, current dictation systems do only the first phase, mapping speech to words, and do not interpret the words any further.

SPEECH RECOGNITION: SOUNDS TO WORDS

While speech recognition systems are in use in practical applications now, they work well only in some specific situations. The important factors affecting the performance of recognition systems include:

1. the size of the vocabulary to be recognized,
2. the range of speakers that need to be handled,
3. the quality of the sound capture devices (e.g. microphones and recording), and
4. the style of the speech itself.

In general, the smaller the vocabulary, the smaller the number of speakers, the better the sound capture, and the more controlled the style of the speech, the better the recognition is. In practice, however, we usually have to balance one aspect against another to get acceptable performance in a specific application. For example, the systems that allow you to make long distance calls entirely by voice must handle hundreds of thousands of customers. They compensate for the problems caused by the large number of speakers by using a very small vocabulary (e.g., just digits and words such as 'yes' and 'no'), and by constraining the style of the speech by giving specific instructions to the person about what to say when. By doing this, the applications are usable and are saving telephone companies millions of dollars a year in operation costs. A very different case involves dictation systems. These must handle large vocabularies, say 40 000 to 100 000 words. To compensate for this, they are trained for a single speaker using a microphone held close to the mouth, and require people to speak carefully. Under these conditions, such systems can attain 95% word accuracy or better for many users.

As we start to relax the constraints more, accuracy starts to plummet. For example, currently the best speech recognition systems, when trying to recognize spontaneous speech in real time between two people having a conversation, can recognize only half of the words correctly.

Most speech recognition systems use the same basic set of techniques. The acoustic signal is digitized and converted into a sequence of sound frequency–intensity plots covering small segments of the speech. These plots are used to extract out a vector of measurements, such as intensity in different frequency bands, changes of intensity in different frequency bands from one window to the next, and the acceleration of changes of intensity in the different frequency bands. The vectors are then classified into categories based on their similarities to 'prototype' vectors. Typically, systems use 256 or 512 different categories, which comprise the *codebook*. At this stage, the signal has been converted into a sequence of symbols from the codebook.

The next phase of analysis uses models of the relevant linguistic events you want to recognize, such as words or phonemes. For large vocabulary recognition, word-based models are too hard to construct, and phoneme-based models are too inaccurate. As a result, most large vocabulary recognition systems use subword models, an intermediate level about the size of syllables, larger than the phoneme, but smaller than a word. Each

subword is represented by a Hidden Markov Model (HMM), from which one can compute the probability that a certain sequence of codebook symbols might have been generated in producing that subword. To perform speech recognition on an input signal represented as a sequence of codebook symbols, one simply finds the sequence of subword that maximizes the probability of producing that input signal.

The power of HMMs is that there are known effective algorithms for estimating the transition probabilities from a corpus of speech data, and for finding the path through a given HMM model that maximizes the probability of observing the input (the Viterbi algorithm).

So far, the description of the system has considered acoustic information only. Using only acoustic information, speech recognizers do not perform well. They must also use higher level linguistic information to predict what word sequences are likely to occur. This is called the language model. There are two types of language models in common use. The first is called an *n-gram model*, which is a probability model that specifies the probability of a given word w following a sequence of the previous $n-1$ words. A 2-gram (or bigram) model, for instance, simply provides the probability that the word w will follow the previous word. Such n-gram models are built by estimating the probability distribution from a large corpus of transcripts of speech. In an ideal world with unlimited data, one would use large amounts of previous context. In practice, however, speech recognition systems typically only use bigram or trigram models. Given an n-gram model, one can construct an HMM and use the training and search algorithms developed for HMMs to drive the recognition process. The other type of language model is the *probabilistic finite-state machine*. This is simply a probabilistic graph that specifies all possible sequences of words that can occur in interactions. This technique is common in practical applications where the vocabulary and range of language is not large.

APPROACHES TO LANGUAGE PROCESSING

As we consider the other levels of language processing, especially language understanding, we have a problem. With speech recognition, we know what the desired result is, namely what words were spoken. But we do not have such a clearly defined notion of what meaning and understanding are. This means it is hard to evaluate how well we are doing. The classic answer to this problem has been the Turing test. A system would be said to understand if a set of human judges could not distinguish a machine from a human by asking any questions they wished for as long as they wished. The problem with this test is that it is an all-or-nothing evaluation. It is hard to use this method to help drive incremental progress since we are so far from the goal. Today, most researchers in the field take a pragmatic approach and consider how well language systems can perform a specific task. For example, say the task is to find relevant webpages given natural language input such as the sentence 'I want to find sources that deal with economic growth in the late nineteenth century'. For such an application, we evaluate how well it does the task, say by checking how many relevant pages it finds (the recall) and what proportion of the pages found are relevant (the precision).

In the early decades of research (1960–1990), it was believed that machines would have to acquire a capability for 'deep' understanding of language before the technology could be useful. Deep understanding involves constructing a precise specification of the meaning of the sentence and being able to perform reasoning on the information. In the 1990s, however, researchers found that 'shallow' statistical analysis techniques that capture only some structure and content of language could be useful in a wide range of applications. For example, most webpage search engines just look for documents that contain the words or short phrases found in the query. While such techniques produce robust systems with reasonable recall, the precision is often a problem. You may find that the system returns so many irrelevant webpages that finding the appropriate ones can be very difficult. In addition to information retrieval, there are many practical applications, which are becoming feasible using statistical approaches, that fall far short of 'deep' understanding including information extraction (e.g., generating a database of merger and acquisitions activity from newspaper reports), information access (e.g., using speech over the telephone to find out information on airline schedules), rough machine translation (e.g., automatically translating equipment maintenance manuals), and writing tools (e.g., spelling correction and grammar checking tools in word processors).

For some period of time, many researchers viewed the deep and statistical processing techniques to be in opposition to each other. More recently, most researchers realize that each area of work addresses different aspects of the problem

and that both are needed for long-term success in the field.

COMPUTATIONAL PHONOLOGY AND MORPHOLOGY

Language is made of words, either realized as sound or in written form. Sometimes words are considered atomic elements of language, but they actually have a rich structure. Many languages use a wide variety of word forms to indicate how words relate to each other in the sentence. In English, we see word forms to encode number and person agreement between pronouns and verbs (*I am, you are, she is, they are, …*), grammatical role in pronouns (*he, his, him*), tense and aspect (*go, went, gone, going*), parts of speech (*destroy, destruction*, *destroyable, destructive, destructively*) and semantically related words (*untighten, retighten, pretighten, overtighten*). The study of the structure of words and how different forms relate to each other is called morphology, and the development of algorithms for processing word forms is computational morphology.

A very useful computational technique is called *lemmatizing*, which identifies the root form (or lemma) and *affixes* of a word for further processing. For example, such a system might break apart the words weave, wove, woven, and weaving into a root form *weave* plus features such as *present, past, pastparticiple*, and *presentparticiple*. Stemming is important as a first pass for producing deeper structural and semantic analyses of sentences as the lemmas typically identify key components of the semantic content. Another application of stemming is in information retrieval, where it would be useful for all the forms of *weave* to map to the same lemma. Thus if you look for documents that include the word *weave*, the program would also find documents that contain the word *wove*.

One of the most influential techniques for morphological analysis uses finite-state transducers (FSTs), which are finite-state machines that produce an output for every input. Such a device would take a word like *happier* as input and produce the output *happy* + *er* using an FST that maps the first four letters to themselves, then maps the *i* to a *y*, inserts a space, and maps the last two letters, *e* and *r* to themselves. One of the most common frameworks for morphological analysis uses a set of FSTs that are run in parallel; all of them must simultaneously accept the input and agree on the output.

Phonology studies the relationship between words and how they are realized in speech. The idealized sounds of language are captured by an alphabet of *phonemes*, each phoneme representing an abstraction of a primitive meaningful sound in the language. In actual fact, the same phoneme can be pronounced very differently in different contexts. These variants within a single phoneme are called *allophones*. Computational models of phonology are important in both speech synthesis and speech recognition work. It is not feasible, for instance, for a speech synthesizer that can read books to have a mapping of all words to their pronunciation. Rather, it often has to produce a phonetic spelling from the orthographic spelling of the word. In general, the same computational techniques used for morphological processing are also used for phonological processing.

PARSING

The process of parsing involves mapping from a sequence of words to an internal representation. A *syntactic* parser takes a grammar and a word sequence, and finds one or more combinations of rules in the grammar that could produce the word sequence. The output then is a parse tree that shows the different phrasal constituents that make up the sentence. A *semantic* parser maps a word sequence to a representation of its meaning in some formal meaning representation language. Most modern grammars and parsers combine these two tasks and construct a syntactic structure and a meaning representation simultaneously using *rule-by-rule compositional semantics*. In such an approach, the rules in the grammar specify not only structural relations (e.g., a noun phrase can consist of an article ('A') followed by a noun ('dog')), but also a fragment of the meaning representation, say, in some form of logic. As rules combine smaller phrases into larger ones, the meaning fragments of the smaller phrases are combined into larger fragments for the entire phrase. It is possible to separate these processing phases and use a grammar that produces a solely syntactic structure, and then define another set of rules for mapping the syntactic structures into meanings. But so far researchers have found little advantage in doing so. It is also possible to forgo syntactic processing altogether, and attempt to build a meaning representation directly from the word sequence. Such approaches are typically only used in quite limited applications in which the sentences remain fairly simple, and the meaning representation is specialized to the particular application and lacks generality.

The most common grammatical formalisms used in computational systems are augmented

context-free grammars. Such grammars have a core context-free grammar, but each rule is associated with a set of features that capture grammatical phenomena such as number agreement and encode semantic information. Most of these systems use *feature unification* and can use quite elaborate typed feature structure systems. For example, the rule

```
NP[AGR ?x] -> ART[AGR ?x] N[AGR ?x]
```

states that a noun phrase (NP) can consist of an article (ART) followed by a noun (N), but only the ART and N have compatible agreement feature (AGR) values. Furthermore, the NP acquires the same agreement feature. For example, the word *the* allows both third person singular and plural forms, so its AGR feature would be a set consisting of 3s (third person singular) and 3p (third person plural). The word *dog*, on the other hand, allows only third person singular, so the AGR feature would be the singleton set {3s}. Feature unification is like set intersection, so these two features can be unified and the result is {3s}. This becomes the AGR value of the newly introduced NP constituent. Likewise, agreement would be enforced between the subject and the verb by the S rule (a rule for sentences) that combines an NP followed by a verb phrase (VP). Note that with the AGR feature, the grammar will not accept sentences such as *A dogs barked* or *The dogs barks* even though the word sequences are fine based simply on the basic word categories. Figure 2 shows a parse tree that is the analysis of the sentence *The dog barked*, showing the basic categories and the AGR feature.

Context-free grammars augmented with feature unification provide the power to express much of natural language in fairly concise ways, and have become the most common grammatical formalism for computational grammars. They have also provided the formal underpinnings for linguistic theories such as head-driven phrase structure grammar (HPSG) and lexical-functional grammar (LFG).

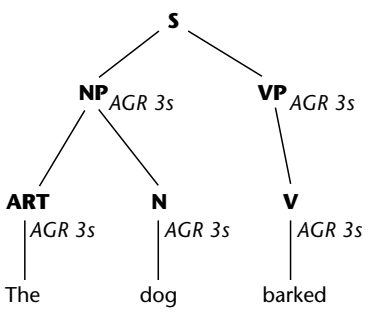

Figure 2. A parse tree.

A parser performs a search process through the possible combinations of grammatical rules to find trees that can account for the input. Most modern parsing systems use some form of chart parsing. A *chart* is a data structure that keeps track of the work done so far in parsing: both the possible constituents that have been found so far, and the rules that have partially matched so far. The parser then runs by constantly updating the chart with new information. There are two properties of chart parsers that make them efficient. The first is that the parser never does the same work twice. Before doing any work, it checks the chart to see whether the work has been done before. The second property is that information is shared across different possible interpretations. For example, a particular noun phrase might be able to be used in a number of different overlap interpretations. That noun phrase, however, appears only once in the chart.

SEMANTICS: LEXICAL AND COMPOSITIONAL

Semantics concerns the meaning of sentences. We need to define a language in which to express that meaning, and we need some method of computing the meaning from the parse tree. To start this process, we need to associate meanings with words. Words typically have many senses (e.g., 'seal' can denote an animal, a gasket for making containers airtight, a symbol representing some authority, or an action of closing an envelope). Such meanings can often be arranged hierarchically according to their properties. For example, a 'seal' is a particular type of animal, which is a living thing, which is a physical object. The properties of being a seal arise from particular properties of seals (e.g., seals bark), from more general properties (e.g., animals eat, physical objects have weight). Such representations are often called *semantic networks*. These properties are important for helping determine the appropriate sense while parsing. For instance, if we have a sentence 'The seal ate a fish', then we can conclude that we are talking about a seal as an animal, and not the seal of a canning jar, or the symbol of the president of the United States.

Other words tend to have more complex semantic structures. A verb, for instance, typically requires a set of arguments to complete its meaning. For instance, the verb 'put' describes some sort of physical action, which is determined once we know who did the action, what was acted upon, and where it went. In many computational representations a complex object is defined as a *type* and a set of *roles*. The roles for the PUT action might

be called AGENT, THEME, and TO-LOC. Such representations have been proposed in philosophy by Davidson, in linguistics by Fillmore, and are often called *frames* in computational work. Expressed in first-order predicate calculus, the meaning of the sentence *Jack put the book in the box* might be

```
∃e . PutEvent(e) & AGENT(e, J1)
  & THEME(e, B1) & TO-LOC (e, B2)
```

where the constants J1, B1, and B2 are defined elsewhere and represent Jack, the book, and the box. In a frame-like knowledge representation, this might be represented as

```
[PUTEVENT e
  [AGENT J1]
  [THEME B1]
  [TO-LOC B2]]
```

but the semantics remains the same.

Compositional Semantics

One of the key ideas used in many modern parsers is compositional semantics, where the semantic form of the sentence is constructed simultaneously with the syntactic form. Each rule in the grammar specifies both syntactic and semantic operations. To make this work, systems use either feature unification or lambda abstraction. For instance, the meaning of a VP 'ate the pizza' might be

```
λ x . [EAT [AGENT x] [THEME P1]]
```

which is a function that takes an argument and places it the AGENT slot. With this interpretation, the semantic component of a grammatical rule for declarative sentences, namely

```
S -> NP VP
```

would apply the meaning of the VP (like *ate the pizza* above) to the meaning of the NP to produce the meaning of the sentence. While the lambda calculus provides a nice formal model for compositional semantics, many parsers do the equivalent thing using feature unification. For example, we could write the same rule as

```
S[LF ?lf] ->
  NP[LF ?subj] VP[SUBJ ?subj LF ?lf]
```

Here, the VP rule would produce a constituent of the form

```
VP[SUBJ ?s LF [EAT [AGENT ?s] [THEME
  P1]]
```

and when the S rule is applied, the *?subj* variable will be bound to the meaning of the subject NP and the LF feature of the new S constituent would be bound to the completed LF in the VP.

Robust Interpretation

In many applications, it is not feasible to require a full syntactic analysis of each sentence. For example, in a spoken dialogue system, speech recognition errors may prevent the parser ever receiving all the correct words spoken. In a system that retrieves relevant articles from a newspaper database, we can't expect to have a grammar that has full grammatical coverage. In these cases, it is important to be able to extract out fragments of meaning from the input. Using a bottom-up chart parser provides one obvious approach. Even if a full syntactic analysis is not found, the chart will contain analyses of parts of the input – the major noun phrases, for instance. And given these analyses it may be possible to infer the intended content of the entire utterance. For example, consider a system that interacts with a user in spoken language to identify good routes for trains. Say the conversation has concerned a particular train TR1. The next utterance is *now send it on to Avon via Bath*, but say the speech recognition output is 'NOISE ENDED TO AVON VIA BATH'. From the fragments, one can recognize a path (to Avon via Bath), and from the discourse context, one knows the topic was train TR1. Thus, it is likely that the speaker intended to send TR1 from Avon to Bath.

For applications such as information retrieval and information extraction from textual databases, most systems forgo full parsing altogether and depend entirely on pattern-based techniques that look for patterns in the input that relate to information of concern.

PRAGMATICS: SPEECH ACTS AND DISCOURSE

Applications that involve interaction in natural language require significant processing beyond deriving the semantic interpretation of an utterance. In everyday language, a conversational system needs to recognize what the intentions of the user are in order to respond appropriately. For instance, a sentence such as *Do you know the time* might be a question about your state of knowledge, a request that you tell the speaker the time, or a reminder that it is late. Each of these different acts is called a *speech act*. Typically, the linguistic structure of the utterance does not identify which speech act has been performed. We need to consider the larger context of the conversation, namely the current situation and

what we know of the user's plans and goals, in order to identify the correct speech act.

The context of a conversation, or discourse in general, is captured by several different components. Two of the most important are the attentional state and the intentional state. The attentional state includes the recent history of the conversation, especially information about what was said in the last utterance. The objects mentioned in the last utterance are the most likely candidates for pronominal reference in the current sentence. In addition, the structure of the last sentence is needed to interpret forms of ellipsis (e.g., *I went to the store. John did too*.) One of the more influential models for pronoun interpretation is *centering theory*. This model places a high reliance on the objects mentioned in the immediately previous sentence, and distinguishes one object as most relevant.

The intentional state captures the motivations of the speakers engaged in the conversation. In general, computational work has focused on practical, or task-oriented, dialogue in which the participants are speaking to each other in order to perform a certain task, be it obtaining information, learning mathematics, getting help on home repair, or designing kitchens. In all these domains, we can represent the reasoning processes of the participants as a form of *planning*. The study of planning has a long history in artificial intelligence and is typically formalized as a search process through possible future actions. Actions are represented as operators that change the world, and are typically described in terms of their preconditions (what must be true when the action is attempted) and effects (what will be true after it is successfully executed). The process of planning starts with a library of actions, an initial world state, a statement of the goal conditions, and searches for a sequence of actions that can be executed starting in the initial state and resulting in a state that satisfies the goal conditions. By modeling the participants' planning processes, we can interpret their utterances by finding out how their utterances further their goals. These techniques can be used to address many problems, including word sense disambiguation (which reading makes sense in the plan), pronoun reference (which objects are most likely to be used in the plan), and most importantly, what speech act is intended. To do this last task we must model speech acts as operators in a planning system. The effects of a speech act are changes in the speaker's and hearer's mental state, namely their beliefs and goals. For example, an effect of a REQUEST act is that the hearer knows the speaker wants to get the hearer to do the requested act. By considering each possible speech act and how their effects might fit into the current task, we can determine which interpretation makes the most sense in context (e.g., a process called *plan inference*). A simple plan-based conversational agent uses plan inference to identify plausible goals of the user, and then uses planning to plan a response that is most helpful given the current task.

GENERATION: MEANING TO WORDS

The generation side of natural language processing has the same distinctions and levels of processing as the interpretation side. It is often viewed as a planning problem, where the input is a set of communicative goals and the output is a series of utterances that realize those goals. The process is typically broken into at least two levels: content planning, in which the system decides *what* needs to be communicated, and surface generation, in which the system determines the details of *how* it is to be communicated.

Content planning can roughly be thought of as mapping from abstract communicative goals (e.g., describe how to find the car in the parking lot) down to a sequence of specific speech acts (e.g., REQUEST that the person first go to the library entrance, then …). Rather than planning from first principles, generation is usually driven by larger scale *schemas* that relate conversational goals and specific circumstances to particular strategies for attaining those goals. By repeatedly refining conversational goals to more specific levels, one eventually ends up at the concrete speech act level. In addition to determining the speech, one must also plan the content of the act. A particular issue is determining what content to mention in order to produce a successful referring expression. In general, one is looking for a small set of properties that will successfully distinguish the intended object from other competitors in the context. For instance, in a setting in which there is a large red ball (B1), a large blue ball (B2), and a small red ball (B3), one might refer to B2 as 'the blue ball', not mentioning size, and B3 as 'the small ball', not mentioning color.

Surface generation can be viewed as the reverse process of parsing. It is given a logical form, the same or similar to the meanings produced by a parser. The challenge is to capture a given meaning in a natural sounding sentence of extended discourse. Some grammatical frameworks are designed in a way that they can be used both for parsing and for generation. Often, however, even when this is the case, different grammars are used.

One reason is that that there is a different set of concerns facing generation. For example, consider the passive construct (e.g., *John baked a cake* vs. *A cake was baked by John)*. A grammar for parsing might simply have rules that map both these sentences to the same logical form. A generator, on the other hand, must make a decision about which to use, and picking the wrong choice can lead to clumsy interactions or utterances that produce incorrect implications (e.g., consider *A cake was baked by John* as the answer to the question *What did John cook?*). In addition, the surface generator may have to make choices between different lexical realizations (e.g., *John donated $5 million to the museum* vs. *John gave the museum a $5 million contribution*).

CONCLUSION

Natural language processing (NLP) technology is becoming an area of great practical importance and commercial application. Within the foreseeable future, NLP will revolutionize the way we use and think about computers in a profound way. On the theoretical side, as the computational models become more sophisticated, we can expect new insights into possible models of human processing that can then become the subject of empirical experimentation.

Navigation

Intermediate article

Ulrich Nehmzow, University of Essex, Colchester, UK

CONTENTS

Navigation is the ability of a mobile agent (living being or machine) to move in a goal-directed way.

INTRODUCTION

Definition of Navigation

The ability of any mobile agent to move from its current position towards a specific location is arguably one of the most important competences it may possess. Only through the ability to navigate can the advantages of mobility be fully exploited. Without goal-directed motion the mobile agent has to resort to random motion, usually an inefficient strategy.

The word 'navigation' derives from the Latin *navis agere* (to steer a ship), and encompasses all skills required to stay operational (e.g. obstacle avoidance), to localize, to build internal representations ('maps'), to interpret these representations, and to plan paths. For the purpose of this article, 'staying operational' is considered an enabling sensor–motor competence, without which no navigation would be possible, rather than a navigational skill, and therefore it is not discussed in detail. The four fundamental competences of navigation are therefore:

- map building
- map interpretation
- self-localization
- path planning.

These four fundamental components of navigation are achieved by techniques which are discussed below. This article gives a general introduction to techniques commonly used by navigating agents, such as dead reckoning, piloting, and use of senses, and gives examples of their application in living beings (especially insects) and technological systems (especially mobile robots).

Terminology

We use the term 'agent' to mean any acting system, be it biological or technological. The term 'map' is used to mean a representation of the agent's physical space. Such a representation could be a conventional map, a topological representation of neighborhood relationships between discernible landmarks, or indeed any item for which there is a one-to-one mapping from that item to the agent's environment.

NAVIGATION TECHNIQUES

Dead Reckoning

The term 'dead reckoning' comes from 'deduced reckoning', a navigation method commonly used by sailors to determine the ship's position, and often entered in the logbook as 'ded. reckoning'. Because of its simplicity, it is the most widely used navigation technique in animals, humans and robots.

Dead reckoning allows the navigator to determine the current position within the map, provided the following information is available:

- map
- known starting location
- current heading
- either current speed or distance traveled.

Figure 1 illustrates the mechanism of dead reckoning.

Starting from a known position (x_0, y_0), the navigator measures the distance traveled (L) and the current heading, the angle α. If L cannot be measured, it can be determined if the speed v and travel time t are measured, using the equation:

$$L = vt \tag{1}$$

In sailing, it was common to determine the ship's speed through the water by throwing a floater attached to a knotted line overboard. The number of knots paid out per unit time determined the ship's speed, hence the term 'knots' for nautical speeds. This method can only measure speed across the water, and the effects of currents on the true

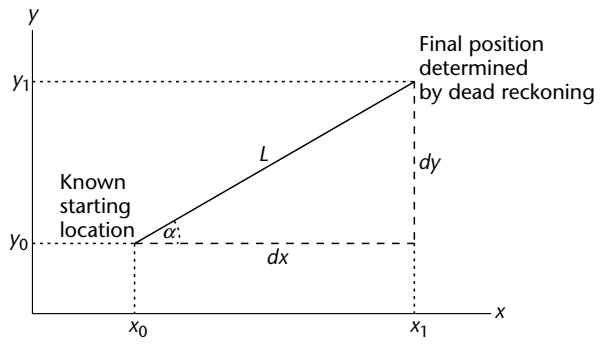

Figure 1. Dead reckoning. The map coordinates are represented by the x and y axes.

speed over ground have to be estimated by the navigator, introducing a dead reckoning error.

Taking the measurements L and α, the navigator can then calculate his current position by eqns 2 and 3 below, with dx and dy given by eqns 4 and 5 respectively. Dead reckoning is therefore also often referred to as 'path integration'.

$$x_1 = x_0 + dx \tag{2}$$

$$y_1 = y_0 + dy \tag{3}$$

$$dx = L\cos\alpha \tag{4}$$

$$dy = L\sin\alpha \tag{5}$$

Problems of dead reckoning

While it is not difficult to obtain a known starting location – every navigator starts at some prominent location, whose coordinates are known – it is difficult to obtain L and α with sufficient accuracy. It is especially important to obtain α as accurately as possible, because every heading error, however small, soon leads to large errors in the position estimate, because of the multiplication with the distance traveled (eqns 4 and 5). Figure 2 shows a robot's position estimate obtained by dead reckoning, completing four identical circuits in its environment.

A typical odometry error for both technological and biological systems is 5 to 10 per cent of the distance traveled (Gallistel, 1990).

Methods of estimating the distance traveled include measuring the speed of a float in water (mentioned above), measuring time while assuming a constant speed, or using optic flow (the apparent movement of images across the retina, which is proportional to speed).

The heading α is most commonly measured using a compass, but can also be determined using celestial bodies, or distant landmarks such as mountains.

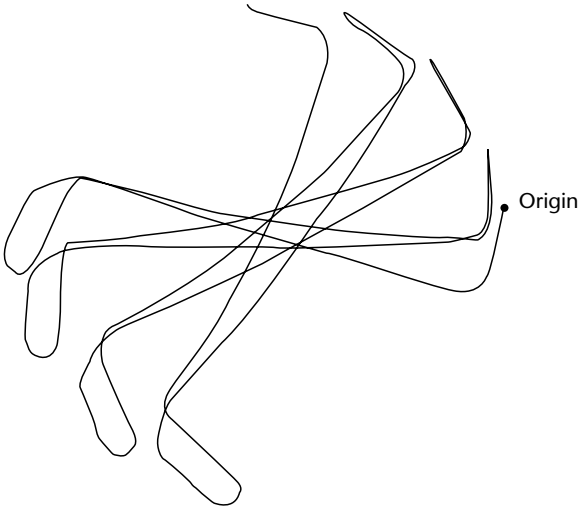

Figure 2. Accumulated dead reckoning error in a mobile robot.

Piloting

'Piloting' refers to navigation by observable features of the landscape – 'landmarks' – rather than by (blind) path integration. It allows self-localization (and therefore map building) and path planning, as shown in Figure 3.

Examples of technological systems that use radio beacons as landmarks are the Loran, Decca and Omega navigation systems, which determine the distance from shore transmitters by measuring the time differences of synchronized atomic clock signals being transmitted from each beacon. Two time signals determine two hyperbolae, whose intersection indicates the receiver's position. Satellite-based global positioning systems like the American GPS, the Russian GLONASS or the European Galileo project exploit the same principle, but give three-dimensional position information, using fixes with (at least) four satellites.

If the distances to the landmarks can be measured, then one distance and the angle is sufficient to determine the current position. In either case, a map is needed.

Problems of piloting

To use landmarks for navigation requires the unambiguous identification of the landmarks. This can be a problem. In natural environments, for instance, landscape features such as trees or mountains can be mistaken. The problem of 'perceptual aliasing' (i.e. the confusion of one landmark for another) in unmodified environments is particularly pronounced in technological systems such as mobile robots, because of the low sensory acuity

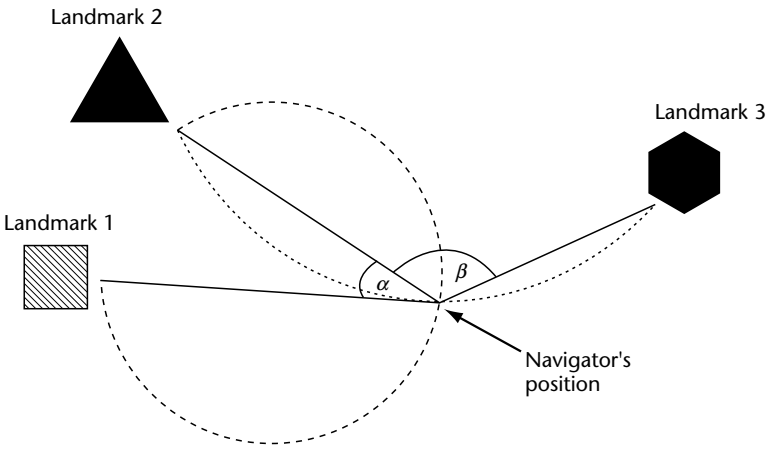

Figure 3. Piloting. The navigator's position is identified by the angles α and β between two clearly identified landmarks. Each angle determines a circle on which the navigator's position lies. The intersection of the two circles determines the navigator's position uniquely.

of robot sensors (Nehmzow, 2000). Navigation beacons (e.g. radio transmitters or lighthouses) therefore transmit identifying signals.

Spatial Representation in Animals and the Cognitive Map

Single-cell recordings in rats (and recently also in monkeys) show that in the CA3 and CA1 fields of the rat's hippocampus there are cells that fire when the rat is in a specific, small area of its environment. These cells are therefore referred to as 'place cells'. In the dorsal presubiculum, another area of the hippocampus, cells have been found whose behavioral correlate is head direction. These cells are therefore called 'head direction cells'.

Such cells are building blocks of navigation behavior, and a number of models have been suggested regarding the hippocampus's role in navigation (Burgess *et al*., 1995).

In 1948, Edward Tolman observed in rats the ability to determine novel shortcuts in a maze – an ability that was later also demonstrated in humans – and introduced the term 'cognitive map' for the rat's spatial representation. According to Tolman's definition, a 'cognitive map' is a representation of the space an agent inhabits, internal to the agent, that allows the agent to perform spatial reasoning, and in particular to determine novel shortcuts. O'Keefe and Nadel (1978) later argued that this cognitive map is located in the hippocampus.

Gould (1986) presented experiments in which honey-bees showed the ability to short-cut between two foraging sites, and proposed that honey-bees possessed cognitive maps. Considerable controversy arose over this claim, and several groups either were unable to replicate Gould's results, or could not rule out the explanation that landmarks seen across the short cut were used by the bees. Many groups argued that there are simpler explanations for the bees' ability to determine novel shortcuts. A summary of these arguments is presented in (Bennett, 1996).

Bennett argues that there are three simpler hypotheses that need to be eliminated first, before the presence of cognitive maps in bees can be considered proven: (1) that the short cut is not truly novel; (2) that path integration has been used, and (3) that familiar landmarks have been recognized from a new angle.

Gallistel (1990) defines 'cognitive map' more loosely as a spatial representation that facilitates spatial reasoning. That animals possess a cognitive map in this sense, i.e. an internal representation of space that is used for any type of navigation, is widely accepted. The debate continues, however, over whether they possess a cognitive map as defined by Tolman, i.e. a memory of landmarks that permits the determination of novel short cuts.

Other Techniques

Dead reckoning and piloting without maps

Both dead reckoning and piloting can be used without a map. Desert ants *Cataglyphis bicolor* (who do not lay pheromone trails), for instance, use path integration on both outward and homeward journeys from and to the nest (Wehner and Srinivasan,

1981), in featureless desert terrain. This is clearly shown when the ant is displaced at the beginning of the return journey, and returns to a position correspondingly displaced from the location of the nest. It then starts a search behavior centered around that position.

Likewise, piloting is possible without using maps. Again, experiments with *Cataglyphis bicolor* show that ants learn the position of a food source located between two visible pillars that serve as landmarks. If just the distance between the pillars is doubled, the ants search near either pillar for food (they cannot use the landmarks any longer for navigation), but if the size of the pillars is doubled as well, they search again between the pillars, at the right location (Wehner and Räber, 1979).

Specially controlled motion

In technological systems (e.g. robot arms), 'guarded motion' can be used to direct the arm reliably to its destination. Guarded motion entails taking the arm to an easily locatable edge, and then trailing it along the edge until the destination is reached.

The equivalent of guarded motion in the animate world is route following, where the navigator uses a naturally occurring route such as a river, a path, a shoreline or a mountain range for direction. Route following is commonly used in animal navigation. Canvasback ducks, for instance, follow the Mississippi river during migration (Waterman, 1989).

Sensors and Sensory Perceptions Commonly Used for Navigation

Of the two fundamental sources of information used in dead reckoning – direction and distance – direction is arguably the more important, given that even very small errors in estimating the current heading will quickly lead to large errors in the position estimate (see eqns 4 and 5, and figure 1). This 'compass sense' could be provided by an ordinary magnetic compass, but there are many other methods of obtaining a reference direction.

Carrier pigeons and many other birds, for instance, possess two independent compass senses. They are born with a magnetic inclination compass that measures the angle between the magnetic field lines and the Earth's surface, so that they can navigate 'pole-wards' and 'equator-wards'. Within the first 12 weeks of their life, they learn the relationship between the sun's movement at their home location and their magnetic compass. The sun compass acquired in this manner is later their preferred source of directional information (Wiltschko and Wiltschko, 1998).

Many insects, for example ants and bees (Waterman, 1989), use the polarization pattern of the sky, the so-called 'electric vector' ('e-vector') for orientation. Using the e-vector is another way of navigating by the sun, as the polarization pattern of the sky is dependent on the sun's position.

Celestial bodies can also provide a compass sense. The apparent motion of the celestial bodies is centered around the visually motionless celestial pole (which is near Polaris in the northern hemisphere). By observing the night sky over an extended period of time, the celestial pole can thus be determined, without any knowledge of constellations. Planetarium experiments with migrating birds, in which arbitrary constellations and movement patterns of celestial bodies can be created, demonstrate that migrating birds can use the night sky to determine the correct heading towards their goal (Waterman, 1989).

Locally occurring gradients can be used by many animals for navigation. Salmon, for instance, find their way back to the area where they were born by following a chemical gradient, the scent of their home waters (Waterman, 1989). They are able to detect minute differences in concentration of certain chemicals, and have a very high success rate in homing.

Carrier pigeons use locally occurring gradients (perhaps introduced through the Earth's magnetic field, or through infrasound from mountain ranges or the sea) to determine the correct heading for their loft (Wiltschko and Wiltschko, 1998).

One special form of path integration uses inertial navigation, doubly integrating the acceleration of the moving agent over time, to determine the navigator's position in space. In technological systems, accelerometers are used for this purpose. These are freely suspended masses, which exert forces onto force meters (e.g., strain gauges) when subjected to acceleration. As an example of biological navigators, rats possess a sense of direction (head direction cells in the anterior thalamus) and angular velocity, facilitating path integration (O'Keefe and Nadel, 1978).

Human Navigation

The seafarers in Polynesia and the Caroline islands routinely cover large distances (several hundred kilometers) between islands, across open sea, without using compass, sextant, or any other navigational instruments traditionally used in the Western world (Kyselka, 1987; Gladwin, 1970).

They achieve this by combining a range of information sources, rather than relying solely on any one navigational tool.

Celestial bodies

Obviously, the sun can be used to give directional information, but the navigators also make extensive use of the celestial bodies of the night sky.

Near the equator, stars rise and set almost vertically. This means that a rising or setting star can be used to indicate a particular direction while it is near the horizon. Navigators in Polynesia and the Caroline islands associate the rising and setting positions of certain stars with certain islands, and can thus use the stars to indicate the correct headings for their destinations.

The declination of a star is that latitude at which the star will pass through the zenith. Although Polynesian navigators do not use longitude and latitude for navigation, they do use the fact that a star passing through the zenith indicates latitude. By associating zenith stars with islands, they can determine whether they have arrived at the right latitude yet.

Landmarks and seamarks

When near the coast, either at departure or arrival, visible landmarks are aligned to give directions. The choice of landmarks obviously depends on the destination, but also on the wind and current situation: sailors select their landmarks to compensate for drift.

Once at sea, the navigators are able to derive direction from the low-frequency swell (not the choppy waves superimposed on the swell), which usually comes from a small number of general directions, because it is caused by (repeatable) weather patterns in a region. Whether the boat is aligned at right angles with the swell can easily be determined by detecting a gyrating movement of the boat, rather than a sideways or pitching motion.

Sea life is an important source of information. Many birds (for example, the booby) fly straight back home at dusk, having foraged over the sea. Certain islands have populations of turtles, or conspicuous fish, and can thus be detected from afar.

Fundamental to all these cues is the navigator's strategy, which is conservative. Sailors in Polynesia and the Caroline islands aim to avoid risk, for instance by selecting courses that will take them to the 'broad' side of an island or an island chain, or by voluntarily making detours via an easily accessible island. They do not rely on a single information source, but combine all the information available (sometimes even the taste of the water!).

Robot Navigation

Navigation strategies

The navigation strategies used in mobile robotics are variations of the methods used by biological navigators: route following, dead reckoning and piloting.

The simplest navigation method, employed by automated guided vehicles, is to detect and follow routes marked in the environment, for instance through buried induction loops, markers on floors, walls or ceilings, or radio beacons. Such navigation systems are robust, but expensive to set up, and inflexible.

Navigation systems for *autonomous* mobile robots, i.e. robots that have no power, control or computing connection to the outside world and that operate in unmodified environments, use navigation techniques similar to those of animals.

Dead reckoning by itself can only be used over very short distances (typically less than 10 meters), because of the accumulation of incorrigible drift error (see Figure 2). Navigation through dead reckoning therefore requires frequent recalibration at a known location, which can limit the active range of a mobile robot.

Landmark-based navigation systems aim to overcome the drawbacks of dead reckoning by representing space and planning motion in relation to identifiable landmarks (piloting). Provided landmarks are identified uniquely, such navigation is reliable, does not suffer from accumulation of incorrigible error, and works over long distances. The main problem landmark-based robot navigation systems face, however, is that, due to low sensor resolution, perceptual aliasing occurs, which leads to confusion and possibly to navigation errors.

Sensors for robot navigation

Dead reckoning, i.e., path integration, is most commonly performed using wheel encoders, which indicate the rotating angle and rotating direction of a wheel. Wheel encoders are purely proprioceptive, meaning that they do not take into account any external information. This is the reason why error accumulated by integration cannot be corrected using dead reckoning alone.

To determine a robot's heading, either wheel encoders or compasses can be used. Of the latter, a number of designs exist, notably flux gate compasses and Hall effect compasses.

Gyroscopes, in particular laser gyroscopes, can be used to measure rotation, and micro-accelerometers can be used to measure translation. They are therefore also suitable for path integration.

'Landmarks' in robot navigation are typically not conspicuous places, but sensory patterns that are recognizable and unique for a particular physical location.

Some commonly used types of sensors are described briefly below.

Sonar sensors

Sonar sensors measure the distance to the nearest object within a cone of typically 25° in front of the sensor, by determining the time it takes for a sound pulse to emanate from a transmitter, be reflected by the object and return to a receiver.

Laser range finders

Laser range finders work on the same principle as sonar sensors, but use light as the transmitted medium. Instead of using time of flight to determine range, phase shift between transmitted and received signal can also be used.

Cameras

Cameras using charge-coupled devices obtain a gray level or color intensity distribution of the image plane, and can be used effectively for landmark identification. However, it is computationally expensive to convert an image consisting of hundreds of thousands of picture elements ('pixels') into a meaningful, concise and identifiable representation.

Infrared proximity sensors

Infrared proximity sensors detect the reflection of emitted infrared light off a nearby object, and can thus detect the presence of (light-colored) objects in the vicinity of the sensor. They do not function well over distances much over a meter, or for detecting dark objects which do not reflect much light.

Tactile sensors

Tactile sensors detect immediate contact with an object, and are therefore only useful for navigation tasks such as route following (e.g. wall following along a corridor).

Representation of space and path planning

Unless the only navigational task is that of returning home, navigation using dead reckoning needs to use a metric map. Such a map contains metric coordinates (for example, Cartesian or polar coordinates) of locations. Simple trigonometry can then be used to compute the path between any two locations.

Landmark-based systems do not necessarily need a metric map: a topological map will usually suffice. Such a map represents the topological (neighborhood) relationships between landmarks, and is sometimes augmented by distance and direction information regarding the landmarks. A pure topological map still allows the determination of paths between arbitrary locations, but does not by itself allow determination of the shortest path.

For many navigation tasks, no map is needed. For instance, to perform a search (e.g. for food), and to return home, path integration and de-integration are sufficient. Similarly, if the home location is marked by a landmark or, more generally, an attractor (e.g. smell), simple taxis (moving towards an attractor) is sufficient.

To plan paths, either metric maps are used directly, and the required heading and distance determined by trigonometry, or the space is first tessellated (partitioned) into cells. Common methods of partitioning space include the Voronoi tessellation and its dual, the Delaunay triangulation. Search techniques (for example, those used in artificial intelligence to search through game trees) can then be used to find a free path.

Such search techniques can also be applied to path planning using topological maps. Reaction–diffusion dynamics are an example of a simple search technique suitable for path planning: a 'token' is placed on the goal location, and propagated in all possible directions at constant speed. The cell neighboring the navigating agent that receives the token first is the one indicating the shortest route to the goal. The process is repeated until the goal is reached.

SUMMARY

The advantages of mobility cannot be fully exploited without the capability to move in a goal-directed way, i.e., the ability to navigate. Virtually all mobile agents, biological or technological, therefore have some degree of navigational capability.

Common navigation strategies include path integration (dead reckoning), taxis (moving towards attractors), using landmarks, and using identifiable routes. These methods are used both by living beings and in robot navigation.

One interesting difference between biological and technological navigation is that biological navigators combine different information sources to a far greater degree than is currently done in robotics. This increases their reliability and robustness.

The combination of sensor signals from different sources (sensor fusion), and the combination of

different navigational strategies to achieve higher degrees of robustness and reliability, are still subjects of research, and a challenge for future robot navigation systems.

Neural Behavior: Mathematical Models

Advanced article

Bard Ermentrout, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

CONTENTS

Neuronal networks are systems of counted equations meant to approximate the connectivity and function of biological neurons.

INTRODUCTION

The range of models of cognitive and neural processes spans many levels of detail, from single-channel dynamics, through models involving different brain regions, to models of social interactions between individuals. The appropriate level of detail depends in part on the types of questions asked. However, there comes a point, when addressing higher-level processes such as cognitive function, where the connection between the models and the actual machinery that underlies neural activity (e.g., channels, dendrites, synapses) appears to be very tenuous. This dissociation is not necessary, nor, in light of the recent rapid progress in experimental neuroscience (especially at the single-cell and molecular levels) is it desirable. Mathematical methods allow us to create bridges that span these different levels.

In order to study behavior and cognition, modelers generally study abstract networks of very simple units. For example, the traditional architecture for 'connectionist' models (McClelland and Rumelhart, 1988) consists of several layers of units that are connected in a feedforward manner by weights and simple nonlinearities. That is, the activity of unit j in layer n is determined by the sum of the activities of the units in layer $n-1$ that are connected to it. By modifying the weights of these interactions through a 'learning rule', it is possible to train these networks to perform a wide range of 'cognitive-like' tasks. Furthermore, by partially disrupting connections between units, a variety of psychopathologies can also be simulated and understood at least at this somewhat crude level.

Individual neurons exist in many shapes and sizes, have thousands of individual ionic channels and synapses, and are connected in networks of millions of different cells. Neurophysiologists are able to determine the channel properties (such as density and kinetics) on only a small piece of a small fraction of the neurons that comprise any given circuit. The synaptic interactions between neurons, and how their past activity influences them, remains a vigorous field of research. The gap between the complex and detailed models of single neurons and the simplified units alluded to in the previous paragraph would appear to be insurmountable. However, under certain assumptions (and whether these are in fact reasonable remains a subject of lively debate), it is sometimes possible to reduce complex units to much simpler versions which resemble the simple units favored by modelers of cognitive and behavioral psychology.

FROM NEURONS TO NEURAL NETWORKS

The usual models for neural networks (e.g. Amari, 1977; Hopfield, 1984; McClelland and Rumelhart, 1988; Wilson and Cowan, 1973) have the form

$$\tau_i \frac{dV_i}{dt} = -V_i + \sum_j W_{ij} F_j(V_j) \tag{1}$$

or

$$\tau_i \frac{du_i}{dt} = -u_i + F_i\left(\sum_j W_{ij} u_j\right) \tag{2}$$

The parameters τ_i represent a time constant, W_{ij} is the strength of the connection to j from i, and F_i is a nonlinearity often related to the firing rate of a neuron. In eqn 1, V_i often represents the voltage

or potential of the unit, while in eqn 2, u_i represents the activity or firing rate of the unit. The philosophy underlying these models is that it is the connections that matter and not the details of the neurons. This is true to an extent for models that do not involve dynamics such as action potentials or oscillations. However, as soon as temporal behavior is introduced, the details of the connections (such as latency) become far more important in determining the behavior.

There are many different connectivities possible for these neural networks. Connectionist models often work with feedforward mechanisms, as illustrated in Figure 1(a). That is, within a 'layer' there are no connections between units, nor are there feedback connections from layers above. In these models, the weights are adjusted by some type of learning rule in order to produce desired output when presented with some set of inputs. To study pathologies, modelers disrupt a fraction of the connections and then analyze the resulting network. In contrast to the simple feedforward network is the fully recurrent network shown in Figure 1(b). In this network, any unit can connect to any other unit. Such models have been used to study associative learning, and many other neural phenomena. Later in this article, we will discuss an example of this type of network as a model for working memory. If the connections between units in a fully recurrent network are symmetric (that is, $W_{ij} = W_{ji}$) then all solutions to eqns 1 and 2 go to equilibrium values (Hopfield, 1984). Thus, given some initial configuration, the network will always converge to a pattern of voltage or activity. This behavior allows the network to associate an input with a final output. Pattern completion is an often-exploited property of these networks.

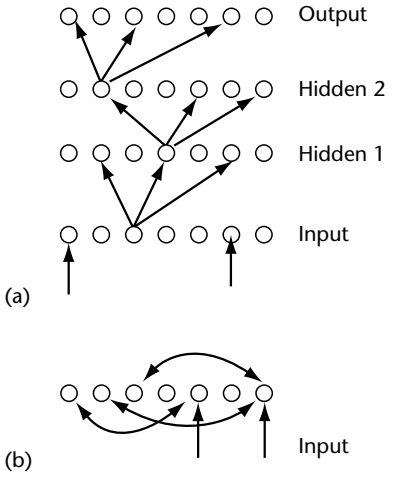

Figure 1. Common types of neural networks. (a) Feedforward network. Inputs come into the lower layer which makes forward connections to a sequence of hidden layers which terminates at the output layer. (b) Recurrent network. Any cell can connect to any other cell.

There are several ways to arrive at eqns 1 and 2 starting from physiological assumptions. The simplest way is to consider a pair of neurons coupled as in Figure 2. The somatic potential of the first neuron is $V_1(t)$. The potential difference between the soma and the axon hillock results in a current, and this current is sufficient to produce a train of action potentials along the axon. These occur at a rate $f(t)$ which is a function of the difference between the somatic potential and the resting potential of the axon hillock. Thus:

$$f(t) = F((V_1(t) - V_A)/R) \tag{3}$$

where $F(I)$ is the firing rate as a function of injected current (see below), V_A is the potential of the axon hillock, and R is the resistance between the two compartments. After a possible delay, the action potentials along the axon terminate at the synapse and allow neurotransmitter to be released. This results in a postsynaptic potential on the dendrite of the postsynaptic neuron. The postsynaptic potential from successive action potentials is summed and possibly filtered by dendritic properties. The result is that the somatic potential of the receiving neuron, $V_2(t)$, is changed to a new value. Assuming linear summation and a linear dendrite, the total potential contributed by the connection is

$$v_{1\to 2}(t) = \int Q(t-s)f(s)\mathrm{d}s \tag{4}$$

where $Q(t)$ is the response measured at the soma to an impulse delivered at the synapse. $Q(t)$ takes into account both the dynamics of the synaptic

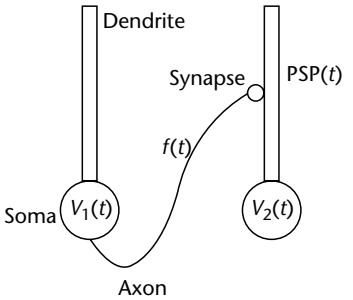

Figure 2. How neural network models are derived from biological neurons. Potentials $V_1(t)$ at the soma produce action potentials which travel down the axon at a rate $f(t)$, producing postsynaptic potentials PSP(t) in the dendrites. These potentials contribute to the somatic potentials $V_2(t)$.

transmission and the cable properties of the dendrite. It is often as simple as a decaying exponential, but more generally is a sum of decaying exponentials vanishing for $t \geq 0$ and vanishes for $t < 0$:

$$Q(t) = Q_0(\exp(-at) - \exp(-bt)) \tag{5}$$

Thus, if there were nothing else in the network but this connection, we would have

$$V_2(t) = V_{2,\mathrm{r}} + \int_{-\infty}^{t} Q(t-s) \times F((V_1(s) - V_\mathrm{A})/R)\mathrm{d}s \tag{6}$$

where $V_{2,\mathrm{r}}$ is the resting potential.

The network analogue of this model is

$$V_i(t) = \sum_j \int_{-\infty}^{t} Q_{ij}(t-s)F_j(V_j(s))\mathrm{d}s \tag{7}$$

where the resting potentials are all set to zero and the resistance is absorbed into the function F. Eqns 1 and 2 can both be derived from this general network under different assumptions. Suppose first that the form of the function Q_{ij} depends only on the postsynaptic neuron and is a single exponential. That is:

$$Q_{ij}(t) = W_{ij}\mathrm{e}^{-t/\tau_i} \tag{8}$$

Then eqn 7 can be rewritten as eqn 1. The interpretation of this is that since the response only depends on the postsynaptic neuron, either the synapses must be fast or the response of the neuron must be slow. Thus, the parameter τ_i is the membrane time constant of the neuron.

On the other hand, suppose that the form of Q_{ij} depends on the presynaptic neuron, that is:

$$Q_{ij}(t) = W_{ij}\mathrm{e}^{-t/\tau_i} \tag{9}$$

Then eqn 7 can be transformed into eqn 2. In this case, the interpretation is that the membrane time constant is short and the synaptic decay rate is slow. The parameter τ_i is the synaptic time constant.

An alternative derivation of eqn 2 starts with a biophysically detailed model with channels, such as the Hodgkin–Huxley model (Ermentrout, 1994). If the synaptic interactions are slow, then a mathematical method called averaging is used to produce equations of the form

$$\tau_\mathrm{i}\frac{\mathrm{d}s_i}{\mathrm{d}t} = -s_i + F_i\left(\sum_j W_{ij}s_j + I_i\right)(1 - s_i) \tag{10}$$

This differs in form from eqn 2 only by the factor $(1 - s_i)$. The interpretation of the variables in this model is quite different, s_i represents the fraction of open synapses occurring as a result of the firing of neuron i, F_i is proportional to the firing rate of the postsynaptic cell as a function of the current, I_i is the external input, and $W_{ij} = g_{ij}(V_{j,\mathrm{syn}} - V_{i,\mathrm{r}})$ is the maximum possible current due to the firing of the synapse. g_{ij} is the conductance of the synapse from j to i, $V_{j,\mathrm{syn}}$ is the reversal potential of the synapse, and $V_{i,\mathrm{r}}$ is the resting potential of the postsynaptic neuron. Thus, it is possible to connect detailed biophysical models with the abstract neural networks that are used in connectionism and other cognitive models.

Models such as eqn 10 can be extended to incorporate other processes such as synaptic depression or facilitation and spike frequency adaptation. For example, adaptation is incorporated by adding a term of the form $-K_i z_i$ to the inputs in eqn 10 and adding one more differential equation:

$$\tau_\mathrm{A}\frac{\mathrm{d}z_i}{\mathrm{d}t} = -z_i + (1 - z_i)G_i\left(\sum_j W_{ij}s_j - K_i z_i + I_i\right) \tag{11}$$

Firing Rates

When a neuron is injected with current, it often fires repetitively. The steady state firing rate is usually a monotonic function of the current. A number of firing rate functions are commonly used. The most common (although it does not directly follow from biophysical models) is the logistic function:

$$F_{\log}(I) = \frac{F_{\max}}{1 + \exp(-r(I - I_\mathrm{T}))} \tag{12}$$

where r is the gain and I_T is the threshold. In the limit as r gets large, this function approaches the step function. Another commonly-used model is the rectified linear model:

$$F_{\mathrm{lin}}(I) = r\max(0, I - I_\mathrm{T}) \tag{13}$$

For $I < I_\mathrm{T}$ the neuron does not fire but for $I > I_\mathrm{T}$ it fires at a rate that is linear. This model has some biological justification: there are a number of neuron models that have a nearly linear firing rate as a function of applied current. A firing rate function related to F_{lin} which fits a variety of cortical inhibitory neurons is the square-root model:

$$F_{\mathrm{sqr}}(I) = r\sqrt{\max(0, I - I_\mathrm{T})} \tag{14}$$

The Naka–Rushton model

$$F_{\mathrm{nr}}(I) = F_{\max}\frac{\max(0, I)^2}{{I_\mathrm{T}}^2 + I^2} \tag{15}$$

is saturating like the logistic model and is used in psychophysical models.

Finally, there is a very simple model for spiking neurons called the integrate-and-fire model. The integrate-and-fire model has enjoyed popularity for many years mainly due to its simplicity. Many variants have been developed but the basic structure of the model remains the same. The equations are

$$\tau \frac{dV}{dt} = -V + RI(t) \tag{16}$$

with the following condition. If $V(t) = V_T$ then the neuron fires and contributes some current to the cells to which it is connected. The voltage $V(t)$ is then immediately reset to $-V_R$. If the injected current I is held constant and is larger than V_T/R then the neuron will fire repetitively at a rate

$$F_{iaf}(I) = \frac{1}{\tau \ln\left[\frac{RI+V_R}{RI-V_T}\right]} \tag{17}$$

For low currents this function is similar to F_{sqr} but at high currents the rate is essentially linear. Several of the above firing rates are shown in Figure 3.

Modeling With Small Neural Networks

Using either the firing rate formulation or the voltage formulation, it is possible to model many neural systems. Suppose that there is no spatial structure to the connections between neurons. Then it is often desirable to reduce the system to as few as two populations of cells. A network of N groups of neurons all mutually inhibiting each other often exhibits what is called 'winner-take-all' behavior. That is, the network will select the group with the largest input and suppress all the others. Wilson (1999) uses one such network to explain the delay in picking a particular object out of a group of distractor objects. Since all distractor neurons are treated equally, their behavior can be combined into one unit. Let T be the activity of the group corresponding to the target and D be the activity corresponding to the distractors. Then the equations are:

$$\tau \frac{dT}{dt} = -T + f(E_T - ND) \tag{18}$$

$$\tau \frac{dD}{dt} = -D + f(E_D - (N-1)D - T) \tag{19}$$

The function f is one of the firing rate functions and N is the number of distractor neurons. The target network has a larger input, E_T. This network behaves as a winner-take-all network in that if both T and D start at zero, both will begin firing but eventually T will fire at a maximal rate and all the distractor neurons will be suppressed. Wilson shows that as the number N of distractor neurons increases, the amount of time for the target to 'win' increases in accordance with the psychophysical data.

By adding adaptation, fatigue, or some other slow negative feedback, it is possible to model perceptual oscillations such as those observed in binocular rivalry or the Necker cube. In these illusions, two figures compete equally for attention in a winner-take-all network. However, the presence of adaptation causes the 'winner' to weaken, allowing the 'loser' to gain strength. This cycle continues with regular periodicity. These simple models enable one to compute switching times and compare them to experimental results. Similar models have been suggested to explain competition at the neural level in recordings of visual tasks in awake monkeys.

Another simple network which has proved useful in the understanding of cortical functioning consists of a population of excitatory (E) and inhibitory (I) neurons:

$$\tau_E \frac{dE}{dt} = -E + f_E(w_{EE}E - w_{EI}I + T_E(t)) \tag{20}$$

$$\tau_I \frac{dI}{dt} = -I + f_E(w_{IE}E - w_{II}I + T_I(t)) \tag{21}$$

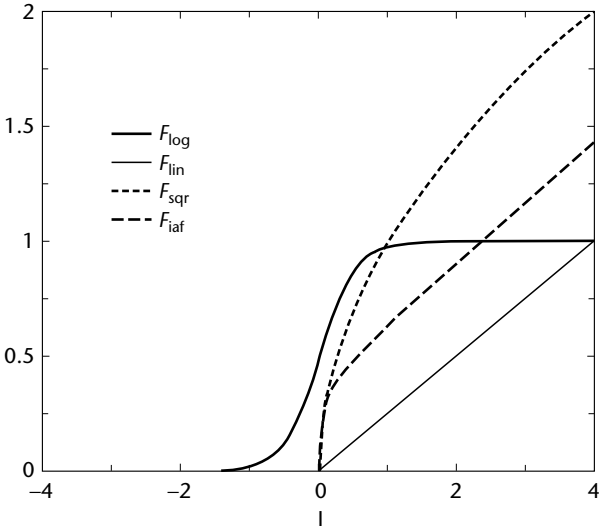

Figure 3. Different firing rate functions for the same applied current.

The functions $T_E(t)$ and $T_I(t)$ represent inputs from the thalamus. Since all excitatory and inibitory activity is combined into just two quantities, this simple system is a good illustration of the local dynamics of a single cortical column. Below, we will connect models of this form into spatial networks. One recent application of eqn 20 has been to the understanding of the response transformations of sensory inputs to the whisker barrel of the rat (Pinto *et al.*, 1996). Barrels are structures within the somatosensory area of the rat which receive inputs from a unique whisker. Eqn 20 was used in a network to predict responses of the barrel to temporally variable stimuli to the whisker corresponding to that barrel. The model predicted that the barrel acts like a differentiator, a prediction that was subsequently verified experimentally.

NETWORKS OF OSCILLATING NEURONS

The neural network models work under the assumption that it is the population rate that matters in cognition and sensory processing. An alternative point of view is that the timing of individual spikes is important. This idea is based on the fact that humans and other animals are able to make perceptual decisions over timescales that preclude the occurrence of more than one or two spikes per neuron in the relevant pathways. It is difficult to imagine how a rate code could work at that time scale. Furthermore, a code based on spike timing provides additional degrees of freedom that are not possible in a code based solely on the rate. Recent experimental work suggests that attention to a salient feature in a visual scene (or in other sensory scenarios) is accompanied by regular oscillations in a relatively narrow frequency band. Von der Malsburg and Schneider (1986) suggested that oscillations could be used to solve the so-called binding problem: how do different features (e.g. color, shape, position) of an object to be recognized get bound together as a coherent whole? They suggested that features could be grouped together if they shared a common phase; that is, if their neural correlates oscillated synchronously. Synchronous activity would result in the activation of specific target regions which shared these features. These theories, along with experimental evidence that supports them to some extent (Gray, 1994), have led to an interest in the types of computations that are possible with spiking and, in particular, oscillating neural networks.

Modeling large networks of spiking neurons presents a computational challenge, since details of the spike production and the synapses must be incorporated. The question of how detailed a model to use must also be addressed. There are several methods for simplifying the analysis and calculations associated with networks of spiking neurons. One idea is to use a very simple model for spiking and synapses. The model favored in most recent theoretical and computational work is the integrate-and-fire model. A network of these neurons has the form

$$\tau_i \frac{dV_i}{dt} = -V_i + R_i I_i(t) + R_i \sum_{j,\ell} \alpha_{ij}(t - t_j^\ell) \qquad (22)$$

with the condition that the voltage of each neuron is reset once it crosses a threshold. The numbers t_j^ℓ are the firing times of the jth neuron, that is, the times at which the neuron crosses its threshold. The functions $\alpha_{ij}(t)$ represent the postsynaptic potentials (similar in form to $Q(t)$ in eqn 5) resulting from the firing of the presynaptic neuron. Thus, suppose that at $t = t_j^\ell$ neuron j crosses threshold for the ℓth time. Then neuron j is immediately reset to a new voltage and each of the neurons to which neuron j projects receives a new contribution, $\alpha(t - t_j^\ell)$. The general behavior of these networks is difficult to analyze. However, it is often possible to find conditions for which waves or synchronous solutions exist, since the pattern of firing times is very regular. Bressloff and Coombes (2000) provide a comprehensive analysis of this class of models.

Another approach to spike timing is to assume a network of neurons each of which is coupled weakly to the other neurons (Hoppensteadt and Izhikevich, 1997). This means that the firing of other neurons does not destroy the oscillation of the target neuron; rather it serves to shift the timing of its next spike. Neurons in the network that are not firing at similar frequencies or not firing at all are effectively decoupled and do not participate in the timing pattern. The advantage of the weak coupling approach is twofold: the equations governing the timing can be derived from the fully detailed cellular models or from experiments; and the resulting equations are amenable to simulation and analysis. Each neuron (or group of neurons) in the circuit is represented by a single number lying on a circle, θ_i, the phase. Typically, zero phase represents the time at which a spike is emitted, but this is arbitrary as long as it is the same for each neuron. The equations have the form

$$\frac{d\theta_i}{dt} = \omega_i + \sum_j H_{ij}(\theta_j - \theta_i) \qquad (23)$$

where $H_{ij}(\phi)$ is a periodic function such as $\sin\phi$. The main quantities of interest are the timing or phase differences between neurons, $\Psi_{ij} = \theta_i - \theta_j$. If these are all zero, then the network is synchronous.

Kelso (1995) applied this class of model in experiments where he asks a subject to tap his fingers in an alternating rhythm and gradually increases the frequency at which the tapping must take place. He finds that at sufficiently high frequencies, the subject spontaneously switches from an alternating rhythm to a synchronous rhythm. In associated electroencephalographic recordings, he sees a qualitative switch in the pattern of the scalp potentials when the switch is made. He suggests a simple phase model. Let θ_L and θ_R be the phases of the left and right fingers. Then

$$\frac{d\theta_L}{dt} = \omega + H(\theta_R - \theta_L, f) \tag{24}$$

$$\frac{d\theta_R}{dt} = \omega + H(\theta_L - \theta_R, f) \tag{25}$$

where f is the frequency required for tapping. It is well documented in the theoretical literature that the shape of the functions H depends on the frequency of the underlying oscillators. (It can be expected that the time constants of the synapses connecting neural circuits are fixed. Changing the underlying frequency of the oscillations thus affects how these synaptic potentials alter the phase of the potentials. For example, it may be that stimuli that directly follow a neuron spike have a much smaller effect on shifting the time of the next spike than do stimuli that come later in the cycle. Since the persistence of a synapse is invariant, changing the frequency of the underlying oscillation drastically alters when the maximum stimulus comes in the cycle.) Since the quantity of interest is the phase difference between the left and right fingers, let $\phi = \theta_R - \theta_L$. Then

$$\frac{d\phi}{dt} = H(-\phi, f) - H(\phi, f) \equiv G(\phi, f) \tag{26}$$

Kelso suggests a particularly simple form for G:

$$G(\phi, f) = -\sin(\phi) - C(f)\sin(2\phi) \tag{27}$$

where $C(f) > 0$ and decreases with f. Clearly, $\phi = 0$ and $\phi = \pi$ are both equilibrium points of eqn 27. As long as $C(f) > 0$, the synchronous solution $\phi = 0$ is stable. For $C(f) > 1/2$ the alternating solution $\phi = \pi$ is also stable, but becomes unstable as f increases and thus $C(f)$ decreases. For $0 < C(f) < 1/2$ the only stable state is synchrony, so that if the subject starts in the alternating mode, then at sufficiently high frequencies, he or she must switch to the synchronous mode.

While the mathematics of the general systems represented by eqns 22 and 23 are reasonably well developed, the application of spiking and oscillatory networks to cognitive processes is only in its infancy. The main reason for this is that the level of modeling that is favored by cognitive theorists does not require detailed knowledge of spike times. As better neurophysiological data become available, spiking models may play a greater role in the modeling of cognitive data.

SPATIALLY DISTRIBUTED NETWORKS

The rapid development of imaging technology has made it possible to ask questions about the spatial distribution of activity at large and small scales. Thus, it is expected that neural network models with explicit spatial structure will play a role in our understanding of the biological mechanisms of cognition. Spatial models are no different from the general models represented by eqns 1 and 2 or eqns 22 and 23 except that the coupling weights of interactions depend on the spatial locations x_i of neurons in the network. In many networks, the coupling depends only on the distances $|x_i - x_j|$ between neurons. Much has been written on the behavior of spatially distributed networks (see Ermentrout (1998) for a review).

A kind of spatially localized self-sustaining activity known as 'bumps' has attracted much recent attention. Bumps are elicited in a spatial neural network by introducing a transient stimulus. Once the stimulus is removed, a local region of sustained firing appears and persists until some other process makes it disappear. The interest in this behavior derives from attempts to model delayed-response visual tasks. In these tasks, a monkey fixates on a target location. A brief stimulus is presented in the periphery and then removed. After a delay of several seconds, the monkey must make a saccade to the point where the peripheral stimulus appears. Thus, the task is a test of short-term or working memory. Cortical recordings during this task indicate that there are spatially localized groups of neurons which fire repetitively during the delay and stop firing once the task is completed. These are believed to be the neuronal correlates of working memory. Bumps have been used to model this neurophysiological behavior. There are many ways to produce these bumps of activity, ranging from simple neural networks such as eqn 2 to networks of spiking neurons with multiple channels and synapses. Since all the mechanisms

for sustained localized activity are based on the same general principles, we will consider the simplest implementation. Three conditions must be satisfied to obtain bump solutions in a neural network: (1) there must be a threshold, that is, small stimuli die out; (2) the spatial connectivity must be laterally inhibitory; (3) the network activity must be self-limiting. The first and third conditions preclude simple linear networks. The second condition says that local interactions are excitatory while the surround is inhibited. A network that is able to produce bumps is the spatial analog of the winner-take-all network with the additional condition that activity be sustained after the stimulus is removed. In a spatially distributed network, the localized bump of activity can be centred at any spatial location. Thus it uniquely specifies the position of the stimulus. Note that the position code in the cortical network could easily correspond to some other sensory modality. For example, auditory frequency is coded as a spatial map in the cortex.

The simplest model for bumps was proposed by Amari (1977). He goes to a continuous space limit and obtains the following equation for the potential:

$$\frac{\partial V(x,t)}{\partial t} = -V(x,t) + \int_{-\infty}^{\infty} J(x-y)F(V(y,t))\mathrm{d}y \tag{28}$$

For the firing rate function he chooses the step function: $F(V) = 0$ if $V < V_T$ and $F(V) = 1$ if $V \geq V_T$. The neurons in this network are either not firing or firing at a maximal rate. The connection function has the form shown in Figure 4(a). Nearby neurons are turned on and distant neurons are turned off. For simplicity, the network is one-dimensional. A bump consists of a localized region of activity and can be assumed to be centred at the origin. The bump is above threshold for $|x| < a$ and below threshold for $|x| > a$, as shown in Figure 4(c). Since the bump is independent of time and $F(V(x))$ is zero for $|x| > a$, the potential distribution satisfies

$$V(x) = \int_{-a}^{a} J(x-y)\mathrm{d}y = W(x+a) - W(x-a) \tag{29}$$

where

$$W(x) = \int_{0}^{x} J(y)\mathrm{d}y \tag{30}$$

The width of the bump, $2a$, is determined from the requirement that at the edges of the bump, the potential is at threshold, V_T:

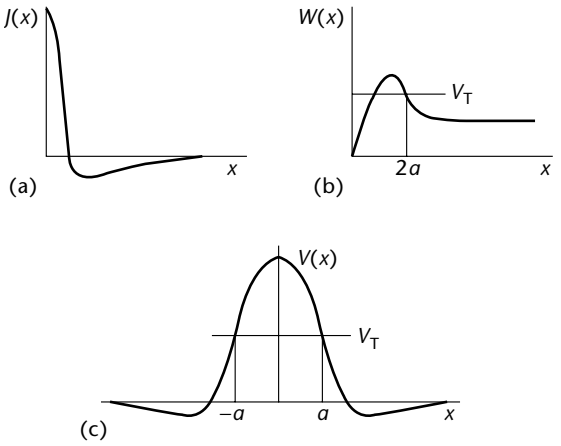

Figure 4. Construction of the 'bump' for a simple neural network. (a) The connection function $J(x)$ between two neurons a distance x apart. (b) The integral of $J(x)$. Intersections with the threshold V_T give the width of the bump, $2a$. (c) A bump of width $2a$ centered at the origin.

$$V(a) = V_T = W(2a) \tag{31}$$

Figure 4(b) shows that with a lateral inhibitory connection function, there are two possible bump widths for a range of thresholds. Amari shows that the bump is stable only if $J(2a) < 0$. Thus, although it is mathematically possible to get a bump without lateral inhibition, the bump will not be stable.

This calculation illustrates the general principles that underly the formation of localized bumps in neural networks. The same ideas have recently been applied to networks of spiking neurons. The main additional requirement for spiking neurons is that the synapses persist for a sufficiently long time. Similar ideas have been exploited to model head direction cells (Zhang, 1996), motor planning (Kopecz and Schoener, 1995), and the representation of the eye position in motor cortex (Salinas and Abbott, 1996).

SUMMARY AND CONCLUSIONS

By thinking about neural networks as simplifications of more complex biophysical systems, we have been able to connect neural networks with the underlying biophysics, simplify the necessary computations, and put ourselves in a position to analyze wide classes of networks which may be relevant to cognitive processes. The approach described in this article is meant to bridge the gap between the 'realistic' many-channel models and the simple 'connectionist' models that are used for modeling many cognitive processes. These

methods are useful because in many cases it is possible to produce models that provide a quantitative connection to the biology while maintaining the computational simplicity of abstract neural networks.

Non-monotonic Logic

CONTENTS

A logic is called non-monotonic if assertions made in a theory in the logic may be retracted when new information is added to the theory.

THE NON-MONOTONIC CHARACTER OF COMMONSENSE REASONING

The use of formal logic as a means for computer programming was first seen in the work of Newell, Simon, and Shaw with their 'logic theory machine' (Newell and Simon, 1956). The work described a system for 'discovering proofs for theorems in symbolic logic'. A few years later, John McCarthy (1959) advocated a logical approach to artificial intelligence (AI), which would lead to the development of non-monotonic logics.

According to this approach, an intelligent agent should have knowledge of its world and its goals and the ability to use this knowledge to infer its course of action. To successfully perform tasks in a changing environment the agent should be able to make tentative conclusions based on available information but be prepared to withdraw some of these conclusions at a later time when further information becomes available.

For instance, I may know that my car is normally in working condition and plan to use it tomorrow for driving to work. Suppose in the morning I discover that the lights were left on and the battery of the car is dead. I then have to abandon my previous plan and look for alternative ways to get to work. The logic-based approach to AI suggests that a mathematical model of an agent capable of such behavior should contain a formal language capable of expressing commonsense knowledge about the world, a precise characterization of the valid conclusions that can be derived from theories stated in this language, and a means by which the agent can arrive at these conclusions. (*See* **Knowledge Representation**)

In the late 1970s, AI researchers tried to build such a model in the framework of classical logic. They quickly discovered that the task is far from trivial. The difficulty is rather deep, and is related to the so-called *monotonicity* of the entailment relation of classical logic. An entailment relation $\models$ between sentences of some logical language $\mathcal{L}$ is called monotonic if for any formulae A, B, and C of $\mathcal{L}$, if $A \models C$ then $A \,\&\, B \models C$ (i.e., if A entails C then so does any extension of A). Monotonicity is natural for classical logic, which was primarily aimed at formalization of mathematical reasoning, where axioms are rarely extended and inferences are long and complex. In mathematics, truth is not invalidated by the addition of new axioms; once proven, a theorem stays proven. In commonsense reasoning, additions to an agent's knowledge are frequent and inferences are usually short but are often based on tentative conclusions. These properties show the inherent non-monotonicity of this type of reasoning and suggest that it may be better modeled by logics with non-monotonic entailment relations. Early definitions of such relations were connected with attempts to clarify reasoning in taxonomic hierarchies (Touretzky, 1986), the meaning of the closed world assumption in databases (Reiter, 1978), and the semantics of the 'negation as failure' operator of logic programming (Clark, 1978). More powerful and general non-monotonic reasoning formalisms – notably circumscription (McCarthy, 1980), default logic (Reiter, 1980), and non-monotonic modal logics (McDermott and Doyle, 1980; Moore, 1985) – appeared almost simultaneously in the early 1980s.

TAXONOMIC HIERARCHIES

Often the knowledge of a reasoning agent contains a collection of classes of objects organized in a taxonomic hierarchy. In the hierarchies illustrated

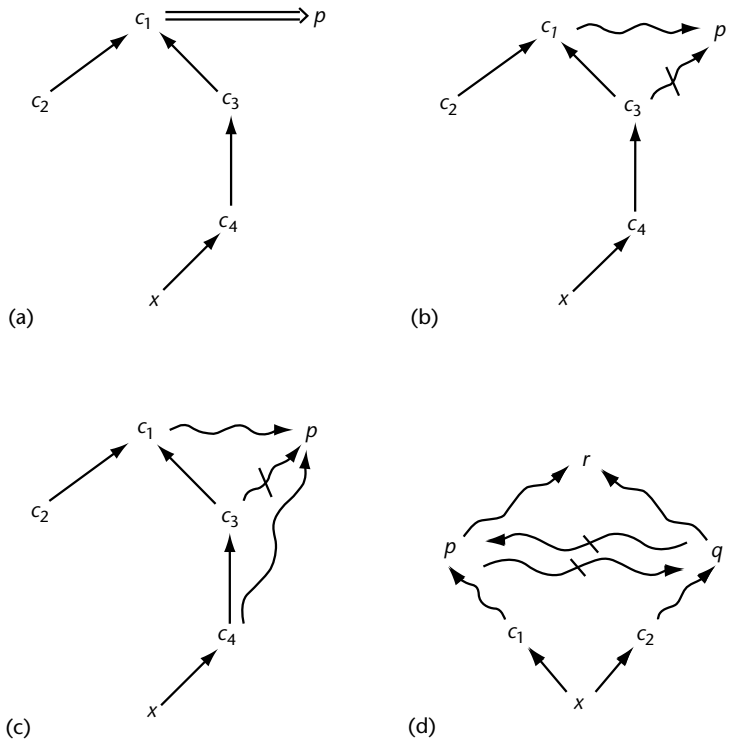

Figure 1. Taxonomic hierarchies. In diagram (a) we can conclude that x has property p. Diagrams (b) and (c) illustrate how the inheritance principle can cause us to modify our conclusions based on new information: in (b) we conclude that x does not have p, but in (c) we conclude again that x has p. Diagram (d) shows an ambiguous situation in which the inheritance principle provides no guidance.

in Figure 1, c_1, c_2, c_3, and c_4 denote classes of objects, $c_i \rightarrow c_j$ indicates that c_i is a proper subclass of $c_j (c_i \subset c_j)$ and $x \rightarrow c$ indicates that x is a member of $c (x \in c)$. Double arrows, such as in Figure 1(a), are used to link classes to properties: $c \Rightarrow p$ means that every element of class c has property p. Hierarchies containing only the elements mentioned above are called *strict*. They are often used to encode the hierarchical structure of a domain in a compact way. To establish that x has property p (denoted by the formula $p(x)$) it is sufficient to find a path from x to p. If no such path exists then x does not have property p. This reasoning can easily be justified by translating a hierarchy H into a first-order theory $T(H)$, such that for every object x of the hierarchy, $T(H) \models p(x)$ iff H contains a path from x to p. Here $\models$ denotes the entailment relation of classical logic.

In Figure 1(b), a link $c \rightsquigarrow p$ indicates only that elements of class c 'normally' have property p. Similarly, $c \not\rightsquigarrow p$ indicates that normally elements of c do not have property p. Statements of this form are called 'defaults'. They do not occur in mathematics, but seem to constitute a large portion of our commonsense knowledge about the world. A substantial part of our education consists of learning defaults and their exceptions, as well as various ways of reasoning with this knowledge. Given the hierarchy of Figure 1(b) a rational agent will have no difficulty in following the path $x \rightarrow c_4 \rightarrow c_3 \not\rightsquigarrow p$ which leads to the conclusion that x does not satisfy p. This is despite the fact that the path $x \rightarrow c_4 \rightarrow c_3 \rightarrow c_1 \rightsquigarrow p$ corresponds to an argument which contradicts this conclusion. This seems to happen because of the use of a commonsense idea known as the *inheritance principle* (Touretzky, 1986) which states that, in our reasoning, more specific information prevails over less specific information. Since c_3 is a proper subset of c_1, we know that the default $c_3 \not\rightsquigarrow p$ is more specific than $c_1 \rightsquigarrow p$, and so we prefer the first argument. Inheritance reasoning is non-monotonic. Expanding the hierarchy by a link $c_4 \rightsquigarrow p$ (see Figure 1(c)) will lead to the creation of a new preferred path, $x \rightarrow c_4 \rightsquigarrow p$. Given this new information we will be forced to change our view and conclude that x satisfies p after all.

The inheritance principle was one of the first useful principles of commonsense reasoning discovered by AI researchers. Attempts to formalize this principle (i.e. to precisely characterize the valid

conclusions that can be drawn by a rational agent whose knowledge is represented by an inheritance hierarchy) led to two distinct approaches to the problem. Direct theories of inheritance focus on paths of the network, viewed as possible arguments, and on defining the relative strengths of these arguments. For the hierarchy in Figure 1 (b), the argument $x \to c_4 \to c_3 \to c_1 \rightsquigarrow p$ is defeated by the argument $x \to c_4 \to c_3 \not\rightsquigarrow p$, which is not defeated by any other argument. Hence the conclusion $p(x)$ is justified. Figure 1(d) shows a more complex hierarchy in which properties p and q are normally mutually exclusive but elements having either one of them normally have property r. Here neither the argument $x \to c_1 \rightsquigarrow p$ nor $x \to c_2 \rightsquigarrow q \not\rightsquigarrow p$ is more specific than the other and hence neither defeats the other. The same is true for the property q; therefore we can conclude neither $p(x)$ nor $q(x)$. The answer given by this hierarchy to the query $r(x)$ depends on the precise definition of plausible counterargument. A 'sceptical' reasoner will argue that since the truths of $p(x)$ and $q(x)$ are unknown we should refrain from making any conclusions about $r(x)$. A 'credulous' reasoner can take a view that the net from Figure 1(d) sanctions the conclusion $p(x) \vee q(x)$, and hence $r(x)$ must be true. A detailed discussion of direct theories of inheritance can be found in Horty (1994).

Indirect approaches to inheritance are based on mapping the network together with the form of inheritance principle used in its semantics to more general theories of non-monotonic reasoning. Some insight into the relationship between direct and indirect approaches can be found in You *et al*. (1999).

THE CLOSED WORLD ASSUMPTION

The following example illustrates another typical situation requiring non-monotonic reasoning. Suppose the list of faculty staff of a small computer science department is posted on the wall of the main office. One may naturally assume that the list is complete: if Michael is not mentioned on it then he is not a faculty member in this department. This is, of course, only an assumption. (It is possible, for example, that the name of a recently appointed faculty member has not yet been added to the list.) Assumptions like this are called *closed world assumptions* (Reiter, 1978). They are frequently used by people acting in everyday situations. Such assumptions are also built into the semantics of databases and logic programming languages such as Datalog and PROLOG. In databases, a table describing a relation r contains the objects satisfying r. Objects that do not occur in the table are assumed not to satisfy r. In logic programming, an answer 'no' to a query q is often interpreted as 'q is false' (instead of a more precise but less useful 'PROLOG interpreter cannot prove q from information given in a program'). The closed world assumption is expressible in practically all general-purpose non-monotonic formalisms, including those discussed below.

NON-MONOTONIC REASONING IN LOGIC PROGRAMMING

Some of the earliest non-monotonic reasoning systems were developed in the framework of logic programming. Originally, logic programs were viewed as collections of clauses (or rules) of the form

$$p \leftarrow \Gamma \tag{1}$$

which is read as 'p if Γ'. Here the head, p, is an atom and the body, Γ, is a sequence of atoms. A clause with an empty body is called a 'fact'. With the advent of practical logic programming languages the rules became more complex. For instance, in the logic programming language PROLOG, the body of a rule is allowed to contain expressions of the form `not q`, interpreted as 'PROLOG interpreter failed to prove q'. Note that 'not' here is different from the negation $\neg$ in classical logic where $\neg q$ is interpreted as 'q is false'. Thus, a program π_0 consisting of the two rules

$$p(X) \leftarrow \texttt{not}\ q(X);\ p(X) \leftarrow r(X) \tag{2}$$

will answer 'yes' to a query $p(a)$. The PROLOG interpreter will attempt to prove $q(a)$, fail to do so, and conclude $p(a)$. If we extend π_0 by the new fact $q(a)$, then the previous conclusion will be withdrawn and the answer to $p(a)$ will become 'no'. This connective `not` is called 'negation as finite failure', and was introduced primarily as a procedural device. The first declarative semantics of this connective was suggested by Clark (1978). Under this semantics, the collection of rules with the head $p(X)$ in π_0 is regarded as a definition of p: a shorthand for the formula

$$\forall X\ p(X) \equiv (\neg q(X) \vee r(X)) \tag{3}$$

This idea is used to translate a program π into a set $\mathrm{comp}(\pi)$ of first-order formulae called the *predicate completion* of π. The theory $\mathrm{comp}(\pi_0)$ consists of statement 3 above, as well as the statements

$$\forall X \neg r(X) \tag{4}$$

and

$$\forall X \neg q(X) \tag{5}$$

and the collection of equality axioms guaranteeing that distinct names in the language represent distinct objects of the domain. The completion comp(π_1) of the program $\pi_1 = \pi_0 \cup \{q(a)\}$ is obtained by replacing statement 5 in comp(π_0) by $\forall X\ q(X) \equiv (X = a)$. By definition, a logic program π entails ($\models$) a literal l (not containing variables) iff l is classically entailed by comp(π). Note that comp(π_0) $\models p(a)$ but comp(π_1) $\models \neg p(a)$.

Work on the semantics of logic programs continued in several directions. The meaning of `not` was refined to make it less dependent on the particular inference mechanisms associated with the PROLOG interpreter (Gelfond and Lifschitz, 1988), and to allow abductive reasoning (Kakas *et al.*, 1992; Denecker and De Schreye, 1992). These approaches were generalized to accommodate programs with rules formed using more complex formulae. The resulting logical languages and entailment relations provide powerful means for representing and reasoning with commonsense knowledge. Suppose we wish to represent the facts that Tweety is a bird and birds normally fly. This can be done by the program consisting of two rules:

$$\texttt{fly}(X) \leftarrow \texttt{bird}(X), \texttt{not} \neg \texttt{fly}(X);\ \texttt{bird}\ (\texttt{tweety}) \tag{6}$$

Since there is no reason to believe that Tweety does not fly, the program concludes `fly (tweety)`. If we learn that Tweety is not a flying bird and expand our program by a new fact, $\neg$ `fly (tweety)`, the resulting program will be consistent and entail that Tweety does not fly.

CIRCUMSCRIPTION

The basic ideas and intuition behind another powerful non-monotonic system called *circumscription* were described and formalized by John McCarthy (1977, 1980). In circumscription, theories are written in classical first-order logic, but the entailment relation is not classical. A formula F is entailed by a circumscriptive theory T if it is true in all minimal models of T. A model M of a theory T is called minimal with respect to some partial ordering $<$ of models if there is no model N of T such that $N < M$. A circumscription policy is used to determine the particular partial ordering $<$ used to circumscribe a theory. In the basic case, a single predicate P is chosen to be circumscribed. Given two models M_1 and M_2, which differ only in their interpretations of P, we say that $M_1 \leq M_2$ if the extent of P in M_1 is a subset of its extent in M_2. We write `circ` (T; P) $\models F$ to indicate that F is entailed from T by circumscription with the policy of minimizing P. Here `circ` (T; P) can be viewed as a second-order formula expressing the above definition. (Recall that second-order formulae allow quantifiers over relations.)

Let us apply this idea to a version of the flying birds example above. We can attempt to express that Tweety is a bird and birds normally fly by first-order sentences

$$T = \{\texttt{bird tweety and}\ \forall X\ ((\texttt{bird}(X) \wedge \neg \texttt{ab}(X)) \supset \texttt{fly}(X))\} \tag{7}$$

where `ab` (X) means that X is abnormal with respect to flying. Obviously, classical first-order logic does not allow us to reach the desired commonsense conclusion that Tweety can fly. If, however, we use circumscription and circumscribe `ab`, then all minimal models under this policy contain `fly (tweety)`; hence `circ` (T; `ab`) $\models$ `fly (tweety)`. This basic form of circumscription is often too restrictive, so many other circumscriptive policies have been formalized. One common policy is to specify certain predicates which are allowed to vary. In this case, models are comparable if they differ in the extent of the varied predicates as well as the circumscribed predicate. As before, the ordering of comparable models is based solely on the extent of the circumscribed predicate in the models. Suppose we add to our example the fact that penguins are birds which are abnormal with respect to flying: (`penguin`(X) $\supset$ `bird`(X) `and` `penguin`($X \supset$ `ab`(X)). Since a model M_0 in which Tweety is a penguin is minimal with respect to ordering defined by the first policy, we no longer have `circ` (T; `ab`) $\models$ `fly (tweety)`. If we modify the policy so that `penguin` can vary, the model M_0 will not be minimal with respect to the new ordering. Under this policy, T concludes `fly (tweety)`. Selection of the right circumscriptive policy lies at the heart of representing knowledge in circumscriptive theories. Even though computing consequences of circumscribed theories are generally intractable (even in propositional cases), for some theories there are reasonably efficient algorithms based on reducing the circumscribed theory to a logic program or a set of first-order formulae.

DEFAULT LOGIC

Another non-monotonic formalism which uses classical first-order logic as its base is default logic (Reiter, 1980). A default theory is a pair (D, W)

where W is a collection of statements of first-order logic and D is a set of default rules, which are statements of the form

$$\frac{A : \mathtt{M}B_1, \ldots, \mathtt{M}B_n}{C} \tag{8}$$

where A, each B_i, and C are classical formulae. A default rule can be read as 'if A is provable and each B_i is possible then conclude C', and can be used as a non-monotonic rule of inference. For instance, a proof of r in a default theory $T_1 = (\{\frac{q:\mathtt{M}r}{r}\}, \{p, p \supset q\})$ consists of a 'classical' step, deriving q, and an application of the default rule of T_1, deriving r. The second step is justified by T_1's inability to prove $\neg r$. A collection of formulae that can be derived from a default theory T in this fashion is called an *extension* of T. Extensions are often interpreted as sets of beliefs which can be formed by a rational agent on the basis of T. The default theory T_1 above has one such extension, Cn (p, $p \supset q$, r), where Cn(S) stands for the set of all 'classical' consequences of S. Default theory $T_2 = (\{\frac{r:\mathtt{M}\neg p}{q}, \frac{r:\mathtt{M}\neg q}{p}\}, \{r\})$ has two extensions, Cn (r, q) and Cn(r, p), and default theory $T_3 = (\{\frac{:\mathtt{M}\neg p}{p}\}, \phi)$ has none. (The latter fact can be attributed to the irrationality of the default rule of T_3.) The precise notion of an extension of a default theory was first defined by a fixed-point construction in Reiter (1980). Although some variants of Reiter's notion of an extension have been advocated, the basic idea of the construction remains the same. Fixed-point constructions somewhat similar to that of Reiter were used in several other early non-monotonic systems. In particular they are used to define the semantics of the 'modal' non-monotonic logics of McDermott and Doyle (1980) and their variants (Moore, 1985). For more details see Marek and Truszczyński (1993).

Default logic is a powerful tool which can be used to give semantics of other non-monotonic formalisms. For instance, the hierarchy in Figure 1(d) can be represented by a default theory $T_4 = (D, W)$ where $D = \{\frac{c_1(X):\mathtt{M}p(X)}{p(X)}, \frac{c_2(X):\mathtt{M}q(X)}{q(X)}, \frac{p(X):\mathtt{M}r(X)}{r(X)}, \frac{q(X):\mathtt{M}r(X)}{r(X)}\}$ and $W = \{c_1(x), c_2(x), \forall X(p(X) \supset \neg q(X))\}$. (Here the rules of T_4 containing variables should be read as a shorthand for the set of their instantiations.) The theory has two extensions: one containing $\{p(x), \neg q(x), r(x)\}$ and another containing $\{q(x), \neg p(x), r(x)\}$. The set of valid conclusions that can be made by a 'credulous' inheritance reasoner on the basis of such hierarchies can now be defined as the set of formulae that belong to all extensions of the corresponding default theory. Default theories can also be used to give a semantics to logic programs. A rule $r = l_0 \leftarrow l_1, \ldots, l_m, \mathtt{not}\ l_{m+1}, \ldots, \mathtt{not}\ l_n$, where the l_i are literals, can be translated to a default rule

$$d(r) = \frac{l_1, \ldots, l_m : \mathtt{M}\bar{l}_{m+1}, \ldots, \mathtt{M}\bar{l}_n}{l_0} \tag{9}$$

Note that $\bar{l}$ stands for the complement of l; i.e. if l is an atom then $\bar{l} = \neg l$, and if $l = \neg a$ where a is an atom then $\bar{l} = a$. A program π consisting of such rules entails a formula F if F belongs to all the extensions of the default theory $d(\pi) = (\{d(r) : r \in \pi\}, \phi)$. It can be shown that the semantics defined in this way coincides with the answer set semantics (Gelfond and Lifschitz, 1991) of logic programs. There is also a close connection with truth-maintenance systems (TMSs) (Doyle, 1979): programs which manage sets of nodes and sets of justifications. A node can be viewed as a set of formulae, while justifications correspond to logic programming (or default) rules. Each justification states that one node should be believed if certain others are believed and certain others disbelieved. The precise mapping establishing this correspondence helped increase our understanding of what is computed by TMSs and at the same time linked theoretical work on non-monotonic reasoning with implemented reasoning systems.

It remains to be seen whether the impressive power of default logic, circumscription, and other 'superclassical' non-monotonic systems will make them tools of choice for representing commonsense knowledge, or if weaker but simpler languages (similar to those based on logic programming) will be preferred by knowledge engineers. In the 1990s substantial progress was made in building practical systems capable of non-monotonic reasoning. In addition to PROLOG and TMSs, we now have efficient systems, such as Smodels (Niemelä and Simons, 1997), CCALC (McCain, 1997), and dlv (Citrigno *et al.*, 1997), capable of computing answer sets of various classes of logic programs and default theories. These systems form the basis for a style of programming in which application problems are encoded so that their solutions are fully described by answer sets of the corresponding program. There are applications of this approach to AI problems such as planning and diagnosis. Non-monotonic systems also played an important role in the development of theories of action and change. In such theories one needs to describe causal laws, which define the effects of performing actions, as well as causal relations between the fluents (propositions whose values depend on time). One also needs to specify which fluents do

not change. The problem of finding a compact representation of what changes and what does not is called the 'frame problem'. In 1986, McCarthy suggested that the second part of this problem might be solved by the use of a default rule that states that actions normally do not change values of fluents. Attempts to solve this and other related problems have motivated much work on non-monotonic logics. More details on this subject can be found in Shanahan (1997).

NON-MONOTONICITY AND PROBABILISTIC REASONING

The formalisms discussed above allow reasoning about the truth or falsity of logical statements. In some cases the truth or falsity can be determined only with a certain degree of plausibility. AI researchers have used a variety of different approaches, such as Bayesian theory, Dempster–Shafer theory, fuzzy logic, and certainty factors, to develop formalisms for reasoning with such information. These formalisms are closely related to work on non-monotonic reasoning. A collection of important papers on probabilistic reasoning methods can be found in Pearl and Shafer (1990). To illustrate the use of such approaches, we consider Bayesian belief networks. Belief networks are applicable in situations where the plausibility of a statement can be given by the mathematical probability of the corresponding event. (*See* **Reasoning under Uncertainty**; **Bayesian Belief Networks**; **Fuzzy Logic**)

Consider the following situation. A person has a burglar alarm in his house and lives in an area where burglaries are fairly infrequent. If there were a burglary, the alarm would probably sound. False alarms sometimes occur as well. Suppose that, while at work, the person gets a call from a neighbor who says that the alarm is sounding. Suppose the person also knows that, while this particular neighbor could be trusted to call if the alarm really was on, the neighbor is also a practical joker and may say the alarm is ringing is a prank. The person has a second neighbor whom he can ask about the alarm. This neighbor lives further away from the person's house and, because of the distance, may not hear the alarm even if it is active. A belief network formalizing information from this example is shown in Figure 2.

In the figure, events are depicted by ovals. Beside each oval is a table giving the conditional probabilities of the event. The statement that 'burglaries are fairly infrequent' is expressed by assigning a very low probability to the event ($P(B) = 0.001$). An

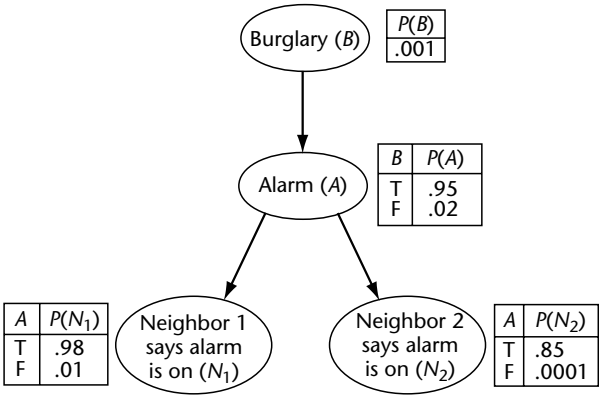

Figure 2. A Bayesian belief network. In this example, an agent knowing N_1 would have a 68% belief in A. This belief drops to 24% of the agent then learns that N_2 is false.

arrow from event X to event Y indicates that Y can be caused by X. The chances of this happening are given by the conditional probabilities in the corresponding table. For example, the table next to the alarm event states that the alarm goes off 95% of the time when there is a burglary and 2% of the time when there is not one. Using the information given in the belief network, algorithms based on Bayesian theory can be used to compute the probability of an event given knowledge of the occurrences of other events. The agent's belief is then based on the computed probability. In the example, Bayesian theory implies that the probability that the alarm sounded given the fact that the first neighbor called is 68%, and hence the agent would believe that the alarm was on. This approach is non-monotonic in that if the agent gets further information he may well change the computed probability, and may therefore alter his beliefs. For example, if the second neighbor calls and says that she does not hear the alarm then the computation returns only a 24% probability that the alarm is on, and therefore the agent changes his belief. A more complete discussion of the relationship between non-monotonic logics and probabilistic reasoning methods can be found in Goldszmidt and Pearl (1996).

Pattern Recognition, Statistical

Intermediate article

Thomas Hofmann, Brown University, Providence, Rhode Island, USA

CONTENTS

Statistical pattern recognition deals with the problem of automatically classifying objects as belonging to one or more classes from a set of possible classes. Objects are typically represented by raw data that may include measured or known object properties and which are summarized in a feature vector. The general goal is to infer suitable classification rules that map feature vectors to class labels based on a training set of objects with known class memberships.

INTRODUCTION

Definition and Challenges

Humans solve pattern recognition problems all the time. Our visual system constantly identifies and recognizes objects and people under highly variable conditions such as pose, viewing angle and illumination. Our auditory system distinguishes sounds and phonetic units from a noisy acoustic data stream. We constantly group, structure, and interpret sensory inputs and integrate them with past experience to guide us in making decisions.

Statistical pattern recognition is a discipline at the intersection of computer science, statistics and engineering that deals with the question of how learning from examples can improve pattern recognition systems. The central problem is that of inductive inference: how can one infer a general recognition rule from a finite set of examples? How can a correct generalization from the available training examples be guaranteed? What algorithms should be used to implement automatic pattern recognition systems?

Pattern recognition research also involves certain problems that are presumed in inductive inference, namely the availability of a suitable representation for patterns (typically as a vector in some 'feature space') and the specification of suitable target classes or concepts.

Supervised Classification and Concept Learning

Formally, one commonly distinguishes between supervised and unsupervised classification. In supervised classification, it is assumed that patterns belong to one or more of a given set of classes and that a training set with correctly labeled examples is available. In unsupervised classification, the main challenge is to identify what the relevant classes are in the first place. The intention is usually to find classes that are in some way natural for the given domain, a task that is most commonly carried out by grouping patterns into clusters of similar patterns ('data clustering').

This article will focus on supervised learning, and for the most part deal with the simple but generic case of binary classification or 'concept learning'. In concept learning, an example can either be positive (being an example of the concept) or negative (not being an example of the concept); formally, the goal is to find a mapping $f: X \to \Omega$ that associates patterns $\mathbf{x}$ from some input space X with their corresponding class or concept labels $f(\mathbf{x})$. The classification function f is also called a 'discriminant function' and in the two-class case ($\Omega = \{-1, 1\}$) it is referred to as a 'dichotomy'. (A problem closely related to classification is regression, where the response variable is continuous and real-valued. In fact, many classification methods have regressional analogs.) Geometrically, one can often visualize a classification function by the decision boundaries it implies. For example, a dichotomy will define a boundary that separates the positive and the negative patterns (see Figure 1).

In statistical pattern recognition, the classification function has to be inferred from a set of examples, the so-called training set $S = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \ldots, (\mathbf{x}_n, y_n)\}$, where each example consists of a pattern $\mathbf{x}_i$ and an associated class label y_i.

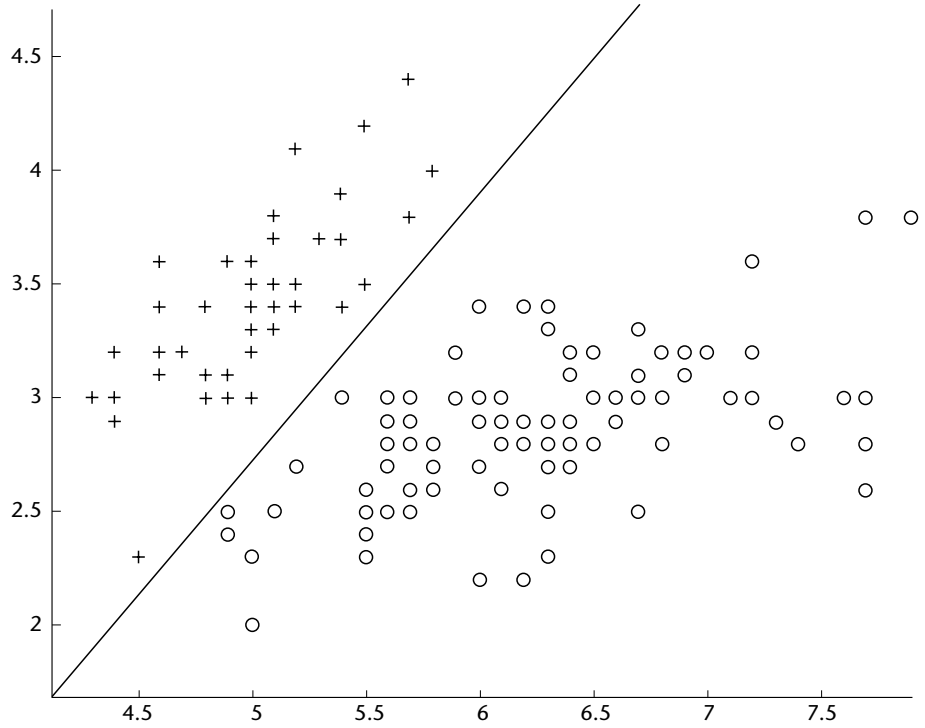

Figure 1. An example of a (linear) dichotomy on a two-dimensional data set. The linear discriminant function is shown as a solid line. 'Positive' examples lie on one side of the line and 'negative' examples on the other.

Classification problems arise in a vast range of applications. For example, in object recognition (e.g. optical character recognition), given a finite set of object classes, images must be classified according to the classes of objects they depict. In speech recognition, waveforms must be mapped to discrete phonetic or syntactic units. In text categorization, documents must be categorized or annotated as dealing with specific topics, being of interest to specific people, or being of a specific genre. In molecular biology, proteins or DNA sequences must be classified as belonging to known families of proteins or known types of signals or genes.

THEORY OF PATTERN RECOGNITION

Bayes-Optimal Classification

Before designing or even engineering a system, one needs to investigate the theoretical limits of the problem and identify the (perhaps unachievable) optimal solution. In order to quantify the goodness of a classifier, one commonly uses the zero–one loss function which assigns a loss of 0 to a correct classification ($f(\mathbf{x}_i) = y_i$) and a loss of 1 to a misclassification ($f(\mathbf{x}_i) \neq y_i$).

One typically assumes that the observed pattern–label pairs are generated independently from some unknown but fixed probability distribution P. The goal in statistical pattern recognition then is to find a classification function that minimizes the expected zero–one loss. The corresponding risk functional in the binary case of $\Omega = \{-1, 1\}$ can be written as

$$\begin{aligned} R(f) &= \int |f(\mathbf{x}) - y| \mathrm{d}P(\mathbf{x}, y) \\ &= \frac{1}{2} \int (1 - f(\mathbf{x})y) \mathrm{d}P(\mathbf{x}, y) \end{aligned} \tag{1}$$

A classifier that minimizes the risk, and hence achieves the best classification accuracy in expectation, is called a 'Bayes-optimal' classifier. It can be proven that a Bayes-optimal classifier assigns a pattern $\mathbf{x}$ to the class $y \in \Omega$ with the highest posterior probability $P(y|\mathbf{x})$, which by Bayes' theorem is given as

$$P(y|\mathbf{x}) = \frac{p(\mathbf{x}|y)P(y)}{\sum_{y' \in \Omega} p(\mathbf{x}|y')P(y')} = \frac{\text{likelihood} \times \text{prior}}{\text{evidence}} \tag{2}$$

Here the 'prior probability' $P(y)$ refers to the probability of sampling a pattern belonging to

class y, and the 'likelihood' $p(\mathbf{x}|y)$ is the class-conditional probability density of patterns $\mathbf{x}$, i.e. it represents the distribution of patterns $\mathbf{x}$ belonging to a particular class y. The normalization in the denominator ('evidence') is the same for all classes and can be ignored in most cases. To illustrate the meaning of Bayes' theorem in this context, assume for simplicity uniform class-prior probabilities. In this case, one would simply favor the class y that has the highest probability (density) to generate the observed pattern.

Since neither the probability distribution $P(\mathbf{x},y)$ nor the derived class-conditional probability densities $p(\mathbf{x}|y)$ are known, the Bayes-optimal classifier represents an unattainable 'gold standard'.

Generalization

The central problem in classification is the problem of generalization: how can the classification risk be minimized without direct access to the underlying distribution that generates the patterns and class labels? Is there an appropriate substitute for the classification risk that could be used to train classifiers and to make formal guarantees about the achieved classification accuracy? In particular, how is the empirical risk, i.e. the classification accuracy achieved on the training sample, related to the true risk? The potentially large discrepancy between the accuracy on training and new test data is often referred to as 'overfitting'.

These fundamental questions are dealt with in computational learning theory. Here we will briefly discuss only the basic philosophy. The Vapnik–Chervonienkis theory (Vapnik, 1999) attempts to derive upper bounds on the difference between the true risk and the empirical risk. This would guarantee (with high probability) that the classifier showing the best performance on the training data will also perform well on new patterns. Ideally, such bounds will be distribution-independent, so that no additional assumptions about P have to be made. Instead, generalization performance will depend on the complexity of the hypothesis class, i.e. the set of classification functions that are considered as candidates. If the hypothesis class is 'too large', it is impossible to guarantee that a finite training set will be sufficient to identify a well-performing classification function (overfitting). If the hypothesis class is 'too small', generalization might be guaranteed, but the training accuracy might be poor (underfitting). In practice, one has to find a balance between these two situations. Vapnik–Chervonienkis theory makes precise the mathematical form of these bounds and how to measure the complexity of a hypothesis class.

More recently, advances have been made in deriving data-dependent generalization bounds. Here one aims at defining appropriate quantities that can be constructively evaluated on the training set and that lead to bounds on the generalization performance. Examples of such data-dependent quantities are geometrical margins (related to 'support vector machines') and ensemble margins (related to boosting algorithms).

In practice, one often prefers an empirical approach to assess the classification accuracy, rather than theoretical bounds. In 'n-fold cross-validation' one partitions the data set into n subsets (a typical value being $n = 10$) and trains a classifier on $(n - 1)$ subsets, while testing classification accuracy on the remaining subset not used for training. This is repeated n times (once for each choice of $(n - 1)$ subsets) and the average of the test errors is used as an estimate of the generalization error. While practical and simple, this procedure does not provide any conceptual insight into how to design classifiers and learning architectures.

Feature Selection and Dimension Reduction

Another important factor is the representation of patterns used for classification. The achievable classification accuracy depends on how much information about the correct class can be derived from the feature representation. This will be reflected in the optimal Bayes error, which depends on the chosen pattern representations. Choosing an appropriate representation requires domain knowledge. For example, how should images, documents, speech waveforms, or molecules be represented? What features should be extracted? Pattern recognition methods need at least some representation as a starting point.

One approach to selecting a feature representation is to include all features that could possibly be relevant to solving the classification problem. Indeed, Bayesian decision theory predicts that extracting more features will generally reduce the Bayes error, since a feature can only help in discriminating classes (in the worst case it can simply be ignored). Yet in practice the situation is more difficult. It is harder to learn in higher-dimensional spaces, and the performance of a classifier may degrade significantly with increasing dimensionality.

A common way to address this problem is to perform feature selection or dimension reduction

as a preprocessing step prior to training the classifier. In feature selection, one often selects or removes one feature at a time, guided either by cross-validation techniques (a computationally expensive procedure, since several classifiers have to be trained at each step) or by surrogate quantities like mutual information between feature and class labels. An alternative is feature reduction by techniques like principal components analysis that map patterns to some lower-dimensional representation.

SUPERVISED CLASSIFICATION METHODS

Bayes Plug-In Classifier

One approach to classification is to take the Bayes-optimal classifier as an ideal starting point and to replace the unknown probability distributions by estimates derived from the training data. The estimated probability distributions can then be used as a 'plug-in' estimator for the true distribution, and the classification problem reduces to the problem of probability density estimation. Additional simplifying assumptions – for example, about the parametric form of the class-conditional probability distributions – are commonly made, in which case the statistical inference problem becomes one of estimating the parameters for each class.

The main problem with this approach is that it is nondiscriminative, i.e. our model might focus on approximating aspects of the distribution of patterns in each class that are irrelevant for discriminating between classes. In particular, it is unclear how the accuracy in estimating class-conditional distributions relates to the performance of the classifier.

Nearest-Neighbor Methods

Nearest-neighbor classification is a 'nonparametric' classification technique, i.e. it does not make any assumptions about the parametric forms of the discriminant functions or the class-conditional distributions. Instead, it relies on the assumption that as the pattern density increases, neighboring patterns will be likely to belong to the same class. The 'k-nearest-neighbor' (kNN) rule determines the class label of a test point by identifying the most popular class among the k closest patterns in the training set. In the simplest case of 1NN, each pattern simply inherits the label of the closest pattern in the training set. In geometric terms, the input space is partitioned into regions of patterns that share the same neighborhood. In the case of 1NN this coincides with the Voronoi tessellation of the input space induced by the training examples. Within each region the class label is constant (see Figure 2).

Despite its apparent simplicity, the asymptotic classification error of the 1NN classifier is known to be at most twice as high as the optimal Bayes error rate (Devroye *et al*., 1996). But this only holds as the number of training data points tends

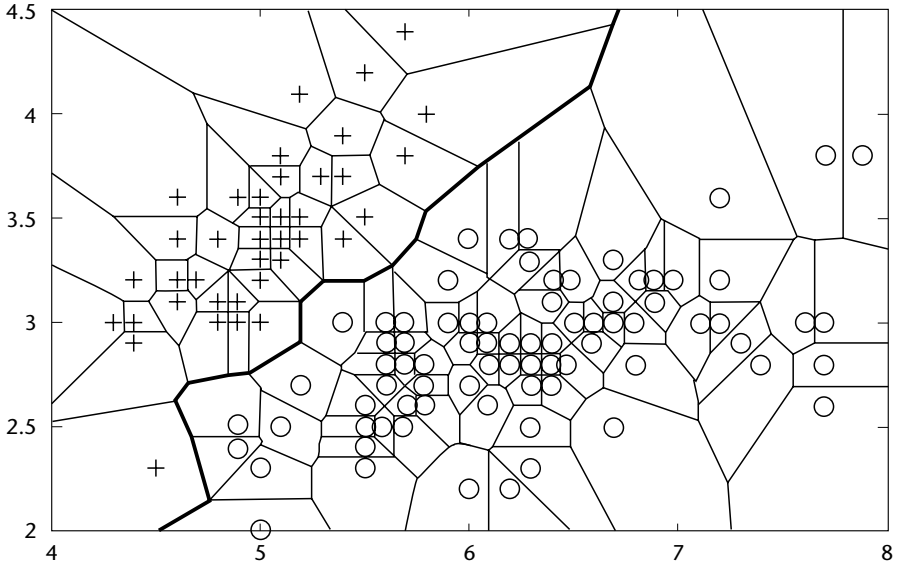

Figure 2. Nearest-neighbor classification for the data set depicted in Figure 1. The thin lines indicate the induced Voronoi tessellation, and the bold line indicates the resulting classifier.

to infinity and patterns densely fill the input space. In practice, this is usually unrealistic, especially in high-dimensional feature spaces. Whether or not kNN classification works well in practice depends strongly on the number of available training examples compared with the dimensionality of the feature space. The choice of a meaningful metric, or similarity function, is also essential: different similarity functions may result in very different classification accuracies.

Linear Classifiers

A common approach in pattern recognition is to restrict the set of classification functions to some family or hypothesis class at the outset. Then, the classifier within that family that performs best in the light of the training data is selected. For example, one may select a classification function from the hypothesis class that has the smallest training error (this is known as 'empirical risk minimization').

In linear classification, the hypothesis class consists of linear discriminants, of the form $f(\mathbf{x}; \mathbf{w}, b) = \text{sign}(\langle \mathbf{x}, \mathbf{w} \rangle + b)$, where $\mathbf{w}$ is a weight vector and b is a scalar offset called the bias. Since the equation $\langle \mathbf{x}, \mathbf{w} \rangle + b = 0$ defines a unique hyperplane with $\mathbf{w}$ being a normal vector, linear classifiers effectively partition the feature space into two half-spaces. In effect, the weight vector specifies a direction in feature space and patterns are projected onto the one-dimensional subspace spanned by $\mathbf{w}$. Within this subspace, features are separated by thresholding at b (see Figure 1).

Given a set of training patterns, how can we determine the optimal linear classifiers? Several methods are available for this purpose.

Perceptron algorithm

The perceptron algorithm is a simple iterative procedure to find a linear classifier, which produces zero training error for linearly separable data sets (i.e. if the positive and negative examples can be perfectly separated by a hyperplane in feature space). The basic idea is as follows. Cycle through the training patterns in some fixed or randomized order. Every time a pattern $\mathbf{x}_i$ is misclassified by the current choice of $\mathbf{w}$ and b, update the weights and bias according to

$$\begin{aligned} \mathbf{w} &\leftarrow \mathbf{w} + y_i \mathbf{x}_i \\ b &\leftarrow b + y_i (\max_i ||\mathbf{x}_i||)^2 \end{aligned} \tag{3}$$

Thus, depending on the label of the misclassified pattern $y_i \in \{-1,1\}$, the pattern is added to or subtracted from the current weight vector and the bias is incremented or decremented by some constant. It can be proven that this will converge towards a solution that separates the training data (Novikoff's theorem). Moreover, it is easy to see from the update procedure that starting from zero weights and bias the ultimate solution can be written as an expansion of the form $\mathbf{w} = \sum_i \alpha_i y_i \mathbf{x}_i$. Here, the nonnegative coefficient α_i corresponds to the number of times an update has been performed for pattern $\mathbf{x}_i$.

Maximum-margin and soft-margin classifiers

For linearly separable data sets, many different linear classifiers will separate the training data perfectly. Is there a good reason to prefer one linear classifier to another? The idea in maximum-margin classification is that each training pattern should not only be correctly classified, but should also be as far away as possible from the decision boundary. For a separating hyperplane, this distance is called the 'margin' of a pattern. The maximum-margin hyperplane is the one that maximizes the minimal margin with respect to a set of training patterns. Geometrically speaking, it will pass through the 'middle' of the space between the convex hulls spanned by the positive and negative examples (see Figure 3).

This very simple idea can be a given a precise mathematical formulation. The maximum-margin hyperplane ($\mathbf{w}^*$, b^*) will fulfill

$$(\mathbf{w}^*, b^*) = \max_{\substack{\mathbf{w}, b \\ ||\mathbf{w}||=1}} \min_i (y_i (\langle \mathbf{x}_i, \mathbf{w} \rangle + b)) \tag{4}$$

The above ideas can be generalized to deal with cases where the data may not be linearly separable or where a perfect separation of training patterns is not necessarily desirable. The resulting classifier is called a 'soft-margin' classifier.

Without explicitly performing the numerical optimization one can show that the optimal weight vector can be written as an expansion over training patterns, $\mathbf{w} = \sum_i \alpha_i y_i \mathbf{x}_i$, with nonnegative weights α_i. Notice that the functional form is similar to the solution found by the perceptron algorithm. The coefficients α_i will be zero for patterns that are on the correct side of the hyperplane and have a margin that is strictly larger than the minimal. Patterns for which $\alpha_i > 0$ are called the 'support vectors'. Intuitively, they are the 'hard' training instances and they determine the decision boundary.

There are strong arguments from learning theory that support the use of maximum-margin or soft-margin classifiers. There exist upper bounds on

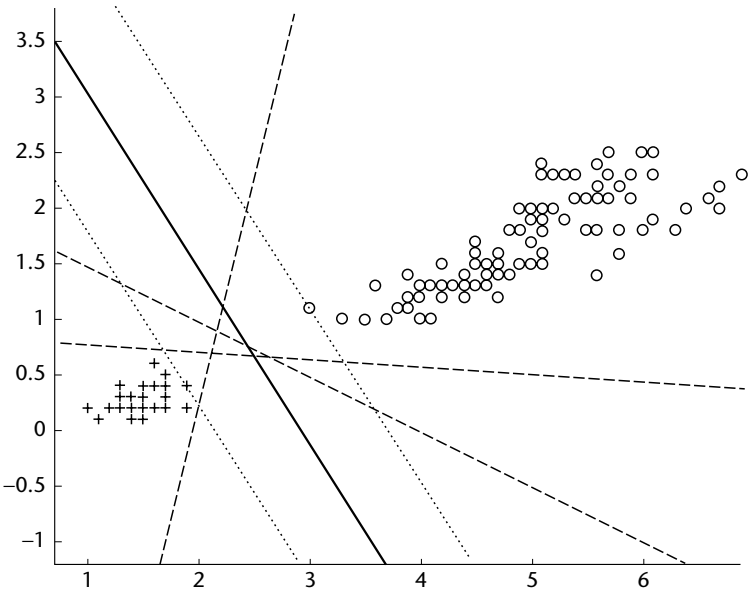

Figure 3. Different linear discriminant functions for a two-dimensional data set. All the lines separate the data without training error, but the maximum-margin hyperplane (bold line) achieves the largest separation margin. The margin is shown by dotted lines; the data points on the dotted lines are the support vectors.

the generalization performance that depend on the maximum margin achieved or the distribution of margins over training examples. Other results bound the generalization error by the sparseness of the solution, i.e. the proportion of training patterns that are support vectors. Detailed discussions can be found in Cristianini and Shawe-Taylor (2000) and Schölkopf and Smola (2002).

Logistic regression

Logistic regression is a statistical technique based on conditional likelihood or cross-entropy. The posterior probability of a class is approximated by a 'generalized linear model':

$$P(y = 1|\mathbf{x}) = \frac{1}{1 + \exp(-\langle \mathbf{x}, \mathbf{w} \rangle - b)} \qquad (5)$$
$$P(y = -1|\mathbf{x}) = 1 - P(y = 1|\mathbf{x})$$

The logistic function maps an affine function of the input nonlinearly to a probability. Geometrically, the equation $\langle \mathbf{x}, \mathbf{w} \rangle + b = 0$ determines a hyperplane on which the posterior probabilities are exactly equal to ½. With increasing distance from this hyperplane, the posterior probabilities approach the extreme values (zero or one).

In logistic regression, $\mathbf{w}$ and b are determined so that the following conditional log-likelihood function is maximized:

$$(\mathbf{w}^*, b^*) = \arg\max_{\mathbf{w}, b} \sum_i \log P(y_i|\mathbf{x};\mathbf{w}, b) \qquad (6)$$

Informally, we are looking for parameter values that maximize the average posterior probability for the correct class.

The remaining numerical optimization problem can be solved, for example, by an iterative algorithm called iteratively reweighted least squares, which performs Newton–Raphson update steps.

Nonlinear Classifiers

Linear classifiers are relatively well understood, but they are severely limited in the type of classification they can achieve. Many interesting problems may not allow a good linear class separation even in an approximate sense. The standard (toy) example is the 'XOR' problem, where we have two positive patterns located in the plane at $(-1,-1)$ and (1,1) and two negative patterns at $(-1,1)$ and $(1,-1)$. No linear classifier can correctly classify these four data points. A whole generation of researchers therefore abandoned linear classifiers to develop neural networks based on the perceptron.

Neural networks

The use of neural networks for pattern recognition is inspired by biological systems. Neural networks implement nonlinear classifiers by explicitly constructing a nonlinear hypothesis class, corresponding to the architecture and topology of the network. There are several types of neural network

architectures, but the most popular is the 'multilayer perceptron' (MLP) with sigmoid transfer functions. An MLP classifier consists of a layer (or layers) of so-called hidden units, which compute new features $\phi(\mathbf{x})$ from the input representation. Each feature is parametrized by a logistic function

$$\phi_i(\mathbf{x}) = \text{logit}(\langle \mathbf{w}_i, \mathbf{x} \rangle + b_i) = \frac{1}{1 + \exp(-\langle \mathbf{w}_i, \mathbf{x} \rangle - b_i)} \quad (7)$$

Thus, each hidden unit is a logistic regression of the input pattern. Finally, an MLP has an output layer with units that compute a function of the output of the hidden units. In the case of binary classification, this is just another single logistic unit $f(\mathbf{x}) = \text{logit}(\langle \phi(\mathbf{x}), \mathbf{v} \rangle + b_0)$. Each hidden unit can be thought of as a feature extractor, and the output unit computes a logistic regression over these new features.

There is no (known) closed-form solution for how to choose the weights of an MLP optimally – for example, to maximize the conditional likelihood function used in logistic regression. In fact, one has to deal with a very high-dimensional nonlinear optimization problem. Standard training procedures are based on gradient information which can be computed efficiently using the 'back propagation' algorithm. This is basically a way to compute the gradient of the error with respect to all weights in the neural network by making use of the chain rule. It propagates error terms from the output layer back to the hidden layers. Of course, gradient methods are only suitable for finding local optima, and this is usually all one can hope for. (*See* **Backpropagation**)

There are a number of issues that have to be addressed in order to utilize neural networks in practical applications. The most important ones are model selection and regularization to avoid overfitting. In model selection, one has to decide on the optimal topology, i.e. the number of hidden units and the connectivity between neurons (such as the number of interconnected layers), a process that can involve significant search effort. In order to regularize the network training, one often uses techniques like weight decay or training with noise. Another popular heuristic is early stopping, whereby the training is stopped before a local optimum is reached.

Decision trees

Decision-tree classification is a technique that is very popular in artificial intelligence, and to some extent in statistics, mainly because of the interpretability of decision trees. A decision tree is a rooted tree – in the simplest and most popular case a binary tree – with a simple test function on patterns associated with each node. Starting at the root node, patterns are transmitted through the tree to a leaf node. The branch a pattern takes at an inner node depends on the outcome of the test at that node. Decision trees are analogous to the 20-question game: each node corresponds to a question and after a finite number of questions a leaf node is reached and a decision is made. Note that the questions asked subsequently depend on the outcomes of previous tests. Usually the types of tests that are performed at inner nodes are restricted to a single feature or attribute. With numerical features, an inner node will typically select one of the features along with a threshold, and transmit patterns to the left branch if the feature is below the threshold, and to the right branch if the feature is above the threshold. Decision trees effectively partition the feature space, each leaf node corresponding to one of the regions in the partition.

Most procedures to train decision trees have two ingredients: a node-purity function which measures how pure the class labels of training patterns transmitted to immediate descendants are (splits that create higher-purity subsets are preferred); and stopping and pruning heuristics which counteract overfitting by limiting the number of nodes in the decision tree.

Kernel-based classifiers and support vector machines

Kernel-based classifiers are an extension of linear classifiers. They exploit the fact that many linear classifiers can be defined purely in terms of inner products between data points. A kernel is a function $(\mathbf{x},\mathbf{y}) \mapsto K(\mathbf{x},\mathbf{y}) \in \mathbb{R}$ that corresponds to an inner product in some new feature space. A kernel can thus be thought of as the composition of two functions, a (possibly nonlinear) mapping to a new feature representation, $\phi(\mathbf{x})$, and an inner product in this new representation, $K(\mathbf{x},\mathbf{y}) = \langle \phi(\mathbf{x}), \phi(\mathbf{y}) \rangle$. In many cases, it is possible to compute effectively a kernel function without explicit access to the embedding ϕ. Then K is an 'implicit mapping' into a new feature space.

Kernels transform the original feature vectors by implicitly mapping them into a new, typically higher-dimensional, feature representation. Linear classifiers in the high-dimensional representation will then correspond to nonlinear classification functions in the original feature space. This simple 'trick' of replacing the inner product in the original representation with an arbitrary kernel yields a

much more flexible and powerful family of classifiers. Some of the most popular kernels are polynomial kernels of degree d, $K(\mathbf{x}, \mathbf{y}) = (\langle \mathbf{x}, \mathbf{y} \rangle + c)^d$, and 'radial basis function' kernels, $K(\mathbf{x}, \mathbf{y}) = \exp(-\| \mathbf{x} - \mathbf{y} \|^2/\sigma^2)$.

Combining kernels with the maximum-margin principle leads to a class of nonlinear classifiers known as 'support-vector machines'. Using the dual representation of the optimal weight vector, these yield solutions of the form $f(\mathbf{x}; \alpha, b) = \Sigma_i \alpha_i y_i K\langle \mathbf{x}_i, \mathbf{x} \rangle + b$. Thus, support-vector machines are linear (soft) maximum-margin classifiers in some implicitly defined feature space. Since the implicit data transformation can be nonlinear, they give rise to nonlinear discriminant functions in the original input representation.

Boosting

Boosting is a technique for combining many 'weak' classifiers (each of which might perform a little better than random guessing) to form a more powerful ensemble. We will focus on a version of boosting called AdaBoost.

In boosting, one incrementally adds weak classifiers to the classifier ensemble in what is called a 'boosting round'. In each round, a relative weight for each pattern in the training set is computed. Then a weak classifier f_t is trained from the weighted examples. This classifier then gets a relative weight α_t and is added to the ensemble. The final classifier will perform a weighted majority vote to determine the class of new test patterns: formally, $F(\mathbf{x}) = \text{sign}(g(\mathbf{x}))$ where

$$g(\mathbf{x}) = \frac{\sum_t \alpha_t f_t(\mathbf{x})}{\sum_t \alpha_t} \tag{8}$$

and t refers to the boosting round.

In AdaBoost, both the weights for the training examples and the weights for the weak learners can be explicitly computed from simple equations. It can be shown that AdaBoost is a greedy optimization scheme to fit an 'additive' (i.e. ensemble) model based on the exponential loss $\sum_i \exp(-y_i\, g(\mathbf{x}_i))$. The negative exponent $y_i\, g(\mathbf{x}_i)$ is called the (ensemble) margin of the pattern $\mathbf{x}_i$; it measures how 'confident' the ensemble is in its vote.

SUMMARY

Statistical pattern recognition deals with the question of how learning from examples can help in the design and implementation of automatic pattern recognition systems. In the 1960s and 1970s, research focused mainly on methods derived from Bayesian decision theory, density estimation, perceptron classifiers, and nearest-neighbor classification. In the late 1980s and early 1990s, the advent of neural networks led to an increased interest in the field and many advances in building nonlinear pattern classifiers. More recently, substantial progress has been made by combining results from computational learning theory with practical algorithms such as support-vector machines and boosting algorithms.

Perceptron

Intermediate article

Simon Haykin, McMaster University, Hamilton, Ontario, Canada

CONTENTS

The perceptron is a neural network designed to simulate the ability of the brain to recognize and discriminate.

INTRODUCTION

The *single-layer* perceptron is the simplest form of a neural network used for the classification of patterns said to be *linearly separable* (i.e., patterns that lie on opposite sides of a hyperplane). Basically, it consists of a single neuron with adjustable synaptic weights and bias. The algorithm used to adjust the free parameters of this neural network first appeared in a learning procedure developed by Rosenblatt in 1958 for his perceptron brain model. The generic 'perceptron' was originally defined by Rosenblatt as a set of input units called 'S-units' that are connected to a second set of units called 'A-units'. The definition of a 'single-layer perceptron' introduced in this article is different from that of Rosenblatt.

If the patterns used to train the perceptron are drawn from two linearly separable classes, then the perceptron algorithm converges and positions the decision surface in the form of a hyperplane between the two classes. The perceptron built around a single neuron is limited to performing pattern classification with only two classes (hypotheses). By expanding the output (computation) layer of the perceptron to include more than one neuron, we may correspondingly perform classification with more than two classes. However, the classes have to be linearly separable for the perceptron to work properly. The important point is that insofar as the basic theory of the perceptron as a pattern classifier is concerned, we need consider only the case of a single neuron. The extension of the theory to the case of more than one neuron is trivial.

The single neuron also forms the basis of an *adaptive filter*, a functional block that is basic to the ever-expanding subject of signal processing. The development of adaptive filtering owes much to the classic paper of Widrow and Hoff in 1960 for pioneering the so-called least-mean-square (LMS) algorithm, also known as the *delta rule*. The LMS algorithm is simple to implement yet highly effective in application. Indeed it is the workhorse of linear adaptive filtering, linear in the sense that the neuron operates in its linear mode when the weights and bias are fixed. Adaptive filters have been successfully applied in such diverse fields as radar, sonar, communications, and biomedical engineering.

Structural extensions of a single-layer perceptron lead to the development of *multi-layer perceptrons*, which distinguish themselves by the use of one or more *hidden layers* of computation nodes. Multilayer perceptrons have been applied successfully to solve some difficult and diverse problems by training them in a supervised manner with a highly popular algorithm known as the *error backpropagation algorithm*, which may be viewed as a generalization of the LMS algorithm.

Basically, error backpropagation learning consists of two passes through the different layers of the network: a forward pass and a backward pass. In the forward pass, an activity pattern (input vector) is applied to the sensory nodes of the network and its effect propagates through the network layer by layer. Finally, a set of outputs is produced as the actual response of the network. During the forward pass, the synaptic weights of the network are all *fixed*. During the backward pass, on the other hand, the synaptic weights are all *adjusted* in accordance with an error correction rule. Specifically, the actual response of the network is subtracted from a desired (target) response to produce an error signal. This error signal is then propagated backward through the network, hence the name 'error backpropagation'. The synaptic weights are adjusted to make the actual response of the network move closer to the desired response in a statistical sense.

The multi-layer perceptron has three distinctive characteristics:

1. The model of each neuron in the network includes a nonlinear activation function. The important point to emphasize here is that the nonlinearity is smooth (i.e., differentiable everywhere) as opposed to the hard-limiting used in Rosenblatt's perceptron. A commonly used form of nonlinearity that satisfies this requirement is a sigmoidal nonlinearity defined by the logistic function:

$$y_j = \varphi_j(v_j) = \frac{1}{1 + \exp(-v_j)}$$

   where v_j is the induced local field (the weighted sum of all synaptic inputs plus the bias) of neuron j, $\varphi_j(v_j)$ is the activation function of neuron j, and y_j is the output of the neuron. The presence of nonlinearities is important because otherwise the input–output relation of the network could be reduced to that of a single-layer perceptron. Moreover, the use of the logistic function is biologically motivated, since it attempts to account for the refractory phase of real neurons.
2. The network contains one or more layers of hidden neurons that are not part of the input or output of the network. These hidden neurons enable the network to learn complex tasks by extracting progressively more meaningful features from the input patterns.
3. The network exhibits a high degree of connectivity, determined by the synapses of the network. A change in the connectivity of the network requires a change in the population of synaptic connections or their weights.

It is through the combination of these characteristics, together with the ability to learn from experience through training, that the multi-layer perceptron derives its computing power. These same characteristics, however, are also responsible for the deficiencies in our present state of knowledge on the behavior of the network. First, the presence of a distributed form of nonlinearity and the high connectivity of the network make the theoretical analysis of a multi-layer perceptron difficult to undertake. Second, the use of hidden neurons makes the learning process harder to visualize. In an implicit sense, the learning process must decide which features of the input pattern should be represented by the hidden neurons. The learning process is therefore made more difficult because the search has to be conducted in a much larger space of possible functions, and a choice has to be made between alternative representations of the input pattern.

The development of the backpropagation algorithm represents a landmark in neural networks in that it provides a computationally efficient method for the training of multi-layer perceptrons. Although it cannot be claimed that the backpropagation algorithm provides an optimal solution for all solvable problems, it has put to rest the pessimism about learning in multi-layer machines that may have been inferred from the book by Minsky and Papert in 1969.

PERCEPTRON CONVERGENCE THEOREM

Figure 1 presents a signal-flow graph of the simplified version of Rosenblatt's perceptron built around a 'winner takes all' neuron, known as the *McCulloch–Pitts model* of a neuron (1943). Such a neuronal model consists of a linear combiner followed by a hard limiter (performing the signum function). The summing node of the model computes a linear combination of the inputs applied to its synapses, and also incorporates an externally applied bias. The resulting sum, that is, the induced local field, is applied to a hard limiter. Accordingly, the neuron produces an output equal to $+1$ if the hard limiter input is positive, and -1 if it is negative.

In the signal-flow graph model of Figure 1, the synaptic weights of the perceptron are denoted by $w_1, w_2, \ldots, w_m$. Correspondingly, the inputs applied to the perceptron are denoted by $x_1, x_2, \ldots, x_m$. The externally applied bias is denoted by b. The induced local field of the neuron is

$$v = \sum_{i=1}^{m} w_i x_i + b$$

The goal of the perceptron is to correctly classify the set of externally applied inputs into one of two classes C_1 or C_2. The decision rule for the classification is to assign the point represented by the inputs to class C_1 if the perceptron output y is $+1$ and to class C_2 if it is -1.

To develop insight into the behavior of a pattern classifier, it is customary to plot a map of the decision regions in the m-dimensional signal space spanned by the m input variables $x_1, x_2, \ldots, x_m$. In the simplest form of the perceptron there are

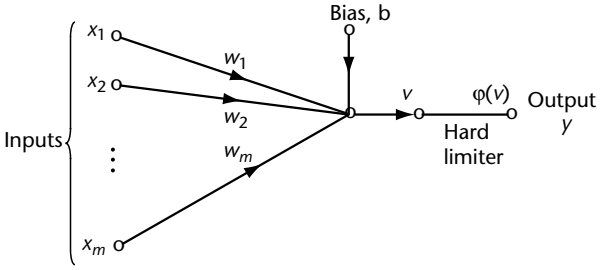

Figure 1. Signal-flow graph of the perceptron.

two decision regions separated by a hyperplane defined by

$$\sum_{i=1}^{m} w_i x_i + b = 0$$

This is illustrated in Figure 2 for the case of two input variables x_1 and x_2, for which the decision boundary takes the form of a straight line. A point (x_1, x_2) that lies above the boundary line is assigned to class C_1 and a point (x_1, x_2) that lies below the boundary line is assigned to class C_2. Note also that the effect of the bias b is merely to shift the decision boundary away from the origin.

The synaptic weights of the perceptron can be adapted on an iteration-by-iteration basis, using an error-correction rule known as the *perceptron convergence algorithm*:

1. If, at iteration n, the nth member of the training set, $\mathbf{x}(n) = [x_1(n), x_2(n), \ldots, x_m(n)]^{\mathrm{T}}$ where superscript T denotes transposition, is correctly classified by the weight vector $\mathbf{w}(n) = [w_1(n), w_2(n), \ldots, w_m(n)]^{\mathrm{T}}$ then no correction is made to the weight vector of the perceptron in accordance with the rule:

   $\mathbf{w}(n+1) = \mathbf{w}(n)$ *if* $\mathbf{w}^{\mathrm{T}}\mathbf{x}(n) > 0$ and $\mathbf{x}(n)$ belongs to class C_1

   $\mathbf{w}(n+1) = \mathbf{w}(n)$ *if* $\mathbf{w}^{\mathrm{T}}\mathbf{x}(n) \leq 0$ and $\mathbf{x}(n)$ belongs to class C_2

2. Otherwise, the weight vector of the perceptron is updated in accordance with the rule:

   $\mathbf{w}(n+1) = \mathbf{w}(n) - \eta(n)\mathbf{x}(n)$ if $\mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n) > 0$ and $\mathbf{x}(n)$ belongs to class C_2

   $\mathbf{w}(n+1) = \mathbf{w}(n) - \eta(n)\mathbf{x}(n)$ if $\mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n) \leq 0$ and $\mathbf{x}(n)$ belongs to class C_1

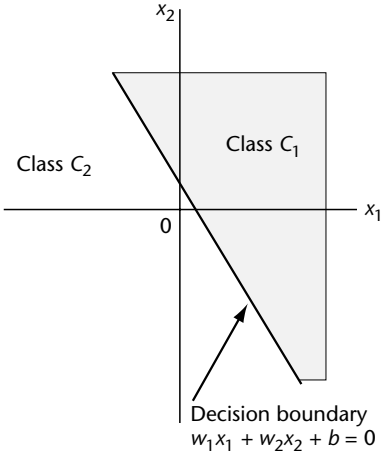

Figure 2. Illustration of the hyperplane (in this example, a straight line) as the decision boundary for a two-dimensional, two-class pattern-classification problem.

where the learning-rate parameter $\eta(n)$ controls the adjustment applied to the weight vector at iteration n.

If $\eta(n) = \eta > 0$, where η is a constant independent of the iteration number n, we have a fixed increment adaptation rule for the perceptron.

We may now state the fixed-increment convergence theorem for Rosenblatt's perceptron.

> Let the subsets of training vectors X_1 and X_2 be linearly separable, from which the inputs presented to the perceptron originate. Starting from the null initial condition $\mathbf{w}(0) = \mathbf{0}$, the perceptron converges after some n_0 iterations in the sense that
>
> $\mathbf{w}(n_0) = \mathbf{w}(n_0 + 1) = \mathbf{w}(n_0 + 2) = \ldots$
>
> is a solution vector for $n_0 \leq n_{\max}$.

The use of an initial value $\mathbf{w}(0)$ different from the null condition merely results in a decrease or increase in the number of iterations required to converge. Regardless of the value assigned to $\mathbf{w}(0)$, the perceptron is assured of convergence.

LEAST-MEAN-SQUARE ALGORITHM

Figure 3 depicts the signal-flow graph of an adaptive filter designed to deal with an unknown dynamical system. The basic difference between this model and that of Figure 1 is the substitution of a linear neuron for the McCulloch–Pitts neuron. Let $d(n)$ denote a desired response at iteration n. According to Figure 3, the corresponding error signal is

$$e(n) = d(n) - \sum_{i=1}^{m} w_i(n)x_i(n) = d(n) - \mathbf{w}^{\mathrm{T}}(n)\mathbf{x}(n)$$

The LMS algorithm is based on the use of instantaneous values for the cost function

$$E(\mathbf{w}) = e^2(n)/2$$

Differentiating $E(\mathbf{w})$ with respect to $\mathbf{w}$ yields

$$\frac{\partial E(\mathbf{w})}{\partial \mathbf{w}(n)} = -\mathbf{x}(n)e(n)$$

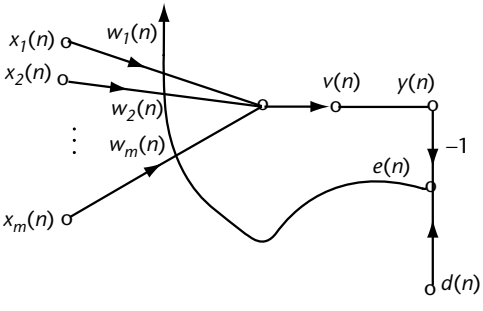

Figure 3. Signal-flow graph of adaptive model for the LMS algorithm.

Using this latter result as an estimate for the gradient vector, we may formulate the LMS algorithm as

$$\begin{aligned}\mathbf{w}(n+1) &= \mathbf{w}(n) - \eta\frac{\partial E(\mathbf{w})}{\partial \mathbf{w}(n)} \\ &= \mathbf{w}(n) + \eta\,\mathbf{x}(n)e(n)\end{aligned}$$

where η is the learning-rate parameter. The feedback loop around the weight vector $\mathbf{w}(n)$ in the LMS algorithm behaves like a low-pass filter, passing the low-frequency components of the error signal and attenuating its high-frequency components. The average time constant of this filtering action is inversely proportional to the learning-rate parameter η. Hence, by assigning a small value to η, the adaptive process will progress slowly. More of the past data are then remembered by the LMS algorithm, resulting in a more accurate filtering action. In other words, the inverse of the learning-rate parameter η is a measure of the memory of the LMS algorithm.

In the LMS algorithm the weight vector $\mathbf{w}(n)$ traces a random trajectory. For this reason, the LMS algorithm is sometimes referred to as a 'stochastic gradient algorithm'. As the number of iterations in the LMS algorithm approaches infinity, $\mathbf{w}(n)$ performs a random walk (Brownian motion) about an optimum solution known as the Wiener solution. The important point is the fact that, unlike the deterministic method of steepest descent that yields the Wiener solution, the LMS algorithm does *not* require knowledge of the statistics of the environment.

BACKPROPAGATION ALGORITHM

Figure 4 shows the architectural graph of a multi-layer perceptron with two hidden layers and an output layer. To set the stage for a description of the multi-layer perceptron in its general form, the network shown here is fully connected. This means that a neuron in any layer of the network is connected to all the nodes/neurons in the previous layer. Signal flow through the network progresses in a forward direction, from left to right and on a layer-by-layer basis.

Figure 5 depicts a portion of the multi-layer perceptron, where two kinds of signals are identified:

1. *Function (input) signals*. A function signal is an input signal, a stimulus that comes in at the input end of the network, propagates forward (neuron by neuron) through the network, and emerges at the output end of the network as an output signal. We refer to such a signal as a 'function signal' for two reasons. First, it is presumed to perform a useful function at the output of the network. Second, at each neuron of the network through which a function signal passes, the signal is calculated as a function of the inputs and associated weights applied to that neuron.
2. *Error signals*. An error signal originates at an output neuron of the network, and propagates backward (layer by layer) through the network. We refer to it as an 'error signal' because its computation by every neuron of the network involves an error-dependent function in one form or another.

The output neurons constitute the output layer of the network. The remaining neurons constitute hidden layers of the network. Thus the hidden units are not part of the output or input of the

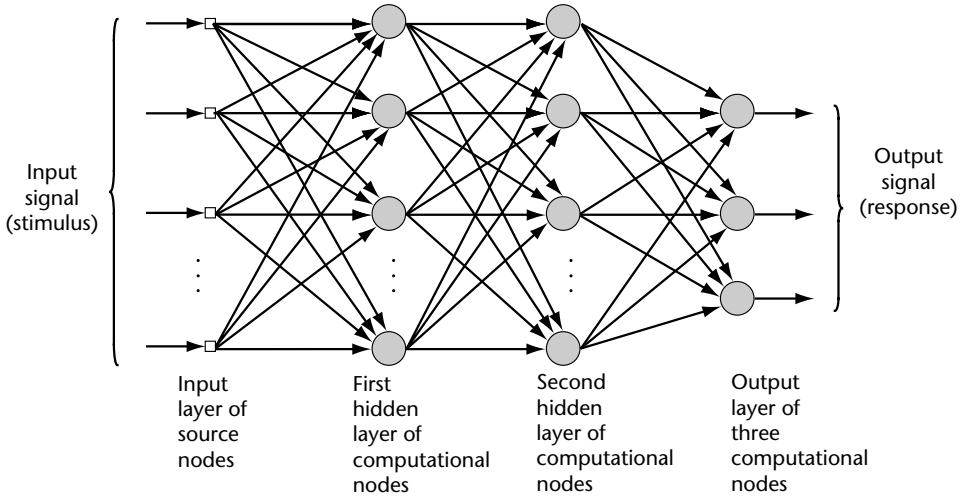

Figure 4. Architectural graph of a multi-layer perceptron with two hidden layers.

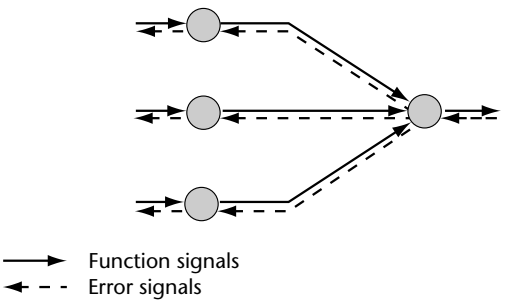

Figure 5. Illustration of the directions of function- and error-signal flows in a multi-layer perceptron.

network – hence their designation as 'hidden'. The first hidden layer is fed from the input layer made up of sensory units (source nodes); the resulting outputs of the first hidden layer are in turn applied to the next hidden layer; and so on for the rest of the network.

Each hidden or output neuron of a multi-layer perceptron is designed to perform two computations:

1. The computation of the function signal appearing at the output of a neuron, which is expressed as a continuous nonlinear function of the input signal and synaptic weights associated with that neuron.
2. The computation of an estimate of the gradient vector (i.e., the gradients of the error surface with respect to the weights connected to the inputs of a neuron), which is needed for the backward pass through the network.

The error signal at the output of neuron j at iteration n (i.e., presentation of the nth training example) is defined by:

$$e_j(n) = d_j(n) - y_j(n), \quad \text{neuron } j \text{ is an output node}$$

We define the instantaneous value of the error energy for neuron j as $[e_j^2(n)]/2$. Correspondingly, the instantaneous value $E(n)$ of the total error energy is obtained by summing $[e_j^2(n)]/2$ over all neurons in the output layer; these are the only 'visible' neurons for which error signals can be calculated directly. We may thus write

$$E(n) = \frac{1}{2}\sum_{j=C} e_j^2(n)$$

where the set C includes all the neurons in the output layer of the network. Let N denote the total number of patterns (examples) contained in the training set. The *average squared error energy* is obtained by summing $E(n)$ over all n and then normalizing with respect to the set size N, as shown by

$$E_{\text{av}} = \frac{1}{N}\sum_{n=1}^{N} E(n)$$

The instantaneous error energy $E(n)$, and therefore the average error energy, E_{av}, is a function of all the free parameters (i.e., synaptic weights and bias levels) of the network. For a given training set, E_{av} represents the *cost function* as a measure of learning performance. The objective of the learning process is to adjust the free parameters of the network to minimize E_{av}. To do this minimization, we use an approximation similar in rationale to that used for the derivation of the LMS algorithm. Specifically, we consider a simple method of training in which the weights are updated on a pattern-by-pattern basis until one epoch, that is, one complete presentation of the entire training set, has been dealt with. The adjustments to the weights are made in accordance with the respective errors computed for *each* pattern presented to the network. The arithmetic average of these individual weight changes over the training set is therefore an estimate of the true change that would result from modifying the weights based on minimizing the cost function E_{av} over the entire training set.

Summarizing the relations that govern the operation of the back propagation algorithm, we may say the following. The correction $\Delta w_{ji}(n)$ applied to the synaptic weight connecting neuron i to neuron j is defined by the delta rule:

$$\begin{pmatrix} \text{weight} \\ \text{correction,} \\ \Delta w_{ji}(n) \end{pmatrix} = \begin{pmatrix} \text{learning-} \\ \text{rate parameter,} \\ \eta \end{pmatrix} \cdot \begin{pmatrix} \text{local} \\ \text{gradient,} \\ \delta_j(n) \end{pmatrix} \cdot \begin{pmatrix} \text{input signal} \\ \text{of neuron } j, \\ y_i(n) \end{pmatrix}$$

The local gradient $\delta_j(n)$ depends on whether neuron j is an output node or a hidden node:

1. If neuron j is an output node, $\delta_j(n)$ equals the product of the derivative $\varphi_j'(v(n))$ and the error signal $e_j(n)$, both of which are associated with neuron j. Here, the prime denotes differentiation of the activation function $\varphi_j(v_j\,(n))$ with respect to the induced local field $v_j(n)$ at iteration n.
2. If neuron j is a hidden node, $\delta_j(n)$ equals the product of the associated derivative $\varphi'_j(v_j\,(n))$ and the weighted sum of the δs computed for the neurons in the adjacent hidden or output layer that are connected to neuron j.

As remarked previously, in the application of the backpropagation algorithm, two distinct passes of computation are distinguished: the forward pass, and the backward pass. In the *forward pass* the

synaptic weights remain unaltered throughout the network, and the function signals of the network are computed on a neuron-by-neuron basis. The function signal appearing at the output of neuron j is computed as

$$y_j(n) = \varphi(v_j(n))$$

where

$$v_j(n) = \sum_{i=0}^{m} w_{ji}(n) y_i(n)$$

where m is the total number of inputs (excluding the bias) applied to neuron j, $w_{ji}(n)$ is the synaptic weight connecting neuron i to neuron j, and $y_i(n)$ is the input signal of neuron j or equivalently, the function signal appearing at the output of neuron i. If neuron j is in the first hidden layer of the network, $m = m_0$ and the index i refers to the ith input terminal of the network, for which we write

$$y_j(n) = x_i(n)$$

where $x_i(n)$ is the ith element of the input vector (pattern). If, on the other hand, neuron j is in the output layer of the network, $m = m_L$ and the index j refers to the jth output terminal of the network, for which we write

$$y_j(n) = o_j(n)$$

where $o_j(n)$ is the jth element of the output vector $\mathbf{x}(n)$. This output is compared with the desired response $d_j(n)$, obtaining the error signal $e_j(n)$ for the jth output neuron. Thus the forward phase of computation begins at the first hidden layer by presenting it with the input vector, and terminates at the output layer by computing the error signal for each neuron of this layer.

The backward pass, on the other hand, starts at the output layer by passing the error signals leftward through the network, layer by layer, and recursively computing the local gradient δ for each neuron. This recursive process permits the synaptic weights of the network to undergo changes in accordance with the delta rule. For a neuron located in the output layer, the δ is simply equal to the error signal of that neuron multiplied by the first derivative of its nonlinearity. The recursive computation is continued, layer by layer, by propagating the changes to all synaptic weights in the network.

Note that for the presentation of each training example, the input pattern is fixed ('clamped') throughout the round-trip process, encompassing the forward pass followed by the backward pass.

DESIGN PRINCIPLES FOR MULTI-LAYER PERCEPTRONS

A particular form of the multi-layer perceptron known as *convolutional network* is designed specifically to recognize two-dimensional shapes with a high degree of invariance to translation, scaling, skewing, and other forms of distortion. This difficult task is learned in a supervised manner by means of a network whose structure includes the following forms of constraints:

1. *Feature extraction*. Each neuron takes its synaptic inputs from a local receptive field in the previous layer, thereby forcing it to extract local features. Once a feature has been extracted, its exact location becomes less important so long as its position relative to the features is approximately preserved.
2. *Feature mapping*. Each computational layer of the network is composed of multiple feature maps, with each feature map being in the form of a plane within which the individual neurons are constrained to share the same set of synaptic weights. This second form of structural constraint has the following beneficial effects:
   - *Shift variance*, forced into the operation of a feature map through the use of convolution with a kernel of small size, followed by a sigmoid (squashing) function.
   - *Reduction in the number of free parameters*, accomplished through the use of weight sharing, which makes it possible to implement the convolutional network in parallel form; weight sharing refers to a common set of synaptic weights that is shared by all the neurons in a given layer of the network.
3. *Subsampling*. Each convolutional layer is followed by a computational layer that performs local averaging and subsampling, whereby the resolution of the feature map is reduced. This operation has the effect of reducing the sensitivity of the feature map's output to shifts and other forms of distortion.

The development of convolutional networks, as just described, is neurobiologically motivated, which goes back to the pioneering work of Hubel and Wiesel in 1962 on locally sensitive and orientation-selective neurons in the visual cortex of a cat.

The lesson to be learned from convolutional networks is two-fold. First, a multi-layer perceptron of manageable size is able to learn a complex, high-dimensional, nonlinear mapping by constraining its design through the incorporation of prior knowledge about the task at hand. Second, the synaptic weights and bias levels can be learned by cycling the simple backpropagation algorithm through the training set.

CONCLUSION

This article has presented a description of the family of neural networks known collectively as the perceptrons, which encompasses Rosenblatt's single-layer perceptron, Widrow and Hoff's single-neuron adaptive filter, and their generalization, namely, multi-layer perceptrons. The single-layer perceptron is trained by means of the perceptron convergence algorithm, the single-neuron adaptive filter is trained by the simple least-mean-square (LMS) algorithm, and the multi-layer perceptron is trained by the backpropagation algorithm, that is a generalization of the LMS algorithm. The article also described a special form of multi-layer perceptrons known as the convolutional network whose design is inspired by neurobiological considerations; a convolutional network is capable of accomplishing complex learning tasks through successive use of convolution and subsampling. Moreover, through the clever use of weight sharing, the number of adjustable weights is significantly reduced despite the use of a large number of neurons.

Problem Solving

Intermediate article

Marsha C Lovett, Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

CONTENTS

Problem solving is the analysis and transformation of information towards a specific goal. This goal may be more or less well-defined; it may be directly attainable or require some insight; and the solution may rely on a large or small body of domain-specific knowledge.

INTRODUCTION

The processes of problem solving cover a broad range of situations. Some problems are 'routine' in that the solver easily recognizes a path to a solution. Other problems require insight to work around a perplexing obstacle. There are other respects in which problems can vary. One of these is the amount of domain-specific knowledge required for solution: knowledge-rich problems come from domains, such as physics, medical diagnosis, and aeroplane flying, that tend to require much specialized knowledge; whereas knowledge-lean problems often come from everyday tasks or general-interest puzzles. Problems can also be classified according to how well-defined the problem is (Reitman, 1965). A well-defined problem clearly specifies what can be taken as 'given' and what constitutes a solution. In contrast, an ill-defined problem leaves one or both of these components at most vaguely specified.

To understand problem solving completely, one must consider all the varieties of problems that can be encountered. What do all of these problem-solving situations have in common? All problems require some process of analysis in which the problem situation is understood and internally represented. From there, the solver manipulates and transforms the situation, seeking a specific solution. In accordance with this process-oriented view, this article defines problem solving as the analysis and transformation of information towards a specific goal. A central goal of problem-solving research, then, is to specify when and how the processes of analysis and transformation are applied as people solve problems. For example, an open question is whether it is exactly the same set of processes, or variants of certain processes, that are involved in solving problems of different types.

MODELING INSIGHT AND THE DISCOVERY OF CREATIVE SOLUTIONS

In 1913, the Gestalt psychologist Wolfgang Kohler travelled to Tenerife to study the problem-solving abilities of chimpanzees. Kohler was interested in chimpanzees' potential to demonstrate insightful problem solving, because he considered insight to be a distinctively human capacity. The most famous of Kohler's observations is of the chimpanzee Sultan 'discovering' a new tool by putting two bamboo sticks together, and then using this tool to retrieve bananas otherwise out of reach (Kohler, 1925).

Kohler's research, along with that of other Gestalt psychologists including Selz, Duncker, Luchins, Maier, and Katona, marked the beginning of modern research on problem solving. Because of the Gestaltists' interest in perception, it is not surprising that they focused their problem-solving research on insight problems, where perception of the problem is critical. When solving insight problems, solvers typically experience an 'aha!' moment when they switch from their initial, 'natural' way of viewing the problem to a new way that lets them see the path to a quick solution.

The central finding of the Gestalt psychologists concerning problem solving was that people have great difficulty in changing the way they represent a problem. This difficulty manifests itself in two

commonly observed phenomena: 'functional fixedness' and 'set effects'. Functional fixedness is the tendency among solvers to view an object only in its typical role. For example, if one's goal involves building a small shelf for a candle and one is given a box of nails, a box of matches, and the candle, it is not immediately apparent that the box of nails (once emptied) could relinquish its role as a container for that of a shelf (Duncker, 1945). Similarly, set effects refer to solvers' tendency to get stuck in a 'mental rut' where a familiar problem-solving approach continues to be applied even when it is no longer appropriate (Luchins, 1942).

The body of work produced by the Gestaltists revealed many interesting problem-solving results (see Duncan, 1959, for a review). However, the approach taken was descriptive, so it did not constitute a systematic exploration of the processes of problem solving.

PROBLEM SOLVING AS SEARCH

With the cognitive revolution of the 1950s and 1960s, psychologists once again embraced problem-solving research, this time with the aim of discerning the mental constructs and processes that could explain intelligent behavior. What developed from their work was a metaphor of the mind as an information-processing system; and a natural analytical framework for theorizing about such a system was the computer. In this context, the seminal work of Newell and Simon (1972) provided a new framework for analyzing the process of problem solving. The basic idea in this framework is that problem solving is equivalent to searching through a space of connected problem states, where each (directed) connection between two states represents the action that would move the solver from one state to the other. At every step in a problem, then, the solver faces the same question: which action should be chosen next?

The basic abstraction in this framework is the problem space, the set of all possible states in a problem along with the state-to-state transitions that connect them. Newell and Simon realized, however, that when a solver encounters a new problem, the entire problem space is not laid out in full. They claimed that the solver requires only three pieces of information to proceed: the initial state, the goal state, and the set of possible operators (actions along with conditions for their applicability). At each step, the solver may face a choice among many possible operators; so there is a need for a mechanism to resolve such conflicts. Choice of the next operator must often be made without domain-specific knowledge, so Newell and Simon developed heuristics for making good choices without such knowledge. They implemented their ideas in a computer program called the 'general problem solver' (GPS), which highlighted the domain-independent structure of problem solving and was able to solve problems requiring different kinds of specialized knowledge (e.g., logical proofs, trigonometric identities, formal integration, and sentence parsing).

PROBLEM SPACES, IMPASSES AND GOAL-DIRECTED SEARCH

Following the success of Newell and Simon's approach, more sophisticated computational models of problem solving were developed in the 1970s and 1980s. Most of these models were designed as 'production systems', in which knowledge for performing a task is represented in the form of 'production rules'. A production rule specifies the conditions of applicability and actions for each operator described in a task's instructions, and takes the form 'If conditions apply, then execute actions.' Production systems typically distinguish between long-term memory, represented in terms of production rules, and working memory, represented by the goals and facts that specify the solver's current mental state. For example, when starting a problem, working memory would include the goal to solve the problem and any facts specified in the problem statement. Each cycle of processing then involves the following steps. First, all of the production rules are matched against the contents of working memory (in particular, the solver's current goal) in order to determine which rules' conditions are met; second, a choice is made among the matching rules to determine which rule or rules will fire; third, the actions of the firing rules are executed. (The simplest case involves selecting a single production rule from the matching set and executing its actions.) Because a production rule's actions tend to change the contents of working memory (through a change to the solver's physical environment or mental state), a different set of production rules will be in the next matching set, and so progress is made in solving the problem.

A variety of production system models were developed to solve problems across a wide range of domains. Nevertheless, it was argued that more progress in understanding human problem solving could be made by developing these domain-specific models under the framework of overarching cognitive architectures. A cognitive architecture defines a specific way of representing knowledge and a

fixed set of mechanisms for processing and acquiring knowledge, just as the brain presumably employs a common set of mechanisms across a variety of tasks. Examples of cognitive architectures, each of which encompasses a family of related production system models, are ACT-R (Anderson and Lebiere, 1998), EPAM (Richman *et al*., 1996), and Soar (Newell, 1990).

One of the mechanisms that a complete cognitive architecture must specify is that of knowledge acquisition. In Soar, there is a single knowledge acquisition mechanism, called chunking. Whenever Soar cannot decide on the next step to take because of a gap in existing knowledge, an 'impasse' is said to have occurred. At this point, a sub-goal is initiated to determine the next step based on general problem-solving heuristics. When this sub-goal is achieved, the chunking process creates a new production rule with its action side being the next step and its conditions side being the set of pre-impasse problem features that were used in determining this next step. Thus, chunking is a way of 'caching' the many steps that were involved in deciding the next step into a single unit of knowledge that is available for future use. The next time Soar encounters the same (or a similar) situation, it will not face an impasse, but can employ the new production rule and take the next step directly.

In ACT-R, there are multiple knowledge acquisition mechanisms, mainly because ACT-R posits two separate long-term memory systems: procedural memory, which represents knowledge of skills in terms of production rules, and declarative memory, which represents knowledge of facts in terms of chunks (not to be confused with the 'chunking' described above). The most important of these mechanisms, called 'compilation', is engaged when no existing production rule is available to be applied next. The compilation mechanism begins by finding a problem in declarative memory whose features are similar to those of the current problem. It proceeds to build an analogy between the two problems, maps the solution step from the past problem to a viable step in the current problem, and constructs a production rule corresponding to that step. The condition side of the new production rule takes into account the specific facts that arose in the two problems, but generalizes them to a certain degree, making the new production rule more broadly applicable.

Both chunking and compilation have been proposed as explanations of the power-law increase in speed observed as people gain practice in solving problems in a domain.

MODEL-BASED REASONING AND PROBLEM SOLVING

While rule-based processing offers a good, general mechanism for problem solving, there may be particular situations in which people choose to invoke other processes. For example, in solving categorical syllogisms, the problem is to determine what implications may be validly derived from a set of logical statements, such as 'all artists are beekeepers; some beekeepers are clever'. Johnson-Laird and Steedman (1978) proposed a theory of reasoning through these problems that did not involve explicit rule-based processing, but rather the generation and evaluation of informal mental models. For example, one participant in their study said: 'I thought of all the little … artists in the room and imagined they all had beekeeper's hats on'. This kind of mental image can be inspected in order to generate new statements about the situation (e.g. 'some of the artists are clever' would be implied by a mental model in which only artist-beekeepers were imagined and some of these were mentally labeled as clever). Such a process does not make any use of formal rules of logical implication. Nevertheless, a production-rule-based model of this process has been developed with the cognitive architecture Soar.

Johnson-Laird and his colleagues found that different solvers choose different (more or less appropriate) mental models to represent a given problem. This choice, in turn, affects the correctness of their conclusions. Moreover, some syllogism problems require multiple mental models in order to adequately represent a possible ambiguity in the original premises. (For example, which of the beekeepers – all artists, all non-artists, or some of both – are the clever ones?) Thus, mental model theory proposes a metric for problem difficulty in terms of the number of mental models required. Empirical research has indeed found that solvers are quick and accurate in solving single-model syllogisms but that they produce more errors as the complexity of the model is increased. Additionally, syllogisms with high imagery value (e.g. those involving artists and painters) are more accurately and easily solved than syllogisms with low imagery value (e.g. those involving artists and 'clever people').

SOLVING PROBLEMS BY ANALOGY

In analogical problem solving, the solution to the current problem (the target) is determined by a past problem-solving episode stored in memory (the

source). There are three main processes that occur during analogical problem solving: (1) noticing the potentially analogous relationship between the target and a particular source; (2) mapping the correspondences between the basic elements of the target and the source; and (3) applying a solution to the target based on that mapping, possibly with some adaptation.

The main empirical result regarding the process of noticing a potential source is that solvers often miss opportunities to do it. That is, when solvers are given a helpful source problem in the same experimental context as the target, the vast majority do not even consider making an analogy (Gick and Holyoak, 1980). Two factors that facilitate this process are: giving solvers a hint to think back to the previous problem (Gick and Holyoak, 1980); and making the source and target problems superficially similar (Holyoak and Koh, 1987). The main factor determining success in the mapping process is structural similarity between the source and target (Gentner and Gentner, 1983), although certain kinds of superficial similarity can play a role here as well (Ross, 1989).

These empirical results have motivated the development of many models of analogical problem solving. Earlier models focused on computational methods for mapping the source to the target (e.g. Gentner, 1983). More recent models have successfully covered the entire process, from selecting a source to solving the target (e.g. Hummel and Holyoak, 1997).

CONNECTIONIST APPROACHES TO PROBLEM SOLVING

The connectionist framework represents knowledge in the form of continuously valued weights connecting nodes in a prespecified network. In connectionist models the main quantity of interest is the activation level of each node; this activation spreads through the network from an input layer, through one or more 'hidden' layers, and eventually to the output layer. The amount of activation propagated along a connection is proportional to the strength of that connection, and the amount of activation at a given node is the sum of the propagated activation along all connections going to that node. Because of this spreading activation mechanism, connectionist models very naturally represent information flow. Nevertheless, until recently these models were mainly applied to lower-level cognitive processes such as attention and perception. (*See* **Connectionism**)

Connectionist networks usually employ distributed rather than symbolic representations of information, so individual nodes in the network tend to represent individual features of a problem, not entire objects. For example, the input layer of a network often represents the features of a problem's initial state, and this information is processed through the subsequent layers until an 'answer' is obtained at the output layer. Connectionist models very naturally encode the similarity between problems in terms of the degree of overlap between sets of features. Not surprisingly, therefore, they have been most extensively applied to analogical problem solving, in which the retrieval of a similar past example is important (see, Holyoak and Barnden, 1994, for a collection of papers).

Connectionist models also specify a learning mechanism for updating the connection weights based on experience. This experience often comes in the form of 'teacher input', which essentially tells the model the correct answer for a given set of input features. The weights are gradually updated, based on repeated feedback of this kind, until the model can automatically generate the correct output pattern in response to a set of input features. Then, because of the model's distributed representations, it is able to produce similar answers to similarly represented inputs, i.e., to solve problems that are not a part of its direct experience. In addition, this mechanism of updating weights allows connectionist models to develop higher-level features in the intermediate layers of the network. These new features can be especially helpful for problems where the input layer's representation is insufficient for generating a solution and hence requires the solver to represent the task in a new way. The 'hidden' nature of these intermediate features is suggestive of the nonconscious aspects of representational change exhibited by solvers (see next section).

COMBINATORIC SEARCH VERSUS PATTERN RECOGNITION

Spurred on by the increasing sophistication of computational models and complexity of the tasks being modeled, empirical problem-solving research in the 1970s and 1980s moved towards a greater emphasis on learning processes. Comparisons between experts and novices were a natural starting point in the study of learning because experts and novices lie at the extreme ends of the learning process (see (Chi *et al*., 1988) for a collection of articles and (Riemann and Chi, 1989) for a

review of the expert–novice literature). Many studies observed experts and novices solving the same problems in a particular task domain, such as chess, physics, or bridge. The kinds of differences that emerged were fairly independent of the domain: experts tend to exhibit qualitatively different problem solving methods from novices. For example, when physics experts approach a problem, they look for a familiar pattern in the problem that determines the relevant physical principle and, from there, take a direct solution approach. Physics novices, on the other hand, tend to conduct a deliberate search over the various physics equations they know, trying one equation for a while, backing up and trying another, and so on.

The expert behavior described by these studies has been explained in terms of a pattern recognition process, whereby a particular pattern of features in the current problem triggers a relevant solution template that is instantiated by the current situation, thereby producing a solution. To gather more data regarding the complex patterns that experts use in solving problems, researchers used additional paradigms that do not ask participants to solve problems at all. For example, experts and novices would be given tasks relating to memory, problem classification, and similarity rating, where the stimuli were generated from problem-solving situations in the experts' domain. The chief result of the memory studies was that experts significantly outperform novices in their recall of realistic problem stimuli, but are indistinguishable from novices in their recall of random problem stimuli. Such findings have been conducted in the domains of chess (Chase and Simon, 1973), bridge (Charness, 1979; Engle and Bukstel, 1978), and medical diagnosis (Patel *et al*., 1986).

More evidence of schema-based representations comes from categorization paradigms. Expert and novice solvers are asked to sort a set of problem descriptions into meaningful groups. Whereas novices tend to sort based on superficial features, experts tend to do so in terms of the problems' solution structures. For example, Chi *et al*. (1981) found that experts sorted problems based on the physical principle that would be invoked in a solution (e.g. Newton's second law), and novices sorted more on the basis of superficial features (e.g. whether the problem involved inclined planes or pulleys). This difference suggests that experts were categorizing problems according to their problem-solving schemas, but novices were not. These findings have been replicated in mathematics (Silver, 1979; Schoenfeld and Herrmann, 1982) and computer programming (Weiser and Sherta, 1983).

SUMMARY

Early research by Gestalt psychologists stimulated interest in problem solving. A substantial development in the theory of problem solving came with Newell and Simon's (1972) framework, which considers problem solving as search through a problem space. Under this framework, choice of the next problem-solving step is fundamental.

Problem-solving research has made much theoretical progress by developing and testing computational models of the processes of problem solving. Much of this work is in the form of production system models, in which skills are represented as production rules and choice of the next problem-solving step is implemented as a choice among matching production rules. Specific kinds of problem solving that have received attention are model-based reasoning and analogical problem solving. Although the processes specified for these two modes of problem solving differ from each other and from the earlier work, they too need to address issues of choice; for example, which mental model to use to represent the syllogism, and, which source problem to draw an analogy from.

Recently, the focus of research has shifted from processes of choice to processes of learning. New empirical research on expert problem-solving behavior and the novice–expert transition shows qualitative differences. This raises the challenge for future models to achieve a qualitative change within learning theories that emphasize the role of gradual, quantitative processes.

Production Systems and Rule-based Inference

Intermediate article

Gary Jones, University of Derby, Derby, UK
Frank E Ritter, Pennsylvania State University, University Park, Pennsylvania, USA

CONTENTS

Production systems are computer programs that reason using production rules. They have been used to create expert systems and models of human behavior.

REASONING AS RULE APPLICATION

A production system is a computer simulation of one or more tasks. Normally, the tasks have some form of goal to accomplish (for example, making a medical diagnosis based on symptom data). From a given starting position in the task the production system successively applies rules, each of which transforms the current task position, until a goal is reached. With certain sets of further constraints, production systems can be used to simulate how people perform tasks (particularly those of a problem-solving nature, which are well suited to the framework of production systems). Some examples of production system frameworks that have been used to simulate human behavior are Soar (Laird *et al*., 1987), ACT-R (Anderson and Lebiere, 1998), and OPS5 (Forgy, 1981).

A production system consists of three components: a long-term memory (in the form of a rule base), a working memory, and an inference engine. The rule base contains rules, the conditions of which must be matched to elements in working memory. The inference engine determines which of the rules in the rule base have all their conditions matched to objects in working memory, and then decides which rule to apply. The application of a rule will usually cause elements in working memory to be added, removed, or altered. Further rules can then be matched by the inference engine.

What distinguishes a production system from any other system that simulates problem-solving behavior (such as a connectionist system) is its use of rules. A rule is an 'if–then' construct, where the 'if' part contains conditions that must be met in order for the rule to be considered for use. If the rule gets used ('fired' or 'applied'), the actions in the 'then' part are performed. The conditions are sometimes called the left-hand side (LHS) of the rule, and the actions the right-hand side (RHS).

Production system behavior can be explained using an example problem of moving a sphere to the exit of a room. Figure 1 shows the layout of a room as a seven-by-eight grid where black squares represent obstacles. Given this scenario there are a variety of rules that will help in moving the sphere to the exit, such as:

`IF` the exit is above the sphere `AND` there isn't an obstacle directly above the sphere `THEN` move the sphere upwards one space. (1)

There are two conditions in rule 1 that need to be met before the action part of the rule is applied: the exit position must be above the sphere, and the position directly above the sphere must be free to

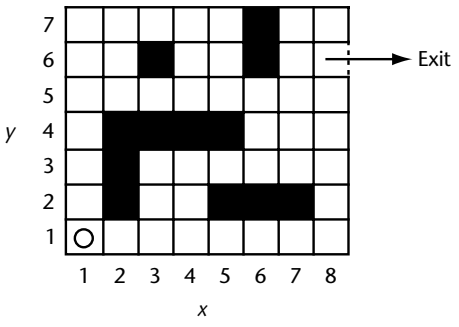

Figure 1. Problem scenario where a sphere has to be guided to the exit of a grid.

move into (i.e. it is not obstructed). If these two conditions apply to the current situation, then the sphere will be moved upwards one space.

Rules are often called productions, or production rules, because they necessarily produce something when they get used (normally changing something within working memory).

At any one time, there may be more than one rule whose conditions are satisfied. The process of collecting all applicable rules into a 'conflict set', and then selecting one of the rules in the conflict set to be fired, is called the recognize–act cycle. The production system stops either when no more rules are able to fire (e.g. ACT-R) or when the task is known to be complete (e.g. Soar).

In addition to being at the core of many expert systems, production systems are often used to simulate human behavior (e.g. Kieras and Polson, 1985; Klahr *et al*., 1987; Newell, 1990; Newell and Simon, 1972; Young, 1976). By successfully simulating human behavior on a task, the production system suggests the processes that may be used when humans perform the task. Although some researchers believe that human thinking need not be rule-based (e.g. Rumelhart *et al*., 1986; Brooks, 1991), there are many (such as Langley, Anderson, and Newell) who believe that it is, or at least can be, fruitfully viewed that way. The question revolves around whether or not human thinking deals with symbols. Rule-based systems use symbols, whereas others, such as connectionist systems, do not. The 'symbolic versus subsymbolic' question is not covered here, but is still widely debated within the cognitive science community.

COMPONENTS AND MECHANISMS OF PRODUCTION SYSTEMS

Two of the three components of a production system are distinct types of memory: working memory (facts) and long-term memory (the rule base). The third component is the inference engine.

Working memory usually contains facts about the world that are relevant to the task the production system is performing. Working memory is usually represented by attribute–value pairs. One element in working memory can have several attribute–value pairs. Using the sphere example, one element (or fact) in working memory will be the position of the exit of the grid. This element might have two attribute–value pairs: the first attribute will be 'x-coordinate', having the value '8', and the second attribute will be 'y-coordinate' having the value '6'.

Long-term memory usually consists of rules that govern the behavior of the production system. The inference engine combines working memory and long-term memory by finding rules whose conditions are matched by elements in working memory. When this happens, the rule can fire.

Production systems work in a cycle of production firings (the recognize–act cycle). Normally, only one production is fired on each cycle. The action of the production often changes what is in working memory and thus enables another production rule to fire. The resulting change may in turn enable a further production rule to fire. This is how the production system produces behavior (for example, maneuvering the sphere to the exit). When no further production rules can be fired, the system halts.

Let us work through an example illustrating this cycle and showing how production application works. Given the problem scenario in Figure 1, we noted that rule 1 matched working memory and could be applied. In that rule, there is a condition that specifies that the exit should be above the sphere's current position. If we did not already know that this was the case, then we would need a rule to work out whether or not the exit was above the sphere. The following rule could accomplish this:

`IF` the y-coordinate of the exit is greater than the y-coordinate of the sphere `THEN` put in working memory that the exit is above the sphere. (2)

Similarly we could have a rule to determine whether there was an obstacle directly above the sphere:

`IF` there is no obstacle having a y-coordinate of 1 less than the y-coordinate of the sphere `THEN` put in working memory that there isn't an obstacle directly above the sphere. (3)

Now suppose the starting position of the room is as shown in Figure 1. Certain elements would be in working memory, for example, the position of the sphere, the position of the exit, and the positions of obstacles.

Rules 2 and 3 can now be matched. The y-coordinate of the exit can be compared with the y-coordinate of the sphere; and, as it is in fact greater, rule 2 can fire. This places the element 'exit is above the sphere' in working memory. Rule 3 can also fire: all the obstacles can be checked as to whether they are directly above the sphere; as none are, the element 'no obstacle directly above

sphere' is placed in working memory. Note that these two rules could have fired at the same time, but most production systems would fire them in sequence (i.e. one recognize–act cycle for each). We will see later, when considering conflict resolution, how the production system determines which rule to fire first.

After these two new elements have been placed in working memory, rule 1 can fire, which moves the sphere upwards one space. Figure 2 shows how working memory changes during the three recognize–act cycles.

INFERENCE THROUGH FORWARD AND BACKWARD CHAINING

The normal way in which a production system processes rules is by matching elements in working memory in the 'if' part of the rule, and then applying the actions in the 'then' part of the rule. This is how the production system in the example above has cycled.

The production system can be seen as working forwards from the starting position (e.g. the problem position in Figure 1) towards a finishing position (the goal), in a series (a chain) of rule applications. This is called forward chaining or data-driven reasoning. Forward chaining is used in the majority of production system domains, including cognitive models of problem solving (an instructive example is the Tower of Hanoi (Anzai and Simon, 1979)).

The opposite of forward chaining is to match the actions of rules to working memory, and if all can be matched, to apply the conditional part of the rule. This method works backwards from the goal to the starting position (i.e. the initial data) and is therefore known as backward chaining, or goal-driven

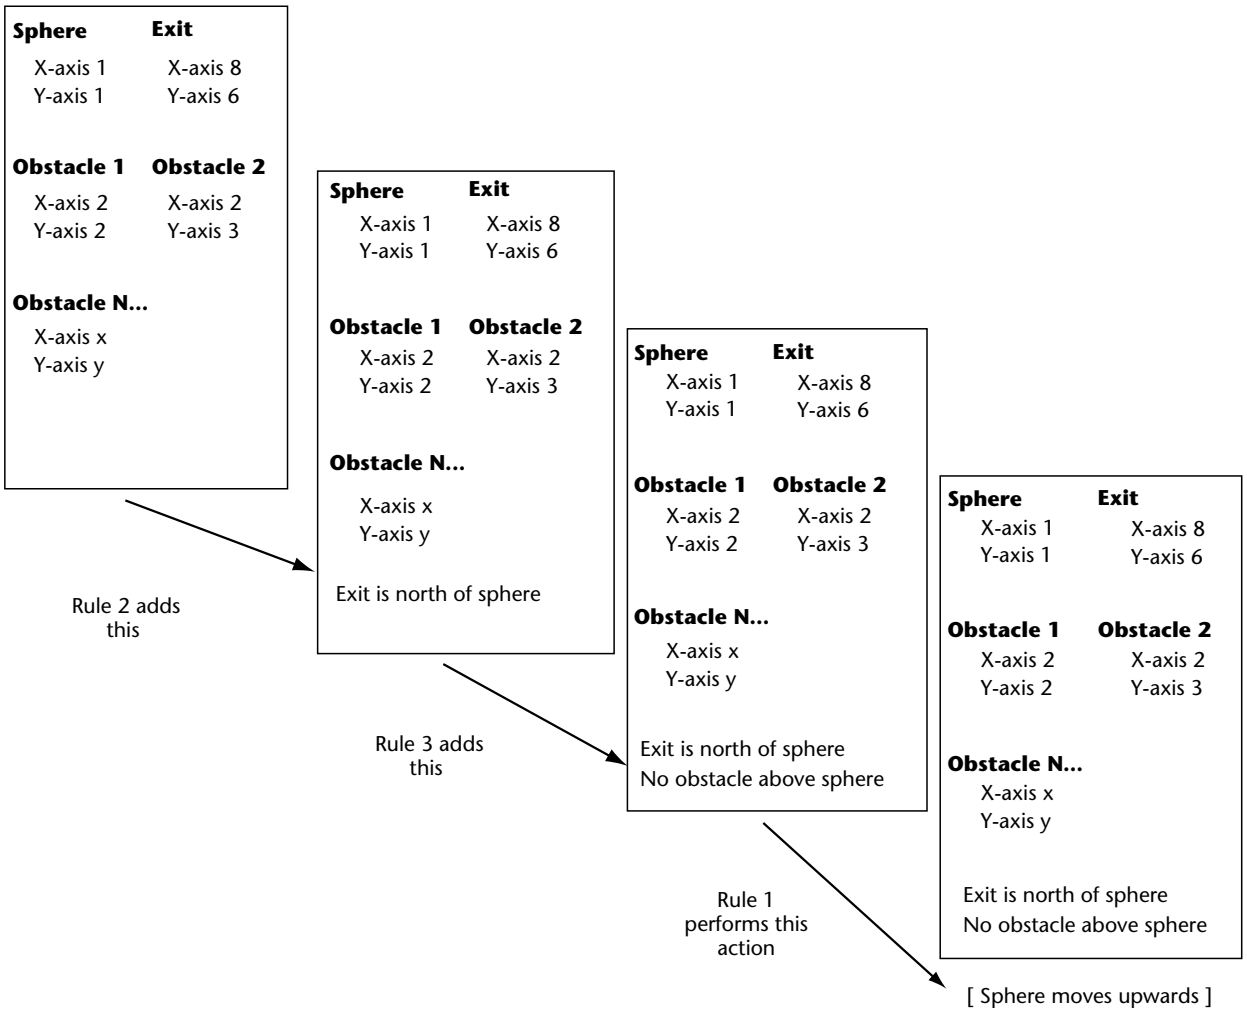

Figure 2. How working memory changes as the sphere production system rules fire.

reasoning. Backward chaining is normally used in domains where you wish to reason backwards from the final state of the world, such as discovering what preconditions led to a patient showing their current set of symptoms. The 'actions' of rules in these cases are often either changes to working memory or questions (to the user of the system) which need to be answered in order to add more facts into working memory. Expert systems often incorporate backward chaining so that they are able to explain how they arrived at their decisions.

Rules and knowledge can be represented at multiple levels. For example, Able (Larkin *et al*., 1980) represents how learning in formal domains such as physics shifts novices from a backward chaining approach of trying to find the values of variables in problem solving, to a forward chaining approach of experts where unknown variables are simply and directly derived from known variables. This model has been implemented in Soar (Ritter *et al*., 1998), which is normally seen as a forward chaining system because it applies its production rules towards a goal. In this case, the domain knowldge rules are implemented as sets of Soar rules. The domain knowledge is initially applied in a backward chaining way, searching from the target variables of the physics problem back towards the givens. With learning, the direction of processing on the knowledge level reverses.

CONFLICT RESOLUTION AND PARALLEL PRODUCTION FIRING

There are occasions when more than one rule can be fired for a given set of working memory elements. In our example above, rules 2 and 3 could both be matched. Figure 3 shows how these two rules could be matched for the elements in working memory that we started with in the example. The general approach in production systems is for the matching process to occur in parallel but the fining process to occur in serial. In the matching process, the inference engine determines which rules have all their conditions matched by elements in working memory. The resulting set of all rules that can be applied is called the conflict set.

When it is possible to fire more than one rule for a given situation, the production system is said to be in conflict. Firing all of the rules in the conflict set in parallel can give rise to inconsistent knowledge and results. Production systems generally resolve this problem by selecting only one of the rules to fire. The selection is made by the inference engine, using 'conflict resolution'. Production systems have used a variety of approaches including:

Textual order. This is the simplest resolution of conflict: simply choose the rule that comes first in the rule base.

Refractoriness. The same rule cannot be applied to the same working memory elements more than once. The inference engine needs to keep track of when elements in working memory were added or changed, in order to calculate whether a rule is being applied on exactly the same elements of working memory or whether there has been a change to those elements.

Recency. Apply the rule whose conditions match the most recently added working memory elements. This technique encourages adaptivity.

Specificity. Choose the rule that is either the most specific (i.e. has the largest number of conditions) or is the least specific (i.e. has the smallest number of conditions). Which of these is chosen is dependent upon the type of domain that is being

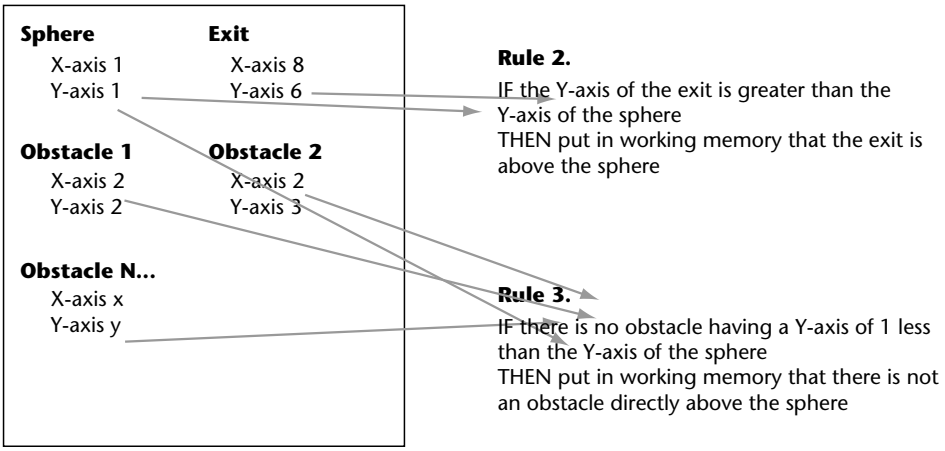

Figure 3. How working memory elements can be matched to conditions in rules.

modeled. For example, in a medical domain we may wish to be as certain as we can when applying a rule, and so we may set the most specific rule to be applied; in a domain involving search, we may wish to be less specific so that the system is less likely to arrive at a dead end.

Saliency. This allows the person writing the production system to set (numerically) how important each rule is. The rule with the highest saliency is selected. Conflict resolution is therefore primarily the responsibility of the production system designer.

Meta-rules. This allows the set of rules that are in conflict to be pruned or reordered based on a higher-order rule. For example, if the conflict set contains two rules, one which mentions high blood pressure leading to a possible heart condition and the other mentioning high blood pressure leading to a possible high temperature, then the production system designer could add a meta-rule which stated that if these two rules are in conflict, then choose the former over the latter.

Although these techniques are usually used independently of each other, there are occasions when more than one needs to be used. For example, it would be possible, when using refractoriness, to be unable to select a unique rule (for example, at the beginning of a production system run). Often, more than one type of conflict resolution is used, but one type is given priority.

Soar has taken a different approach. All matched rules are allowed to fire in parallel, but they are not allowed to modify working memory directly. They provide suggestions for changes to working memory, and a preference calculus is used to resolve contradictions and implement the changes.

STRUCTURE OF PRODUCTIONS

Productions can be represented in numerous ways. They can be represented as plain sentences (like rules 1–3 above); they can be represented in a structured editor as objects; or they can be represented as a list of clauses, which is how Soar and ACT-R represent them. The code sample below shows how rule 2 could be represented in ACT-R:

```
(p check-if-exit-is-above-sphere
  =goal>
    ISA           move-sphere-to-exit
    to-move       =sphere
    exit          =exit
  =exit>
    ISA           Exit
    Y-coordinate  =exit-y-coordinate
  =sphere>
    ISA           Sphere
    Y-coordinate  =sphere-y-coordinate
  =greater-than-fact>
    ISA           Greater-than-fact
    big-num       =exit-y-coordinate
    small-num     =sphere-y-coordinate
 = =>
  =new-working-memory-element>
    ISA           Sphere-location-fact
    location      exit-is-above-sphere
)
```

Parentheses are used to delineate the rule, which is introduced by `p` and then a name. This rule has four conditions, each consisting of a single working memory element; these are marked by = and then a name (in ACT-R – other systems use different conventions). Each condition must be matched to elements that are present in the working memory of the system.

Every element in working memory in ACT-R has an `ISA` ('is a') attribute–value pair, which defines the working memory element type. All variables in ACT-R are preceded by =. The first condition of a rule in ACT-R is always the `goal` condition. (The goal is often part of the conditions of rules in goal-directed production systems.) The `goal` condition states that there must be a goal in working memory of the type `move-sphere-to-exit`. If this does exist, it is matched; the value of the `to-move` attribute is placed in the `=sphere` variable, and the value of the `exit` attribute is placed in the `=exit` variable. Note how these same variables are then used in the next two conditions, signifying that what is `to-move` should be a memory element of the type `Sphere`, and where it is moved to should be a memory element of the type `Exit`.

The second condition specifies a match to an `Exit` element in working memory, and if this element exists it must have a `Y-coordinate` value (this will be stored in the `=exit-y-coordinate` variable). The third condition specifies a match to a `Sphere` element in working memory, and if this element exists it must also have a `Y-coordinate` value (this will be stored in the `=sphere-y-coordinate` variable). The fourth condition specifies a match to a `Greater-than-fact` element in working memory. This denotes knowledge of which numbers are larger than others. The variables that were set in the second and third conditions are used in the fourth condition to see if `=exit-y-coordinate` is greater than `=sphere-y-coordinate`. If the rule can be fired, then a

new working memory element is created, which specifies that the exit is above the sphere.

The number of input or output clauses is not limited by this syntax. In ACT-R the variables are bound (i.e. matched) in the order in which they are written, whereas in Soar they need not be. Rules in ACT-R and some other systems also have weights associated with them. These weights are updated by learning algorithms to represent the rule's probability of success, its cost, and other attributes. The weights may be used in a variety of ways, for example, to choose the most useful rule. Soar does not include these attributes.

THE RETE ALGORITHM

Most production systems include hundreds of rules; some include thousands. One includes nearly a million rules (Doorenbos, 1994). If each rule is checked individually to see if it matches, the time taken to create the conflict set will depend linearly on the number of clauses in the whole rule set. With small rule sets, this is not a problem; but as the size of models in production systems has grown, this causes a significant bottle-neck, particularly where the clauses have to be matched against sets of objects.

The RETE algorithm (Forgy, 1982) was created as a way to speed up the matching process by taking advantage of the reuse of clauses and the fact that working memory elements change slowly. For example, consider the three rules below, based on the sphere example:

IF the exit is above the sphere's current position AND there isn't an obstacle directly above the sphere THEN move the sphere upwards one space. (4)

IF the exit is above the sphere's current position THEN move the sphere upwards one space. (5)

IF there isn't an obstacle directly above the sphere THEN move the sphere upwards one space. (6)

These rules overlap, both in their conditions and in their actions. (The example is for illustration only: it would be unwise to move the sphere upward by only checking if the exit was above it, as rule 5 does.)

In essence, the RETE algorithm creates a network representing the whole rule set. The matching is then based on changes to working memory. As elements leave or enter, the state of the network is updated. Thus the time taken by the matching process depends linearly on the number of changes to working memory instead of on the number of rules.

For example, the RETE network for rules 4–6 would combine the first clauses of rules 4 and 5 as a top node. If the exit's position changed, then and only then would the clause be updated. When the conflict set is needed, all the clauses that are matched are already noted in the network. So if the exit is above the sphere's current location, then rule 5 would be waiting in the conflict set. Whether rule 4 was in the conflict set would depend on whether the working memory element matching its second clause had been added. The addition of the working memory element would also have satisfied rule 6 at the same time.

The presence of the RETE algorithm is not always noticed by people who use production systems, but it has drastically improved their speed and therefore their usefulness. RETE is used by both OPS5 and Soar. Further refinements of match optimization have also been developed.

PRODUCTION SYSTEMS AS COGNITIVE ARCHITECTURES

A cognitive architecture proposes a theory of the human information processing apparatus. Some production systems, such as ACT-R and Soar, have been used to implement such theories. Their intention is to model the types of process and structures that generate human behavior (e.g. what the constraints on memory are), and use these models to simulate human behavior. If the same architecture can be used to accurately simulate behavior across domains, then this provides evidence that the human brain may resemble the cognitive architecture. Cognitive architectures have been used to simulate the behavior of both adults (e.g. Jones *et al.*, 1999) and children (e.g. Jones *et al.*, 2000).

SUMMARY

Productions systems have been used to organize and apply knowledge in a variety of domains. While there remain questions as to whether knowledge can be modeled directly as structures in a production system, they provide a fruitful way to think about human behavior.

Rate versus Temporal Coding Models

Introductory article

Michael N Shadlen, University of Washington, Seattle, Washington, USA

CONTENTS

Information is represented in the brain by the electrical activity of neurons. A number of current theories attempt to explain this neural code of information and how it is used by the brain to achieve perception, action, thought, and consciousness.

INTRODUCTION

All theories about how the brain functions are based on the idea that information is represented by the electrical activity of neurons. The question of how neurons represent information is therefore fundamental to all branches of neuroscience. What is the neural code of information, and how is it used by the brain to achieve perception, action, thought, and consciousness? In other words, which aspects of a neuron's electrical activity convey information about the environment and our mental states?

It is common practice in many laboratories to display the electrical activity from one or more neurons in an animal while it looks at, hears, and reacts to its environment. This neural activity appears as a sequence of very brief events, known as action potentials or spikes, separated by gaps of variable duration (Figure 1). The intervals between spikes can be as long as a few tenths of a second or shorter than a hundredth of a second. The spikes and the intervals between them convey the neuron's message. If we wish to decipher the neural code, we need to know how to read these messages.

Certain facts are well established. The only message that one neuron can give another neuron in another part of the brain about what it has computed must be represented in the sequence of spikes that are transmitted along its axon. The timescale for neural computations involved in perception, thought, and action is too short to allow gene expression, protein synthesis, and chemical cascades to play a part in carrying information. Spikes are the only items in the alphabet, but unlike letters, there is only one kind. The spikes are all-or-nothing events – size does not matter. The question is how to read this sequence of spikes emitted by neurons as a function of time.

In its broadest sense, temporal coding refers to three types of problem. First and most obvious, neurons must code information that changes as a function of time. Stimuli come and go and change their intensity; behavior – and the thought behind it – is dynamic. Insofar as spikes code information, they must code information that changes as a function of time. Second, there is a possibility that the time structure of neural activity could be used to represent information. That is, spike times and intervals could expand the alphabet that the brain uses to encode stimuli, sequences of actions, and ideas. Third, neurons must ultimately code time itself: how much has elapsed, when an expected event is likely to occur, and so on. This article

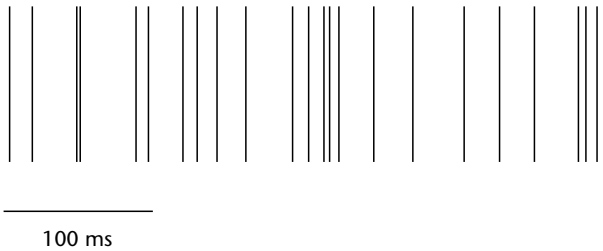

Figure 1. Neural spike trains. Neurons encode information using electrical impulses known as action potentials or spikes. A sequence of impulses is called a spike train. Information processing in the brain occurs through the interactions of neurons that communicate with one another by transmitting spikes. A sequence of spikes like this one was emitted by a neuron in the visual cortex in response to a moving light. Notice the irregular intervals between the spikes. This is a common feature of spike trains in the cerebral cortex.

examines the first two forms of temporal coding; the coding of time itself is only just beginning to be studied at the neural level.

A MENU OF TEMPORAL CODES

It makes sense to confine speculation about the neural code to neurons whose role in perception and behavior are known to at least some degree. Although the properties of neurons in much of the brain remain mysterious, the function of many neurons has been elucidated in some detail, especially in the primary sensory and motor areas of the brain. Thus far, this knowledge has rested on the fact that neurons emit more spikes in less time when a restricted set of conditions holds – such as when light of a particular orientation is present in a tiny region of the visual field and moving in a particular direction. Put simply, the neurons that we know the most about signal information by changing the rate at which they emit spikes.

The spike 'rate code' is thus well established as the vanguard neural code, and we will consider its role in temporal coding in a moment. However, there may be other ways to encode information in spike trains in addition to spike rate. In principle, these alternatives could expand the alphabet that the brain uses to encode information. Table 1 looks at the evidence for four putative neural codes: the time-varying rate code, which uses spike rate to code time-varying signals in the environment or in the state of a calculation; the spike bar code and the rate waveform code, which use time itself to evoke information about objects; and the synchrony code, which uses a pattern of spikes across many neurons to encode information. Each of these codes would promote a different scheme for encoding information in trains of spikes. We will consider each of them in turn, keeping in mind that they are not mutually exclusive ideas.

It should be stated at the outset that many ideas about temporal coding are just that: ideas. This is an active area of research that is being updated continually on the basis of new information obtained at all levels of inquiry, from the channels responsible for electrical activity in parts of the neuron, up to recordings from intact brains in behaving animals. Therefore, in addition to describing the ideas behind the putative temporal codes, this article will try to evaluate the evidence in support of each code.

The evidence for a temporal code can be divided broadly into four categories (see Table 1). First, the code can be detected reliably from neurons upon repeated exposure to the coded stimulus or upon repeated actions or circumstances. Second, the neural signal – its presence, absence, intensity or quality – is associated with variation in an animal's perception or behavior. If a neural signal putatively codes the color red, the animal should be less likely to 'report' (via its behavioral response) that it has seen red when the neural signal is absent or degraded. Third, when the signal is introduced to the brain artificially through electrical microstimulation, it causes an animal to act or perceive in accordance with the information thus encoded. Fourth, the properties of neurons – synapses, passive and active electrical properties – must be capable of preserving the coding scheme. If a proposed code were to require that action potentials occur within 1 ms of each other, we could reject the code on the basis of the fact that neurons have refractory periods of at least 1 ms before they can fire a second action potential.

Note that the first three items require experiments on the intact brain, although the first does not require the animal actually to do anything. The last item is informed by experiments that address how neurons work, namely, the reliability of their synapses and the way in which electric current is gathered by the dendrites and converted to action potentials at the initial segment of the axon.

With these guidelines in mind, let us turn to the four putative temporal codes and evaluate them based on the four categories of evidence.

Table 1. Evidence for four candidate temporal codes

	Code			
Type of evidence	*Rate*	*Spike bar*	*Waveform*	*Synchrony*
Reproducibility of response	✓	✓	✓	✓
Correlation of response with behavior	✓	✓		
Brain stimulation mimics inferred message	✓	✓	✓[a]	
Biophysical plausibility	✓	✓	✓	✓

[a]Evidence comes from one experiment in peripheral nerve responsible for taste.

Time-varying Rate Code

Neurons throughout the brain, spinal cord, and peripheral nervous system alter their rate of spike discharge to represent a change in intensity. Examples include pressure at a spot of skin, contrast in a spot on the visual field, the salience of a moving visual display, the proximity of an intended eye movement to a place in the visual field, and the force exerted by a muscle. The time-varying rate code is thus the best-known example of a temporal code. It is clearly the dominant principle of activation in the peripheral nervous system: the more spikes, the greater the intensity of the stimulus or the greater the force of the muscle contraction.

The rate code applies in the cortex as well, but there is a catch. Because the spikes emitted by a neuron occur at irregular intervals, the spike rate cannot be discerned from the interval between two spikes. From the point of view of a neuron that is receiving the message about rate, it would need to wait for several spikes to get a sense of their average rate. However, simple perceptual tests show that the brain is capable of processing information about changes in sensory stimuli that occur very quickly, as fast as one or two spike intervals. Evidence from neuroanatomy and neural recording experiments suggests that the cortex solves this problem by representing rate using several neurons. Because the receiving neuron obtains many samples of the same message, all with different erratically spaced spikes, it can estimate the spike rate by averaging across neurons in a short period (Figure 2).

The time-varying ensemble spike rate is a simple temporal code that allows the brain to keep track of dynamic changes in the sensory environment. In principle, it can be used to represent the intermediate stages of neural computations that underlie changes in mental states, idea formation, decision-making, and emotions.

Of the four categories of evidence described above, all support a role for spike rate in the coding of information.

1. Changes in spike rate are reliably reproduced in laboratory conditions when the same stimuli (or behavior) can be presented repetitively.
2. Variability in the spike rate predicts sensitivity to weak stimuli; for example, when monkeys make difficult judgments about sensory stimuli, their rate of errors can be predicted by the variability in the spike rate of appropriate neurons in the sensory cortex. In parts of the association cortex, it is possible to know which way an animal will decide about an ambiguous stimulus by measuring the spike rate.

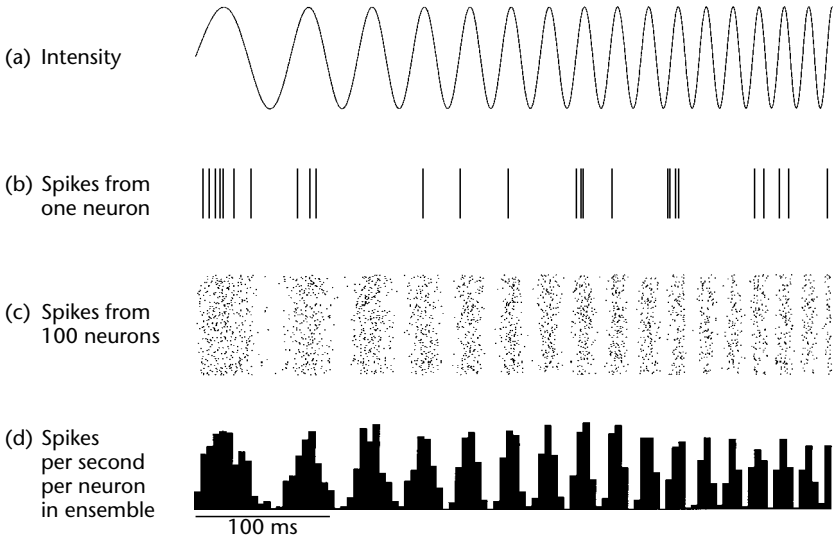

Figure 2. Time-varying rate code. How do neurons encode information that changes as a function of time? (a) A time-varying signal is shown at the top of the figure. This could represent a changing light intensity, or a quantity used in a calculation for directing atttention, say, to a bouncing ball. In this example, the signal intensity changes slowly at first (left) but eventually the changes occur more rapidly. (b) A single neuron emits spikes more often when the intensity is high, but the intervals between spikes preclude encoding the rapid changes in signal intensity. (c) If there are many neurons that emit spikes in this fashion, then their average (d) provides a reasonable approximation to the signal. This ensemble coding takes advantage of the presence of many neurons that encode the same information by changing their rate of spike discharge.

3. Electrically stimulating small groups of neurons (300–1000) to higher rates causes movements and, in a few cases, apparent changes in perception. In one remarkable example from the visual cortex, investigators measured the spike rate from individual neurons in association with visual stimuli. On the basis of changes in spike rate, they deduced the message represented by that neuron and its neighbors. This deduction is really a hypothesis about the neural code. In one of the few direct tests of this hypothesis, the investigators stimulated the neurons by passing small amounts of alternating current through the electrode. This stimulation caused animals to report perception of the stimulus, consistent with the message the investigators had inferred from the spike rate.
4. There is ample evidence from biophysics that neurons increase their rate of spike discharge when they receive more excitatory input. Exactly how neurons achieve a stable rate of firing in response to synaptic input is an active area of research. The source of variability in the spike discharge, hence the reliability of the rate code, is also an active area of investigation. As mentioned earlier, the variable spike discharge seems to be a property of cortical neurons, which for unknown reasons are much more variable in their response than are neurons in subcortical structures.

In short, there is ample evidence that the brain uses a time-varying rate code to mark the intensity of a stimulus, action or variable in a computation. The actual identity of a stimulus (e.g. its color, location, direction of movement), the particular action, or the fact that a variable is subtracted or added is coded by the neuron's location in the brain, namely its connections to other neurons and presumably its position in space in the cortex. According to this view of temporal coding, the rich set of symbols that the brain uses to encode information derives mainly from wiring in the patterns of neurons that can be activated under a variety of conditions (through development and learning). The rate code is just a way to represent the degree of this activation – the amount of evidence for a proposition that is represented by the identity of the neuron or neural ensemble. This idea is sometimes referred to as a labeled-line or place code.

In contrast, we now turn to two putative neural codes that use the pattern of spikes as a function of time to encode different features of the environment. By using time to code something else, they have the potential to achieve a much higher degree of complexity than the rate code.

Spike Bar Code

The intervals between spikes in cortex tend to be quite variable, but depending on one's point of view, this variability can be seen as a nuisance (as above) or as a potential code. Figure 3 illustrates

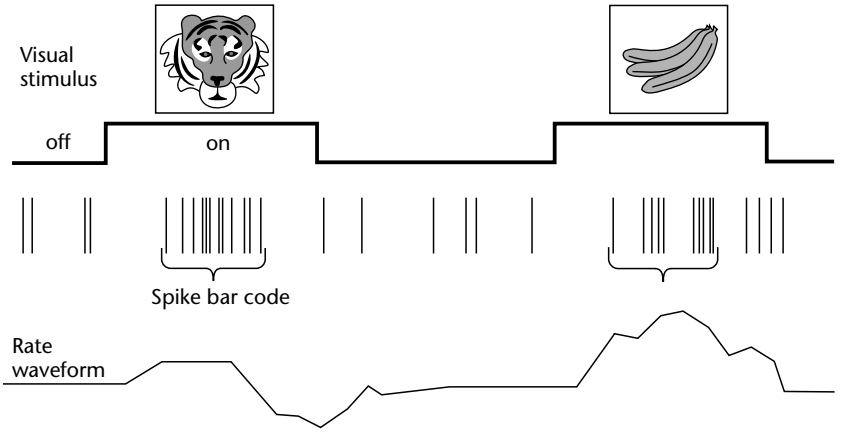

Figure 3. Spike bar code and rate waveform code. Spike activity from an idealized neuron occurs in association with the appearance of two visual stimuli. Brackets identify patterns of spikes that could provide distinct labels for 'tiger' and 'banana' akin to a bar code used to identify merchandise in retail stores. This idea and other related spike interval codes are improbable because specific spike patterns do not occur with any systematic regularity in the cortex. The jagged trace below the spikes represents the ensemble spike rate that might be obtained by averaging the activity from many neurons increasing and decreasing their rate of discharge in a manner similar to the spike train shown. According to this scheme, the exact pattern of spikes from each neuron would not carry information; rather, each neuron contributes to the average spike rate (as in Figure 2). The spike rate waveform has a different shape in association with the tiger and banana. It has been suggested that this rate waveform could encode stimuli. Note that both the spike bar code and the rate waveform codes would allow the same neuron to encode a variety of messages and that both use time to encode stimuli that are not changing.

a rather extreme idea for a temporal code, which this author terms a 'spike bar code'. The example shows a neuron that emits a different pattern of spikes when different pictures are presented to vision. The particular pattern of intervals separating the spikes could in principle symbolize a complex object. There are many possible patterns of spikes that a neuron could emit in a 300 ms window of time – roughly the amount of time between successive scanning eye movements. Therefore, the bar code could provide a rich alphabet for coding information.

The spike bar code illustrates an intriguing idea, but at present there is little evidence to support its use in the brain (see Table 1).

1. There is no example of a neuron in the cortex that emits the same pattern of spikes in association with a particular stimulus or behavior. There are occasional reports of patterns of spikes that seem to occur more often than expected by chance in some parts of the cortex, but not in association with a particular stimulus or action, and the claim that the patterns do not occur by chance has been contested.
2. Without clear evidence of specific patterns, it is impossible to test whether they predict errors in perception or variability in behavior.
3. To the minimal extent that anyone has tried to mimic patterns of activity in the brain, the effort has not yielded anything of interest.
4. The main evidence in favor of such a code is that it is not ruled out by what we know about how neurons generate action potentials.

In particular, neurons seem to be capable of emitting action potentials with a precision of below 1 ms in response to the same amount of current. The argument then goes like this: if the intervals between spikes can be controlled so precisely, then the brain must be using these intervals for coding. Of course, we do not really know that the intervals between spikes can be controlled precisely; we know only that the source of imprecision is not the part of the neuron that converts the current it collects to an action potential.

Besides the lack of experimental evidence for the spike bar code, there are two additional problems. First, the signal would need to be deciphered by neurons at the receiving end. It is hard to imagine a mechanism that would allow a neuron to respond selectively to a spike pattern that extends by more than a few tens of milliseconds or a few spikes. Second, it takes time to decode such a message. At a minimum, it would take the length of the message itself (about 300 ms for the messages depicted in Figure 2). It is hard to reconcile such a scheme with the rapidity of sensory processing.

Rate Waveform Code

The rate waveform code is related to the bar code in that it also uses the temporal changes in spike production to encode information. In this case, it is not the precise pattern of spikes and intervals but rather the rate of spike production that codes information. In the example in Figure 3, a benign stimulus (the banana) causes the spike rate to rise and then return to baseline, whereas in response to a threatening stimulus (the tiger) the rate rises and then falls below baseline before returning to baseline (i.e. it has a positive and negative phase). The spikes themselves occur more or less randomly, but with greater or lesser frequency in accordance with these rate waveforms. As noted earlier, this implies that many neurons undergo similar rate fluctuations.

There is better evidence for the rate waveform code than for the bar code.

1. In the visual cortex, some stimuli give rise to transient increases in spike rate followed by a rapid return to baseline, whereas others lead to more sustained responses. Usually, different neurons respond in these modes, but there are examples of the same neuron responding to one kind of stimulus with sustained activity and to another more transiently. The best example of a temporal code of this sort is found in the taste system, where different tastes (e.g. sweet and bitter) cause the same neuron to undergo different patterns of rate change.
2. The second type of evidence is lacking, however. If different waveforms connote different messages, then one would like to witness a correlation between the variation in response waveform and an animal's perception. Experiments of this type have not been tried or have been unsuccessful.
3. The third type of evidence, manipulation of the code, has been tried in the taste system of rats. When the brainstem nucleus that receives taste information is stimulated, rats respond as if they had tasted bitter or sweet, depending on the pattern of firing rate change induced by the stimulation. Experiments of this type have not been tried in the cortex. The closest example is a negative finding: changing the temporal pattern of activity in the somatosensory cortex does not interfere with a monkey's ability to discriminate flutter vibration frequency.
4. Because neurons can modulate their firing rate, there are no obvious theoretical obstacles to the coding of information with a rate waveform.

Although we do not yet know how a rate waveform would be decoded, it is in principle no more difficult a problem than decoding any time-varying function, as occurs in visual neurons that respond to stimuli moving in a particular direction and speed.

Synchrony Code

The last item on the menu is the synchrony code. This is a popular example of a code that would exploit temporal and spatial relationships between spikes to encode information (spatial in this context refers to places in the brain). The idea is that simultaneous spikes from two or more neurons might encode information. A natural candidate for the kind of information to be encoded is the relation between parts of objects or elements of movement. That is, synchronous spikes could represent combinations of features that are themselves encoded by single neurons or ensembles of neurons with similar properties.

Like the spike bar code, the synchrony code exploits the irregular intervals between spikes. As illustrated in Figure 4, another implication of irregularly spaced spikes is that the odds of any two neurons emitting a spike at the same moment (say, within 3 ms of each other) is a relatively rare chance event. It has been suggested that under particular circumstances, neurons can produce synchronous spikes in excess of the rate expected by chance. These synchronous spikes could constitute a special code. In vision, for example, it has been proposed that synchronous spikes are used to bind together separate features of objects into coherent wholes (Figure 4) and even to promote the representation of vision to conscious awareness.

Despite the enthusiasm for this code, there is little evidence to support it.

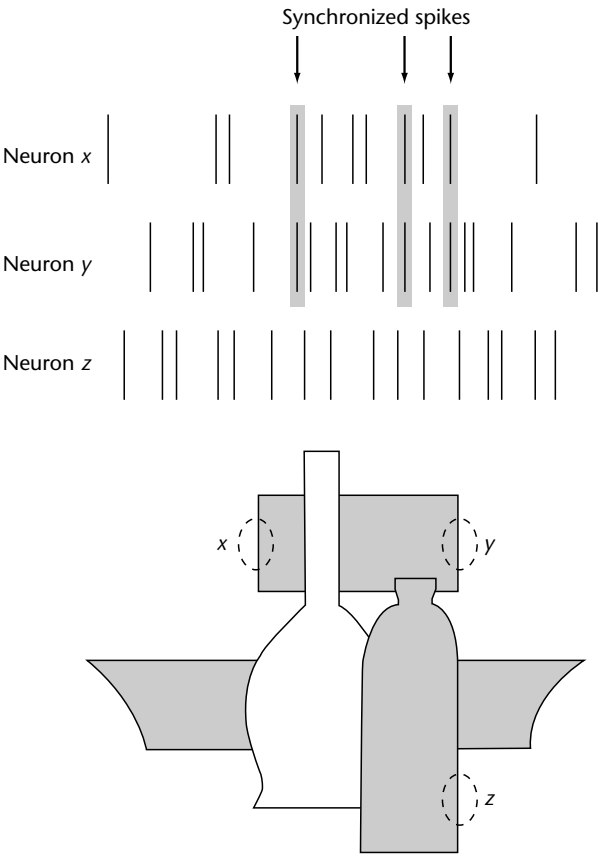

Figure 4. Synchrony code. Idealized responses from three neurons to a visual scene consisting of bottles and shapes. The three neurons respond to vertical contours marked by the dashed ellipses. The ellipses are not part of the scene. The spikes from each of the neurons exhibit variable intervals. On three occasions, spikes from neurons x and y occur within 3 ms of each other (arrows and gray highlight). Using this criterion, there are no synchronous spikes between neuron z and the other neurons. It has been proposed that synchronous spikes could encode information about the scene. For example, the synchronous spikes could indicate that the contours at the locations represented by x and y are part of the same object, whereas the contours represented by neurons y and z are not part of the same object. Despite much enthusiasm for this idea, the experimental evidence is weak.

1. There are many examples of pairs of neurons that emit synchronous spikes reliably. Typically, these are neurons that lie near each other in the brain and receive common synaptic input. There are also reports of neurons that encode different visual features but tend to respond synchronously when the two features are bound to a common object.
2. The few attempts to correlate synchronous spikes with behavior have failed to provide supporting evidence for a synchrony code. For example, synchronous spikes occur just as often whether a pair of features represented by the neurons is bound to a single object in the foreground or is split, with one feature in the background.
3. Experiments in which synchrony has been mimicked by means of stimulation have been performed in the motor system, but there is no report of any experiments in which sensory neurons have been stimulated in and out of synchrony. This might be technically difficult because stimulation always tends to synchronize the neurons near the stimulating electrode. On the other hand, some investigators have tried to disrupt synchrony by imposing asynchronous flicker to different component features of an object. This seems to have no effect on perception and thus casts doubt on the idea that synchronous discharge encodes anything special.
4. Much of what we know about synaptic physiology would indicate that synchronous spikes are more effective than asynchronous spikes at inducing a response from a postsynaptic neuron. However, cortical neurons receive many hundreds of excitatory inputs for every spike they emit. It is far from clear how synchronous spikes that convey information are to be distinguished from the rest of these spikes.

CONCLUSION

The topic of temporal coding is fundamental to basic and clinical neuroscience. The ability to read the neural code will help neuroscientists understand how the brain represents information and uses it in novel computations that underlie thought and behavior. Understanding the neural code may one day provide the ability to use brain recordings to control prosthetic devices in people who suffer from spinal cord and nerve injury.

The evidence at hand favors the use of spike rate to encode the intensity of values whose meaning is given by the identity of the neuron or group of neurons emitting spikes. This ensemble rate code is a temporal code because it provides a means to represent intensity (or magnitude) as a function of time. The alternative codes use time to encode meaning. These putative codes could expand the brain's ability to represent information in the same way that the Morse code allows two symbols (dot and dash) to encode all the letters of the alphabet (or the computer binary character code, which allows two numbers, 1 and 0, to encode all typographic symbols). There is some evidence for spike timing codes in the peripheral nervous system and in brainstem structures that are specialized for processing sound, but the idea is largely unsupported in the cerebral cortex.

Real-valued Computation and Complexity

Advanced article

Felipe Cucker, City University of Hong Kong, Hong Kong

CONTENTS

The theory of real-valued computation and complexity deals with foundational aspects of scientific computation. Here the basic unit of information is the floating-point number and a computational model whose basic unity of information is a real number reasonably captures this feature.

INTRODUCTION

In problems of learning and intelligence the traditional mathematical foundations are derived from Gödel and Turing. This is reflected in the debate over whether machines will ever be able to think as humans do. Most recently, the discussion about Roger Penrose's book (Penrose, 1989) reflected this foundational issue.

However, developments in the theory of learning in both machines and humans, revolve mainly around continuous mathematics. For example, real number analysis plays a role via the Hodgkin–Huxley equations and statistical learning theory.

For this reason one is led to consider alternative foundations for intelligence modeling, learning and computation.

AN ALTERNATIVE FORMALISM FOR COMPUTATION

'Scientific' computation is a domain of computation based mainly on the equations of physics. For example, from the equations of fluid mechanics, scientific computation helps us to design better aeroplanes, or predict the weather. The theory underlying this kind of computation is called numerical analysis.

There is a substantial conflict between theoretical computer science and numerical analysis. These two subjects have common goals but have grown apart. For example, computer scientists are uneasy with the differential calculus, while numerical analysts thrive on it. On the other hand numerical analysts see no use for the Turing machine.

This conflict has at its roots another age-old conflict, that between the continuous and the discrete. Computer science is oriented by the digital nature of machines and by its discrete foundations (Turing machines). On the other hand, differential equations are central to numerical analysis and this discipline depends heavily on the continuous nature of the real numbers.

The developments that began with the work on the theory of computable functions by Gödel, Turing and others in the 1930s have given a firm foundation to computer science as a rigorous discipline. Turing machines provide a unifying, formalized concept of algorithm. Thus computer scientists have been able to develop a complexity theory which permits discussion of lower bounds of all algorithms without ambiguity.

The situation in numerical analysis is quite the opposite. Algorithms are primarily a means to solve practical problems. There is not even a formal definition of algorithm in the subject.

A major obstacle to reconciling scientific computation and computer science is the present view of the machine, i.e. the digital computer. As long as the computer is seen simply as a finite or discrete object, it will be difficult to systematize numerical analysis. The belief that the Turing machine is inadequate as a foundation for real number algorithms led to the machine model proposed in Blum *et al*. (1989). This model takes its inputs from $\mathbb{R}^\infty$, the disjoint union of $\mathbb{R}^n$ for $n \geq 1$, and returns as outputs elements of this space. During the computation it performs arithmetic operations and comparisons and has the ability to 'move' information (i.e. real numbers) around within its

state space (roughly, its 'tape'). This last feature, equivalent to the addressing instructions on a RAM, allows for some form of management. The *size* of a point $x \in \mathbb{R}^\infty$ is the unique $n = \text{size}(x) \in \mathbb{N}$ such that $x \in \mathbb{R}^n$. Running time, which is defined as the number of operations, comparisons and movements, is then considered as a function of the input size.

REAL-VALUED COMPUTATIONAL COMPLEXITY

Probably the most important result in Blum *et al*. (1989) is the existence of NP-complete problems over the reals (and other rings as well). The 'P = NP' question had been at the heart of research in discrete complexity theory and a specific goal of Blum *et al*. (1989) was to extend this question to computations involving real numbers.

A set S is *decidable in polynomial time*, or in the class P, if there is a machine M deciding S whose running time is bounded, for all inputs of size n, by a polynomial function of n. Classically, S is a set of strings over a finite alphabet. Over the reals, the same definition can be used by taking S to be a set of points in $\mathbb{R}^\infty$. In this case we write $\text{P}_\mathbb{R}$ instead of P. Similarly, a function $\varphi : \mathbb{R}^\infty \to \mathbb{R}^\infty$ is *computable in polynomial time* if there is a machine M computing $\varphi(x)$, for all $x \in \mathbb{R}^\infty$, in time bounded by a polynomial in size (x).

The definition of the class NP over $\mathbb{R}$ is slightly more elaborate, and can be done in several ways. Here we modify the machine model and endow it with the ability to guess points $y \in \mathbb{R}^\infty$ (with cost size (y)). We call such an extended machine *nondeterministic*.

A set S (of points in $\mathbb{R}^\infty$) is in $\text{NP}_\mathbb{R}$ if there exists a nondeterministic machine M satisfying the following two conditions:

1. For all $x \in \mathbb{R}^\infty$, the running time of M with input x is bounded by a polynomial in size (x).
2. For all $x \in \mathbb{R}^\infty$, $x \in S$ if and only if there exists a *guess* $y \in \mathbb{R}^\infty$ such that the computation of M with input x and guess y ends in an accepting state (or, equivalently, returns 1).

COMPLEXITY OF A PROBLEM OVER THE REALS

As an example of a computational problem over the reals, we now focus on feasibility of real polynomials.

Consider polynomials $f_1, \ldots, f_k \in \mathbb{R}[X_1, \ldots, X_n]$. The problem at hand is to decide if there exists a common root $\xi \in \mathbb{R}^n$. Thus, one seeks an algorithm, in fact an algebraic algorithm over $\mathbb{R}$, which on input $f = \{f_1, \ldots, f_k\}$ returns 1 if and only if there is a $\xi \in \mathbb{R}^n$ such that $f_i(\xi) = 0$ for all i, and returns 0 otherwise.

By an algebraic algorithm we have in mind a machine whose computations involve the basic arithmetic operations and whose branching depends on order comparisons.

The input f to such a machine can be thought of as the vector of coefficients of the f_i in $\mathbb{R}^N$ where N is given by the formula

$$N = \sum_{i=1}^{k} \binom{n + d_i}{n} \tag{1}$$

where d_i is the total degree of the polynomial f_i, $i = 1, \ldots, k$. Thus, this N represents the size $S(f)$ of the input f.

A particular feature of the real numbers enables us to consider the same problem with only one polynomial at the cost of slightly increasing the degree. We associate to the polynomials $f_1, \ldots, f_k$ the single polynomial $g = \sum_{i=1}^{k} {f_i}^2$. Now g has the property that for every $\xi \in \mathbb{R}^n$, ξ is a common root of all the f_i if and only if $g(\xi) = 0$. Therefore, solving our problem for the f_i is equivalent to solving it for g. Moreover, if not all the f_i are linear then the degree of g is at least 4. Let us restrict our attention to degree-4 polynomials and consider the following problem, which we call 4-FEAS:

> Given a degree-4 polynomial in n variables with real coefficients, decide whether it has a real zero.

Again, the input g for this problem can be regarded as a vector in $\mathbb{R}^N$ where

$$N = \binom{n+4}{4} \tag{2}$$

is the size $S(g)$ of this input.

An algorithm for solving this problem was first given by Tarski in the context of exhibiting a decision procedure for the theory of real numbers. In the context of complexity theory, Tarski's algorithm is highly intractable. The number of arithmetic operations performed by this algorithm grows in the worst case by an exponential tower of n 2s. Collins devised another algorithm that solved 4-FEAS within a number of arithmetic operations bounded by

$$2^{2^{s(g)}} \tag{3}$$

More recent algorithms have achieved single exponential bounds.

Since evaluating g at a point $x \in \mathbb{R}^n$ has cost bounded by a linear function of the size of g, 4-FEAS is in NP over $\mathbb{R}$. The machine considers a guess x and evaluates $g(x)$, accepting if $g(x) = 0$. A guess leading to acceptance proves the existence of a zero of g.

A result in Blum *et al*. (1989) shows a certain universality of 4-FEAS with respect to this property of being NP-complete over $\mathbb{R}$. As a consequence, 4-FEAS belongs to $\mathrm{P}_{\mathbb{R}}$ if and only if $\mathrm{P}_{\mathbb{R}} = \mathrm{NP}_{\mathbb{R}}$.

It is an open question whether the 4-FEAS problem is intractable; that is, whether there is no algorithm solving 4-FEAS in polynomial time. This would imply $\mathrm{P}_{\mathbb{R}} \neq \mathrm{NP}_{\mathbb{R}}$.

FUTURE DIRECTIONS

The real machines in Blum *et al*. (1989) assume exact arithmetic. But rounding is a part of how machines and biological intelligence work. Thus, one needs to extend the above to accommodate rounding and approximate reasoning (see, for example, Cucker and Smale (1999)).

Real-valued Mathematical Tools for Cognitive Modeling

Intermediate article

Erkki Oja, Helsinki University of Technology, Espoo, Finland

CONTENTS

Many cognitive models use continuous mathematical formalisms like optimization in vector spaces by gradient descent, multivariate probability distributions, and data compression by coding.

THE DIVERSITY OF MATHEMATICAL FORMALISMS USED IN COGNITIVE MODELS

A great variety of mathematical models are used in cognitive science. The central concept is a symbol processing system. Thus, linguistic models, logic, and algorithms are essential tools. The linguistic models mostly employ concepts from discrete mathematics, although probabilistic models are becoming more popular, for example in natural language processing.

However, many connectionist models like artificial neural networks (Rumelhart and McClelland, 1986) are based on distributed and real-valued (contrary to discrete-valued) representations for which the most natural mathematical framework is a *vector space*. A vector is simply an ordered set of scalars, which are called the elements of the vector. In this article, a vector is denoted in boldface, and the elements of an n-dimensional vector $\mathbf{x}$ are denoted by x_i, $i = 1, \ldots, n$. Transformations between such vectorial representations are appropriate *continuous functions*, linear or nonlinear, applied on the vectors. Optimizing these functions is a central problem. Optimization is usually based on some cost function that must be minimized; hence techniques based on gradient descent are widely used. (*See* **Distributed Representations**)

Often, especially in models of sensory processes, real-world stimuli are modeled, and their vast variability is best described by *probabilistic models*. These are given as multivariate probability distributions. An essential problem is the propagation of the stimuli through the sensory pathways. A high degree of data compression is necessary to remove the redundancies. For modeling this compression, the theory of communication channels and *information theory* can be used. It is based on the coding length of a message or signal, with the key question being the optimality of the code used. (*See* **Pattern Recognition, Statistical**)

SEARCH IN CONTINUOUS SPACES: NUMERICAL OPTIMIZATION

The typical approach to many of the problems in cognitive science is based on parameterized functions. In neural networks, we search for the best nonlinear mapping between given inputs and outputs. In parametric statistics, we search for the density model that best describes our data within a family of parametric densities. In information theory, we may be seeking a transformation of signals transmitted in parallel such that the mutual information between the parallel signals is minimized, giving optimal coding. In all these cases we are searching for the best parameter vector in a continuous multivariate space.

The solution method is based on *cost functions*, also called objective functions. These are scalar functions $J(\mathbf{w})$ of a multivariate vector $\mathbf{w}$, whose elements w_i are the unknown parameters of the

model. The function $J(\mathbf{w})$ must be carefully designed so that the optimal vector of parameters that we are seeking occurs at a minimum. For example, in neural network training, the cost function is the sum of the squared distances between the outputs given by the network for the given input vectors, and the desired outputs that are associated with those input vectors. The smaller the value of this cost function, the more closely the true outputs follow the desired outputs. In this case, the unknown parameters, or elements of the vector $\mathbf{w}$, are all the weights and offsets of all the neurons in the network. The dimension of $\mathbf{w}$ can be very high, in the thousands or even more, so solving this problem is a demanding task. An often occurring problem is that the function $J(\mathbf{w})$ does not have just one global minimum but several local minima.

Minimization of multivariate functions, possibly under some constraints on the solutions, is the central problem of *optimization theory* (Fletcher, 1987; Luenberger, 1969). Mostly, the algorithms are based on the *gradients* of the cost functions. If the solution is constrained so that the parameter vector is not allowed to have all possible values, then often the method based on Lagrange multipliers is the most feasible one (Luenberger, 1969). Sometimes, the cost function $J(\mathbf{w})$ is so complex that it has no gradient, or computing the gradient is computationally too expensive. Then one must resort to random search methods, like simulated annealing or genetic algorithms (Goldberg, 1989).

GRADIENT FOLLOWING METHODS

In *gradient descent*, we minimize a function $J(\mathbf{w})$ iteratively by starting from some initial point $\mathbf{w}(0)$ of the high-dimensional parameter space, computing the gradient of $J(\mathbf{w})$ at this point, and then moving in the direction of the negative gradient or the steepest descent by a suitable distance, to get a new point $\mathbf{w}(1)$. Once there, we repeat the same procedure at the new point, and so on. For iteration step $t = 1, 2, \ldots$, we have the update rule

$$\mathbf{w}(t) = \mathbf{w}(t-1) - \alpha(t)[\partial J/\partial \mathbf{w}]|_{\mathbf{w}=\mathbf{w}(t-1)}$$

with the gradient $\partial J/\partial \mathbf{w}$ taken at the point $\mathbf{w}(t-1)$. The gradient of $J(\mathbf{w})$ is a vector, whose elements are the partial derivatives of $J(\mathbf{w})$ with respect to the elements w_i of $\mathbf{w}$. The parameter $\alpha(t)$ gives the length of the step taken in the direction of the negative gradient. It is called the *step size* or sometimes the learning rate. The iteration is continued until it converges, which in practice happens when the distance between two consequent solutions $\mathbf{w}(t)$ and $\mathbf{w}(t-1)$ goes below some small tolerance level.

Geometrically, a gradient descent step means going downhill. The graph of $J(\mathbf{w})$ is the multidimensional equivalent of a mountain terrain, and we are always moving downward in the steepest descent. This shows a possible disadvantage of gradient descent: it will lead to the closest valley or local minimum instead of the global minimum. The method offers no way to escape from a local minimum. So, good initial values $\mathbf{w}(0)$ are very important in initializing the algorithm.

An example of gradient descent is the error back propagation algorithm widely used in neural network training (Rumelhart and McClelland, 1986). The nonlinear cost function used is notorious for its local minima and there is a large body of literature devoted to the minimization problem. (*See* **Backpropagation**)

SECOND-ORDER METHODS AND DYNAMIC ADJUSTMENT OF STEP SIZE

A drawback of the simple gradient descent optimization method is the speed of convergence: a large number of iteration steps may be needed to reach a minimum of the cost function. The speed can be controlled with the step size $\alpha(t)$, but it can be shown that unless the step size is carefully adjusted to the shape of $J(\mathbf{w})$, the method converges *linearly* (Luenberger, 1969). Defining the error at step t as the Euclidean distance between $\mathbf{w}(t)$ and the true solution at the local minimum $\mathbf{w}^*$, linear convergence means that at the next step $t+1$, the error is a linear fraction of the error at step t.

Faster convergence can be achieved by a *second-order method*, in which the error at step $t+1$ is proportional to the *square* of the error at the previous step. When the error becomes small, close to convergence, its square at the next iteration step can be orders of magnitude smaller still, leading to very fast convergence. The most widely used second-order iteration method is Newton's method. Applied to minimizing the cost function $J(\mathbf{w})$, Newton's method also uses the second-order partial derivatives $\partial^2 J(\mathbf{w})/\partial w_i \partial w_j$ of $J(\mathbf{w})$, that make up the so-called Hessian matrix. It is often denoted by $[\partial^2 J(\mathbf{w})/\partial \mathbf{w}^2]$. The iteration for minimizing the function $J(\mathbf{w})$ is now

$$\mathbf{w}(t) = \mathbf{w}(t-1) - \left[\partial^2 J(\mathbf{w})/\partial \mathbf{w}^2\right]^{-1} [\partial J/\partial \mathbf{w}]\,|_{\mathbf{w}=\mathbf{w}(t-1)}$$

Note how the scalar-valued step size $\alpha(t)$ in the usual gradient descent update rule is now replaced with a matrix that is the inverse of the Hessian,

computed at the point $\mathbf{w}(t-1)$. The algorithm can make use of the local shape of $J(\mathbf{w})$, which results in quadratic or second-order convergence (Luenberger, 1969).

On the other hand, Newton's method is computationally much more demanding per iteration than the steepest-descent method. The inverse of the Hessian has to be computed at each step, which is prohibitively heavy for many practical cost functions in high dimensions. It may also happen that the Hessian matrix becomes close to a singular matrix, which has no inverse. One remedy is to regularize the algorithm by adding small positive numbers to the diagonal; this is the basis of the Marquardt–Levenberg algorithm. Sometimes the Hessian is approximated by its diagonal only, and then the inversion becomes very simple, yet the algorithm is a clear improvement over the usual steepest descent. Newton's method can be seen as the optimal way for *dynamic adjustment* of the step size as the iteration goes on.

For error functions that can be expressed as sums of squares, one can apply the Gauss–Newton method instead of Newton's method. Also the conjugate gradient method provides a compromise between the steepest-descent and Newton methods (Luenberger, 1969). All these algorithms are fairly complex to use in practice, and it is advisable to resort to well tested numerical software to perform the computations.

LINEAR PROGRAMMING

Perhaps the simplest special case for the cost function $J(\mathbf{w})$ is a *linear function*: a weighted sum of the elements w_i. Many practical problems result in linear cost functions, at least as good approximations, which are recommended because of their mathematical tractability. Now the problem of minimizing $J(\mathbf{w})$ is meaningless, however, unless some extra conditions are added. A linear function has no minima or maxima, but approaches plus or minus infinity just like a (non-horizontal) straight line in the two-dimensional coordinate system. What are needed to make the problem well defined are constraints on the unknown parameters w_i. This leads to the standard *linear programming problem* (Dantzig, 1963):

$$\text{minimize } J(\mathbf{w}) = \sum\nolimits_i c_i w_i \text{ under the } N \text{ constraints } \sum\nolimits_k a_{jk} w_k \leq b_j, \quad j = 1, 2, \ldots, N$$

The notation $\sum_i$ means taking the sum over all the appropriate indices i. Here, the given numbers c_i determine the cost function, and the given numbers a_{jk} and b_j determine the constraints on the solution vector $\mathbf{w}$.

The equations have an easy geometrical interpretation. Imagine the usual two-dimensional coordinate plane, but now the two axes are the two components w_1 and w_2. Then the constraints will in practice enclose a convex polygonal region, the so-called feasible set for the solution. All the solutions $\mathbf{w} = (w_1, w_2)$ must be within this closed region. The cost function is linearly decreasing within this region in some direction that is determined by the two coefficients c_1 and c_2. It is easy to see that the minimum is usually attained in a corner of the feasible region, in which just two of the borders of the region meet, determined by two of the N constraints. The solution of the problem is based on finding out which of the corners gives the minimum. The same geometrical intuition generalizes to any dimensions for $\mathbf{w}$.

There is a highly popular and successful algorithm for solving the linear programming problem, the so-called Simplex method (Dantzig, 1963). It is available in a large number of software packages.

DEALING WITH UNCERTAINTY: THE BASICS OF PROBABILITY THEORY

Probability theory deals with random events. If A is a random event, it is meaningful to give it a *probability* $P(A)$. It usually has the interpretation that, in a very long sequence of trials, with A one of the possible outcomes – tossing a coin or dice is the most classical example – the probability $P(A)$ gives the relative frequency for the occurrence of A. It is also possible to interpret the probability subjectively, as the degree of belief in the given outcomes. If $A_1, \ldots, A_n$ are all the possible outcomes of one trial, then their probabilities sum up to one: $\sum_i P(A_i) = 1$. If there is another trial with the possible outcomes $B_1, \ldots, B_m$, then basic probability theory will tell us how to formulate probabilities for various combinations of possible outcomes of the two trials.

Basic probability theory suffices for the case of discrete events. However, in continuous mathematical models, the theory has to be extended to deal with random real-valued variables and vectors. The central mathematical concept is then the probability density.

SAMPLE SPACES, PROBABILITY MASS, AND PROBABILITY DENSITY

A scalar *random variable* $x = x(\omega)$ is defined over a *sample space* Ω. The sample space totally determines

the probability structure of x. It is hidden in the sense that only the values of the variable x are observable, not the argument ω. The concept of the sample space is necessary to rigorously develop the probability theory for continuous variables, starting from measure theory (Doob, 1953). For example, the *distribution function* of x, defined as $F(\xi) = P(x(\omega) \leq \xi)$, actually means the probability measure of that region in Ω over which this inequality is true. However, in practice the sample space is not explicitly mentioned at all and the random variable is just denoted by x.

The derivative of the distribution function, if it exists, is called the *probability density function* of x (or just the density) and denoted by $f(\xi) = dF(\xi)/d\xi$. It then clearly follows that

$$P(\xi_1 \leq x \leq \xi_2) = \int_{(\xi_1 \leq u \leq \xi_2)} f(u)\mathrm{d}u$$

The integral of the density is taken over the interval (ξ_1, ξ_2). The variable u is just a dummy variable, necessary in integration, but having no significance. The integral is only a function of the end points ξ_1 and ξ_2. Through this kind of integral, the probability density function $f(\xi)$ can be used in practice to compute the *probability mass* of any interval of x. It follows from this definition that the integral of the density over the whole x-axis is equal to one.

All this generalizes in a straightforward way to multivariate random entities called random vectors. In cognitive modeling, we quite often wish to model probabilities of several interrelated variables. The distribution of a vector $\mathbf{x}$ with n elements x_i is defined as $F(\xi) = P(\mathbf{x} \leq \xi)$, where the vectorial inequality must be understood element by element. The variable ξ also has n elements ξ_i. The density is the derivative of this with respect to all the components ξ_i, defined as $f(\xi) = \partial^n F(\xi)/\partial\xi_1\partial\xi_2 \ldots \partial\xi_n$ Again, given a region Γ in the n-dimensional ξ-space, its probability mass is given by the integral of the density $f(\xi)$ over the region Γ. The integral over the whole n-dimensional space is equal to one (see, e.g. Morrison, 1967).

COMMON PROBABILITY DISTRIBUTIONS

When computing with probability densities, they must be given explicit mathematical forms. The most often used probability density is the normal or *gaussian* density (see Papoulis, 1991). It is defined for one random variable x as

$$f(x) = 1/(\sigma\sqrt{2}\pi)\exp[-(x-\mu)^2/(2\sigma^2)]$$

We have here adopted the simplified notation, widely in use, where the symbol for the random variable x is also used as the argument in the density, instead of some auxiliary variable ξ. The two parameters σ and μ that completely define this function have a very clear meaning: μ is the *mean value* of x, and σ is the standard deviation, whose square is called the *variance* of x. These are the two first moments of this density. It can be shown from the above equation that these parameters satisfy

$$\mu = E\{x\} = \int x\, f(x)\mathrm{d}x$$

$$\sigma^2 = E\{(x-\mu)^2\} = \int (x-\mu)^2 f(x)\mathrm{d}x$$

The integrals are taken from minus infinity to plus infinity and define the *expectations* (denoted by E{}) of x and $(x-\mu)^2$, respectively. These are the theoretical definitions; if we have available a sample from a random variable x that we assume to be gaussian, then the mean and variance are easily estimated by the sample average and the sample standard deviation, respectively. The importance of the gaussian distribution is largely due to the central limit theorem, stating that a sum of independent random variables, under very general conditions, tends to be gaussian. For instance, random noise can often be considered to arise from a large number of small independent additive effects, and is therefore naturally modeled as gaussian.

The multivariate generalization of the gaussian density is given by

$$f(\mathbf{x}) = \text{constant} \times \exp[-1/2(\mathbf{x}-\boldsymbol{\mu})^{\mathrm{T}}\ \mathbf{C}^{-1}(\mathbf{x}-\boldsymbol{\mu})]$$

where $\boldsymbol{\mu}$ is the mean vector of $\mathbf{x}$ and $\mathbf{C}$ is the *covariance matrix*. The covariance matrix has the variances of the elements x_i on the diagonal, and the off-diagonal elements are the covariances.

Two other important densities (given here for a scalar case only, with zero means) are the *Laplace density* $f(x) = \lambda/2\exp(-\lambda|x|)$, where λ is a parameter controlling the variance, and the *uniform density* $f(x) = 1/(2a)$ on the interval $x \in [-a, a]$. These are representatives of two different non-gaussian densities: the Laplace density has thicker 'tails' than the gaussian, and hence its higher-order moments are larger. The uniform density is totally concentrated to a limited interval and has no tails at all.

Density estimation, given only a sample of variables or vectors, is often necessary when developing probabilistic models. This always means approximations. If none of the above densities suffices, then the most usual approximation is a

mixture of gaussians: for scalar x, this is $f(x) = \sum_i P(i)\, f(x|\mu_i, \sigma_i)$ where $f(x|\mu_i, \sigma_i)$is one of the component gaussians, also called a kernel function, with its own mean and standard deviation, and $P(i)$ is the probability that the random vector $\mathbf{x}$ is distributed according to the ith component density. The $P(i)$ sum up to one, which implies that the integral of $f(x)$ over the whole x-axis is equal to one as it should be. Any density can, in principle, be approximated by a mixture of gaussians, and again for this problem there exists good software, usually based on the expectation-maximization algorithm.

CONDITIONAL PROBABILITIES AND BAYES' RULE

In many estimation and inference approaches, we may ask the following question: we have two random vectors, $\mathbf{x}$ and $\mathbf{y}$, and we know that they are dependent. If we are able to measure one of the vectors, say $\mathbf{x}$, and we have a sample of observations available, what can we say about the other, dependent vector $\mathbf{y}$? To answer this kind of questions in a disciplined way, the notion of *conditional probability* is necessary.

First of all, let us denote by $f_{x,y}(\mathbf{x}, \mathbf{y})$ the joint density of $\mathbf{x}$ and $\mathbf{y}$. If $\mathbf{x}$ has n elements and $\mathbf{y}$ has m elements, then this is a function of $m + n$ elements. The density of $\mathbf{x}$, denoted by $f_x(\mathbf{x})$, is obtained from this by integrating over all values of $\mathbf{y}$, and vice versa for $f_y(\mathbf{y})$, the density of $\mathbf{y}$. We define the conditional density of $\mathbf{x}$, given $\mathbf{y}$, as

$$f_{x|y}(\mathbf{x}|\mathbf{y}) = f_{x,y}(\mathbf{x}, \mathbf{y})/f_y(\mathbf{y})$$

This is in complete analogy with discrete probabilities where the conditional probability of an event A, given another event B, is the joint probability of A and B divided by the probability of B. The function $f_{x|y}(\mathbf{x}|\mathbf{y})$ is a proper density function for $\mathbf{x}$, whose integral over all $\mathbf{x}$ is equal to one, as it is very easy to see. In this function, the conditioning quantity $\mathbf{y}$ is usually considered as a fixed parameter vector, although it is actually a random vector, too.

Because a symmetrical definition holds for the conditional density of $\mathbf{y}$, given $\mathbf{x}$, we have two ways to express the joint density: either as $f_{x|y}(\mathbf{x}|\mathbf{y}) f_y(\mathbf{y})$ or as $f_{y|x}(\mathbf{y}|\mathbf{x})\, f_x(\mathbf{x})$. These must be equal, which written in a slightly different way gives

$$f_{y|x}(\mathbf{y}|\mathbf{x}) = [f_{x|y}(\mathbf{x}|\mathbf{y})/f_x(\mathbf{x})]\, f_y(\mathbf{y})$$

This important equation is called the *Bayes' rule* (Morrison, 1967; Papoulis, 1991). It has a central role in Bayesian estimation and inference. The most common interpretation is that $\mathbf{y}$ is a vector-valued quantity that we wish to estimate based on observations contained in vector $\mathbf{x}$. The rule says how the *prior density* of $\mathbf{y}$, $f_y(\mathbf{y})$, is transformed by the observation data $\mathbf{x}$ into a *posterior density* $f_{y|x}(\mathbf{y}|\mathbf{x})$. The function $f_{x|y}(\mathbf{x}|\mathbf{y})$ that is central in this transformation is often called the *likelihood function* of the data $\mathbf{x}$. For instance, based on the observations, a very wide and non-informative gaussian prior density $f_y(\mathbf{y})$ can change into a sharp non-gaussian posterior density $f_{y|x}(\mathbf{y}|\mathbf{x})$ that gives us valuable information about the most likely values of $\mathbf{y}$. (*See* **Bayesian and Computational Learning Theory**)

MEASURING STRUCTURE: THE BASICS OF INFORMATION THEORY

Probability theory gives one approach to modeling the structure of observations and quantities through their multivariate probability distributions. An alternative, but related, approach is provided by *information theory*. Here the emphasis is on coding. By an efficient coding of observations, they can be stored in memory or transmitted over a communication channel. Finding a suitable code depends on the statistical properties of the data. A completely random quantity cannot be coded with a shorter code than the measurements themselves. However, if there is structure in the quantity, like a speech waveform or a picture, then a much shorter code is possible.

THE COMMUNICATION CHANNEL, NOISE, AND THE BIT

The basic framework for information theory is the *communication channel*: a string of symbols are transmitted from a transmitter to a receiver. Let us denote by X the symbol transmitted at a given moment. It is a random variable that has a known number of discrete symbols, say $s_1, s_2, \ldots, s_n$, as possible values. The probability (or relative frequency) of s_i occurring in the symbol string is denoted by $P(X = s_i)$. Then the *entropy* of X is defined as (see Cover and Thomas, 1991)

$$H(X) = -\sum_i P(X = s_i)\ \log P(X = s_i)$$

The minus sign in front makes entropy nonnegative, because $P(X = s_i)$ is between 0 and 1 and its logarithm is therefore negative or zero. The base of the logarithm is traditionally 2. Then the unit of entropy is called a *bit*. If we have only two possible

symbols, with equal probabilities, it is easy to see that the entropy has exactly the value of 1, or one bit. The entropy gives the degree of information that we obtain by observing the value of X. For two symbols, the maximal information is one bit in the case when the two possibilities are equally likely and no intelligent guess can be made. On the other hand, if one of the probabilities is 1, the other 0, then the entropy is equal to 0. In this case, the outcome can be completely predicted and no additional information comes from the observation.

Usually, in any realistic communication channel, there is *noise* present that will occasionally distort the symbols and cause errors. Some noise detection and correction mechanism has to be introduced.

OPTIMAL CODES

In computers and digital systems, binary codes are used. Everything is represented by just two symbols, traditionally noted as 0 and 1. An entity having these two possible values is also called a bit, although originally a bit is the measuring unit for entropy. In digital circuit hardware, a bit is formed using two different voltage levels. A binary string of length eight, a byte, can represent 256 different discrete symbols, for instance 256 different magnitudes of a signal amplitude or pixel gray level. A very relevant question is, whether we actually need eight bits for this or is there some way to use a shorter code.

One way to solve this is to use codes of variable length: for symbols occurring often, a shorter code is used. Then the codes for infrequent symbols become longer, in order not to mix up the codes. For instance, if 0 alone is the code for the most often occurring symbol, then the other codes must start with 1. There is a deep central result saying that the minimum average length of the binary code is given by the entropy of the symbols. Such a code is called an *optimal code*. There exist many practical coding methods that try to get as close to this lower bound as possible (Cover and Thomas, 1991). If noise is present that may introduce errors in the codes, then error detection and correction are necessary. This means adding extra redundant bits by which the errors can be handled, but then the code will also be longer in practice.

The entropy bound is not limited to digital communication systems, but must hold for any communication channel, even for the sensory systems in man and animals. No matter what coding the systems use, they cannot escape this bound. Essentially, this means that the more random or unpredictable the signals to be transmitted are, the higher is their entropy and the less compression is possible.

ENTROPY, MUTUAL INFORMATION, AND MINIMUM DESCRIPTION LENGTH

Entropy was defined above for discrete probability distributions. It can be extended to multivariate continuous densities by the concept of *differential entropy*, defined as (Cover and Thomas, 1991)

$$H(\mathbf{x}) = -\int f(\mathbf{x}) \log\, f(\mathbf{x}) \mathrm{d}\mathbf{x}$$

where $\mathbf{x}$ is a random vector. The *mutual information* of the elements x_i of $\mathbf{x}$ is defined as

$$I(x_1, \ldots, x_n) = \sum\nolimits_i H(x_i) - H(\mathbf{x})$$

One interpretation is based on coding lengths: mutual information approximates the reduction in coding length that results from coding the whole vector $\mathbf{x}$ using some vector code, as compared to coding each individual element x_i separately. Another interpretation is obtained by writing the mutual information in the form

$$I(x_1, \ldots, x_n) = \int f(\mathbf{x}) \log\, [f(\mathbf{x}) / \prod\nolimits_i f(x_i)]\, \mathrm{d}\mathbf{x}$$

where $\prod_i f(x_i)$ is the product of the marginal densities of $\mathbf{x}$. From this it is seen that the mutual information becomes zero when the joint density $f(\mathbf{x})$ equals the product of its marginal densities. But then the elements x_i are independent and give no information about each other. The more dependent the elements are, the higher is the mutual information and the more efficient it is to code the vector $\mathbf{x}$ as a whole.

Often, the observations $\mathbf{x}$ are assumed to follow some model from a family of possible models. Then the question arises which is the best or optimal model. This has been answered in the *minimum description length principle* (Rissanen, 1978) and related approaches. We define the best model as the one giving the shortest code when the model itself is coded first, and then the observation data are coded based on the model. If the model is given by the parameters $\mathbf{M}$ of a parametric density for $\mathbf{x}$, then we get from Bayes' rule

$$-\log\, P(\mathbf{M}|\mathbf{x}) = -\log\, P(\mathbf{x}|\mathbf{M}) - \log\, P(\mathbf{M}) + \text{constant}$$

There the expectations of $-\log\, P(\mathbf{M})$ and $-\log\, P(\mathbf{x}|\mathbf{M})$ give the optimal coding lengths of the models and the data, given the model. Minimizing

these means actually finding the model whose posterior probability is the highest.

Reasoning about Time

Intermediate article

Paolo Terenziani, Univ. Piemonte Orientale 'Amedeo Avogadro', Italy

CONTENTS

Reasoning about time is a fundamental task in many 'intelligent' activities. From the standpoint of artificial intelligence, it includes representing and making inferences about the dynamic phenomena of the world, change, persistence and temporal constraints between activities.

INTRODUCTION

The human way of perceiving and understanding the world incorporates at a deep level the notion of time. Time seems to be a primitive entity to which objects in the world are related. In particular, the notions of action, causality and change are intrinsically related to the notion of time. Events occur in a given state of the world and cause changes in that state. Only in a static world with no changes would there be no notion of time. Thus, time plays a fundamental role in any model of reality, and reasoning about time is essential in most intelligent activities. For instance, dealing with time is important in many different areas of computer science, including process simulation, databases, protocol, guideline and workflow management, and many areas of artificial intelligence (AI), such as planning, scheduling, diagnosis, expert systems, natural language understanding and knowledge representation. Therefore, many researchers in AI have attempted to define suitable formalisms to represent time-related phenomena and to reason with them.

TEMPORAL PRIMITIVES AND THE STRUCTURE OF TIME

The definition of the basic primitives (i.e., the ontological analysis) of time is a matter of debate within the AI community. First of all, one has to choose between time points and time intervals as the basic temporal entities. There are intuitive and technical arguments in favour of both choices. Time points are taken as the basic primitives, for example, in the situation calculus (McCarthy and Hayes, 1969). Other authors have suggested that time intervals are more intuitive than the abstract mathematical notion of points, and have pointed out some technical problems arising from the use of time points (Allen, 1983).

Next, one has to specify a suitable structure for the temporal domain. For instance, time may be regarded as a discrete collection of temporal elements or, on the other hand, as a dense collection (so that between any two temporal elements there is always a third). Moreover, time may be unbounded (infinite in one or both directions) or bounded. Some ordering relation (temporal precedence) must be defined on the set of temporal elements. This may be linear (i.e., the temporal structure is totally ordered) or branching (for example, each branch may represent a possible future evolution of the given world). Circular time is also used in some applications. (See Van Benthem (1983) for a detailed analysis of these alternatives.)

Naturally, different approaches have been proposed and different choices made, depending on the specific phenomena and tasks at hand. However, one can distinguish two broad streams in research about time within the AI community, henceforth called 'general-purpose' and 'constraint-based' approaches.

GENERAL-PURPOSE (LOGICAL) APPROACHES

General-purpose approaches mainly focus on the definition of a formalism general enough to represent a wide range of temporal phenomena. Such approaches aim at dealing with the dynamic aspects of the world, at describing the internal structure of actions and events occurring in the world, and at modeling how the world changes in response to such actions and events. Although very different formalisms have been devised most of them are first-order or modal logical formalisms.

The Situation Calculus

An important example is the situation calculus (McCarthy and Hayes, 1969). The situation calculus adopts a very natural (and widely used) way of introducing time in first-order logic: functions and predicates are extended with an additional argument representing the time at which they are to be interpreted. Specifically, in the situation calculus, the temporal argument denotes a situation, i.e., 'the complete state of the universe at an instant of time' (McCarthy and Hayes, 1969). 'Propositional fluents' (i.e. functions from situations to truth-values) are used to describe facts. For instance, a situation s in which a person p is in place x and it is raining in place x can be described as follows:

$$\text{at}(p, x, s) \wedge \text{raining}(x, s) \tag{1}$$

Causation is modeled using the propositional fluent $F(a, s)$ stating that situation s will be followed by a situation that satisfies the propositional fluent a. For instance, one could use F to assert that if a person is out in the rain he will get wet:

$$\forall x \forall p \ \forall s \ \text{raining}(x, s) \wedge \text{at}(p, x, s) \wedge \\ \text{outside}(p, s) \Rightarrow F(\lambda s' \ \text{wet}(p, s'), s) \tag{2}$$

Actions are modeled using the 'situational fluent' *result*. result(p, a, s) denotes the situation that results when the person p carries out the action a in the situation s. For instance, the following formula represents the axiom schema that, if in a situation s a person p has a key k that fits the safe sf, then in the situation resulting from the action of opening sf with the key k, the safe is open.

$$\text{has}(p, k, s) \wedge \text{fits}(k, sf) \wedge \text{at}(p, sf, s) \\ \Rightarrow \text{open}(sf, \text{result}(p, \mathit{open}(sf, k), s)) \tag{3}$$

Action and Change

Difficult problems arise when dealing with the interplay between actions and changes of the world. Many researchers have realised that one is not able to infer everything about a situation resulting from an action without having a very large number of axioms describing how the action relates to the world and changes it. First, one has to specify all the conditions that a situation s must satisfy in order that an action a may be performed in that situation. The number of such conditions tends to be very large even for simple actions (for example, I can drive a car if I have a car, a driving license, petrol in it … but also I must have hands, I must not be blind and the car must have wheels …). This is the so-called 'qualification problem'. Secondly, one has to specify everything that changes as a result of the action (if I am driving, I am moving, the the atmosphere is changing because of the exhaust produced by the car …). This is called the 'ramification problem'. The specification of everything that does not change is called the 'frame problem'. In classical first-order logic, it is not easy to express notions such as 'everything that is not explicitly asserted to change remains unchanged'. Dealing with the qualification, ramification and frame problems involves a certain capacity for 'nonmonotonic' reasoning. That is, one must be able to make inferences not only from known facts about the world (situation), but also from assumed facts. For instance, if I parked my car in front of my house yesterday, I can assume that the car is still there today, and draw conclusions on the basis of such an assumption (called a 'persistence assumption'). However, such conclusions are defeasible, in the sense that they may have to be retracted if further information about the world becomes available (for example, the police telephone to advise me that my car has been stolen). In the AI literature, many different logical frameworks have been devised in order to deal with nonmonotonicity (see the survey in Lee, Tannok and Williams, (1993). In recent years, many approaches have been devised that deal with the above problems by taking advantage of the 'negation by failure' of logic programming. For instance, a formulation of the situation calculus based on logic programming that deals with the frame problem has been recently proposed (Kowalski and Sadri, 1997).

Temporal (Modal) Logic

Another popular way of introducing the notion of time into a logical framework is by means of modal logics dealing with time (usually called 'temporal logics'). Modal logics were originally introduced to study the different 'modes' of truth. For example, a property p may be false in the present world, and yet the assertion 'possibly p' may be true if there is another possible world where p is true. A temporal logic is a type of modal logic in which each possible world is associated with a temporal element. A temporal precedence relation (akin to the 'accessibility' relation in modal logics) relates temporal elements, and the standard modal operators are reinterpreted over the temporal context. Any temporal logic must provide some temporal operators in order to describe and reason about how the truth-values of assertions vary with time. Different temporal logics have been devised to deal with

linear time or branching time; and both propositional and first-order temporal logics have been devised. A simple example of a temporal logic is propositional linear temporal logic (PLTL) (Emerson, 1990). PLTL adopts linear time, and introduces the temporal operators Fp ('sometime p'), Gp ('always p'), Xp ('next time p') and pUq ('p until q'). Given the current situation s_{now}, the above assertions evaluate to true if and only if the following conditions hold:

Fp: p is true in at least one of the situations that follow s_{now}.

Gp: p is true at s_{now} and in all situations following s_{now}.

Xp: p is true in the situation that immediately follows s_{now}.

pUq: p is true at s_{now} and in all situations between s_{now} and the first situation (following s_{now}) in which q is true.

A survey of different temporal logics can be found in Emerson, 1990.

CONSTRAINT-BASED APPROACHES

Constraint-based approaches mainly focus on the definition of a representation formalism and of reasoning techniques to deal specifically with temporal constraints between temporal entities (time points or intervals), independently of the events and states associated with them. For instance, given three time intervals I_1, I_2 and I_3, if I_1 is before I_2 and I_2 is before I_3, then one can infer that I_1 is before I_3, independently of the events that occurred in I_1, I_2 and I_3. By restricting the problem in this way, one can obtain better results than general-purpose approaches. For example, with a careful definition of the temporal constraint language, one can define specialized reasoning techniques that make inferences such as the one above in a more efficient way than, say, a standard theorem-prover for first-order logic. There is a trade-off between the expressiveness of the constraint language and the computational complexity of the inference techniques that are possible with it, and this is a central topic of research (see the survey in (Vila, 1994)).

Because dealing with temporal constraints is a fundamental task in so many AI applications, there has been much research aimed at building application-independent and domain-independent temporal constraints managers. These are intended to be *specialized knowledge servers* that represent and reason with temporal constraints, and that cooperate with other software modules in order to solve problems in different applications (Console and Terenziani, 1999). For instance, a temporal constraints manager could cooperate with a planner, in order to check incrementally the temporal consistency of a plan. Specialized temporal constraints managers are very useful from the computational point of view, as they allow programmers to focus on problems specific to their domain and application and to design modular software architectures. Temporal constraints managers can be distinguished on the basis of the types of temporal constraints they deal with.

Representing and reasoning with qualitative temporal constraints

Qualitative temporal constraints concern the relative positions of time points or intervals. J.F. Allen's interval algebra (IA) was an attempt to formalize these. Allen defined the 13 primitive qualitative relations between time intervals shown in Figure 1 (Allen, 1983).

These relations are exhaustive and mutually exclusive, and can be combined to represent ambiguities. For example, the constraint I_1 (BEFORE, CONTAINS,OVERLAPS)I_2 represents the fact that the time interval I_1 is before I_2, overlaps I_2 or contains I_2.

Temporal inference is based on two algebraic operations on relations between time intervals: intersection and composition. Given two possibly ambiguous relations R_1 and R_2 between two time intervals I_1 and I_2, the temporal intersection $R_1 \cap R_2$ is the most constraining relation between I_1 and I_2. For example, the temporal intersection between

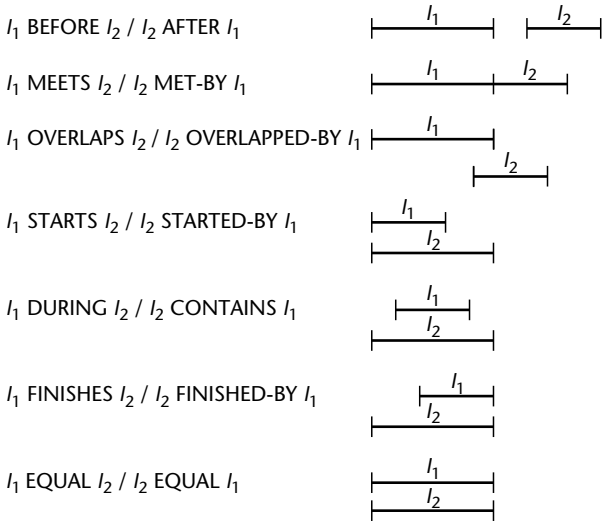

Figure 1. Qualitative relations between intervals in Allen's Interval Algebra.

$$R_1 : I_1(\text{BEFORE}, \text{CONTAINS}, \text{OVERLAPS})I_2 \quad (4)$$

and

$$R_2 : I_1(\text{BEFORE}, \text{MEETS}, \text{OVERLAPS})I_2 \quad (5)$$

is

$$R_1 \cap R_2 : I_1(\text{BEFORE}, \text{OVERLAPS})I_2 \quad (6)$$

Given a relation R_1 between I_1 and I_2 and a relation R_2 between I_2 and I_3, the composition $R_1@R_2$ gives the resulting relation between I_1 and I_3. For example, the composition of

$$R_1 : I_1(\text{BEFORE})I_2 \quad (7)$$

and

$$R_2 : I_2(\text{BEFORE}, \text{CONTAINS}, \text{OVERLAPS})I_3 \quad (8)$$

is

$$R_1@R_2 : I_1(\text{BEFORE})I_3 \quad (9)$$

In Allen's approach, temporal inference is performed by a path consistency algorithm that computes the transitive closure of the constraints by repeatedly applying intersection and composition. Abstracting from many optimizations, such an algorithm can be schematized as follows. Let R_{ij} denote the (possibly ambiguous) relation between I_i and I_j. For all triples of time intervals $< I_i, I_k, I_j >$, do $R_{ij} \leftarrow R_{ij} \cap (R_{ik}@R_{kj})$.

The time taken by Allen's algorithm increases as the cube of the number of time intervals. However, such an algorithm is not complete for IA (checking the consistency of a set of temporal constraints in IA is NP-hard). Other researchers have tried to design less expressive but more tractable formalisms. For example, the point algebra (PA) is defined similarly to IA, but the temporal elements are time points. Thus, there are only three primitive relations ($<$, $=$, and $>$), and four ambiguous relations (($<$, $=$), ($>$, $=$), ($<$, $>$), and ($<$, $=$, $>$)) between them. In PA, the constraint closure can be computed in polynomial time by algorithms that are both sound and complete. The price to be paid for tractability is a loss of expressive power: not all (ambiguous) relations between time intervals can be mapped onto relations between their endpoints. Another interesting algebra is the continuous point algebra (CPA), which consists of all relations in PA except for the inequality relation ($<$, $>$). Allen's path consistency algorithm is both correct and complete for such an algebra (see the survey in Vila, 1994).

Representing and reasoning with quantitative temporal constraints

Quantitative temporal constraints involve metric time and include *dates* ('John arrived on 10 October 1999 at 10.00'), *durations* ('John worked for 3 hours') and *delays* ('John arrived 10 minutes after Mary'). Different approaches have been developed to deal with quantitative temporal constraints, and their complexity depends on the types of constraints taken into account. The simplest case is when temporal information is available in the form of dates that exactly locate points and intervals on the timeline. However, in many cases, metric temporal information is not so precise: one can have approximate dates, durations, and delays:

The time interval I_1 ended on 10 October 1999, between 10.00 and 10.15. (10)

I_1 lasted between 20 and 30 minutes. (11)

I_2 started between 20 and 40 minutes after the end of I_1. (12)

In such cases, temporal reasoning is important in order to infer new temporal constraints and to detect inconsistencies. For instance, from the three constraints above one can infer that I_2 started on 10 October 1999, between 10.20 and 10.55, so that the set of constraints above is inconsistent with the constraint

I_2 started at 10.10. (13)

Problems become more complex if disjunctions of temporal constraints are taken into account:

I_2 started $20-30$ or $50-60$ minutes after the end of I_1. (14)

Many approaches have been developed to deal with these problems. For instance, the temporal constraint satisfaction problem (TCSP) model (Dechter, Meiri and Pearl, 1991) is based on the primitive notions of time points and distances between time points. A TCSP is a set of constraints of the form

$$P_i([l_1, u_1], \ldots, [l_n, u_n])P_j \quad (15)$$

where P_i and P_j denote time points ranging over a dense domain, and l_I and u_i ($l_i \leq u_i$) are real numbers, stating that the temporal distance between P_i and P_j is between l_i and u_i for some i. For instance, if we denote by I^- and I^+ the starting and ending points of a time interval I, the temporal constraint sentence 14 can be represented as:

$$I_1{}^{+}([20,30],\ [50,60])I_2{}^{-} \quad (16)$$

TCSP can easily be applied to graphs, where nodes represent time points and arcs are labelled with distances. Dechter, Meiri and Pearl developed an optimized path-finding algorithm to perform temporal reasoning with a graph representation. Their algorithm takes exponential time. However, if disjunctions of distances are not allowed (i.e., all constraints are of the form $P_i([l_1, u_1])\ P_j$), the resulting constraint problem (called the simple temporal problem (STP)) can be solved in cubic time using a standard algorithm for finding the shortest path between each pair of nodes in the graph (such as Floyd Warshall's algorithm, see Papadimitriou and Steiglitz, 1982). These algorithms are both correct and complete for STP. Finally, notice that constraints (10–12) (but not constraint (14)) can be easily mapped onto an STP. In particular, dates can be represented as distances from a given reference time which is unique for the overall set of constraints.

Hybrid approaches

Recently, various integrated approaches have been devised in order to deal with both qualitative and quantitative temporal constraints. Some researchers have proposed combining a standard specialized manager dealing only with qualitative temporal constraints with another manager dealing only with quantitative temporal constraints, and to let the two managers cooperate by exchanging pieces of information whenever new constraints are inferred. However, it has not been proven that the exchange of information between the two managers ever terminates.

Others have proposed high-level constraint languages in which both qualitative and quantitative temporal constraints can be represented, using reasoning techniques based on a homogeneous constraint framework. For example, in the LaTeR temporal constraint manager (Console and Terenziani, 1999), the high-level language allows one to deal with both time points and time intervals, and to express both quantitative and qualitative temporal constraints. The language has been carefully restricted so that all the constraints can be mapped onto an STP framework. In particular, this means that LaTeR can deal with quantitative temporal constraints such as those in sentences 10–12 (but not sentence 14), with all qualitative constraints between points except the inequality relation (i.e., with CPA), and with all qualitative constraints between time intervals that can be mapped onto CPA. While the user interacts with LaTeR through the high-level language, LaTeR internally translates all constraints into an STP framework, in which it performs temporal reasoning.

Recently (Jonsson and Backstrom, 1998), a homogeneous framework has been proposed, based on linear programming, that deals with all the types of constraints discussed above, and that also allows one to express constraints on the relative durations of events, such as: 'John takes at least 30 minutes more than Fred to drive to work.'

FURTHER ISSUES

L. Vila's survey (Vila, 1994) gives an overview of other issues concerning temporal reasoning techniques.

Terenziani has presented a high-level language to model user-defined periodicity (e.g., 'the first Monday of each month'), and a constraint language which extends IA to consider qualitative relations between periodic events (Terenziani, 1997). Terenziani's approach deals with constraints such as: 'Between 1 January 1999 and 31 December 1999, on the first Monday of each month, Mary went to the post office before going to work.' Temporal reasoning over such constraints can be performed by a path consistency algorithm which extends Allen's one. Such an algorithm is sound and operates in polynomial time, but is not complete for the high-level constraint language.

SUMMARY

Many logical approaches have been devised by AI researchers to deal with time, action and change, including the situation calculus, modal temporal logics and nonmonotonic logics. Other approaches have focused on the treatment of qualitative or quantitative temporal constraints, or both, in order to provide efficient domain-independent representation and reasoning techniques.

Reasoning under Uncertainty

Intermediate article

Francisco J Díez, UNED, Madrid, Spain

CONTENTS

Most artificial intelligence applications, especially expert systems, have to reason and make decisions based on uncertain data and uncertain models. For this reason, several methods have been proposed for reasoning with different kinds of uncertainty.

INTRODUCTION

We often have to make decisions based on uncertain knowledge, not only in our private lives (which job to take, which house to buy, where to invest our money) but also in professional activities, such as medicine, economics, politics, engineering, and education. Therefore, any reasoning method that tries to replicate human reasoning must be able to draw conclusions from uncertain models and uncertain data. Models may be uncertain because of indeterminism in the real world or because of our lack of knowledge. Furthermore, data may be incomplete (pieces of information may be not available in a diagnostic case), ambiguous (a pronoun in a sentence may refer to different subjects), erroneous (patients may lie to their doctors, or sensors may be faulty), or imprecise (because of the limited precision of measuring devices, subjective estimations, or natural language).

This article reviews some of the uncertain reasoning methods that have been proposed in the field of artificial intelligence.

NAIVE BAYES

The oldest method applied in uncertain reasoning is probability theory. Probabilistic reasoning concentrates basically on computing the *posterior probability* of the variables of interest given the available *evidence*. In medicine, for example, the evidence consists of symptoms, signs, clinical history, and laboratory tests. A diagnostician may be interested in the probability that a patient suffers from a certain disease. In mineral prospecting, we may wish to know the posterior probability of the presence of a certain deposit given a set of geological findings. In computer vision, we might be interested in the probability that a certain object is present in an image given observation of certain shapes or shadows.

The probability of the diagnoses given the available evidence can be computed by the generalization of Bayes' theorem to several variables. However, the direct application of this method would need a prohibitive number of parameters (probabilities), which grows exponentially with the number of variables involved. Two assumptions were introduced to simplify the model. The first assumption is that the diagnoses are mutually exclusive; i.e. each patient can suffer from at most one disease and each device can have at most one failure at a time. It is then possible to consider a variable D taking n values, as many as the number of possible diagnoses. The second assumption is that the findings are conditionally independent given each diagnosis d_i, so:

$$P(f_1,\ldots,f_m \mid d_i) = P(f_1 \mid d_i)\cdot\ldots\cdot P(f_m|d_i), \quad 1 \le i \le n \tag{1}$$

where f_k represents one of the possible values of a finding F_k. Under these assumptions, the posterior probability of d_i can be computed as follows:

$$P(d_i \mid f_1,\ldots,f_m) = \frac{P(d_i)\cdot P(f_1|d_i)\cdot\ldots\cdot P(f_m|d_i)}{\sum_j P(d_j)\cdot P(f_1|d_j)\cdot\ldots\cdot P(f_m|d_j)} \tag{2}$$

In this simplified model, the number of parameters is proportional to the number of variables: it requires n prior probabilities $P(d_i)$ plus, in the case of m dichotomous findings, $n \times m$ conditional probabilities $P(f_k \mid d_i)$.

Although this method was used in the construction of diagnostic medical systems in the 1960s, it was severely criticized because its assumptions are usually unrealistic (Szolovits and Pauker, 1978). In fact, the assumption of exclusive diagnoses is a reasonable approximation only when the probability of the simultaneous presence of two diseases or two failures is very low. In medicine, however, it is common for a patient to suffer from multiple disorders. Also, the assumption of conditional independence is unrealistic when there are causal associations among findings other than those due to the diagnoses included in the model. Because of the crudeness of such assumptions, this method is often called 'naive Bayes' or 'idiot Bayes'. Even under these assumptions, the model still requires a large number of parameters, which may be difficult to obtain.

MYCIN'S CERTAINTY FACTORS

MYCIN was a rule-based expert system developed in the 1970s as a decision support tool for antibacterial therapy (Buchanan and Shortliffe, 1984). To accommodate uncertainty, MYCIN associated a certainty factor with each rule and, consequently, with each proposition.

The certainty factor of each rule 'if E then H', $CF(H, E)$, is a measure of the degree to which evidence E confirms hypothesis H. When E increases the probability of H, so that $P(H|E) > P(H)$, then $0 < CF(H, E) \leq 1$. The higher the increase in probability, the higher the certainty factor. When E contributes evidence against H, so that $P(H|E) < P(H)$, then $-1 \leq CF(H, E) < 0$. The value of each certainty factor in MYCIN's rules was obtained from human experts when formulating the rules.

Analogously, MYCIN assigned a certainty factor to each assertion. The result was a set of quadruplets of the form illustrated in Table 1. Thus we know with absolute certainty that the patient's name is John Smith; there is strong evidence indicating that the form of organism-1 is rod, weak evidence that it is staphylococcus, weak evidence that it is not a streptococcus, and absolute certainty that the form of organism-2 is not rod.

When the user introduces a piece of evidence, such as $A =$ 'the form of organism-1 is rod', MYCIN states that $CF(A) = 1$. Given the rule

Table 1. Certainty factors of assertions as represented in MYCIN

Object	*Attribute*	*Value*	*CF*
patient	name	John Smith	1.0
organism-1	morphology	rod	0.8
organism-1	identity	staphylococcus	0.2
organism-1	identity	streptococcus	−0.3
organism-2	morphology	rod	−1.0

'if A then B' with certainty factor $CF(B, A)$, the certainty factor for B can be computed as $CF(B) = CF(A) \cdot CF(B, A)$. If there is a second rule 'if B then C', then $CF(C) = CF(B) \cdot CF(C, B)$. This value $CF(C)$ might, in turn, be used in the application of a third rule 'if C then D', and so on.

There was also an equation for combining convergent rules, such as 'if E_1 then H' and 'if E_2 then H', which support the same hypothesis H. The certainty factor of a composed antecedent, such as 'if A and not B', was computed by applying these equations:

$$CF(\text{not } E) = 1 - CF(E) \tag{3}$$

$$CF(E_1 \text{ and } E_2) = \min(CF(E_1), CF(E_2)) \tag{4}$$

$$CF(E_1 \text{ or } E_2) = \max(CF(E_1), CF(E_2)) \tag{5}$$

Although the performance of MYCIN was comparable to that of human experts in the field of infectious diseases, the certainty factor model was soon criticized for its mathematical inconsistencies. One of them is that it does not consider correlation between propositions. For instance, if there are two hypotheses, $H_1 =$ 'organism-1 is a streptococcus', with $CF(H_1) = 0.6$, and $H_2 =$ 'organism-1 is a staphylococcus', with $CF(H_2) = 0.3$, then $CF(H_1 \text{ and } H_2) = \min(0.6, 0.3) = 0.3$, whereas it should be $CF(H_1 \text{ and } H_2) = 0$, because the hypotheses are mutually exclusive.

Another problem is the lack of sensitivity in eqns 4 and 5; for example $\min(0.2, 0.9) = \min(0.2, 0.2)$ and $\max(0.9, 0.9) = \max(0.9, 0.2)$.

Furthermore, MYCIN might assign a higher certainty factor to a hypothesis H_2 even if it is less probable than another hypothesis H_1. This anomaly could occur because certainty factors of rules were defined as measures of confirmation (the relative increase in belief), while certainty factors of propositions were interpreted as measures of absolute belief.

It was also pointed out that the combination of convergent rules is valid only under some conditions. These conditions resemble those of

conditional independence in the naive Bayes model. However, while the assumption of conditional independence might in particular cases be justified by means of causal arguments, no argument can be made for the assumptions that are implicit in the combination of rules. Therefore, MYCIN's model, rather than solving the main problem of the naive Bayes, ran into more serious troubles (see Buchanan and Shortliffe, 1984, ch. 10–12; Pearl, 1988, sec. 1.2). (*See* **Learning Rules and Productions**; **Expert Systems**; **Resolution Theorem Proving**; **Deductive Reasoning**; **Rule-based Thought**)

PROSPECTOR'S BAYESIAN MODEL

PROSPECTOR was an expert system for geological prospecting developed in the 1970s (Duda *et al.*, 1976). Like MYCIN, PROSPECTOR used if–then rules, but instead of using ad hoc certainty factors, it was based on the theory of probability. Each rule had two parameters, namely the likelihood ratios, which were obtained from human experts' estimations.

The propagation of evidence in PROSPECTOR consisted in computing the probability of the consequence of a rule given the probability of the antecedent. In order to simplify the computation, PROSPECTOR made several assumptions of conditional independence, in addition to approximations and interpolations aimed at smoothing the inconsistencies in the probabilities elicited from human experts.

PROSPECTOR became the first commercial success of artificial intelligence when it assisted in the discovery of a deposit of molybdenum worth about one million dollars. However, this achievement did not lessen criticism of the use of probabilistic methods in expert systems. The assumptions and approximations required by PROSPECTOR were still largely unjustified.

DEMPSTER–SHAFER THEORY

In 1968, Dempster proposed a probabilistic framework based on lower and upper bounds on probabilities. In 1976, Shafer developed a formalism for reasoning under uncertainty that used some of Dempster's mathematical expressions, but gave them a different interpretation: each piece of evidence (finding) may support a subset containing several hypotheses. This is a generalization of the 'pure' probabilistic framework in which every finding corresponds to a value of a variable (a single hypothesis).

The main criticism of this theory from a semantic point of view is the lack of robustness of the combination of evidence. Given three single hypotheses and two findings, it may happen that a hypothesis receiving almost no support from any individual finding is confirmed by the combination of them, while the other two hypotheses are discarded (Zadeh, 1986). Also, a small modification of the evidence assignments may lead to a completely different conclusion. This paradox poses no problem for Dempster's (1968) interpretation (lower and upper probabilities) or to Pearl's (1988, sec. 9.1) interpretation (probability of provability), but seems counterintuitive in Shafer's (1976) interpretation, and for this reason some researchers have proposed alternative formalisms based on different combination rules.

The main problem of the Dempster–Shafer theory in its original formulation is that its computational complexity grows exponentially with the number of hypotheses. One of the solutions proposed consists in building a network of frames of discernment (in fact, a network of random variables), whose axiomatic definition is reminiscent of the properties of conditional independence of Bayesian networks.

BAYESIAN NETWORKS

A Bayesian network (Pearl, 1988) is a probabilistic model that consists of a finite set of random variables $\{V_i\}$ and an acyclic directed graph whose nodes represent those variables and whose arcs represent, roughly speaking, probabilistic dependences between variables.

Dependences are quantified by means of a set of conditional probability distributions (CPDs). Each CPD involves a node and its parents in the graph: $P(v_i \mid pa(v_i))$. (Node V_i is a parent of V_j if there is a link $V_i \rightarrow V_j$ in the graph.) In the case of discrete variables, each CPD is given by atable of probabilities. The product of all the CPDs is a joint probability over all variables, from which it is possible to obtain any other marginal or conditional probability, such as the *a posteriori* probability of any variable given a set of evidence.

There are basically two ways of building a Bayesian network. The *automatic* process involves taking a database and applying one of the many algorithms that yield both the structure and the conditional probabilities. The *manual* process involves two stages: building the structure of the network by selecting the variables and drawing causal links among nodes, as in Figure 1; and then

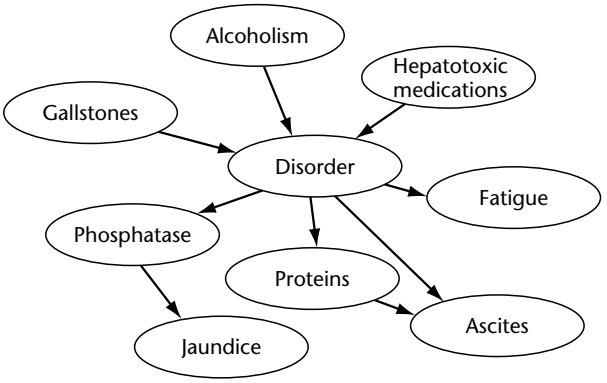

Figure 1. A simplified fragment of HEPAR-II, a medical Bayesian network.

estimating the corresponding conditional probability distributions. (*See* **Machine Learning**)

Ideally, those probabilities should be obtained from objective data, such as databases or epidemiological studies, but in practice the lack of objective data often forces the knowledge engineer to obtain the probabilities from human experts' estimations.

Bayesian networks overcome the limitations of the naive Bayes method in two ways. Firstly, they can diagnose the simultaneous presence of several diseases or failures, because each disease can be represented by a different node. Secondly, the properties of conditional independence are justified either by the statistical independencies in the database, in the case of automatic construction, or by the use of a causal graph elicited from a human expert.

Bayesian networks are also superior to PROSPECTOR in the justification of conditional independencies, but at the price of an increase in computational complexity (the time spent in computing the posterior probabilities).

Causal Bayesian networks have additional advantages, such as the ease with which the model can be extended or refined and its reasoning explained to users.

The main criticisms of Bayesian networks are the difficulty of building the network and the computational complexity of evidence propagation, which is NP-hard: the time required by exact probability updating algorithms depends mainly on the structure of the network, while the complexity of stochastic algorithms depends mainly on the numerical parameters (probabilities). (*See* **Computability and Computational Complexity**; **Bayesian Belief Networks**)

INFLUENCE DIAGRAMS

Influence diagrams are extensions of Bayesian networks which, in addition to random variables, capture available decision options and preferences (utilities). Random variables are represented by circles or ovals, decision nodes as squares or rectangles, and utility nodes as diamonds or parallelograms. Influence diagrams are decision support tools. They permit one to select the optimal decision, the decision that maximizes the expected utility. They overcome the limitations of Bayesian networks in their explicit representation of utilities and in the possibility of selecting the questions to ask or the tests to perform (goal-oriented reasoning). Influence diagrams are closely related to decision trees and Markov decision processes (see Pearl (1988) chapter 6). (*See* **Markov Decision Processes, Learning of**; **Decision-making**)

FUZZY LOGIC AND FUZZY SETS

Some of the sentences that we use in our daily life, such as 'it is cold today', are neither completely true nor completely false. These propositions are called *fuzzy*. In fact, most of the adjectives that we use daily could be interpreted as fuzzy predicates (e.g., 'young', 'rich', 'tall', 'happy', 'healthy', 'big', 'good', 'cheap', 'dark', 'crowded', 'heavy', 'fast', 'modern').

Since in classical logic it is usual to assign 0 to false propositions and 1 to true propositions, some logicians have built multivalued logics in which $v(p)$, the truth-value of proposition p, might also take values between 0 and 1. The truth-value of a composed proposition (negation, conjunction, disjunction, implication, etc.) is a function of the truth-values of the propositions that compose it: for instance, $v(p \wedge q) = f_{\wedge}(v(p), v(q))$.

Different choices of these logical functions lead to different logics. For instance, Lukasiewicz logic, Kleen logic, and standard fuzzy logic take the 'minimum' function for $f_{\wedge}$. Other fuzzy logics may use different triangular norms for $f_{\wedge}$. (A triangular norm is any function $f_{\wedge}$ that is commutative, associative, and monotone, and satisfies $f_{\wedge}(1, a) = a$.)

Similarly, there are several implication functions $f_{\rightarrow}$, all of which satisfy certain conditions. In principle, it would be possible to do inference with fuzzy propositions and fuzzy predicates, but in practice fuzzy inference is usually based on fuzzy sets and fuzzy relations, as shown below.

Given a set A and an element x, the truth-value of the proposition '$x \in A$' is usually called *membership*

degree and is represented by $\mu_A(x)$. Whereas in the case of crisp (classical) sets $\mu_A(x)$ is either 0 or 1, in the case of fuzzy sets $\mu_A(x)$ may be any number in the interval [0, 1].

Each operation on fuzzy sets corresponds to a fuzzy-logical operation. For instance, intersection corresponds to conjunction, since $\mu_{A\cap B}(x) = v(x\in A \wedge x\in B) = f_\wedge(\mu_A(x), \mu_B(x))$. Therefore, fuzzy logic can be viewed as the basis of fuzzy set theory. However, it is more usual to view fuzzy set theory as the basis for fuzzy logic.

The rule 'if $P_A(x)$ then $P_B(y)$', where A and B are fuzzy sets and P_A and P_B are their associated predicates, is translated into a fuzzy relation given by $\mu_{A\to B}(x,y) = f_\to(\mu_A(x), \mu_B(y))$. Modus ponens consists in combining this rule with an assertion $P_{A'}(x)$ in order to obtain a new set B'. This process is performed by composing the set A' with the relation $\mu_{A\to B}$. The resulting set B' depends on the logical functions involved in the composition. In many applications of fuzzy logic this choice is made more or less arbitrarily – a typical choice is min as a norm, max as a conorm and Lukasiewicz's implication – and leads to inconsistencies and counterintuitive results (Fukami *et al*., 1980). The correct way to approach this problem consists in determining the desirable properties of fuzzy inference and then selecting $f_\vee$, $f_\wedge$, and $f_\to$ coherently in order to ensure such properties (see, for instance, Trillas and Valverde, 1985).

The main criticism of fuzzy logic is the lack of a clear semantics, which leads to an arbitrariness in the application of fuzzy techniques. In particular, there are several definitions of degrees of membership, but apparently none of them is used when building real-world applications. All fuzzy systems use numbers between 0 and 1, but the semantics of those numbers and the way of assigning them differ significantly from application to application. Accordingly, there is no clear criterion for determining which norm or conorm to use in each case.

Additionally, there are several techniques of fuzzy reasoning. We have already mentioned that the properties of the fuzzy inference depend on the choice of logical functions, and knowledge engineers are often unaware of the inconsistencies that may result from an arbitrary choice. There are also other patterns of inference with fuzzy rules that are not based on the composition of relations, and other reasoning techniques, such as those involving fuzzy numbers and fuzzy clustering, not presented in this article. As a result, fuzzy logic consists in practice of a toolbox of heterogeneous techniques without clear indications for deciding which tool to use in any particular case. Users of fuzzy logic often devise ad hoc solutions for the representation and combination of knowledge and data. (*See* **Fuzzy Logic**; **Vagueness**)

ROUGH SETS

Rough sets (Pawlak, 1991) have been developed since the 1980s as a tool for data analysis. In simple terms, the starting point is a data table which represents, for each object, the values of some attributes and a label c: $(a_1, \ldots, a_n, c)$. The final objective of the analysis is to infer some classification rules of the form: 'If the attributes of a new object take values $(a_1, \ldots, a_n)$ then this object is c.'

Both the theoretical foundations and the interpretation of rough sets are completely different from those of fuzzy sets. The lack of a precise boundary of a fuzzy set is a consequence of the vagueness of some concepts, such as 'big' or 'tall', and does not necessarily entail uncertainty. In contrast, the lack of a precise boundary of a rough set derives from the coarseness of the background knowledge implicit in the data table. However, the two theories are complementary and are usually categorized together as 'soft computing'.

NON-MONOTONIC LOGICS

Non-monotonic logics are an attempt to model a pattern of human reasoning that consists in making plausible, although fallible, assumptions about the world, and revising them in the light of new evidence. Upon hearing that 'Tweety is a bird', one might assume that 'Tweety can fly' just because 'most birds fly'; however, further evidence that 'Tweety is a penguin' will lead one to retract this assumption. The name 'non-monotonic' refers to the fact that the addition of new clauses may lead to either adding or retracting a previous conclusion. In classical logic new information never invalidates previous conclusions.

Several non-monotonic logics have been proposed, such as Reiter's logic, McCarthy's circumscription, Doyle's truth maintenance systems, and Cohen's theory of endorsements, each based on some implicit assumptions about uncertainty and preferences. Virtually all have been shown to lead to undesirable behavior under some circumstances.

All these logics are based on qualitative reasoning patterns, and thus differ from the other methods described above, which use and propagate numerical information. Qualitative models are easier to build, because they do not need to estimate quantitative parameters. On the

other hand, they are unable to weight conflicting evidence. (*See* **Quantitative Reasoning**)

CONCLUSION

Probability is the oldest formalism for reasoning under uncertainty, and served as the first foundation for computer-based reasoning systems in the 1960s. The unrealistic assumptions of the naive Bayes model used in the first diagnostic systems, the desire to differentiate the evidence in favor of a hypothesis from the evidence against it, and the need for a rule-based reasoning method, led to the development of MYCIN's model of certainty factors. It was later shown that this model had serious inconsistencies and required even more unrealistic assumptions than those of naive Bayes. PROSPECTOR used a Bayesian framework for reasoning with rules, but it also relied on unjustified assumptions and approximations. Dempster–Shafer theory was an attempt to overcome some of the limitations of probabilistic reasoning, but its computational complexity prevented it from being used in practice. Fuzzy sets and fuzzy logic emerged as tools for representing the vagueness of natural language, and led to numerous applications in engineering, medicine, and many other fields.

These four methods – MYCIN, PROSPECTOR, Dempster–Shafer, and fuzzy sets – were developed in the 1970s. In those years, many computer scientists were convinced that probability was not an adequate framework for the problems addressed by artificial intelligence and expert systems. However, the emergence of Bayesian networks and influence diagrams in the 1980s proved that it was possible to build probabilistic models for real-world problems. Many expert systems and software packages based on these techniques became commercial products in the 1990s.

Some researchers nowadays take the position that probability is the only correct framework for uncertain reasoning. Others, while agreeing that probability theory is the best technique when there is enough statistical information, argue that it is hard to use in many practical cases, and for this reason artificial intelligence still needs alternative formalisms.

CONTENTS

Reinforcement learning is one of the means by which animals and artificial systems can learn to optimize their behaviour in the face of rewards and punishments. Reinforcement learning algorithms have been developed that are closely related to methods of dynamic programming, which is a general approach to optimal control. Reinforcement learning phenomena have been observed in psychological studies of animal behaviour, and in neurobiological investigations of neuromodulation and addiction.

INTRODUCTION

One way in which animals acquire complex behaviours is by learning to obtain rewards and to avoid punishments. Reinforcement learning (RL) theory is a formal computational model of this type of learning. To see that some theory is needed, consider the fact that in many environments animals need to perform unrewarded or unpleasant preparatory actions in order to obtain some later reward. For example, a mouse may need to leave the warmth and safety of its burrow to go on a cold and initially unrewarded search for food.

Is it possible to explain learning to take such an unpleasant decision in terms of learning to obtain a large but distant reward? What computational abilities does an agent need in principle for this type of learning? What capacity for episodic memory is necessary? Does an agent need to be able to plan ahead by envisioning future situations and actions? If an agent is doing something without immediate reward, how does it learn to recognize whether it is making progress towards a desirable goal? It is these questions that the theory of reinforcement learning seeks to answer.

RL theory comprises a formal framework for describing an agent interacting with its environment, together with a family of learning algorithms, and analyses of their performance.

THE REINFORCEMENT LEARNING FRAMEWORK

In the standard framework for RL, a learning agent – an animal or perhaps a robot – repeatedly observes the state of its environment, and then chooses and performs an action. Performing the action changes the state of the world, and the agent also obtains an immediate numeric payoff as a result. Positive payoffs are rewards and negative payoffs are punishments. The agent must learn to choose actions so as to maximize a long-term sum or average of the future payoffs it will receive.

The agent's payoffs are subjective, in the sense that they are the agent's own evaluation of its experience. The ability to evaluate its experience in this way is an essential part of the agent's prior knowledge. The payoffs define what the agent is trying to achieve; what the agent needs to learn is how to choose actions to obtain high payoffs. For this framework to be sensible, the agent must be able to visit the same or at least similar states on many occasions, to take advantage of its learning.

A standard assumption is that the agent is able to observe those aspects of the state of the world that are relevant to deciding what to do. This assumption is convenient rather than plausible: it leads to great simplification of the RL problem. We will not here consider the important problem of how the agent could learn what information it needs to observe.

In the conventional framework, the agent does not initially know what effect its actions have on the state of the world, nor what immediate payoffs its actions will produce. In particular it does not know what action it is best to perform. Rather, it

tries out various actions at various states, and gradually learns which one is best at each state so as to maximize its long-term payoff. The agent thus acquires what is known as a *closed-loop control policy*, or a rule for choosing an action according to the observed current state of the world.

From an engineering perspective, the most natural way to learn the best actions would be for the agent to try out various actions in various states, and so learn a predictive model of the effects its actions have on the state of the world and of what payoffs its actions produce. Given such a model, the agent could plan ahead by contemplating alternative courses of action and the states and payoffs that would result. However, this approach to learning does not seem at all plausible for animals. Planning ahead involves accurately envisioning alternative sequences of actions and their consequences: the animal would have to imagine what states of the world would result and what payoffs it would receive for different possible sequences of actions. Planning ahead is particularly difficult if actions may have stochastic effects, so that performing an action may lead to one of several different possible states.

One of the most surprising discoveries in RL theory is that there are simple learning algorithms by means of which an agent can learn an optimal policy without ever being able to predict the effects of its actions or the immediate payoffs they will produce, and without ever planning ahead. It is also surprising that, in principle, learning requires only a minimal amount of episodic memory: an agent can learn if it can consider together the last action it took, the state when it chose that action, the payoff received, and the current state.

The simplest RL algorithms require minimal episodic memory of past states and actions, no prediction of effects of actions, and very simple computations. The speed of learning, and efficiency of use of experience, can be improved if the agent has greater abilities. A continuum of improvement is possible. If an agent has or constructs partial models of the effects of its actions, or if an agent can remember and process longer sequences of past states and actions, learning can be faster and the agent's experience can be used more efficiently.

Markov Decision Problems

Formally, an RL agent faces a Markov decision problem (MDP). An MDP has four components: states, actions, and transition and reward distributions.

The state at time t, for which we use the notation $x(t)$, characterizes the current situation of the agent in the world. For an agent in a maze, for instance, the relevant state would generally be the location of the agent. The action the agent takes at time t is called $a(t)$. Sometimes there may be little or no choice of actions. One consequence of taking the action is the immediate payoff or reward which we call $r(x(t), a(t))$, or sometimes just $r(t)$. If the rewards are stochastic, then $\hat{r}(x(t), a(t))$ is its mean. The other consequence of taking the action is that the state changes. Such changes are characterized by a *transition* distribution, which allows them to be stochastic. In the simplest RL problems, state-transition distributions and the rewards depend only on the current state and the current action, and not on the history of previous actions and states. This restriction is called the Markov property, and ensures that the description of the current state contains all information relevant to choosing an action in the current state. The Markov property is critically necessary for the learning algorithms that will be described below.

We typically use a set of matrices $P_{xy}(a)$ to describe the transition structure of the world. Here, $P_{xy}(a)$ is the probability that the state changes from x to y given that action a is performed. Conventionally, the agent starts off not knowing the transition matrices or reward distributions. Over the course of repeated exploration, the agent has to work out a course of action that will optimize its return.

As an example of a Markov decision process, consider a hypothetical experiment in which a rat presses levers to obtain food in a cage with a light. Suppose that if the light is off, pressing lever A turns the light back on with a certain probability, and pressing lever B has no effect. When the light is on, pressing lever A has no effect, but pressing lever B delivers food with a certain probability, and turns the light off again. In this simple environment there are two relevant states: *light on* and *light off*. Lever A may cause a transition from *light off* to *light on*; in *light on*, lever B may yield a reward. The only information that the rat needs to decide what to do is whether the light is on or off. The optimal policy is simple: in *light off*, press lever A; in *light on*, press lever B.

The goal for an agent is solving a Markov decision problem is to maximize its expected, long-term payoff, known as its *return*. A mathematically convenient way to formalize return is as a discounted sum of payoffs. That is, starting from state $x(0) = x$ at time $t = 0$, it should choose actions $a(0), a(1), \ldots$ to maximize

$$\left\langle \sum_{t=0}^{\infty} \gamma^t r(x(t), a(t)) \right\rangle_{x,r} \quad (1)$$

where the $\langle\rangle_{x,r}$ indicates that an average is taken over the stochasticity in the states and the payoffs. The factor $0 \leq \gamma < 1$ is called the *discount factor* and controls the weighting of payoffs that happen sooner relative to those that happen later. The larger γ, the more important are distant payoffs, and, typically, the more difficult the optimization problem.

Other definitions of return are possible. A Markov decision problem is said to be *absorbing* if there is a state or set of states which define the end of a trial (like the goal of the maze), allowing a new trial to start. The infinite sum of expression 1 is effectively truncated at these states, which is equivalent to specifying degenerate transition matrices and reward distributions there. In this case, it is possible to learn to optimize the sum total payoff that the agent receives before reaching the terminal state.

If, on the other hand, the MDP is such that it is always possible to return to every state, it is possible to learn to optimize the average payoff. A policy that optimizes average payoff will also optimize discounted payoff for a value of γ sufficiently close to 1. RL algorithms can be adapted to use any of these definitions of return; we will consider only total discounted reward here. For convenience, we also assume that the problem is finite, i.e. there are only finitely many states and possible actions.

DYNAMIC PROGRAMMING

The obvious problem with optimizing a goal such as that in expression 1 is that the action taken at time 0 can affect the rewards at time $t \gg 0$. In effect, one has to take into consideration all possible sequences of actions. However, the number of such sequences of length t typically grows exponentially as a function of t, making it impractical to consider each one in turn. Dynamic programming (Bellman, 1957) offers a set of methods for solving the optimization problem while (generally) avoiding this explosion, by taking advantage of the Markov property. The two main methods are called policy iteration and value iteration, and we discuss them in turn.

Policy Iteration

A *policy* is an assignment of actions to states – e.g. a recipe that says: push lever A if the light is off and push lever B if the light is on. In general, policies can be stochastic, specifying the probability of performing each action at each state. It can be shown that the solution to the optimization problem of expression 1 can be cast in terms of a deterministic policy which is constant over time, so the agent performs the same action every time it gets to a given state. Policies without time-dependence are called *stationary*. We will, for the moment, consider stationary deterministic policies. We use the notation $\pi(x)$ for the action that policy π recommends at state x.

In policy iteration, a policy is first *evaluated*, and then *improved*. Policy evaluation consists of working out the value of every state x under policy π, i.e. the expected long-term reward obtained by starting from x and following policy π. That is

$$V^{\pi}(x) = \left\langle \sum_{t=0}^{\infty} \gamma^t r(t) \right\rangle_{x,r} \quad (2)$$

where the states follow from the transitions with $x(0) = x$ and $r(t) = r(x(t),\ \pi(x(t)))$. We can separate the first and subsequent terms in the sum,

$$V^{\pi}(x) = \hat{r}(x, \pi(x)) + \gamma \left\langle \sum_{t=0}^{\infty} \gamma^t r(t+1) \right\rangle_{x,r} \quad (3)$$

which, using the Markov property, is

$$= \hat{r}(x, \pi(x)) + \gamma \sum_{y} P_{xy}(\pi(x)) V^{\pi}(y) \quad (4)$$

The second term in both these expressions is just γ times the expected infinite-horizon return for the state at time $t = 1$, averaged over all the possibilities for this state. Eqn 4 is a linear equation for the values $V^{\pi}(y)$, and so can be solved by a variety of numerical methods. Later, we will see how to find these values without knowing the mean rewards or the transition distributions.

Policy improvement uses the values $V^{\pi}(x)$ to specify a policy π' that is guaranteed to be at least as good as π. The idea is to consider at state x the non-stationary policy which consists of taking action a (which may or may not be the action $\pi(x)$ that policy π recommends at x) and then following policy π thereafter. By the same reasoning as above, the expected value of this is

$$Q^{\pi}(x, a) = \hat{r}(x, a) + \gamma \sum_{y} P_{xy}(a) V^{\pi}(y) \quad (5)$$

The new policy is

$$\pi'(x) = \max_{a} \{Q^{\pi}(x, a)\} \quad (6)$$

from which it is obvious that $Q^{\pi}(x,\ \pi'(x)) \geq Q^{\pi}(x,\ \pi(x))$. Since the actions at all states are thus

only improving, the overall policy can also only improve, simultaneously at every state. If policy π' is the same as policy π, then it is an optimal policy (of which there may be more than one). The values $V^{\pi}(x)$ and $Q^{\pi}(x, a)$ associated with an optimal policy are called the optimal values or the optimal action values and are often written $V^{*}(x)$ and $Q^{*}(x, a)$. We will see later how to improve a policy without having explicitly to maximize $Q^{\pi}(x, a)$. Since the problem is finite, and the policy is improved at each iteration, policy iteration is bound to converge to the optimal policy. Although, in the worst case, policy iteration can take an exponential number of steps, it is generally very fast.

Value Iteration

Value iteration is the main alternative to policy iteration. For one version of this, a set of values $Q(x, a)$ (which are called Q-values) is updated simultaneously according to the formula

$$Q'(x,a) = \hat{r}(x,a) + \gamma \sum_{y} P_{xy}(a) \max_{b} Q(y,b) \qquad (7)$$

Although the Q-values are not necessarily the Q^{π}-values associated with any policy π, as in eqn 5, one can show that iterating eqn 7 infinitely often will lead to the optimal Q-values. Then, eqn 6 can be used to find the associated optimal policy. The proof that value iteration works depends on a contraction property. That is, a particular measure (called the L_{∞} norm) of the distance between $Q(x, a)$ and $Q^{*}(x, a)$ is greater than that between $Q'(x, a)$ and $Q^{*}(x, a)$ by a factor of at least $\gamma < 1$. Thus, the values converge exponentially fast to the optimal values. The optimal policy can actually be derived from them even before convergence.

TEMPORAL DIFFERENCES

Implementing either policy or value iteration requires the agent to know the expected rewards and the transition matrices. If the agent does not know these, but rather has to learn just by interacting with the environment (e.g. by pulling the levers), then what can it do? Methods of temporal differences were invented to perform prediction and optimization in these circumstances. There are two principal kinds of temporal difference method, an actor-critic scheme (Barto, Sutton and Anderson, 1983), which parallels policy iteration, and has been suggested as being implemented in biological RL, and a method called Q-learning (Watkins, 1989), which parallels value iteration.

Methods of temporal differences were invented (Sutton, 1988; Sutton and Barto, 1987) to account for the behaviour of animals in psychological experiments involving prediction; the links with dynamic programming were only made much later (Watkins, 1989; Barto, Sutton and Watkins, 1990). A number of related suggestions were made by Werbos (1990).

Actor–Critic Learning

In actor–critic learning, the *actor* specifies a policy, which the *critic* evaluates. Consider first a fixed policy or actor π. The critic has to find a set of values $V^{\pi}(x)$ that satisfy eqn 4 based on samples $\{x(t), r(t)\}$ from the transition and reward structure of the world (writing $r(t) = r(x(t), a(t))$ for convenience). It does this by maintaining and improving an approximation $V(x)$ to these quantities.

Two ideas underlie the temporal difference algorithm. One is to use averages from random samples to determine means; the second is to use a form of bootstrapping, substituting the incorrect estimates $V(y)$ as approximations for $V^{\pi}(y)$ in eqn 4. First, consider the quantity

$$r(0) + \gamma V^{\pi}(x(1)) \qquad (8)$$

which comes from the random reward and transition consequent on choosing action $\pi(x)$ at state $x(0) = x$. The expected value of this is

$$\langle r(0) + \gamma V^{\pi}(x(1)) \rangle_{r(0), x(1)} = \hat{r}(x, \pi(x)) + \gamma \sum_{y} P_{xy}(\pi(x)) V^{\pi}(y) \qquad (9)$$

which is just $Q^{\pi}(x, \pi(x))$, the quantity on the left-hand side of eqn 3. Therefore,

$$r(0) + \gamma V^{\pi}(x(1)) - V(x) \qquad (10)$$

could be used as a sampled error in the current estimate of the value of state x, namely $V(x)$, and an algorithm such as

$$V(x) \rightarrow V(x) + \varepsilon[r(0) + \gamma V^{\pi}(x(1)) - V(x)] \qquad (11)$$

when applied over the course of many trials might be expected to make $V(x) \approx V^{\pi}(x)$. Here, ε is a *learning rate*. In fact, this is a form of a stochastic, error-correcting, learning rule like the delta rule. The same is true for all subsequent timesteps.

Of course, expression 8 contains $V^{\pi}(x(1))$, which is exactly the quantity that we are trying to estimate, only at state $x(1)$ rather than $x(0)$. The second key idea underlying temporal difference methods is to substitute the current approximation $V(x(1))$

for this quantity. In this case, the sampled error parallel expression 10 is

$$\delta(0) = r(0) + \gamma V(x(1)) - V(x) \tag{12}$$

which is called the *temporal difference*. The temporal difference term for subsequent timesteps is defined similarly:

$$\delta(t) = r(t) + \gamma V(x(t+1)) - V(x(t)) \tag{13}$$

The learning rule

$$V(x(t)) \rightarrow V(x(t)) + \varepsilon\delta(t) \tag{14}$$

is called the temporal difference learning rule. It can be considered as a prediction error or a measure of the inconsistency between the estimates $V(x(t))$ and $V(x(t+1))$.

Despite the apparent approximations, circumstances are known under which $V(x) \rightarrow V^{\pi}(x)$ as the number of trials increases, so implementing policy evaluation correctly. In fact, this is also true in the case that the policy is stochastic, that is $\pi_a(x)$ is a probability distribution over actions a associated with states x.

The other half of policy iteration is policy improvement, patterned after eqn 6. Here, the idea is to use a stochastic policy (rather than the deterministic ones that we have hitherto considered), which is defined by a set of parameters, called the action matrix M_{ax}. Then, rather than implement the full maximization of eqn 6, we consider changing the parameters, using the result of policy evaluation in order to increase the probabilities of actions that are associated with higher values of $Q^{\pi}(x,\ a)$. A natural way to parametrize a stochastic policy is to use a softmax function:

$$\pi_a(x) = \frac{\exp(M_{ax})}{\sum_b \exp(M_{bx})} \tag{15}$$

The normalization forces $\sum_a \pi_a(x) = 1$ for all states x. Here, the larger M_{ax} is compared with M_{bx}, the more likely action a is at state x.

Consider the temporal difference δ after convergence, i.e. when $V(x) = V^{\pi}(x)$. In this case,

$$V(x) = V^{\pi}(x) = \sum_a \pi_a(x) Q^{\pi}(x,a) \tag{16}$$

is the average value of the actions specified by policy π. If action a is better than average, then $Q^{\pi}(x,\ a) > V(x)$; if action a is worse than average, then $Q^{\pi}(x,\ a) < V(x)$. Thus, π could be improved by changing the action matrix according to

$$M_{ax} \rightarrow M_{ax} + \varepsilon[Q^{\pi}(x,a) - V(x)] \tag{17}$$

However, if the agent takes action $a(0) = a$ at state $x(0) = x$, then

$$\delta(0) = Q^{\pi}(x,a) - V(x) \tag{18}$$

and so the actor learning rule is

$$M_{a(0)x(0)} \rightarrow M_{a(0)x(0)} + \varepsilon\delta(0) \tag{19}$$

using just the same temporal difference term as in eqn 14.

Normally, the action values are changed according to eqn 19 before the critic has converged, and there is no proof that the combined estimation and optimization procedure is guaranteed to find an optimal policy. Nevertheless, it is found to work well in practice. Note that learning is based on following, and simultaneously trying to improve, a policy.

Q-Learning

Q-learning is a temporal difference version of value iteration. It applies to eqn 7 the same two ideas underlying actor–critic learning. That is, it maintains and improves values $Q(x,\ a)$, employing

$$r(0) + \gamma \max_b Q(x(1), b) \tag{20}$$

as a sampled version of the right-hand side of eqn 7. The overall update at time t is

$$Q(x(t), a(t)) \rightarrow Q(x(t),\ a(t)) + \varepsilon\left[r(t) + \gamma \max_b Q(x(t+1), b) - Q(x(t), a(t))\right] \tag{21}$$

As in value iteration, a policy can be defined at any time according to

$$\pi(x) = \max_a Q(x,a) \tag{22}$$

Unlike the actor–critic scheme, circumstances are known under which Q-learning is guaranteed to converge to the optimal policy.

Exploration and Exploitation

One of the most important issues for the temporal difference learning algorithms is maintaining a balance between exploration and exploitation. That is, the agent must sometimes choose actions that it believes to be suboptimal in order to find out whether they might actually be good. This is particularly true in problems which change over time (which is true of most behavioural experiments), since actions that used to be good might become bad, and vice versa.

Temporal difference algorithms that can be guaranteed to work usually require much experimentation: all actions must be repeatedly tried in all states. In practice, it is common to choose policies that employ some exploration (such as choosing a random action some small fraction of the time, but otherwise the action currently believed to be best).

EXTENSIONS TO TEMPORAL DIFFERENCE LEARNING

We have presented a very simple form of temporal difference learning algorithm, but it has been extended in various ways. First, it is possible to learn the transition matrices and rewards and then use standard dynamic programming methods on the resulting estimated model of the environment (this is called a model-based method). It is also possible to integrate the learning of a model with the temporal difference learning methods, as a way of using the samples of transitions and rewards more effectively. There is substantial evidence that animals build models of their environments, although it is not clear how they use this information to learn appropriate behaviours.

Second, the idea behind eqn 8 is to use $V^{\pi}(x(1))$ as a stochastic sample of $\sum_y P_{xy}(\pi(x))V^{\pi}(y)$ to replace all but the first reward term in the infinite sum of eqn 3. One could equally well imagine collecting two actual steps of reward $r(0) + \gamma r(1)$, and using $V^{\pi}(x(2))$ as a sample of the all but the first two terms in eqn 3. Similarly, one could consider all but the first three terms, etc. It turns out to be simple to weigh these different contributions in an exponentially decreasing manner, and this leads to an algorithm called TD(λ), where the value of λ is the weighting, and the value $\lambda = 0$ corresponds to eqn 8. The remaining bootstrap approximation is the same as before. The significance of λ is that it controls a trade-off between bias and variance. If λ is near 1, then the estimate is highly variable (since it depends on long sample paths), but not strongly biased (since real rewards from the reward distribution of the environment are considered). If λ is near 0, then the estimate is not very variable (since only short sample paths are involved), but it can be biased, because of the bootstrapping.

Third, we described the temporal difference algorithm using a unary or *table-lookup* representation in which we can separately manipulate the value $V(x)$ associated with each state $x(t)$. One can also consider parametrized representations of the values (and also the policies), for instance the linear form

$$V(x) = \mathbf{w} \cdot \boldsymbol{\phi}(x) \tag{23}$$

where $\mathbf{w}$ is a set of parameters, and $\boldsymbol{\phi}(x)$ is a population representation for state x. In this case, the temporal difference update rule of eqn 14 is changed to one for the parameters:

$$\mathbf{w} \rightarrow \mathbf{w} + \varepsilon\delta(t)\boldsymbol{\phi}(x(t)) \tag{24}$$

Again, this is similar to the delta rule. Representational schemes more sophisticated than eqn 23 can also be used, including neural networks, in which case $\nabla_{\mathbf{w}} V(x(t))$ should be used in place of $\boldsymbol{\phi}(x(t))$.

FORMALIZING LEARNING IN THE BRAIN

We have stressed that animals and artificial systems face similar problems in learning how to optimize their behaviour in the light of rewards and punishments. Although we have described temporal difference methods from the perspective of the engineering methods of dynamic programming, they are also interesting as a way of formalizing behavioural and neurobiological experiments on animals. Briefly, it has been postulated that a prediction error signal for appetitive events with some properties like that of the temporal difference signal $\delta(t)$ (eqn 13) seems to be broadcast by dopaminergic cells in the ventral tegmental area, to control the learning of predictions, and by dopaminergic cells in the substantia nigra to control the learning of actions. The model is, as yet, incomplete, failing, for example, to specify the interaction between attention and learning, which is critical in accounting for the results of behavioural experiments. LOGIC AND THE LANGUAGE OF THOUGHT

Johnson-Laird and Savary (1995) present the following 'illusion' (illusion 1):

1. If there is a king in the hand then there is an ace, or if there isn't a king in the hand then there is an ace (but not both).
2. There is a king in the hand.

Given these premises, what can one infer?

Almost certainly your verdict is this: one can infer that there is an ace in the hand. And you reached this verdict despite the fact that we introduced the problem as an 'illusion', which no doubt, at least to some degree, warned you that something unusual was in the air. Why do we refer to it as an *illusion*? Because your verdict seems correct, even perhaps obviously correct, and yet a little logic suffices to show not only that are you wrong, but that in fact what you can infer is that there *isn't* an ace in the hand.

Of course, not everyone is tricked. How do we explain the fact that Jones is, while Smith is not? The explanation offered by traditional cognitive science is that both Jones' and Smith's cognition involves knowledge: knowledge that is represented in logic (or logic-like systems), and knowledge that is processed by reasoning. So, an explanation of why some subjects 'crack' the illusion and others do not must be couched in terms of such representation and reasoning. According to one view, thinking, at least of the 'high-level' sort, takes place in a logic-like language; in other words, logic is the 'language of thought' for *Homo sapiens* (Braine, 1998; Fodor, 1975). We are not concerned here with whether or not this view is true. (For an argument in its favor, see Bringsjord and Ferrucci (1998).) Our concern is rather with presenting the simplest of those formal languages that are popular candidates for the language of thought. We want to explain logic as a means for both representing knowledge and reasoning with that knowledge.

To begin, we note that modern symbolic logic has three main components: one is purely syntactic, one is semantic, and one is metatheoretical in nature. The syntactic component includes specification of the alphabet of a given logical system, the grammar for building well-formed formulae (WFFs) from this alphabet, and a proof theory that precisely describes how and when one formula can be proved from a set of formulae. The semantic component includes a precise account of the conditions under which a formula in a given system is true or false. The metatheoretical component includes theorems, conjectures, and hypotheses concerning the syntactic component, the semantic component, and connections between them. The two simplest and most used logics for representation in cognitive science are the propositional calculus (also known as 'propositional logic' or 'sentential logic') and the predicate calculus. The second of these subsumes the first, and is often called 'first-order logic' (FOL). We now proceed to characterize the three components for both the propositional calculus and FOL, starting with the former.

PROPOSITIONAL LOGIC

Grammar

The alphabet for propositional logic is simply an infinite list $(p_1, p_2, \ldots)$ of propositional variables (traditionally p_1 is p, p_2 is q, and p_3 is r), and the five familiar truth-functional connectives $\neg$, $\rightarrow$, $\leftrightarrow$, $\wedge$, and $\vee$. These connectives can, at least provisionally, be read, respectively, as 'not', 'implies' (or 'if… then…'), 'if and only if', 'and', and 'or'. In

cognitive science it is often convenient to use propositional variables as mnemonics that help one remember what they are intended to represent. For an example, recall illusion 1. Instead of representing 'there is an ace in the hand' as 'p_i', for some $i \in \{1, 2, \ldots\}$, it would be convenient to represent this proposition as 'A'. Now, the grammar for propositional logic is composed of the following three rules:

1. Every propositional variable p_i is a WFF.
2. If ϕ is a WFF, then so is $\neg\phi$.
3. If ϕ and ψ are WFFs, then so is $(\phi * \psi)$, where $*$ is one of $\wedge$, $\vee$, $\rightarrow$, and $\leftrightarrow$. (We allow outermost parentheses to be dropped.)

This implies, for example, that $p \rightarrow (q \wedge r)$ is a WFF, but $\rightarrow q$ isn't. To represent the declarative sentence 'if there is an ace in the hand, then there is a king in the hand' we could use $A \rightarrow K$.

Syntactic Proofs (Proof Theory)

A number of proof theories are possible. One such system is an elegant Fitch-style system of natural deduction, $\mathcal{F}$ (Barwise and Etchemendy, 1999). (Such systems are commonly referred to as 'natural' systems.) In $\mathcal{F}$, each of the truth-functional connectives has a pair of corresponding inference rules, one for introducing the connective, and one for eliminating the connective. Proofs in $\mathcal{F}$ proceed in sequence line by line, with successive line numbers incremented by 1. Each line includes a line number, a formula (the one deduced at this line), and, in the rightmost column, a rule cited in justification for the deduction. We use a vertical ellipsis ⋮ to indicate the presence of 0 or more lines in the proof not explicitly shown.

Here is the rule for eliminating a conjunction:

⋮	⋮	⋮
k	$\phi \wedge \psi$	
⋮	⋮	⋮
m	ϕ	k $\wedge$-Elim
⋮	⋮	⋮

Intuitively, this rule says that if at line k in some derivation you have somehow obtained a conjunction $\phi \wedge \psi$, then at a subsequent line m, one can infer to either of the conjuncts alone.

Now here is the rule that allows a conjunction to be introduced; intuitively, it formalizes the fact that if two propositions are true then the conjunction of these two propositions is also true:

⋮	⋮	⋮
k	ϕ	
⋮	⋮	⋮
l	ψ	
⋮	⋮	⋮
m	$\phi \wedge \psi$	k,l $\wedge$-Intro
⋮	⋮	⋮

An important rule in $\mathcal{F}$ is 'supposition', according to which you are allowed to assume any WFF at any point in a derivation. The catch is that you must signal your use of supposition by setting it off typographically, as follows:

⋮	⋮	
k	ϕ	supposition
	⋮	
⋮	⋮	

Often a derivation will be used to establish that from some set Φ of propositional formulae a particular formula ϕ can be derived. In such a case, Φ will be given as suppositions (or, as we sometimes say, 'givens'). To say that ϕ can be derived in $\mathcal{F}$ from a set of formulae Φ we write

$$\Phi \vdash_{\mathcal{F}} \phi$$

When it is clear from context which system the deduction is to take place in, the subscript on $\vdash$ can be omitted. Here is a proof that puts to use the rules presented above and establishes that $((p \wedge q) \wedge r) \vdash_{\mathcal{F}} q$:

1	$(p \wedge q) \wedge r$	given
2	$(p \wedge q)$	1 $\wedge$-Elim
3	q	2 $\wedge$-Elim

Now here is a slightly more complicated rule, one for introducing a conditional. It basically says that if you can carry out a subderivation in which you suppose ϕ and derive ψ, you are entitled to close this subderivation and infer to the conditional $\phi \rightarrow \psi$:

⋮		⋮
k		ϕ supposition
⋮		⋮
m		ψ
⋮		⋮
n	$\phi \rightarrow \psi$	k–m $\rightarrow$-Intro

Figure 1. A proof of modus tollens in $\mathcal{F}$, constructed in Hyperproof.

As we said, in a Fitch-style system of natural deduction, the rules come in pairs. Here is the rule in $\mathcal{F}$ for eliminating conditionals:

k	$\phi \rightarrow \psi$	
⋮	⋮	⋮
l	ϕ	
⋮	⋮	⋮
m	ψ	k, l $\rightarrow$-Elim

Here is the rule for introducing $\vee$:

⋮	⋮	⋮
k	ϕ	
⋮	⋮	⋮
m	$\phi \vee \psi$	k $\wedge$-Intro
⋮	⋮	⋮

And here is the rather more elaborate rule for eliminating a disjunction:

⋮	⋮	
k	$\phi \vee \psi$	
⋮	⋮	
l	ϕ supposition	
⋮	⋮	
m	χ	
⋮	⋮	
n	ψ supposition	
⋮	⋮	
o	χ	
⋮	⋮	
p	χ	k, l–m, n–o $\vee$-Elim

The rule $\vee$-Elim is also known as 'constructive dilemma'. The intuition behind this rule is that if one knows that either ϕ or ψ is true, and if one can show that χ can be proved from ϕ alone, and from ψ alone, then χ must be true.

Next, here is a very powerful rule corresponding to proof by contradiction (sometimes called 'indirect proof' or 'reductio ad absurdum'). Notice that in $\mathcal{F}$ this rule is ¬-Intro:

⋮	⋮	
k	ϕ supposition	
⋮	⋮	
m	$\psi \wedge \neg \psi$	
⋮	⋮	
n	$\neg \phi$	k–m ¬-Intro

Sometimes a natural deduction system can be a little awkward, because by insisting that inference rules come exclusively in the form of pairs for each truth-functional connective, it leaves out certain rules that are exceedingly useful. Two examples are *modus tollens* and DeMorgan's laws. The former rule allows one to infer $\neg\phi$ from $\phi \rightarrow \psi$ and $\neg\psi$. This rule can be established through a proof in $\mathcal{F}$, as shown in Figure 1. This proof was constructed in the Hyperproof construction environment (Barwise and Etchemendy, 1994). The core of this proof is *reductio ad absurdum*, or ¬-Intro.

DeMorgan's laws for propositional logic sanction moving from a formula of the form $\neg(\phi \wedge \psi)$ to one of the form $\neg\phi \vee \neg\psi$, and vice versa. The laws also allow an inference from a formula of the form $\neg(\phi \vee \psi)$ to one of the form $\neg\phi \wedge \neg\psi$, and vice versa. When, in constructing a proof in $\mathcal{F}$, we want to use modus tollens or DeMorgan's laws, or some other time-saving rule, we can make the inference, using the rule of 'tautological consequence' as a justification. This rule (abbreviated as 'Taut Con' in Hyperproof) is designed to allow the human proof constructor to declare that a given inference is obvious, and could with more work be fully specified using only the rules of $\mathcal{F}$. Hyperproof responds with a check to indicate that an attempted inference is in fact correct. In Figure 2, Hyperproof approves of our use of 'Taut Con', which corresponds in this case not just to DeMorgan's law, but also to the useful inference of $\phi \wedge \neg\psi$ from $\neg(\phi \rightarrow \psi)$.

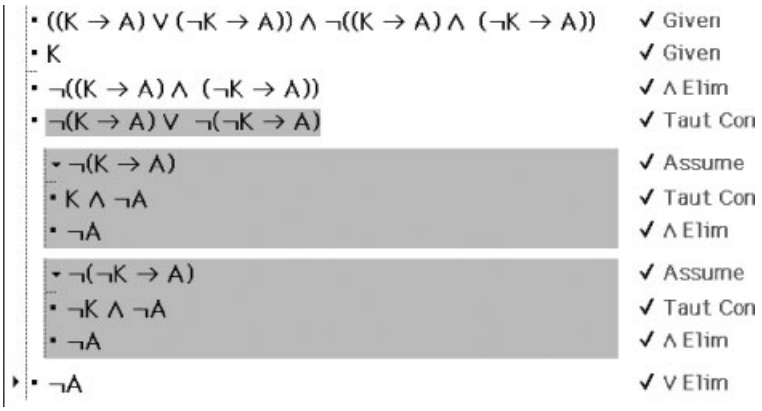

Figure 2. A proof in $\mathcal{F}$ that there is no ace in the hand. The premises are shown in the first two lines.

A formula provable from the null set is called a 'theorem', and where ϕ is such a formula we write $\vdash \phi$ to express this fact. Here are two examples: $\vdash (p \wedge q) \rightarrow q$; $\vdash (p \wedge \neg p) \rightarrow r$. We say that a set Φ of formulae is 'syntactically consistent' if and only if no contradiction can be derived from Φ.

Semantics (Truth Tables)

The precise meaning of the five truth-functional connectives of the propositional calculus is given via truth tables, which tell us what the truth-value of a statement is, given the truth-values of its components. The simplest truth table is that for negation, which informs us, unsurprisingly, that if ϕ is T then $\neg\phi$ is F and if ϕ is F then $\neg\phi$ is T:

ϕ	$\neg\phi$
T	F
F	T

Here are the remaining truth tables:

ϕ	ψ	$\phi \wedge \psi$
T	T	T
T	F	F
F	T	F
F	F	F

ϕ	ψ	$\phi \vee \psi$
T	T	T
T	F	T
F	T	T
F	F	F

ϕ	ψ	$\phi \rightarrow \psi$
T	T	T
T	F	F
F	T	T
F	F	T

ϕ	ψ	$\phi \leftrightarrow \psi$
T	T	T
T	F	F
F	T	F
F	F	T

Notice that the truth table for disjunction says that when both disjuncts are true, the disjunction is true. This is called 'inclusive' disjunction. In 'exclusive' disjunction, it's one disjunct or another, but not both. This distinction becomes particularly important if one is attempting to symbolize parts of English (or any other natural language). It would not be natural to represent the sentence 'George will either win or lose' as '$W \vee L$', because under the English meaning there is no way both possibilities can be true, whereas by the meaning of $\vee$ it would be possible that W and L are both true. We can use $\vee_x$ to denote exclusive disjunction, which we define through the following truth table:

ϕ	ψ	$\phi \vee_x \psi$
T	T	F
T	F	T
F	T	T
F	F	F

It is worth mentioning another issue involving the meaning of English sentences and their corresponding symbolizations in propositional logic: the issue of the oddity of 'material conditionals' (formulae of the form $\phi \rightarrow \psi$). Consider the following English sentence:

> If the Moon is made of green cheese, then Dan Quayle will be the next President of the United States.

Is this sentence true? If we were to ask 'the man on the street', the answer might well be: 'Of course not!' Or perhaps we would hear: 'This isn't even a meaningful sentence; you're speaking nonsense.' However, when represented in the propositional

calculus, the sentence turns out true. Why? The sentence is naturally represented as $G \rightarrow Q$. Since G is false, the truth table for $\rightarrow$ classifies the conditional as true. Results such as these have encouraged some to devise better (but much more complicated) accounts of the conditionals seen in natural languages (e.g. Goble, 2001). These accounts are beyond the scope of this article; we will be content with the conditional as defined by the truth table for $\rightarrow$ presented above.

Given a truth-value assignment υ (i.e., an assignment of T or F to each propositional variable p_i), we can say that υ 'makes true' or 'models' or 'satisfies' a given formula ϕ; this is written $\upsilon \models \phi$.

Some formulae are true on all models. For example, the formula $((p \vee q) \wedge \neg q) \rightarrow p$ is in this category. Such formulae are said to be 'valid' and are sometimes referred to as 'validities'. To indicate that a formula ϕ is valid we write $\models \phi$.

Another important semantic notion is 'consequence'. An individual formula ϕ is said to be a consequence of a set Φ of formulae provided that every truth-value assignment on which all of Φ are true is also one on which ϕ is true; this is written $\Phi \models \phi$.

The final concept in the semantic component of the propositional calculus is the concept of consistency: we say that a set Φ of formulae is 'semantically consistent' if and only if there is a truth-value assignment on which all of Φ are true.

Cracking Two Illusions

We now have at our disposal enough logic to 'crack' illusion 1. In this illusion, 'or' is to be understood as exclusive disjunction, so (using obvious symbolization) the two premises become $((K \rightarrow A) \vee (\neg K \rightarrow A)) \wedge \neg((K \rightarrow A) \wedge (\neg K \rightarrow A))$ and K.

Figure 2 shows a proof in $\mathcal{F}$, constructed in Hyperproof, that demonstrates that from these two givens one can conclude $\neg A$.

Now, consider another illusion (illusion 2):

1. The following three assertions are either all true or all false:
   - If Billy is happy, Doreen is happy.
   - If Doreen is happy, Frank is as well.
   - If Frank is happy, so is Emma.
2. Billy is happy.

Can it be inferred that Emma is happy?

Most people answer 'yes', but for the wrong reasons. They notice that since Billy is happy, if the three conditionals are true, one can 'chain' through them to arrive at the conclusion that Emma is happy. But this is only part of the story, and the other part has been ignored: it could be that all three conditionals are false. Other people realize that there are two cases to consider (conditionals all being true, and conditionals all being false), and because they believe that when the conditionals are all false one cannot prove that Emma is happy, they respond with 'No'. But this response is also wrong. The correct response is 'yes', because in both cases it can be proved that Emma is happy. This can be shown using propositional logic; the proof, again constructed in Hyperproof, is shown in Figure 3. This proof establishes

$$\{\neg(B \rightarrow D), \neg(D \rightarrow F)\} \vdash E$$

Note that the trick is exploiting the inconsistency of the set $\{\neg(B \rightarrow D), \neg(D \rightarrow F)\}$ in order to get a contradiction. Since everything follows from a contradiction, E can then be derived.

Metatheoretical Results

At this point we can give some metatheory for the propositional calculus. In general, metatheory would deploy logical and mathematical techniques in order to answer such questions as whether or not provability implies consequence, and whether or not the converse holds. When provability implies consequence, a logical system is said to be 'sound'. This fact can be expressed as: 'if $\Phi \vdash \phi$ then $\Phi \models \phi$'. Roughly, a logical system is sound if true formulae can only yield (through proofs) true formulae; one cannot pass from the true to the false.

When consequence implies provability, a system is said to be 'complete'. This is expressed by: 'if $\Phi \models \phi$ then $\Phi \vdash \phi$'.

The propositional calculus is both sound and complete. It follows that all theorems in the propositional calculus are valid, and all validities are theorems. This last fact is expressed more formally as: '$\models \phi$ if and only if $\vdash \phi$'.

FIRST-ORDER (PREDICATE) LOGIC

A Logical Illusion in Quantified Reasoning

Consider another illusion (illusion 3), a more complicated one that cannot be adequately represented in propositional logic. Here it is, adapted slightly from Yang and Johnson-Laird (2000):

Only one of the following statements is true:
- At least one of the beads is red.
- None of the beads are red.

Is it possible that none of the red things are beads?

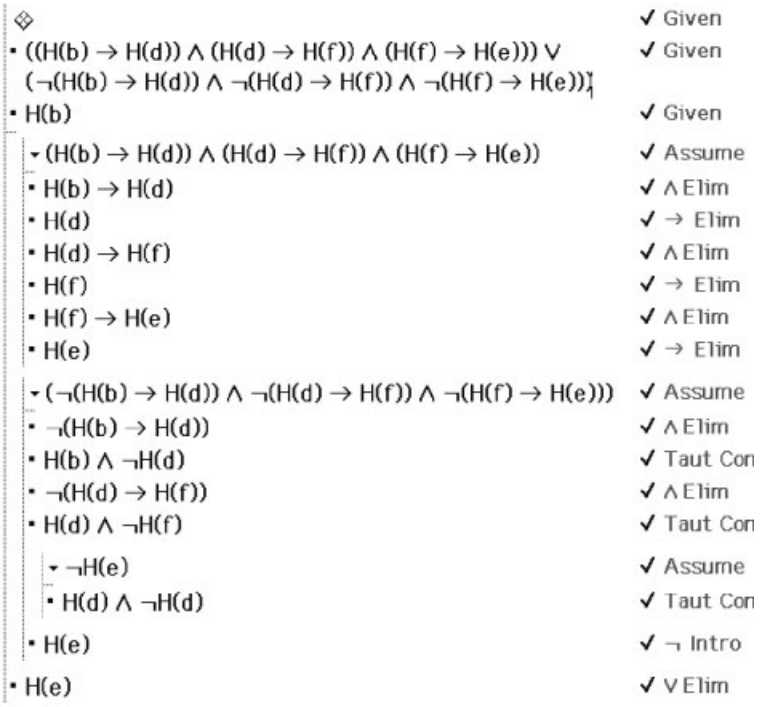

Figure 3. A proof in $\mathcal{F}$ that 'Emma is happy'.

We can remove all the mystery by turning to FOL, which we will introduce after explaining why the propositional calculus isn't expressive enough to represent this puzzle. The propositional calculus can represent propositions, but it cannot represent the internal structure of propositions: for example, propositions to the effect that certain objects have certain properties. In the propositional calculus, 'at least one of the beads is red' would be represented by some propositional variable, say N. We know that from 'at least one of the beads is red' it follows that 'at least one of the beads is red or blue'. The second statement here would be represented by some other propositional variable, say B. Clearly, $\{N\} \nvdash B$ in the propositional calculus. What is needed is some way to represent the fact that N says that at least one of a particular kind of object has a specific property, viz., being red. Only with such machinery can we get to the bottom of illusion 3.

The Syntactic Machinery of FOL

Our alphabet will now be augmented to include the following: the identity or equality symbol $=$; variables x, y,…; constants ('proper names' for objects) c_1, c_2,…; relational symbols R, G,… (e.g., R for 'being red'); functors (functions) f_1, f_2,…; the existential quantifier $\exists$ ('there exists at least one …'); the universal quantifier $\forall$ ('for all …'); and the familiar truth-functional connectives $\neg$, $\vee$, $\wedge$, $\rightarrow$, and $\leftrightarrow$.

Predictable 'formation rules' are introduced to allow us to represent propositions like those in illusion 3. With these rules, we can now write such things as $\exists x(Bx \wedge Rx)$, which says that there exists at least one thing x that has property B and property R. As in propositional logic, sets of formulae (say Φ), given certain 'rules of inference', can be used to prove individual formulae (say ϕ); such a situation is expressed by expressions having exactly the same form as those introduced above (e.g., $\Phi \vdash \phi$). The rules of inference for FOL in such systems as $\mathcal{F}$ include those we saw for the propositional calculus, and also new ones: two corresponding to the existential quantifier $\exists$, and two corresponding to the universal quantifier $\forall$. For example, one of the rules associated with $\forall$ says, intuitively, that if you know that everything has a certain property, then any particular thing a has that property. This rule, known as 'universal elimination' (or 'universal introduction') allows us to move from some formula $\forall x\phi$ to a formula with $\forall x$ dropped, and the variable x in ϕ replaced with the constant of choice. For example, from 'all beads are red', that is, $\forall x(Bx \rightarrow Rx)$, we can infer by $\forall$-Elim that $Ba \rightarrow Ra$, and if we happen to know that in fact Ba we can now infer by familiar propositional reasoning that Ra. The rule $\forall$-Elim in $\mathcal{F}$ is

$$\begin{array}{l|ll} k & \forall x \phi & \\ \vdots & \vdots & \vdots \\ l & \phi(\frac{a}{x}) & k\,\forall\text{-Elim} \end{array}$$

where $\phi(\frac{a}{x})$ denotes the result of replacing occurrences of x in ϕ with a.

Semantics (Interpretations)

FOL includes a semantic side, which systematically provides meaning (i.e., truth or falsity) for formulae. Unfortunately, the formal semantics of FOL are more tricky than the truth tables that are sufficient for the propositional level. In FOL, formulae are said to be true (or false) on 'interpretations' or 'models'; that some formula ϕ is true on an interpretation $\mathcal{I}$ is often written as $\mathcal{I} \models \phi$. (We say that $\mathcal{I}$ satisfies, or models, ϕ.) For example, the formula $\forall x \exists y Gyx$ might mean, on the standard interpretation for arithmetic, that for every natural number n, there is a natural number m such that $m > n$. In this case, the 'domain' is the set $\mathbb{N}$ of natural numbers; and G symbolizes 'is greater than'. Much more could of course be said about the formal semantics (or 'model theory') for FOL; but this is beyond the scope of the present article. For a full discussion using the traditional notation of model theory, see Ebbinghaus *et al*. (1984). There it is shown that FOL, like the propositional calculus, is both sound and complete.

Cracking the Illusion

We now have the tools to crack illusion 3. Yang and Johnson-Laird (2000) found that very few untrained reasoners answered the question in illusion 3 correctly – but these authors tacitly assumed that 'none of the beads are red' should be represented in a manner that entails that there do exist some beads. If we side with this interpretation, then the question becomes whether in both cases it can be proved that it's not possible that none of the red things are beads. That is, can it be proved that in both cases a contradiction arises if one assumes that none of the red things are beads? The first case is shown as an explicit Hyperproof-constructed proof in $\mathcal{F}$ in Figure 4.

This proof can be expressed informally as follows. We begin by assuming in the first line that the first statement of illusion 3 is true and the second statement is false. In the next line we assume that there are some red things, and that none of them are beads. Next, we isolate the proposition that there are some red beads, by deriving it from the first line. In the fourth line, we assume, in keeping with the third line, that some arbitrary object a is a red bead. Now we derive that all red things are not beads directly from line 2, by the $\wedge$-Elim rule. From this it follows by universal elimination that if the particular object a is red, it can't be a bead. Since we know that (under our assumptions) a is red, we can infer by modus ponens ($\rightarrow$-Elim, here) that a isn't a bead. But we are operating under the assumption that a is a bead (see line 4), so we have a contradiction. We use the propositional variable Z to represent an explicit contradiction. (Often the symbol $\perp$ is used for this purpose.) Since everything follows from a contradiction, we simply deduce Z from the contradiction of $B(a)$ and $\neg B(a)$. The reason is that we need to obey the rule of existential elimination, which insists that if something ϕ follows from assuming that some arbitrary thing (a in the proof) has some property, then we can infer that ϕ follows from the general existential claim that something x has that property – provided a doesn't occur in ϕ. At this point we have shown that Z, that is, a contradiction, arises if

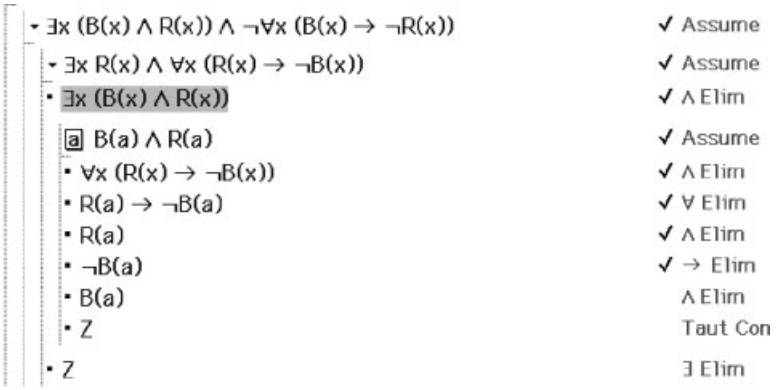

Figure 4. A derivation of a contradiction in $\mathcal{F}$.

we assume that none of the red things are beads. We leave it to our readers to ascertain whether the second case of illusion 3 can be dealt with in a similar way.

Representations in Logics Beyond FOL

Many declarative sentences cannot be represented in FOL. Consider the sentence: 'If two things x and y are identical, then for every property F that x has, y has it as well, and vice versa.' This is known as Leibniz' law (LL), and it seems self-evident. But LL cannot be represented in FOL. However, LL can be represented in second-order logic (SOL), in which one can quantify not only over individual objects, but over properties as well. In SOL, LL becomes:

$$\forall x \forall y (x = y \leftrightarrow \forall X (Xx \leftrightarrow Xy))$$

Note that this formula contains a part meaning 'for every property X', which cannot be expressed in FOL. FOL permits quantification only over objects, not over the properties they can have. For an introduction to SOL, see Ebbinghaus *et al*. (1984); for a discussion of logics that can represent even more difficult constructions, see Goble (2001).

THE SITUATION CALCULUS

FOL is not only suitable for representing static information. It has long been used with great success to represent dynamic environments. One of the schemes for doing this is the 'situation calculus', which we will briefly describe, in connection with the 'wumpus world' test-bed. An example of a situation in this world is shown in Figure 5. The objective of the agent in this world is to find the gold and bring it back without getting killed. Pits are always surrounded by breezes or by other pits, the wumpus is always surrounded on at least three sides by a stench, and the gold glitters in the square in which it's positioned. The agent dies if it enters a square with a pit or a wumpus in it. (In the figure, the agent has managed to reach the gold.)

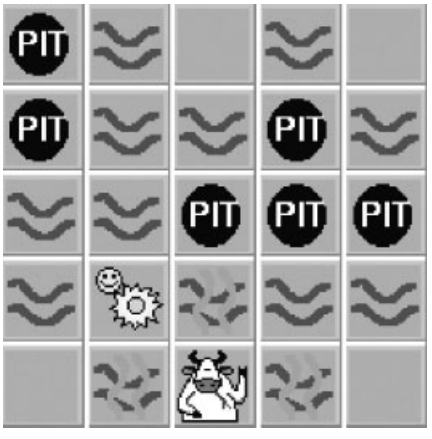

Figure 5. A typical wumpus world.

We can use the situation calculus to represent change in this world. First, we conceive of the world as consisting of a sequence of 'situations', essentially 'snapshots' of the world. Situations are generated from previous situations by actions. Properties in the world that can change over time are represented by inserting an extra constant to denote situations into the relevant formulae. For example, to describe the location of an agent a in the wumpus world at two situations s_0 and s_1, we could say that a is 'At' the square at row 1 and column 1, i.e., (1, 1), in situation s_0, and 'At' location (1, 2) in s_1. This would be written by:

$$\text{At}(a, (1,1), s_0) \wedge \text{At}(a, (1,2), s_1)$$

In order to use the situation calculus it is necessary to represent how the world changes from one situation to the next, by using the function

$$\text{Result}(\text{action}, \text{situation})$$

to refer to the situation that results from performing an action in some initial situation. With this function we can have sequences like that shown in Figure 6, in which, as a start, we have:

$$\text{Result}(\text{Forward}, s_0) = s_1$$
$$\text{Result}(\text{Backward}, s_1) = s_2$$
$$\text{Result}(\text{Turn}(\text{right}), s_2) = s_3$$
$$\text{Result}(\text{Forward}, s_3) = s_4$$

The 'Result' function also allows us to use FOL to represent such general rules about the wumpus world as that the agent isn't holding anything after a 'Release' action:

$$\forall x \forall s \neg \text{Holding}(x, \text{Result}(\text{Release}, s))$$

For more on the situation calculus for the wumpus world and beyond, see Russell and Norvig (1994), which includes discussion of the infamous 'frame problem', which plagues such general rules.

THE CHALLENGE TO LOGIC-BASED REPRESENTATION IN COGNITIVE SCIENCE

Illusion 2 shows that cognizers sometimes conceive of 'disproofs'. Specifically, a cognizer fooled by illusion 2 imagines an argument for the view that

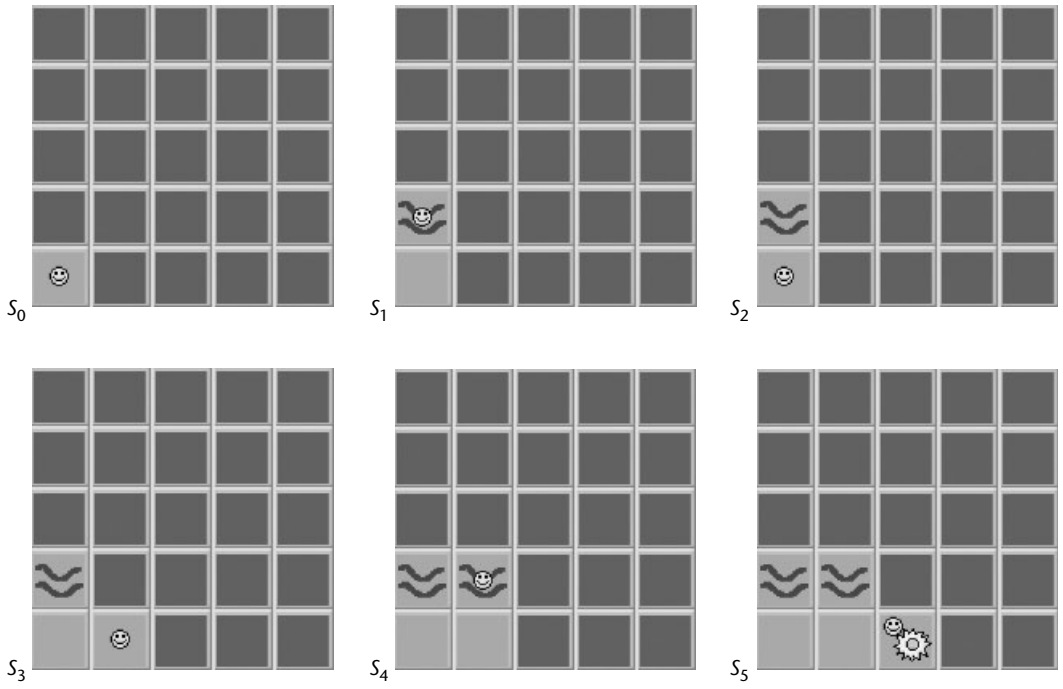

Figure 6. Situations s_0 to s_5 of a sequence in the wumpus world, linked by actions. (Program available at Escobar, 2002.)

there is no way to derive 'Emma is happy' from the negated trio of conditionals and 'Bill is happy'. Such arguments cannot be expressed in $\mathcal{F}$. However, a new theory, 'mental metalogic' (Yang and Bringsjord, 2001a,b; Rinella *et al*., 2001), provides a mechanism in which step-by-step proofs (including disproofs) can at once be syntactic and semantic, because situations can enter directly into line-by-line proofs (see Figure 7). Hyperproof can be viewed as a simple instantiation of part of this theory. In Hyperproof, one can prove such things as that $\Phi \nvdash \psi$, not only such things as $\Phi \vdash \psi$.

Suppose that in illusion 2, a 'tricked' cognizer moves from a correct representation of the premises when the conditionals are all true to an incorrect representation when the conditionals are false. Suppose, specifically, that the negated conditionals give rise to a situation, envisaged by the cognizer, in which four people *b*, *d*, *f*, and *e* are present, the sentence 'Billy is happy' is explicitly represented by a corresponding formula, and the question is whether it follows from this given information that Emma is happy. This situation is shown in Figure 8. Notice that the full logical import of the negated conditionals is nowhere to be found in this figure.

Next, given this starting situation, a disproof in Hyperproof is shown in Figure 9. Notice that a new, more detailed situation has been constructed, one which is consistent with the information given

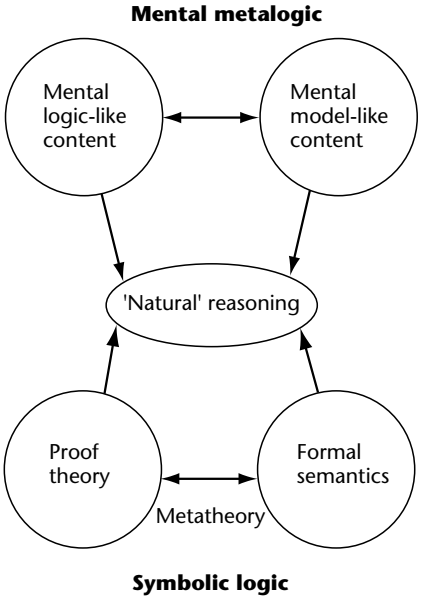

Figure 7. The symmetry of mental metalogic with symbolic logic.

(hence the 'CTA' rule which, if correctly used, **c**hecks the **t**ruth of the **a**ssumptions) and in which it is directly observed that Emma isn't happy. This demonstrates that Emma's being happy can't be deduced from the given information. So, though untrained human reasoning may not conform to normative patterns, erroneous thinking can

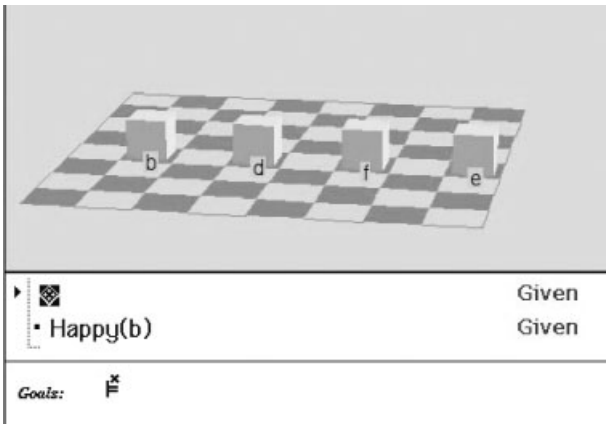

Figure 8. The start of a disproof that may be in the mind of cognizers.

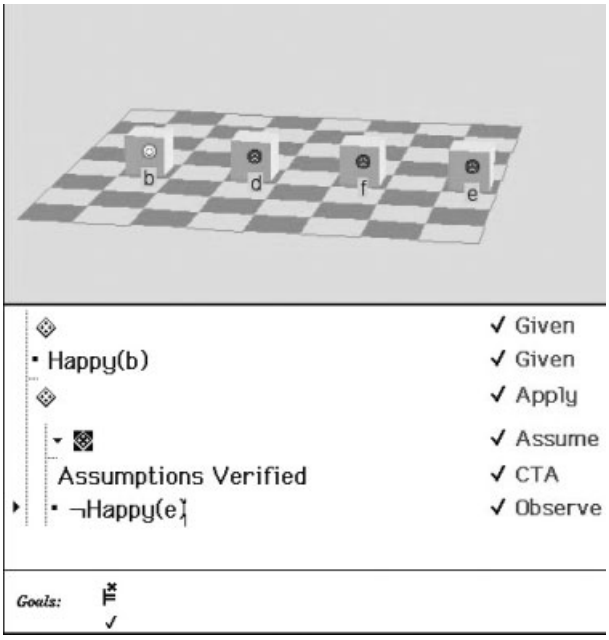

Figure 9. The completed disproof that may be in the mind of cognizers.

nonetheless be represented by logic, even when it involves pictorial reasoning. (For the reasons why Hyperproof derivations like that in Figure 9 cannot be reduced to purely syntactic reasoning, see Barwise and Etchemendy (1995).)

Resolution Theorem Proving

Intermediate article

Larry Wos, Argonne National Laboratory, Argonne, Illinois, USA

CONTENTS

Resolution theorem proving is the finding of proof of theorems, usually by contradiction, by applying inference rules each of which relies on unification.

INTRODUCTION

Puzzle solving, chess playing, computer program writing, and theorem proving in mathematics are satisfying endeavors. What is required to succeed in such activities? The essential factor is careful and deep reasoning: the ability to make useful, and often difficult, inferences.

Such fine reasoning must avoid various pitfalls, such as reliance on a hidden and erroneous assumption. For example, what is the problem with the following two 'facts'?

Plato likes absolutely everybody.
Absolutely nobody likes Plato.

Imagine what would be needed for a computer program to consider this question, and deeper questions. To submit questions and problems of various types to a computer program, a general language is needed. To draw conclusions in a rigorous manner, sound inference rules are needed. To 'know' when the question has been answered or the problem solved, a test for assignment completion is needed. And, at least for deep questions and hard problems, much more is needed for the program to be successful. (*See* **Problem Solving**)

This article describes such a language, diverse inference rules, a test for success, and other elements including the use of strategy. For modern computers are startlingly fast, a strategy to control the program's reasoning is necessary. Without some strategy, the program will almost certainly fail, especially if the task is a deep question or hard problem.

The objective of the field called 'automated reasoning' is to design and implement a program that applies flawless logical reasoning. At the heart of automated reasoning is 'resolution theorem proving': finding proofs of theorems, usually by contradiction, by applying inference rules each of which relies on 'unification' (see below). A number of automated reasoning programs have been produced: some of them are very powerful; some are freely available; and some have been used to make significant contributions to mathematics, logic, microchip design, and program verification.

Typically, an automated reasoning program given our two 'facts' about Plato would find a flaw (in the form of a contradiction) in a few milliseconds. In the program's 'clause language' (in which logical 'not' is denoted by '−'), the program would consider the two statements `LIKES(Plato,x)` (for all `x`) and `-LIKES(y,Plato)` (for all `y`) and substitute `Plato` for `x` in the first and `Plato` for `y` in the second and recognize that a contradiction had been found. The typical test for successful assignment completion is the discovery of a contradiction.

PROOF AND REFUTATION

In trying to prove a theorem of the form '*P* implies *Q*', there are two obvious approaches. In the first approach (often taken by a person, and almost never by a reasoning program), one begins with the elements of *P* and makes deductions until one recognizes that *Q* has been deduced. In the second approach (often taken by a mathematician, and almost always by a reasoning program), one assumes *Q* to be false and begins reasoning from that assumption together with *P* until a contradiction is found.

Thus, the reasoning program, when it seeks proofs by contradiction, seeks refutations of

inconsistent sets. Therefore, whether the context is puzzle solving, circuit design, program verification, or theorem proving in mathematics, the user is asked to phrase the question or problem in a manner that permits the program to seek a refutation in order to complete the assignment.

THE CLAUSE LANGUAGE

Except for the concept of equality (which is a built-in concept in some of the more powerful automated reasoning programs), the program knows nothing. Whatever information is thought to be needed must be supplied. It can be supplied in first-order predicate calculus or in the clause language. (Some programs instead rely on higher-order logic, on LISP, or on some other language.) If the information is supplied in first-order predicate calculus, many programs then convert the supplied information into the clause language.

The clause language relies on just two explicit logical connectives, 'not' and 'or', here denoted respectively by '−' and '|', and one implicit connective, 'and'. (There are various different notational conventions.) Other connectives are expressed in terms of 'not' and 'or'. For example, 'if *P* then *Q*' is replaced by (the logically equivalent) 'not *P* or *Q*'.

The language also relies on constants (such as `a`, `b`, `c`, `0`, and `Plato`), functions (such as `f`, `g`, `h`, `mother`, `youngest_daughter`, and `sum`), and relations called 'predicates' (such as `female`, `subset`, and `equals`). Variables (conventionally denoted by expressions beginning with lower-case `u` through `z`) are implicitly universally quantified, each meaning 'for all', and their scope is just the clause in which they occur. For example, the fact that everybody is female or male, and the fact that nobody is both female and male are, respectively, conveyed to the program with the following two clauses:

```
FEMALE(x)|MALE(x).
-FEMALE(x)|-MALE(x).
```

In these clauses, each of the items separated by 'or' is called a 'literal', and a clause is the 'or' of its literals with the requirement that no literal may appear more than once in a clause. The 'empty clause' contains no literals. The occurrence of the variable `x` in the two given clauses is, in effect, coincidental: the program will behave in the same way if the second clause has its occurrences of `x` replaced by `y`.

As for existence, the language relies on appropriate (Skolem) functions; existentially quantified variables are not acceptable. For example, the fact that for every `x` there exists a `y` greater than `x` is expressed with the following clause:

```
GREATERTHAN(f(x),x).
```

The dependence of `y` on `x` – the fact that as `x` varies, `y` may vary – is reflected in this clause. In contrast, when such a dependence is not present, as in the statement that there exists a nonnegative number `y` such that for all nonnegative `x`, `y` is less than or equal to `x`, a constant (function of no arguments) suffices:

```
LESSOREQUAL(a,x).
```

An important, and sometimes overlooked, subtlety of the language is the contrast between the use of functions and predicates. Functions require uniqueness (they must be unambiguous and well defined), whereas predicates do not. For example, a function can be used to convey information to the program about maternal grandfather because there is no ambiguity; but a predicate is required if the information is merely about grandfather because then there is ambiguity, in the sense that more than one choice exists. For a second example, the notion of successor (to a number) is unique and well defined, and a function suffices; but the concept of divisor requires the use of a predicate.

The clause language is a frugal language; and from the user's or researcher's perspective, a richer language would appear to be preferable. However, its lack of richness, rather than being a hindrance to the program and to automated reasoning in general, is an advantage. More richness would interfere with the formulation of computer-oriented inference rules, and, more important, with the introduction of powerful and effective strategies for controlling the reasoning. (*See* **Knowledge Representation**)

UNIFICATION

Computer-oriented reasoning differs from person-oriented reasoning in the former's emphasis on generality. The use of 'unification', a procedure essential to many aspects of automated reasoning including inference rules, illustrates this difference. Unification takes two expressions and seeks a most general substitution of terms for variables that, when applied to each expression, yields two (possibly) new expressions that are identical (Robinson, 1965b). In the earlier example about Plato, unification succeeded, yielding the substitution of `Plato` for both `x` and `y` to discover a contradiction. Of

course, unification can fail, as is the case with the following two clauses:

```
P(x,x).
-P(f(y),y).
```

No contradiction can be derived from these two clauses: ignoring the 'not' symbol, there is no substitution that can be applied to the two to yield identical expressions.

The following three clauses serve to illustrate the generality of a program's reasoning (in contrast to that often employed by a person):

```
-P(x,y,z)|Q(y,z,x).
P(a,b,u)
Q(b,z,a).
```

Given the first two clauses and the appropriate inference rule (that which unifies the first literals of the first two clauses), a reasoning program would correctly deduce the third clause. Various other conclusions could have been drawn by sound reasoning, for example the following:

```
Q(b,b,a).
Q(b,a,a).
Q(b,c,a).
Q(b,h(b,a,b),a).
```

However, these less general conclusions would not have been drawn by a reasoning program because of its preference for generality and because unification would not have yielded the appropriate substitution.

For a second example (of a type familiar to logicians): where the program might deduce a clause that (in effect) says that '*x* implies *x*', a person might prefer to deduce that '(*y* implies *z*) implies (*y* implies *z*)'. The latter deduction is an 'instance' of the former: it can be obtained by replacing the variable '*x*' by the term '(*y* implies *z*)'. A person's preference is often based on experience, intuition, and knowledge of what is likely to suffice for the task at hand; the program lacks all three of these advantages. Conversely, while the generality of the program's approach contributes to its effectiveness, such generality can actually interfere with a person's attempt to solve a problem.

INFERENCE RULES

Unification plays an essential role in inference rules. Any inference rule is required to be 'sound': to yield conclusions that follow inevitably from the hypotheses to which it is applied. Some inference rules apply to pairs of hypotheses in the form of clauses; some apply to more than two; and one important inference rule applies to a single hypothesis. One commonly used inference rule treats the relation of equality as understood (built in).

The inference rule that dominated the field in the early 1960s was 'binary resolution' (Robinson, 1965b), sometimes loosely called 'resolution'. This rule requires two clauses as hypotheses, focuses on one literal in each clause with the same predicate and opposite sign, and seeks to unify the chosen literals. If unification succeeds, the two literals are canceled (ignored), and the unifier (substitution) is applied to the remaining literals in both clauses, which are then used to form a new clause by taking their 'or', ignoring duplicates. The example above involving *P* and *Q* illustrates the use of binary resolution. For another example, consider the following clauses.

```
-P(a,x)|-Q(x).
P(y,b)|-R(y).
-Q(b)|-R(a).
```

The third clause can be obtained from applying the inference rule to the first two clauses.

As defined, binary resolution requires the presence of another inference rule, *factoring*, in order to guarantee that assignments that should be completable can be completed. In factoring, the program focuses on a single clause, chooses two of its literals that are alike in both predicate and sign, and seeks to unify the two. If the program is successful, it applies the unifier to the clause to yield the conclusion. For example, factoring applied to the first of the following four clauses yields (depending on the two literals being unified) three different conclusions, the second through the fourth.

```
Q(f(x),y)|Q(f(u),g(v))|Q(f(x),
  g(v)).
Q(f(x),g(v)).
Q(f(x),g(v))|Q(f(u),g(v)).
Q(f(x),y)|Q(f(x),g(v)).
```

As the following simple example shows, binary resolution without factoring may not find the desired refutation for two inconsistent clauses:

```
P(x)|P(y).
-P(u)|-P(v).
```

Among other commonly used inference rules, 'hyperresolution' (Robinson, 1965a) requires that the deduced clause be free of 'not'; 'UR-resolution' (McCharen, 1976) requires that the conclusion be nonempty and free of 'or'; and 'paramodulation' (Robinson, 1969) provides equality-oriented reasoning. Hyperresolution and UR-resolution can consider as hypotheses two or more clauses at a time; paramodulation focuses on pairs of clauses. These inference rules are generally much more

powerful than binary resolution. Many have been generalized to a class of 'linked inference rules' (Veroff and Wos, 1992), replacing syntactic criteria with semantic criteria for conclusion acceptance.

Paramodulation is an example of a type of reasoning well suited to the computer but ill suited to a person. Consider the two clauses below:

```
EQUAL(sum(x,minus(x)),0).
EQUAL(sum(y,sum(minus(y),z)),z).
```

Unification is applied to the term `sum(x,minus(x))` in the first clause and to the term `sum(minus(y),z)` in the second clause, yielding a substitution that asks for `x` to be replaced by `minus(y)` and `z` by `minus(minus(y))`. The application of this substitution produces two new clauses that contain two identical expressions. By the nature of equality, one can then substitute from the first new clause into the second new clause to obtain

```
EQUAL(sum(y,0),minus(minus(y))).
```

STRATEGY

The introduction of strategy has contributed more than any other component to the advance and successes of automated reasoning. Some strategies restrict the program's reasoning; some direct it; and some affect it in some other way. Without strategy, the program can continue rather aimlessly and without success, often becoming overwhelmed by information that proves useless for the task at hand. (Of course, the same is true for a person studying a deep question or hard problem.)

The various strategies that have proven powerful in automated reasoning are dependent neither on the clause language nor on the program that implements them. However, most reasoning programs implement only a small subset of strategies.

Of the restriction strategies, the 'set of support' strategy has proven the most powerful (Wos *et al.*, 1965). With this strategy, the user chooses a subset T of the input clauses, and the program is not allowed to draw a conclusion from hypotheses all of which are input clauses not in T. In other words, the program is restricted to drawing conclusions that are recursively traceable to one or more clauses in T. In effect, the input clauses not in T are used only to complete the application of an inference rule.

The set of support strategy meshes beautifully with proof by contradiction, in that a reasonable choice for T is 'not Q' where the theorem to be proved is 'P implies Q'. A more effective choice of T is 'not Q' together with those elements of P that are not basic information (axioms). Another possible choice for T, often more effective still, is just those elements of P that are not axioms.

A very different type of restriction strategy requires the user to place an upper bound on the complexity of deduced information that is retained. In the same spirit, the user can forbid the program to retain any conclusion in which more than k distinct variables occur, where k is chosen by the user. The program can also be forbidden to retain new conclusions that contain any term designated as undesirable. For example, if the function n denotes negation, the user may decide that new conclusions in which $n(n(t))$ is present for some term t are to be discarded. This strategy has enabled a reasoning program to discover proofs that had been missing for many decades, perhaps by exploring paths that were counterintuitive to human minds.

Other strategies direct a program's reasoning and focus. For example, R. Overbeek's 'weighting' strategy (McCharen, 1976) enables the user to impose knowledge, experience, and intuition on the program's actions. Templates can be included that (in effect) assign priorities to various types of term. For example, the user can instruct the program to give high priority to sums of products, lower priority to terms in which 'minus' occurs, and little or no priority to terms in which '0' occurs. (*See* **Learning from Advice**)

The 'resonance' strategy (Wos, 1995) also enables the user to impose knowledge, experience, and intuition on the program. The user supplies equations or formulae whose functional pattern (treating all variables as indistinguishable) is conjectured to merit preference.

A naive and in some sense natural direction strategy is breadth first ('first come, first served') search. Its opposite, depth-first search, is found in programs based on logic programming (see below). Although such programs can prove simple theorems quickly, for even moderately deep theorems they usually lack sufficient power. Nevertheless, a breadth-first search can occasionally prove profitable. The related 'ratio' strategy combines complexity preference (through weighting) with breadth-first searching. (*See* **Search**)

Unlike restriction strategies and direction strategies, the 'hot list' strategy (Wos and Pieper, 1999) enables the program to repeatedly revisit some user-chosen items among those input. For example, consider the theorem that asserts commutativity for rings in which $xxx = x$ for all x. If the clause equivalent of '$xxx = x$' is placed in the hot list, then each time a new clause is retained, and before any other reasoning action is taken, the hot list strategy

will apply the chosen inference rules to the new clause together with the clause equivalent of '$xxx = x$'. This strategy can radically reorder the space of retained conclusions and, in turn, the clauses chosen to drive the program's reasoning. Sometimes proofs that would otherwise have been out of reach are easily proved by a program using a hot list.

SUBSUMPTION AND REDUNDANCY

The fact that 'Kim's daughter is female' is a trivial consequence and instance of the fact that 'everybody's daughter is female'. If the latter information is present and the former deduced, 'subsumption' (Robinson, 1965b) will purge the less general bit of information. The program prefers generality. If both bits of information were retained, then there would be redundancy, which would interfere with effectiveness. Subsumption significantly reduces the amount of information useless to the program among the set of conclusions that can easily be deduced and retained.

To discover whether one clause subsumes a second, the program seeks a substitution of terms for variables in the first that yields a subset of the second, even if the first clause consists of more literals than does the second. In the following example, the first clause subsumes the second:

```
P(a,x)|P(y,b).
P(a,b).
```

DEMODULATION AND SIMPLIFICATION

Although a person often automatically simplifies expressions (for example, replacing '$0 + t$' by 't', where t is a term) a reasoning program does not, unless instructed to do so. Therefore, if appropriate actions are not taken, there can be much semantic redundancy within the database of deduced information (for example, '$a + b = c$', '$a + b = c + 0$', '$0 + a + b = c$'). Subsumption cannot deal with this type of redundancy. Rather, it is avoided by means of 'demodulation' (Wos *et al.*, 1967).

The inclusion in the input of appropriate demodulators (rewrite rules) enables a reasoning program to simplify newly deduced conclusions and to put them in canonical forms. For example, the program can automatically right-associate expressions, rewriting '$(a + b) + c$' as '$a + (b + c)$'. Sometimes, the set of input demodulators can be supplemented by new ones deduced during the program's study of a question or problem.

SOUNDNESS AND COMPLETENESS

Inference rules must be sound; that is, any conclusion that is drawn must follow inevitably from the hypotheses to which the rules are applied. (Of course, a false conclusion can be drawn if the program is given false information, such as 'finches are mammals'.) This soundness property guarantees that the proofs the program finds are without flaw, barring a bug in the program or the inclusion of erroneous items. However, in case one suspects that a supplied proof is not sound, many programs can provide detailed accounting of their reasoning.

Typically, automated reasoning programs may be refutation complete; that is, they may be configured in such a way that when given an inconsistent set of statements, they will, in theory, eventually complete a proof by contradiction, although an infeasible amount of time may be required in practice. Such completeness is often sacrificed for the sake of effectiveness. Indeed, many combinations of strategies, inference rules, and procedures are not refutation complete but are nevertheless widely used. In such cases, the counterexamples to completeness are usually bizarre and not relevant to serious studies. The set of possible proofs of a theorem is often so large that the absence of refutation completeness is not a practical problem.

'Deduction-completeness' is the guarantee that a consequence of the given hypotheses will eventually be deduced. Few reasoning programs are deduction complete. For example, even though Kim is mentioned in a puzzle and the program is told that everybody is female or male, the program is unlikely to explicitly deduce that Kim is female or male. The inference rule of instantiation would suffice to draw this conclusion from the more general fact, but that rule is rarely offered by a reasoning program because of the difficulty of adequately controlling its use. There is usually an infinite set of instances, and often it is not the simplest instance that is needed.

LOGIC PROGRAMMING

Logic programming languages have instruction sets based on the direct use of clauses. PROLOG is the best known. There are many similarities between logic programming and automated reasoning (Wos and McCune, 1991). In the mid-1980s, some researchers thought that the most effective way to automate logical reasoning was to base the design of a program on logic programming.

Such a program is very fast at proving simple theorems (Stickel, 1988). However, it lacks the power needed to tackle deep questions and hard problems. One of the main drawbacks is the absence of a diverse set of strategies. Implicitly, such a program does rely on a depth-first search and on the set of support strategy; but many additional strategies are needed in order to achieve the power required to prove interesting theorems.

Another serious drawback is the lack of information retention. Experiments strongly suggest that a program must retain new conclusions if it is to succeed in tackling deep questions and hard problems.

SUCCESSFUL APPLICATIONS

Despite the obstacles that seemed to many to be insurmountable even in the late 1970s, automated reasoning has prospered. Two distinct areas of success should be mentioned: design and verification, and mathematics and logic. (*See* **Problem Solving**)

The Boyer–Moore theorem prover has been used to prove the invertibility of the Rivest–Shamir–Adleman public key encryption algorithm (Boyer and Moore, 1984). Several major chip manufacturers now use automated reasoning programs to facilitate chip design by proving theorems.

In mathematics and logic, open questions have been answered, missing proofs found, and existing proofs improved upon in various ways. Of the open questions that have been answered, the most famous success was the proof that every Robbins algebra is a Boolean algebra (McCune, 1997). More recently, new two-axiom systems for Boolean algebra using the Sheffer stroke have been found (Veroff, 2001). Automated reasoning programs have also made substantial contributions to the theory of groups (Hart and Kunen, 1995; Kunen, 1992), combinatory logic (Glickfeld and Overbeek, 1986; Wos, 1993), abstract algebra (McCune and Padmanabhan, 1996), and logical calculi (Harris and Fitelson, 2001; Fitelson and Wos, 2001).

Perhaps the future will witness a combination of applications from each of these two areas: for example, the application of proof-shortening techniques used for mathematics and logic to the design of simpler chips and circuits.

Robotics

Introductory article

Luc Steels, Vrije Universiteit, Brussels, Belgium
Andreas Birk, International University, Bremen, Germany

CONTENTS

Robotics is the science of the construction and control of programmable machines suitable for flexible handling in various physical tasks like manipulation and locomotion.

INTRODUCTION

The science of robotics as well as the concept of a robot itself is not well defined from an industrial nor a scientific viewpoint. The Robotics Industries Association (RIA) defines a robot as a 're-programmable multi-functional manipulator designed to move material, parts, tools, or other specialized devices through variable programmed motions for the performance of a variety of tasks'. Nowadays, almost any device used in automation fits this definition to some degree. But the prototypical idea behind this definition is the most common form of a robot, the robot arm. The main applications of robot arms in industry are production tasks like welding and assembly, followed by packaging and storage tasks. Industry automation is still by far the largest market for robots, though slowly, new applications are on the rise like medical robotics or service and entertainment robots.

From a cognitive science point of view, robots are a platform for developing and testing precise theories on how sensorimotor behaviors might work. They do not prove whether certain mechanisms are used by animals or humans but they help to examine the plausibility and consequences of these mechanisms. At the same time ideas from the empirical study of living systems, both their capacities and the underlying brain structures and processes, are a continuing source of inspiration for building new types of robots and new software systems to control them. So there is a profound interaction between the robotics research carried out by artificial intelligence workers and the investigations of sensorimotor intelligence in other areas of cognitive science.

The History of Robotics 1: Science Fiction

In contrast to the industrial reality of the robot arm as the most common robotic device, the popular notion of a robot is strongly influenced by science fiction, which even coined the name of the device as well as the name of the field. The term 'robot' was introduced in 1921 by the Czech writer Karel Capek in his satirical drama '*R.U.R., Rossum's Universal Robots*'. The robots in this play are artificial humanlike creatures forced to work; the Czech word 'robota' means work. Capek's robots are, from a science fiction viewpoint, not really robots but Cyborgs as their control or 'brain' was supposedly based on re-engineered biological matter.

The field of robotics was invented by another science fiction writer called Isaac Asimov. His stories dealt mostly with the philosophical and moral implications of artificial humanlike creatures. The main ingredients of Capek's and Asimov's vision include a human-shaped body, superhuman strength, high cognitive capabilities, and a devotion to serve or – depending on the genre – to destroy mankind. Popular perception is strongly influenced by these visions but it is far removed from the reality of robotics research.

The History of Robotics 2: Beginnings

The industrial roots of robotics started in 1958 with the foundation of a pioneering company called Unimation (Universal Automation). Unimation produced a five-axes hydraulic robot arm based on a patent by George Devol and financed by Joseph Engelberger. From then on, robot arms started to become more and more important in automation.

In the scientific field of robotics, there was an early connection with artificial intelligence (AI). In

the Stanford Artificial Intelligence Laboratory (SAIL), founded in 1965, a robot arm was built in 1968 and very soon mobile robots followed, for example the famous robot Shakey, built in the Stanford Research Institute (SRI) from 1966 onwards, which was designed to receive instructions in natural language, and then plan and carry out a trajectory of movements in a real-world environment perceived through a camera.

Shakey was equipped with quite elaborate sensors for that time. Cameras, wireless communication with a host computer, optical range sensors, and bumper sensors were all pioneered on this robot. Most of the processing was done remotely on a DEC PDP-11, a supercomputer at that time, but less powerful than today's hand-held computers. Given the available computer power it is not surprising that the robot's behavior was very slow and hence observers viewed it as a failure. Nevertheless, Shakey was a major advance in the field, particularly from the viewpoint of overall architecture, and interaction between sensorimotor intelligence and cognition. Most subsequent projects explored the same general principles, constantly improving all aspects of the system and aided by steady advances in all enabling technologies of robotics: batteries, sensors, computers and mechanical components.

The History of Robotics 3: Successful Applications and Humanoid Robots

From the early 1990s, the cumulative effect of all these advances gave rise to a steady stream of functioning robots. Most of them were designed for specific purposes: cutting the grass, inspecting pipes, washing windows in high-rise buildings, checking and repairing telephone wiring, and of course various forms of factory automation. The advances have started to give rise to new applications for handicapped humans, such as artificial arms, hands, legs, etc. that are sometimes driven by signals captured from neuronal circuits. Research activities have also benefited from the massive advances in enabling technology. It has become feasible to build robots that test a theory on how a certain biological organism performs specific sensorimotor functions. This has given rise to the field of animal robotics, which operates in close collaboration with ethology and neuroscience. Only low-level organisms, typically insects, have been studied extensively so far but one can expect a steady rise in complexity until mammals or aspects of human sensorimotor intelligence come within reach.

The most recent exciting development concerns humanoid robots or humanoids. These are robots with a human shape (two legs, two arms, a torso, and head with two cameras), designed to exhibit human-like behaviors such as biped walking, sharing of attention by eye gaze following and gesture recognition, etc. The first humanoids have now been demonstrated in the laboratory and the first applications can be seen in the area of entertainment robotics.

The remainder of this article divides robotics research into five areas: the execution of action; the interpretation of the world through various sensors; behaviors that integrate sensing and actuating into useful building blocks; the architecture that integrates sensing and actuating into coherent goal-driven behavior adapted to the environment; and interactions among robots.

EFFECTORS, ACTUATORS, AND DEGREES OF FREEDOM

Any robot interacts with the physical world in one way or another, typically by manipulating objects or by changing their location. The parts of a robot designed for this purpose are known as effectors. An end-effector is the effector at the end of a robot arm, for example in the form of a gripper.

Actuators

Actuators provide the mechanical power that drives the active joints of a robot. There are three main classes of actuators, based on electromechanics, hydraulics, and pneumatics.

Hydraulic and pneumatic actuators are mainly used for linear motion based on pistons, though some special-purpose rotational motors of both kinds exist. Hydraulics are mainly used in applications where very high forces are needed, especially in large industrial robot arms. Pneumatic actuators suffer from the fact that air is – in contrast to hydraulic liquids – compressible, which makes control more difficult. Nevertheless, pneumatic actuators are commonly used as a lightweight alternative to hydraulics in applications where electrical motors cannot be used. Examples are environments where the potential sparking of electrical motors is a hazard, like chemical plants, or environments where sensitivity to radiation plays a role, like nuclear power plants.

A special form of pneumatic actuator is the pneumatic muscle, or McKibben actuator, which consists of an extendable bladder with a net woven around it. When the bladder is inflated,

the muscle evenly contracts and exhibits a pulling force at its endpoints.

Electric motors are the most common source of mechanical power for robots. Almost all electric motors are based on electromagnetism. The few exceptions are, for example, motors based on the piezo-effect – that certain ceramics change their shape when a voltage is applied to them – and electrochemical effects of some experimental classes of polymers.

Electric motors are seldom used on their own as actuators; exceptions are so-called direct drive set-ups. Electric motors tend to provide high rotational speed and low torque. Therefore they have to be combined with gears to be useful as an actuator. Gears serve several purposes. First, they can be used to convert speed to torque. Second, they can convert the type of motion, for example changing a rotation into a translation, or inverting the direction of a rotation. The main problems with gears are power and precision losses due to friction and the backlash, i.e. the small imprecision between the teeth of intermeshing gears.

Robot Arms

Robot arms are the prototypical industrial robots used for manipulation. Their usage is dominated by three tasks, namely welding, assembly, and packaging.

The structure of robot arms is similar to that of human arms with shoulder, elbow, and wrist. Each of these parts can be implemented in different ways, leading to different possible forms of motion. Each part of a robot arm can have several degrees of freedom (DOF). The most common approach is two DOF in the shoulder, one DOF in the elbow, and two to three DOF in the wrist. To the wrist, a hand or other end-effector is attached, which itself has additional degrees of freedom, ranging from a single one in a gripper to dozens in some so-called dextrous hands.

Components for Wheeled Locomotion

Most mobile robots use wheeled locomotion with a differential drive, although legged robots are becoming more and more common. A differential drive consists of two actively driven wheels on the same axis. Typically, this axis crosses the center of the drive platform. One or sometimes two passive, so-called castor-wheels are used to support the drive platform. A differential drive has many advantages. It can turn on the spot, it is easy to control, and the mechanical design is rather simple. Therefore, it is quite popular for autonomous devices, especially for mobile robots.

The Ackerman drive consists of four wheels on two axles, as in a car. The rear axle supplies the propulsion for the vehicle, powered by a single motor. The front axle is used for steering. For the steering operation, the two passive front wheels can be set in two steering angles, reducing slippage of the wheels.

When turning, not just one of the passive front wheels but also one of the rear drive-wheels has to turn faster than the other. This problem is solved by a passive mechanical solution in the form of a so-called differential gear. The Ackermann drive is useful for cars with a human operator at the steering wheel and a single combustion-based engine for propulsion. But it is much less suited for robots as the mechanical set-up is rather complex and it is difficult to control. Its main advantage is that it needs a single motor for propulsion, which can be quite powerful.

The syncho-drive is especially designed for mobile robots. Each of its three or four wheels is actively driven and steered. So the driving force is evenly applied to the ground, preventing problems from passive castors or steering wheels. The disadvantage of the synchro-drive is its mechanical complexity. Every wheel has to be actively oriented in the same direction, and it has to turn with exactly the same speed as the others.

The synchronization of the rotation and angle of the wheels is achieved by mechanical coupling through two belts. A single propulsion and single steering motor drive each belt respectively. The problem is to transmit the propulsion to the wheels while being able to steer them. This is done by special drive units. They consist of metal tubes through which an axle transmits the propulsion power vertically. At the lower end of this axle, a conical gear transmits power to the wheels. On the outside of the tube, a gear is mounted that allows the tube to rotate with the wheel axle, thus enabling the robot to be steered.

SENSORS: VISION, PROPRIOCEPTION, FORCE SENSING, TACTILE SENSING, SONAR

Initially, robots were primarily open loop devices. Detailed models of a robot were used to compute the necessary activations of actuators to reach a given target objective like, for example, the desired position of an end-effector in a welding application. Closed loop control, in contrast, uses error information derived via sensors to achieve the target

objective. Closed loop control is inherently more stable than open loop control and it frees the designer to some extent from the onerous task of modeling the robot in minute detail. Moreover sensor technology has greatly benefited from the developments in microelectronics making sensors smaller, mass production making them cheaper, and information processing making the output of sensors more reliable and ready to use. Consequently closed loop control is now more and more common in industrial robotics.

Vision

Most sensor systems are tailored to register a particular physical property, like infrared reflection, and hence are useful only for a particular task, such as obstacle avoidance. A vision system, in contrast, is more versatile. Visual stimuli can be used in many ways, for example to estimate distance to objects as well as for object recognition. Vision sensors or cameras provide a flow of large amounts of data with detailed information about the outside world and strong spatial and temporal resolution. The processing of this data is typically done by software, which can be changed and adapted much more easily than the more hardware-dependent processing of other sensor systems.

This advantage of being based on large amounts of data from the environment is also at the same time the major downside of vision. It is far from obvious how meaningful information can be extracted from the mass of data that a camera generates. In addition, it is questionable whether vision is just a kind of sensor that passes information to higher cognitive functions or whether vision is strongly embedded in cognition and action, a position known as active vision.

Vision is usually structured into the following stages. The first stage is image acquisition, where an image as an array of pixels of color or grayscale values is captured as a snapshot of the environment. Image processing is the second stage, where a series of transformations on the original image is performed. At every step, a new image is generated out of images from previous processing stages. Noise is eliminated and interesting properties are amplified, for example through edge detection, segmentation, shape from shading, etc. The third stage is high-level vision where an image is transformed into an abstract representation that can be used for planning or natural language dialogs.

Research on vision is typically divided into machine vision and artificial vision. The field of machine vision deals with vision from an application-oriented perspective, whereas artificial vision is more oriented towards cognitive aspects. The differences in the emphasis of both fields manifests itself mainly in the level of image acquisition. In machine vision, structural changes to the environmental set-up are commonly exploited, especially in commercial robotics applications. For example, special illumination eases segmentation, structured light improves the estimation of distances, background illumination enhances the contrast between objects and their surroundings, artificial landmarks are put in the environment, etc.

For both fields, machine vision and artificial vision, image acquisition and image processing are regarded as the least difficult parts. Especially for image processing, there are a large number of well established techniques like thresholding of pixel values or edge detection procedures. On the other hand, the extraction of qualitative descriptions from a visual image is extremely difficult, mostly because there is usually not enough information in the image itself to perform the interpretation. So context, prior expectation, and convention must be used in a top-down manner to guide the vision system, which is why many researchers now argue for active vision.

Proprioception

Proprioception is concerned with locating the parts of a mechanism in space. It is the basis for kinematic and dynamic control of robot arms as well as localization and navigation of mobile robots. Proprioception relies on sensors for measuring the positions of motors. These are typically encoders mounted on the drive shaft.

There are two main types of encoder, absolute and incremental. An absolute encoder detects the absolute angular position of the axle. The output of an incremental encoder is a pulse whenever the axle has turned by some fixed amount, so the output is a rectangular wave with a frequency proportional to the rotational speed of the axle. Incremental encoders typically have two output signals with a 90 degrees phase shift, enabling the detection of the direction of rotation of the axle. An incremental encoder often has an additional index channel that outputs a single pulse at one fixed absolute position for calibration purposes.

Encoders are technically implemented in many different ways. Mechanical solutions, such as those based on switches, are very rare for professional equipment due to wear problems. Serious encoders are contactless and based on optical sensors, such as via disks with slits or black and white patterns.

For mobile robots, direction is important proprioceptive information. When using shaft encoders on the drive motors and dead reckoning (vector addition of driven distances), there is a cumulative error: the longer the robot drives, the less precisely its position and orientation are known. Therefore, special purpose sensors like magnetic compasses and gyroscopes are often used in addition to shaft-encoders to measure direction.

Force Sensing

There are two main types of force sensor: strain gauge and pressure sensors. Strain gauges are based on Lord Kelvin's discovery in 1856 that the resistance of a conductor is proportional to its length and inversely proportional to its area, depending on a conductivity constant of the material. So, when a conductor is strained, its length increases and its area decreases thus leading to an overall increase of its resistance. To amplify this effect, a strain gauge contains a wire which is looped several times over the carrier material so that several parts of the wire are strained at the same time. The carrier material is usually some sort of plastic which protects the wire from damage. The quality of the sensor strongly depends on this material, because cheap versions wear out very quickly. Strain gauges are typically based on semiconductors to minimize the material constant, such that the overall resistance of the component is strongly dominated by the actual strained part.

Elastomers (compressible plastics) are a popular basis for pressure sensors. With the addition of metallic particles, elastomers can be made conductive. When this material is sandwiched between two electrodes, the resistance of this sensor decreases when it is pressed. Two effects are taking place. First, the distance between the two electrodes decreases and so, linearly, does the resistance. In addition the conductivity of the elastomer increases as the conductive particles come closer to each other. Depending on the design of the sensor, this second effect can lead to nonlinear sensitivity of the sensor.

The force sensors presented so far have in common that the range of forces to which they react is defined through the properties of the underlying materials of the sensors. In addition, it is possible to measure forces based on springs. A wide range of springs is available, allowing sensors for very small as well as very large forces. Within the admissible range of a spring, a force leads to an extension of the spring proportional to the strength of the force. This extension can be measured for example with a linear potentiometer or with a shaft encoder.

Tactile Sensing

Getting 'in touch' with the outside world is one of the most basic needs for a robot. The most simple touch sensors are switches. There are very small microswitches as well as very large ones that can handle high currents. Also the mechanical activation part of switches can differ substantially. The two most common forms are buttons and levers that react when they are pressed. The main disadvantage of switches is that they are mechanical, so they suffer from wear.

Proximity sensors react to the presence of objects that are very close without being in direct contact. Proximity sensors are typically used like switches, but they have the major advantage that they do not suffer from mechanical wear. The major disadvantage of proximity sensors is that they are limited with respect to the materials that they can sense. Therefore, they are mainly used in industrial applications where the parameters of the objects involved are known.

Tactile mats or 'artificial skins' are sensors that provide high-resolution information about contacts with a surface. They are still a basic research topic as they suffer from fundamental unsolved technical problems, especially with respect to manufacturing and meaningful data processing.

Sonar

Sonar sensors are active sensing systems. They emit a signal to probe the environment. The 'speaker' emits a short sound, called a ping, and a microphone listens for a reflection of the sound from the nearest surface. The ping is in the ultrasound range for convenience as these frequencies are too high for humans to perceive. Some animals, especially dogs, are nevertheless very sensitive to these frequencies.

Based on the time-of-flight between emission and reception of the sound, and the speed of sound in air, the distance to the object that caused the reflection can be calculated. In addition, it is possible to use the Doppler-effect to measure the relative speed between the sensor and the object. If both move towards each other the sound is compressed and its frequency increases. When they move away from each other the opposite effect takes place and the frequency decreases. Bats are heavy users of sonar sensing, but exploit the Doppler-effect and not the time-of-flight.

Sonar can be used, for example, on mobile systems for obstacle avoidance and map building by accumulating distances to objects from different positions and angles. In addition, sonar can be used for absolute positioning based on beacons. There are two ways to calculate the time the sound takes to travel from the beacon. Either a calibration signal like a radio pulse is emitted to mark the time when the ping is sent. Or the pings are sent in a fixed temporal pattern and the time differences between received pings are used to calculate relative position changes. Next, the actual position has to be determined. With one beacon and two receivers, distance from and orientation towards the beacon can be determined. With two or three beacons using different sounds, simple or proper triangulation can be used to determine the absolute position of the robot.

Issues in Sensing

The problems involved in interpreting sonar sensor data are representative for the key issue in sensing, namely how can a sufficiently accurate interpretation of the world be obtained to engage in appropriate action. In general it is never straightforward and usually impossible to derive absolutely reliable accurate information about the environment in sufficient time.

Thus for sonar sensing, there is the problem of reflection strength. The echo of the sound heavily depends on the type of surface from which it is reflected. Best suited are plain, straight walls. Corners or walls covered with an irregular structure, like a bookshelf, swallow the sound, so there is insufficient reflection. Next there is the problem of multiple echoes. There can be several reflections of the same ping from different objects located at different distances. Therefore, the system has to wait between repeated samples until all echoes of the first ping have (most probably) died out. As a result, the sampling rate is rather low. This is especially a problem when sonar is used for obstacle avoidance on a fast-moving robot. Third, sonar sensing gives low angular resolution. The opening angle of an ultrasound sensor is rather large. If the robot features several sonar sensors then either different frequencies for each sensor have to be used or the sensors have to be activated one after another, causing an additional slow-down of the sampling rate. Next, there is the problem for any active sensing method, that several similar systems may cause sensor pollution; that is, the active signals from different systems may cause interference. Therefore, the sound frequencies have to be adjusted if several systems use ultrasound in the same environment.

Finally, ultrasound sensors are affected by environmental conditions. The speed of sound in air is not constant, but depends on the temperature, the humidity, and atmospheric pressure. Within office environments these factors are nearly constant. But for precise operations, particularly outdoors, the time-of-flight calculations have to be calibrated. The most critical effect on the speed of sound is usually caused by temperature changes.

These various problems are encountered in all types of sensing. One of the main lessons of robotics is that the relationship between the physical world and its interpretation by a cognitive agent is very complex.

BEHAVIORS

Behaviors integrate sensing and actuating into a coherent functionality that can be reliably called upon by higher-level modules. Typical examples of behaviors are manipulation, locomotion, and navigation. Each behavior requires some representation of the world and sensing to fine-tune the behavior while it is being performed.

Manipulation

Kinematics is the general science of mechanical motion. On an abstract mechanical level, a robot consists of stiff parts called links and movable parts called joints. Active joints are powered by actuators, otherwise they are called passive. The degrees of freedom (DOF) of a mechanical system is the number of variables needed to locate every part of the system in a fixed coordinate system. A rigid body has, for example, six degrees of freedom in a general three-dimensional coordinate system, namely three DOF for its position along the x-, y- and z-axes and three DOF for its angular orientation along each of these axes. The rotational components are commonly denoted by the roll, pitch, and yaw of the body. The combined vector of the location and orientation components is known as the *pose* of the body.

Given a precise mechanical model of a robot, kinematics attempts to answer two questions. First, there is the problem of forward kinematics: given a value for each of its DOF, compute the resulting pose for at least one part of the robot. Typically, this part is the end-effector in the case of robot arms. Second, there is the problem of inverse kinematics: given the desired pose of at least

one part of the robot, compute a feasible set of values for each DOF that leads to this pose.

The state of an n-DOF robot is characterized from a kinematics viewpoint by n real-valued numbers, each of them describing the momentary state of the robot according to its DOF. The state or 'configuration' of the robot can thus be seen as a point p in the n-dimensional space of real numbers $\mathbb{R}^n$. The subspace of $\mathbb{R}^n$ that consists of all feasible states of the robot is known as the *configuration space*. A movement of the robot from one state A to another state B is hence possible only if there is a continuous trajectory from A to B in the configuration space.

Obstacles in the real world can be mapped to parts of the configuration space. The remaining part of the configuration space that is not occupied by obstacles is the configuration free space, or free space for short. Finding a feasible motion of the robot corresponds to finding a trajectory in the free space. This approach is most feasible when the obstacles are static, as the free space has to be computed only once.

The term 'generalized configuration space' is applied to methods where the DOF of objects other than just the robot are included in the configuration. These objects are obstacles that move, or objects that change their shape due to manipulation by the robot. The configuration space of a general rigid object in 3D is the six-dimensional space of its pose; i.e., its location and orientation. The generalized configuration space of parts A and B is the Cartesian product of each individual generalized configuration space. It follows that the number of dimensions and the size of the generalized configuration space is usually large.

There are several ways to deal with this problem. One possibility is to partition the space finitely into many states to which standard planning techniques can be applied. The problem with this approach is that no general method for this partitioning is known. A second possibility is to plan the object motions first and then plan the robot motions. The main problem is that this approach is not complete, so it might lead to an omission of feasible solutions. Finally, there is the third possibility: to place constraints on the motions of the objects to simplify planning.

Walking

Walking is a fascinating option for the locomotion of robots. Unfortunately, the technology of artificial walking is still in its infancy although some impressive results have been achieved. Walking allows robots to negotiate rough outdoor terrain, and is required for access to standard indoor environments. A wheeled robot cannot for example cope with a simple staircase.

The main problems with walking are its mechanical complexity and its energy consumption. The mechanical complexity is high because many degrees of freedom are needed by default. A minimal six-legged walker has 12 DOF, namely two in the hip of each leg; and a two-legged walker typically needs at least 10 DOF, namely two in the hip, one in the knee and two in the ankle. Energy consumption is high for several reasons. First, walking includes, in addition to propulsion, some lift. Second, it is very difficult to control the dynamics of walking so that not too much energy is wasted in the form of heat, for example through stress. Nature has optimized natural walkers tremendously in this respect, using not only active components like muscles, but also passive components like tendons to absorb and reuse energy.

There are two basic forms of walking: static walking and dynamic walking. In the case of static walking, the center of gravity of the walker is permanently within the support area, that spanned by the parts of the robot that touch the ground. In the case of dynamic walking, the center of gravity is not supported constantly. Therefore, dynamic walking is also called 'controlled falling'. Static walking is obviously much easier to control. In a static environment, there are no time constraints on static walking. The system can be switched off at any time in the walking process without falling over.

Dynamic walking is more difficult as severe timing constraints apply and the dynamics as well as the kinematics of the system have to be taken into account. But dynamic walking can be much more energy-efficient than static walking. Therefore, it will probably be adopted for autonomous robots in the long run.

Navigation

Navigation is getting from one location to another. It implies two other tasks, namely mapping and localization. *Mapping* deals with the construction of a spatial representation of the environment. *Localization* deals with the determination of the current spatial position of the robot in the map. Navigation can be structured into furthera behaviors, namely path planning and obstacle avoidance.

Maps

Maps are world models used by mobile robots to navigate through their environment. They restrict the representation of the environment to a two-dimensional plane. The 'free space' is the part of the environment where the system can move without restrictions, that is where no obstacles hinder the free movement of the system. Landmarks are locations in the free space which can be distinguished by the sensors. They serve as orientation points for navigation.

The representation of obstacles in maps is usually chosen such that the robot can be treated as a point. First a virtual boundary for the mobile system is chosen that represents it as a sphere of a fixed radius. Checking collisions between the virtual boundary and obstacles is efficiently done by expanding the obstacles by the radius of the robot and treating the robot as a point.

The two major types of maps currently used are Euclidean and topological maps. With a Euclidean map, each point in space is represented according to its metric distance to all other points in the space. Given two locations in a Euclidean map, their exact metric distance can be determined. A topological map represents locations and their adjacency. This representation does not necessarily include an exact metric.

Topological maps are typically represented as a graph. The nodes are distinct places and the edges represent adjacency relations between locations. A labeled edge from A to B can for example represent by which type of motion the robot gets from A to B, but without exact distance information. In this case, the topological map represents with which action the system can transit from one node to an other.

One option for Euclidean maps is to use a list of the exact locations and boundaries of the obstacles. Polygons are a common form of representation of the obstacles. Another alternative is to use a decomposition of the plane into cells. In doing so, each cell is labeled as free space or obstacle. A grid is a uniform partition of the space. It is used as a basis for efficient processing in many algorithms. The quadtree representation is an example of an uneven partition of the space into cells. Computations on this form of representation are usually lengthy for path planning, but the memory requirements are much less than needed for a grid.

Path Planning

A map is only useful if it is combined with appropriate algorithms for navigation. In the case of topological maps, where the environment is represented by graphs, general graph search techniques, like Dijkstra's algorithm for finding the shortest path, can be used.

For a Euclidean map, it is possible to compute a graph-like representation that is also known as a skeleton. This can, for example, be a Voronoi diagram or a visibility graph. A Voronoi diagram consists of curves, where each point on the curve is equidistant from two or more obstacles. In a visibility graph, the obstacles are typically represented as polygons. The corners of the polygons are the nodes of the graph. Two nodes are connected via an edge if and only if they are visible to each other; that is, a straight line connection between them goes only through the free space.

Potential field methods constitute another family of approaches to the path planning problem. Attraction and repulsion obtained from electrical fields are used on a grid representation of the world. The goal is modeled as an attractor and obstacles have repellent fields. The different fields overlay each other and give a gradient towards the goal while avoiding obstacles. The main difficulty with potential fields is that the robot might get stuck in a local optimum.

ARCHITECTURE

The role of the robot's architecture is to invoke appropriate behaviors to satisfy certain goals. This typically involves planning. Two kinds of architectures have been proposed. The classical or logic-based planners start from a description of the goal and use logical inference to decompose the goal into subgoals based on a description of the pre- and postconditions of each action. The preconditions describe what the state of the world has to be before an action can be performed and the postconditions describe the effect of an action. The decomposition generates a search space when there is more than one way to decompose a goal into subgoals, and heuristic criteria must be used to find the fastest or optimal solution.

This very general and high-level approach is very effective when a logical description of the world is available but has been proven problematic on real-world robots for several reasons.

First of all, the real-world environment of a robot is much too complex for any detailed *a priori* planning. Hence, planning for real-world robots must include options to react to environmental conditions during the execution of the plan. Second, computation resources – processing power, disk space, etc. – are typically very limited for

robots, especially for mobile ones. It is therefore necessary to adopt a minimal approach to planning, depending on the workload of the robot and the urgency of a task. Third, a planning module for a robot is not an independent component, but it must be grounded in the available functions of the robot. A classic planner usually does not care about the actual execution of primitives in the plan, the physical state of the robot (e.g., the level of the battery), and often relies on a high level of abstraction. Last but not least, a planner for a robot has to deal with concurrency. There are always many more than just one or two goals or jobs to do to keep the robot operational.

One alternative to classical planning is known as reactive planning. It starts with a crude default plan which typically comes from a library of template plans or is generated by some fast off-line method. While the default plan is executed, there is continuous revision going on, trying to improve the current plan depending on sensor input and available computational resources. The plan can for example be modified on the basis of a set of plan transformations from a library leading to a higher utility, or simply due to changed environmental conditions.

Another alternative to classical planning is a behavior-based architecture which relies as much as possible on emergent behaviors, motivational systems and strong reactivity to changes in the environment. Behavior-based architectures emphasize dynamics. Sensory states are directly coupled to actuator states and modulated by motivational states. This architecture is strongly influenced by animal decision-making models from ethology.

Another way to classify robot architectures focuses on the flow of data from sensors to motors. Planning, world-modeling, and sensor/motor-control can be seen as three levels, ordered by a descending amount of abstraction and decreasing time-horizons at each level. A vertical flow of data over these levels then corresponds to the 'sense–model–plan–act' cycle underlying early robots like Shakey. A horizontal flow of data from the sensors to the motors allows short, fast paths or reactiveness as promoted in behavior-based architectures. Typically, a successful system will incorporate both types of data streams. This is known as a hybrid architecture.

INTERACTIONS AMONG ROBOTS

Research in robotics is not confined to single robots. Cooperation among robots and collective robotics is a recent and very active research field. Work in this area has focused on one hand on handling the additional complexity due to the higher number of robots. An example for such a coordination problem is joined path planning where the motion of several robots together has to be scheduled such that they do not conflict with each other. Another group of researchers is attempting to exploit the benefits of multiple robots, to use the added value of cooperation. Examples include cooperative sensing, where different robots collectively construct an interpretation of the environment, or cooperative problem-solving like box-pushing tasks.

Cooperation has been explored using two approaches. The first one is self-organization. Self-organization achieves global coherence based on only local behaviors and local interactions between the elements of a system. An example is path formation in ant societies or swarming based on local attraction and repulsion. Coordination of multiple robots can also be achieved through pre-programmed explicit group structures based on assigned roles and hierarchical commands. For many tasks that have to be performed as a team, like playing soccer, coordination can be based on a separation of space, like midfield, defence area, and so on, and on roles that are assigned to team members depending on their capabilities and the requirements of the role in each spatial area.

CONCLUSION

Robotics is a very difficult field because it requires the integration of many different technologies and implementation techniques. The value of robotics for cognitive science is that it allows the precise testing of specific theories about sensorimotor intelligence and embodied action in the world.

Samuel's Checkers Player

Introductory article

Jonathan Schaeffer, University of Alberta, Edmonton, Alberta, Canada

CONTENTS

Arthur Samuel's checkers-playing program of the 1960s was a milestone in the history of computer science and artificial intelligence.

INTRODUCTION

Arthur Samuel was one of the pioneers in artificial intelligence research. His seminal articles on machine learning are classics, and they laid the foundation for the field of reinforcement learning. His ideas were demonstrated in his checkers-playing program, arguably the first successful artificial intelligence program ever built.

Samuel's interest in checkers was piqued in 1948 after hearing about Claude Shannon's work with chess. Samuel decided to build a program to play checkers, a game that required less infrastructure to program than did chess, as a means of creating a visible project that could attract research dollars. It is difficult today to imagine the conditions under which Samuel began his 30-year quest to build a strong checkers program. In his (unpublished) autobiography he wrote:

> I started writing a program for a machine that did not yet exist using a set of computer instructions that I dreamed up as they were needed. … My first checkers program for the University of Illinois' Illiac was never actually run because the Illiac was still only a paper design when I left that University for IBM in 1949. It was not until 1952 that I had my program running on the experimental model of the IBM 701. Incidentally, this first program was written directly in machine code – before we even had a symbolic assembler.

However, the credit for building the first working checkers program went to Christopher Strachey who demonstrated it in 1952.

Samuel, although not a strong checkers player, found the prospect of harnessing the new technology to create an 'intelligent' checkers-playing machine irresistible. After moving to IBM and finally getting access to the computing resources he needed, he became determined to succeed with his program:

> IBM in those days did not take kindly to one of their engineers wasting company time playing checkers, even if it was against a machine, and so most of my checkers work had to be done in my own time. I dressed my efforts up with a certain amount of respectability by adding a learning feature to the program but even then it was the use of the program as a computer test vehicle which could be adjusted to run continuously that got me the machine time that I needed to try out my experimental learning routines.

Samuel gave a successful demonstration of his program on television in 1956. Thomas Watson, president of IBM, arranged for the program to be exhibited to IBM shareholders. He predicted that it would result in a 15-point rise in the price of IBM stock. It did.

Samuel's program is best remembered for a famous match against Robert Nealey, the US blind champion, in 1962. The program won one of the games in the match, thereby creating a milestone in the history of computer science. Samuel's early success, and in particular the Nealey game, had the unexpected side-effect of checkers being labeled a 'solved' game. From that point on, research into building high-performance game-playing programs switched almost exclusively to chess.

Although it was Samuel's early success with his checkers program that ensured his place in computing history, his contributions to machine learning have stood the test of time. His ideas of rote learning and reinforcement learning are the basis for many techniques that are in common use today.

ROTE LEARNING

Samuel followed Shannon's recipe for building a chess program. First, the program used an alpha-beta search algorithm to analyze possible move sequences. For example, the program might consider all possible legal sequences for both sides five moves into the future as part of its decision-making process. Then, at nodes where the search stops (so-called *leaf* nodes), knowledge would be used

to assess how good or bad the checkers position was, by means of an *evaluation function*. The evaluation scores would be minimized and maximized back to the root by the alpha-beta algorithm. The move in the current position receiving the highest alpha-beta score would be selected to be played in the game.

Samuel wanted his program to learn from experience. He accomplished this using rote learning.

For each move in a game, the program would do an alpha-beta search to decide on its best move. Suppose that this search considered all possibilities five moves into the future. After completing the search, the program would then record the position and the result of the search (the move chosen and an assessment of how good it was) in a database.

During subsequent games, the database of past search results would be queried. Suppose the program was searching five moves ahead, and three moves into the search it encountered a position that was in the database. Instead of continuing the search, the previous result for that position was retrieved from the database and used instead. This approach has two advantages. Firstly, the search is faster since some of the search effort has been eliminated and replaced by the database information. Secondly, the result of the search is more accurate because the database result represents more accurate information than would have been obtained by continuing the search. In this example, since three moves had been played, an additional two moves ahead would have been searched to arrive at a result. Instead, the database result provides a five-moves-ahead assessment.

The database of game moves would grow with every game played, creating a valuable repository of knowledge. However, the computers Samuel used had limited memory (measured in kilobytes, not megabytes) and he had to restrict the amount of data kept. He introduced the idea of 'forgetting', allowing the program to delete (or forget) game moves that had not been useful in a long time.

Samuel's ideas about rote learning are still applied today in most major game-playing programs. However, the availability of inexpensive memory has changed the scope. Instead of only the final result from a search being saved, whole subtrees of a search are now cached in a table (often called the transposition table) which is accessed dynamically throughout the search. The transposition table allows rote learning within a search (creating many more opportunities for increased search depth), the elimination of move cycles, the detection of transposed move sequences, and improved move ordering. Rote learning between games, as used by Samuel, is used in many commercial game products, allowing the program to avoid repeating mistakes.

EVALUATION FUNCTIONS

The evaluation function used in Samuel's program was based on consultations with strong checkers players and the extensive literature on the game. Samuel identified over 40 pieces of knowledge that might be useful for assessing the strength of a position. The problem then becomes how to combine these pieces of knowledge (or *features*) into a numeric assessment.

Initially, Samuel combined the features linearly:

$$\text{evaluation} = \sum_{i=1}^{n} w_i \times f_i \tag{1}$$

where n is the number of features, f_i is a feature, and w_i is the *weight* (or importance) of the feature. For example, in checkers two features that are correlated with success are the piece count (the relative number of pieces on the board for each side) and centre control (which side controls the central squares on the board). Piece count (f_1) is usually much more important than centre control (f_2), and hence has a much higher weighting ($w_1 >> w_2$).

Samuel wanted his program to learn the weights automatically. This would allow him to add knowledge to the program without having to evaluate how good or bad the knowledge was. During the automatic tuning, if a piece of knowledge was bad or inconsequential, the weight would drift towards a value of 0, effectively becoming irrelevant (and possibly being removed completely from the program).

A search is intended to produce a result that is a (good) predictor of the final result of the game. Presumably, a search conducted on move $i + 1$ of a game will give a better approximation of the final game result than a search conducted on move i. The weights of the evaluation function can be modified (some increased and others decreased) so that the move-i search result can be closer to the move-$(i + 1)$ search result. This technique is commonly known as *hill climbing*, where the weights are incrementally modified to try and give the best results over the (large) set of test data. Thus what happens in a game can be used to adjust the program to be a better predictor.

The weight adjustments were automated. This allowed Samuel's program to play against itself and improve its weights without human intervention. In effect, the program could learn to play better checkers by itself.

Samuel later modified the evaluation function to include what he called *signature tables*. Subsets of features were grouped together and separately weighted. The results of these subgroups could be hierarchically combined to produce a final evaluation score. The hierarchical evaluation function allowed for nonlinear relationships between terms, giving greater flexibility in what could be achieved in the evaluation function. Samuel reported a significant improvement in his program's performance with signature tables compared with the simple linear evaluation function.

Samuel's work with a learning system that automatically adjusted the weights of features in an evaluation function was a precursor of *temporal difference learning* methods. However, this was only recognized as a valuable learning algorithm after Sutton extended and formalized this work. One remarkable success of this type of learning was Gerry Tesauro's backgammon program, which played over a million games to learn its evaluation function weights. The result is a program that is as good as (and possibly better than) the strongest human players.

AFTERMATH

In 1966 Samuel's program played exhibition matches with the world champion Walter Hellman and his challenger Derek Oldbury. The program lost every game. Samuel sought advice from strong checkers players on how to strengthen his program. Herschel Smith met Samuel in 1967 and advised him to add databases of strong opening moves and common endgame sequences. Smith writes of that encounter:

> [Samuel's] response was: 'I cannot do that. That reduces the game of checkers to simple table look-up.' He believed the machine-learning concept was essential to his program and would not compromise. He put it to me this way: 'I did not teach the computer how to play checkers; I taught it how to learn to play checkers.'

Eventually, Samuel acquiesced and added databases of opening moves to his program, but it never approached master level. The Nealey result had been a fluke, but the damage was done: the notion that checkers is 'solved' persists to this day.

Samuel continued to tinker with his program into the 1970s, but it was eclipsed by the Duke program. Samuel's dream of a checkers program that could take on the best human players was not realized until 1990, when the program Chinook earned the right to play a match for the world championship by coming second to world champion Marion Tinsley in the US Championship. Ironically, Arthur Samuel died a few days before the Chinook success. In 1994, Chinook became the first game-playing program to win a human world championship by winning the World Man-Machine Checkers Championship.

Samuel's pioneering work in machine learning remains a milestone in the artificial intelligence literature. His two seminal papers are still frequently cited in the literature, four decades after the research was originally done. In the fast-moving field of computing science, there are few papers that remain relevant a few years after they appear let alone a few decades.

Eric Weiss, in his 1992 article, eloquently put Samuel's accomplishments into perspective:

> Clearly the accomplishment for which he is most famous is his checkers program. He lavished the most effort on it over the longest period and it is…recognized as the world's first self-learning computer program. I will go further and claim that it is the first functioning artificial intelligence program. Thus in spite of Samuel's own opinion…that he considered his [engineering] patents to be more important, the world will remember him for his Great Game.

Search, Adversarial

Intermediate article

Dana S Nau, University of Maryland, Maryland, USA

CONTENTS

Adversarial search, or game-tree search, is a technique for analyzing an adversarial game in order to try to determine who can win the game and what moves the players should make in order to win.

INTRODUCTION

Adversarial search is one of the oldest topics in artificial intelligence (AI). The original ideas for adversarial search were developed by Shannon (1950) and independently by Turing in 1951, in the context of the game of chess – and their ideas still form the basis for the techniques used today. Computer programs based on adversarial search techniques are now as good as, or better than, humans in several popular board games and card games (see Table 1).

GAME TREES

Adversarial search is based on the notion of a *game tree*, a mathematical structure that represents the positions that might result from every possible series of moves in a game. Game trees can be used to model any game that satisfies the following restrictions:

- The game is played by two players, who make moves sequentially rather than simultaneously. This excludes most popular video games, and also the kinds of games studied in the branch of economics known as classical game theory.
- The game is *finite*. At each turn a player can choose from only a finite number of possible moves, and the game is guaranteed to end within some finite number of moves.
- The game is *zero-sum*; i.e. the amount that one player wins is precisely equal to the amount that the other player loses.
- The game contains no elements of chance (although we will later look at how to incorporate certain kinds of chance elements into game-tree searching).

Figure 1 shows a simple example of a game tree for a game between two players called Max and Min. Square nodes represent positions where it is Max's move, and round nodes represent positions where it is Min's move. The leaf nodes represent positions where the game has ended, and the numbers below them represent the payoffs for Max (recall that Min's payoff is always the negative of Max's payoff).

THE MINIMAX ALGORITHM

At the node n_4 of Figure 1, Max's best move is to go to n_8 to get the payoff of 5. At the node n_5, Max's best move is to go to n_{10} to get the payoff of 8. If we know that Max will always make the best move, then this means that at the node n_2, Min's best move is to go to n_4 so that Max's payoff will be 5 rather than 8. Generalizing this analysis, it follows that if both players play perfectly from some node n onward, then the payoff for Max is the *minimax value* of n, which is the value computed by the following algorithm:

```
procedure minimax(n)
  if n is a leaf node then return the
    payoff for Max at n;
  compute the children n_1,...,n_k
    of n;
  for i=1,...,k,
    let m_i=minimax(n_i);
  if it is Max's turn to move at n then
    return max(m_1, m_2,...,m_k);
  else return min(m_1, m_2,...,m_k)
```

The algorithm's name comes from the famous *minimax theorem* of von Neumann and Morgenstern. However, the principle embodied in the algorithm – that a player should maximize the minimum payoff for every alternative – is what decision theorists call the *maximin decision criterion*.

As an example, Figure 2 gives the minimax values for the tree in Figure 1. These values can be

Table 1. Popular board games that computer programs can play as well as, or better than, humans

Game	*Best programs*	*Ability*	*Primary techniques*
Checkers	Chinook (Schaeffer, 1997)	Better than best humans	Game-tree search
Othello	Hannibal (Geoffroy, 2000) and Logistello (Buro, 2000)	Better than best humans	Neural networks, game-tree search
Scrabble	Maven and CrossWise (Alexander, 2001)	Comparable to best humans	Simulation
Chess	Deep Blue (IBM Corp. 1997)	Comparable to best humans	Game-tree search
Backgammon	TD-gammon (Tesauro, 1995)	Comparable to best humans	Neural networks

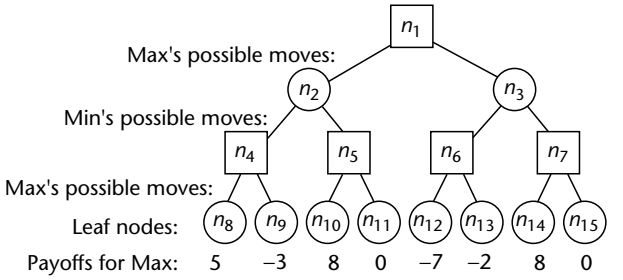

Figure 1. A game tree for a very simple game between two players, Max and Min. This game tree has two properties that most game trees do not have: at each position before the end of the game, each player always has exactly two moves; and the game always ends after exactly three moves.

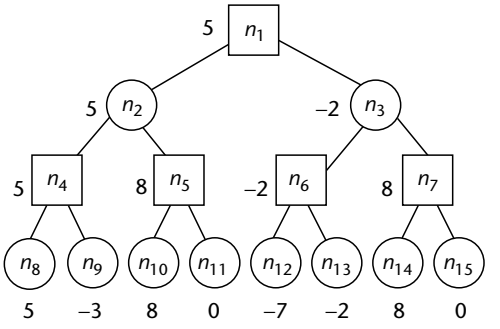

Figure 2. Minimax values for the nodes of the game tree of Figure 1.

used to decide what move to make at any node of the tree: Max should always move to the child that has the largest minimax value, and Min should always move to the child that has the smallest minimax value. Theoretically, this rule is only correct against infallible opponents (Pearl, 1984), but in practice it works well enough against any good opponent.

ALPHA–BETA PRUNING

Suppose that we are computing the minimax value for the node n_1 of Figure 1, and that we have

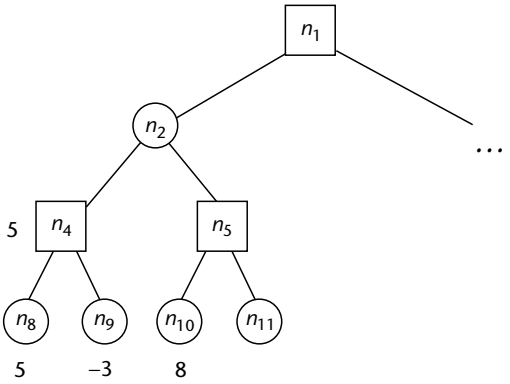

Figure 3. An example of alpha–beta pruning. In this example, it is not necessary to compute minimax(n_{11}), because it cannot possibly affect minimax(n_2) and minimax(n_1).

already computed $\texttt{minimax}(n_4) = 10$ and $\texttt{minimax}(n_{10}) = 11$ as shown in Figure 3. Then

$$\texttt{minimax}(n_2) = \texttt{min}(5, \texttt{minimax}(n_5)) \leq 5;$$
$$\texttt{minimax}(n_5) = \texttt{max}(8, \texttt{minimax}(n_{11})) \geq 8.$$

It follows that we do not need to know what minimax(n_{11}) is, because there is no way for minimax (n_{11}) to affect minimax(n_2) and minimax(n_1). Generalizing this analysis gives us the following algorithm, which is called the *alpha–beta pruning algorithm*:

```
procedure alphabeta (n, α, β)
  if n is a leaf node then
    return the payoff for Max at n
  else if it is Max's move at n then
    let n1, ..., nk be the children of n
    for i = 1, ..., k do
      α = max (α, alphabeta(ni, α, β))
      if α: ≥ β then return α
    end
    return α
  else /* it must be Min's move */
    let n1, ..., nk be the children of n
    for i = 1, ..., k do
      β = min(β, alphabeta(ni, α, β))
```

```
      if β≤α then return β
    end
    return β
  end if
end alphabeta
```

Alpha–beta pruning is guaranteed to compute a node's minimax value, and in general it will visit far fewer nodes than the minimax algorithm. There also are several other algorithms having this same property (Pearl, 1984), but because of its simplicity and low overhead, alpha–beta pruning is the one that is most widely used. In the worst case, alpha–beta pruning will visit every node that the minimax algorithm visits, but in the best case, it can search a tree of roughly twice the depth as the minimax algorithm in roughly the same amount of time (Knuth and Moore, 1975).

LIMITING THE DEPTH OF THE SEARCH

Most game trees contain far too many nodes to allow the entire tree to be searched quickly, even with a tree-pruning algorithm such as alpha–beta. Another way to visit fewer nodes is to stop searching at some arbitrary search depth d, and instead to estimate the minimax values of the nodes at this depth using a *static evaluation function*. This gives the following modification to the alpha–beta algorithm:

```
procedure alphabeta (n, d, α,β)
  if n is a leaf node or d=0 then
    return e(n)
  else if it is Max's move at n then
    let n1,...,nk be the children of n
    for i=1,...,k do
      α=max(α, alphabeta(ni,d–1,
        α,β))
      if α≥β then return α
    end
    return α
  else /* it must be Min's move */
    let n1,...,nk be the children of n
    for i=1,...,k do
      β=min(β, alphabeta(ni,d–1,
        α,β))
      if β≤α then return β
    end
    return β
  end if
end alphabeta
```

A search to depth d is likely to yield inaccurate results if something happens (such as an exchange of material in the game of chess) that makes a large change in the minimax values just beyond the cutoff depth d. In order to avoid this *horizon effect*, it is best to modify the above algorithm so that instead of stopping when $d = 0$, it keeps searching until it reaches a node that is *quiescent* (in chess, a node where there are no pending exchanges of material). However, this means that at different branches of the search tree, the evaluation function may be applied to nodes of different depths. Since a move usually strengthens the position of the player who makes the move, nodes at which Max has just moved are likely to get higher evaluations than nodes where Min has just moved. This can cause the computer program erroneously to prefer branches that end at an odd depth. To overcome this, practical implementations of game-tree search will usually include a *biasing factor* that is added to node evaluations at even depths and subtracted from node evaluations at odd depths.

SPEEDING UP THE SEARCH

Although there exist games and game trees in which searching deeper will produce worse decision-making (Nau, 1983), a deeper search will produce significantly better decisions in nearly all practical situations (Kaindl, 1988). However, in order to do a deeper search, a search algorithm must visit exponentially many more nodes, which makes it impossible to search very deeply unless the algorithm is extremely fast. Here are several techniques for speeding up the search.

Databases of standard openings. Sometimes it is possible to develop databases of various standard ways to start a game. As long as the computer's opponent uses one of these standard openings, the computer can make moves very quickly by retrieving them from the database.

Thinking on the opponent's time. In order to decide what move to make, a search algorithm will need to predict what node the opponent is likely to move to. After making its move, a computer program can immediately begin a game-tree search starting at this node, thereby saving some time if the opponent actually makes the predicted response.

Iterative deepening. One problem with the procedure described in the previous section's problem is deciding what value to use for the cutoff depth d. If we make d too large, then the search will take too long – but if we make d too small, then it will reduce the accuracy of the decision-making. One way to solve this problem is to choose a value for d that we know is not too large. If we finish our search more quickly than expected, then we can increment d and search again. Since the number of nodes visited usually grows exponentially with the search depth, this usually will not take significantly

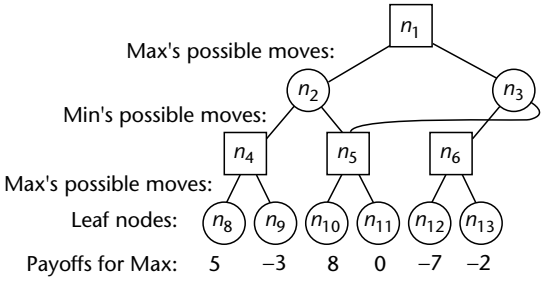

Figure 4. A game graph having the same minimax values as the game tree of Figure 1.

more time than if we had used the correct value of d the first time around.

Transposition tables. The term 'game tree' is a misnomer: most games actually correspond to graphs such as the one in Figure 4. We can take advantage of this by using a *transposition table*, a cache of recently visited positions and their minimax values. If we visit a node that we visited a short time ago, we can retrieve its value from the transposition table rather than computing it again.

Move ordering. For alpha–beta pruning, the difference between the best case and the worst case depends on the order in which the moves are considered. At a node where a cutoff is to occur, the best case is if the cutoff occurs at the first child that is visited – which occurs if the children appear in order of decreasing minimax values when it is Max's move, or in order of increasing minimax values when it is Min's move. A way to make this occurrence more likely is to sort a node's children in decreasing order of their evaluation-function values when it is Max's move, and in increasing order of their evaluation-function values when it is Min's move.

Specialized hardware. An expensive but effective technique, used in the Deep Blue program, is to design special-purpose computer hardware to speed up its game-tree search.

OTHER KINDS OF GAMES

Not all games are amenable to the 'brute-force' game-tree search techniques described above. Here are several examples:

- *Backgammon* incorporates a chance element, namely the rolls of the dice. The game-tree model can be generalized to model the dice rolls, but it produces too large a game tree to be searched in a reasonable amount of time. However, through the use of machine-learning techniques, static evaluation functions can be created that are good enough to work well with only a shallow game-tree search. Thus, the best computer backgammon programs play as well as the best human beings (Tesauro, 1995).
- *Bridge* incorporates both chance and imperfect information: the cards are dealt randomly, and no player knows all of the other players' cards. As in backgammon, the game-tree model can be extended to model this, but it produces too large a game tree to search in a reasonable time. Research in bridge has produced a variety of techniques for reducing the size of this game tree, ranging from Monte Carlo simulation to AI planning. Bridge programs are not yet as good as the best humans, but may get there in the next few years.
- *Poker* includes not only chance and imperfect information, but also presents the difficulty of recognizing what kind of betting strategy the opponent is using. Current programs play much worse than good human players.
- *Go*, unlike the above games, fits the game-tree model perfectly. However, its game tree is huge because there are hundreds of possible moves at each node. This makes it impossible to search the game tree to any significant depth. Currently, the best available computer programs are ranked below the level of an average amateur.
- Most current *video games* are action-oriented games that emphasize hand-to-eye coordination. However, a few of them (warcraft, command and conquer, civilization, etc.) involve longer-term strategic reasoning. These games incorporate several features not discussed above. For example, one may need to plan actions that have various time durations, which may overlap those of the opponents' moves. Computer-science game-playing research is only just beginning to address such problems, and thus the strategic reasoning capabilities of such computer programs still remain very poor.

CONCLUSION

The biggest successes for adversarial search techniques have been in board games such as chess, checkers, othello, and backgammon. The best computer programs for these games are now as good or better than the best human players. However, the techniques used in most of these programs work rather differently from human thought processes: the programs work by examining as many board positions as possible within the time constraints, often examining many thousands of positions in order to decide which move to make – and in contrast, the best humans examine at most a few dozen positions in order to decide upon their moves. How humans are able to do this is still ill-understood.

Search

Introductory article

Richard E Korf, University of California, Los Angeles, California, USA

CONTENTS

A search is a trial-and-error exploration of alternative solutions to a problem.

INTRODUCTION

Search is a universal problem-solving mechanism in artificial intelligence (AI). In AI problems, the sequence of steps required for solution of a problem are not known *a priori*, but often are determined by a systematic trial-and-error exploration of alternatives. The kinds of problems addressed in this article include single-agent problems and two-player games.

Sliding-tile puzzles, including the 3×3 'eight puzzle' (see Figure 1) and its larger relatives the 4×4 'fifteen puzzle' and 5×5 'twenty-four puzzle', are often used in the AI literature as examples of single-agent problems. The eight puzzle consists of a 3×3 square frame containing eight numbered square tiles, and an empty position called the blank. The legal operators slide any tile that is horizontally or vertically adjacent to the blank into the blank position. The problem is to rearrange the tiles from some random initial configuration into a particular goal configuration.

The sliding-tile puzzles are common test-beds for research in search algorithms, because they are very simple to represent and manipulate, yet finding optimal solutions to larger-sized problems is computationally very expensive. Other well-known examples of single-agent problems include Rubik's cube, theorem proving, the traveling salesman problem, vehicle navigation, and the wiring of VLSI ('very large-scale integrated') circuits. In each case, the task is to find a sequence of operations that map an initial state to a goal state.

The second major class of search problems includes two-player games such as chess, checkers, Othello, go, and backgammon.

First to be described here is the problem-space model on which search algorithms are based. The article then considers brute-force searches, including breadth-first, uniform-cost, depth-first, depth-first iterative-deepening, and bidirectional search. Next, it examines various heuristic searches, including pure heuristic search, the A* algorithm, iterative-deepening A*, and depth-first branch-and-bound. Finally, it considers two-player game searches, including minimax and alpha–beta pruning. The efficiency of these algorithms, in terms of the quality of the solutions they generate, the amount of time they take to execute, and the amount of computer memory they require, are of central concern throughout. Since search is a universal problem-solving method, what limits its applicability is the efficiency with which it can be performed.

THE PROBLEM-SPACE MODEL

A 'problem space' is the environment in which a search takes place. A problem space consists of a set of possible states of the problem, and a set of operators that change the state. For example, in the eight puzzle, the states are the possible permutations of the tiles, and the operators slide a tile into the blank position. A 'problem instance' is a problem space together with an initial state and a goal condition. In the case of the eight puzzle, the initial state would be whatever permutation the puzzle starts in, and the goal condition would be the desired permutation. The problem-solving task is to find a sequence of operators that map the initial state to the goal state.

A 'problem-space graph' is often used to represent a problem space. The states of the space are represented by nodes of the graph, and the operators by edges between nodes. Edges may be undirected or directed, depending on whether their corresponding operators are reversible or not. The task in a single-agent problem is to find a path in the graph from the initial node to a goal node. Figure 1 shows a small part of the problem-space graph for the eight puzzle.

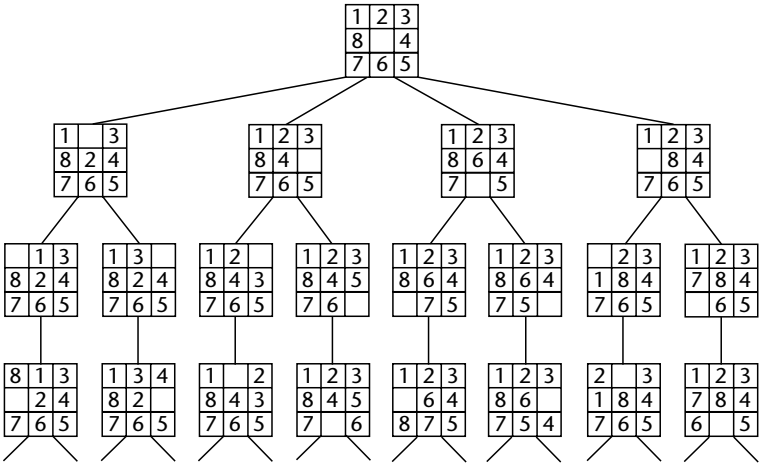

Figure 1. A small fragment of the problem-space graph for the eight puzzle, presented as a search tree.

Although most problem spaces correspond to graphs with more than one path between any pair of nodes, for simplicity they are often represented as trees, where the initial state is the root of the tree. The cost of this simplification is that any state that can be reached by two different paths will be represented by duplicate nodes, increasing the size of the tree. The benefit of a tree is that the absence of cycles simplifies many search algorithms. Here we will restrict our attention to trees, but there exist more general graph versions of most of the algorithms described.

One feature that distinguishes AI search problems from many other graph-searching problems is the size of the graphs involved. For example, the entire chess graph is estimated to contain over 10^{40} nodes. Even a simple problem like the twenty-four puzzle contains almost 10^{25} nodes. Therefore, the problem-space graphs of AI problems are never represented by listing each state, but rather by specifying an initial state and a set of operators to generate new states from existing states. Furthermore, the size of an AI problem is rarely expressed as the number of nodes in its problem-space graph. Rather, the two parameters of a search tree that are used to determine the efficiency of search algorithms are its 'branching factor' and its 'solution depth'. The branching factor is the average number of children of a node. For example, the average branching factor of the eight puzzle search tree is $\sqrt{3}$, or about 1.732, assuming that the parent of a node is not included as one of its children. The solution depth of a problem instance is the length of a shortest path from the initial state to a goal state, or the length of a shortest sequence of operators that solves the problem. Thus, if the goal were in the bottom row of Figure 1, the depth of the problem instance represented by the initial state at the root would be three.

BRUTE-FORCE SEARCH

The most general search algorithms are 'brute-force' searches, which do not require any domain-specific knowledge. All that is required for a brute-force search is a specification of the state space, the initial state, and the goal condition. The most important brute-force techniques are breadth-first, uniform-cost, depth-first, depth-first iterative-deepening, and bidirectional search.

In the descriptions below, to 'generate' a node means to create the data structure corresponding to that node, and to 'expand' a node means to generate all the children of that node.

Breadth-First Search

Breadth-first search expands nodes in order of their distance from the root, generating one level of the tree at a time until a solution is found (see Figure 2). If we take a family tree as an analogy, a breadth-first search would expand all the individuals in one generation before expanding the individuals of the next generation. It is most easily implemented by maintaining a queue of nodes, initially containing just the root, and repeatedly removing the node at the head of the queue, expanding it, and adding its children to the tail of the queue.

Since it never generates a node in the tree until all the nodes at shallower levels have been generated, breadth-first search always finds a shortest path to a goal. Assuming each node can be generated in

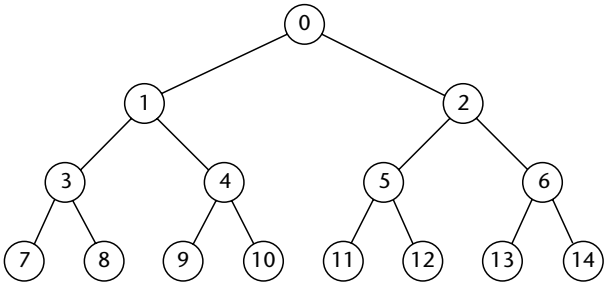

Figure 2. Order of node generation for breadth-first search.

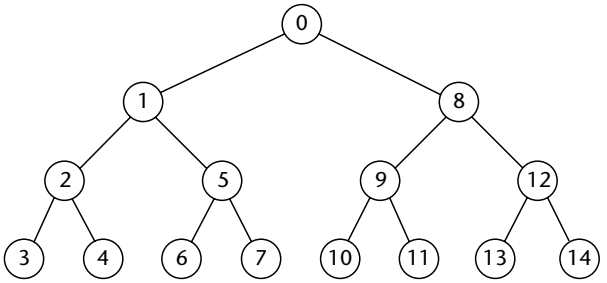

Figure 3. Order of node generation for depth-first search.

constant time, the amount of time used by breadth-first search is proportional to the number of nodes generated, which is a function of the branching factor b and the solution depth d. Since the number of nodes at level d is b^d, the total number of nodes generated in the worst case is $b + b^2 + b^3 + \ldots + b^d$, and the asymptotic time complexity of breadth-first search is $O(b^d)$.

The main disadvantage of breadth-first search is its memory requirement. Since each level of the tree must be saved in order to generate the next level, and assuming the amount of memory is proportional to the number of nodes stored, the space complexity of breadth-first search is also $O(b^d)$. As a result, breadth-first search is severely space-limited in practice, and will exhaust the memory available on typical computers in a matter of minutes.

Uniform-Cost Search

In some cases, a cost can be associated with each edge of a problem-space graph. For example, if the graph represents a network of roads, then the cost of an edge may be the distance of the corresponding road segment. In such cases, uniform-cost search, also known as Dijkstra's single-source shortest-path algorithm, is often used. Instead of expanding nodes in order of their depth in the tree, uniform-cost search expands nodes in order of their total cost, where the total cost of a node is the sum of the edge costs from the root to the node. At each step, uniform-cost search expands next a node whose total cost is lowest, among all nodes generated but not yet expanded.

Whenever a node is chosen for expansion by uniform-cost search, a lowest-cost path to that node has been found. The worst-case time complexity of uniform-cost search is $O(b^{c/m})$, where c is the cost of an optimal solution and m is the minimum edge cost. Unfortunately, uniform-cost search suffers the same memory limitation as breadth-first search. Indeed, if all edges have the same cost, then uniform-cost search reduces to breadth-first search.

Depth-First Search

Depth-first search overcomes the space limitation of breadth-first search by always generating next a child of the deepest unexpanded node (see Figure 3). Returning to our family tree analogy, depth-first search expands a complete line of descendents, from parent to child to grandchild and so on, before backing up and generating the next line. After all the descendents of one child are generated, then the next child is generated.

Both breadth-first and depth-first search can be implemented using a list of unexpanded nodes; breadth-first search manages the list as a 'first-in, first-out' queue, whereas depth-first search manages the list as a 'last-in, first-out' stack. More commonly, depth-first search is implemented recursively, with the recursion stack taking the place of an explicit node stack.

The advantage of depth-first search is that its space requirement is only linear in the maximum search depth, rather than exponential as in breadth-first search. The reason is that the algorithm only needs to store a stack of nodes on the path from the root to the current node. The time complexity of a depth-first search to depth d is $O(b^d)$, as in breadth-first search, since it generates the same set of nodes albeit in a different order. Thus, in practice, depth-first search is time-limited rather than space-limited.

The disadvantage of depth-first search is that it may not terminate on an infinite tree, but simply go down one path forever. Even a finite graph can generate an infinite tree. The usual solution to this problem is to impose a cut-off depth on the search. Although the ideal cut-off is the solution depth d, this value is rarely known in advance of actually solving the problem. If the chosen cut-off depth is less than d, the algorithm will fail

to find a solution, whereas if the cut-off depth is greater than d, a large price is paid in execution time, and the first solution found may not be an optimal one.

Depth-First Iterative Deepening

Depth-first iterative deepening (DFID) combines the best features of breadth-first and depth-first search. DFID first performs a depth-first search to depth one, then performs a depth-first search to depth two, and continues to perform depth-first searches to successively greater depths, until a solution is found (see Figure 4).

Since it never generates a node until all shallower nodes have been generated, the first solution found by DFID is guaranteed to be a shortest path. Furthermore, since at any given point it is executing a depth-first search, saving only a stack of nodes, and the algorithm terminates when it finds a solution at depth d, the space complexity of DFID is only $O(d)$.

Although it may appear that DFID wastes a great deal of time in the iterations prior to the one that finds a solution, this extra work is usually insignificant. To see this, note that the number of nodes at depth d is b^d, and each of these nodes is generated just once, during the final iteration. The number of nodes at depth $d-1$ is b^{d-1}, and each of these is generated twice, once during the final iteration and once during the penultimate iteration. In general, the number of nodes generated by DFID is $b^d + 2b^{d-1} + 3b^{d-2} + \ldots + db$. This is asymptotically $O(b^d)$ if b is greater than one, since for large values of d the lower-order terms become insignificant. In other words, most of the work goes into the final iteration, and the cost of the previous iterations is relatively small. The ratio of the number of nodes generated by DFID to the number generated by breadth-first search on a tree is approximately $b/(b-1)$. In fact, DFID is asymptotically optimal in terms of time and space among all brute-force shortest-path algorithms on a tree.

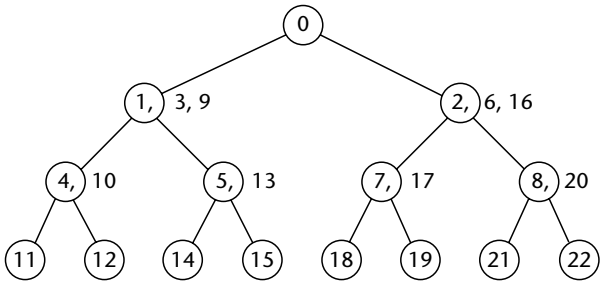

Figure 4. Order of node generation for depth-first iterative deepening.

If the edge costs vary, then one can run an iterative-deepening version of uniform-cost search, where the depth cut-off is replaced by a cut-off on the total cost of a node. At the end of each iteration, the threshold for the next iteration is set to the minimum total cost of all nodes generated but not expanded on the iteration just completed.

In a tree, there is only one path from the root to any given node. In more general graphs, however, such as a network of roads, there is often more than one path between a given pair of nodes. In that case, breadth-first search may be much more efficient than any depth-first search. The reason is that a breadth-first search can detect multiple paths to the same state, eliminating the duplicate paths, whereas a depth-first search cannot. Thus, the complexity of breadth-first search grows only as the number of nodes at a given depth, while the complexity of depth-first search grows as the number of paths of a given length. For example, in a square grid, the number of nodes within a radius r of the center is $O(r^2)$, whereas the number of paths of length r is $O(3^r)$, since there are three children of every node, not counting its parent. Thus, in a graph with a large number of such multiple paths, breadth-first search is preferable to depth-first search, if sufficient memory is available.

Bidirectional Search

Bidirectional search is a brute-force algorithm that requires an explicit goal state, not just a test for a goal condition. The main idea is to simultaneously search forward from the initial state and backward from the goal state until the two search frontiers meet. The path from the initial state is then concatenated with the inverse of the path from the goal state to form the complete solution path.

Bidirectional search guarantees optimal solutions. Assuming that the comparisons for identifying a common state between the two frontiers can be done in constant time per node, by hashing for example, the time complexity of bidirectional search is $O(b^{d/2})$ since each search need only proceed to half the solution depth. Since at least one of the searches must be breadth-first in order to find a common state, the space complexity of bidirectional search is also $O(b^{d/2})$. Thus, bidirectional search is space-limited in practice.

Combinatorial Explosion

The problem with all brute-force search algorithms is that their time complexities grow exponentially with problem size. This phenomenon is called

combinatorial explosion, and it severely limits the size of problems that can be solved with these techniques. For example, while the eight puzzle, with about 10^5 states, is easily solved by brute-force search, the fifteen puzzle contains over 10^{13} states, and cannot be solved with brute-force techniques. Development of faster machines will not have a significant impact on this problem: the 5×5 twenty-four puzzle contains almost 10^{25} states, for example.

HEURISTIC SEARCH

In order to solve larger problems, domain-specific knowledge must be added to improve search efficiency. The term 'heuristic search' has both a general meaning and a more specialized technical meaning. In a general sense, the term 'heuristic' is used for any advice that is often effective, but isn't guaranteed to work in every case. Within the heuristic search literature, however, the term usually refers to a 'heuristic evaluation function'.

Heuristic Evaluation Functions

In a single-agent problem, a heuristic evaluation function estimates the cost of an optimal path between a pair of states. For example, Euclidean or 'airline' distance is an estimate of the highway distance between a pair of locations. A common heuristic function for the sliding-tile puzzles is called Manhattan distance. It is computed by counting the number of moves along the grid that each tile is displaced from its goal position, and summing these values over all tiles. For a fixed goal state, a heuristic evaluation is a function that estimates the 'distance' from any given node to the given goal state.

The key properties of a heuristic evaluation function are that it estimate actual cost, and that it be inexpensive to compute. For example, the Euclidean distance between a pair of points can be computed in constant time. The Manhattan distance between a pair of states in a sliding-tile puzzle can be computed in time proportional to the number of tiles.

In addition, most common heuristic functions are lower bounds on actual cost. A heuristic function that is guaranteed to be less than or equal to the quantity it is estimating is said to be 'admissible'. For example, the airline distance is a lower bound on the road distance between two points, since the shortest path between a pair of points is a straight line. Similarly, Manhattan distance is a lower bound on the actual number of moves necessary to solve a sliding-tile puzzle instance, since every tile must move at least its Manhattan distance to its goal position, and each move only moves one tile.

A number of algorithms make use of heuristic functions. These include pure heuristic search, the A* algorithm, iterative-deepening A*, and depth-first branch-and-bound. Heuristic information can also be employed in bidirectional search.

Pure Heuristic Search

The simplest of these algorithms, pure heuristic search, expands nodes in order of their heuristic values. It maintains a 'closed list' of those nodes that have already been expanded, and an 'open list' of those nodes that have been generated but not yet expanded. The algorithm begins with just the initial state on the open list. At each cycle, a node on the open list with the minimum heuristic value is expanded, generating all of its children, and then placed on the closed list. The heuristic function is applied to the children, and they are placed on the open list in order of their heuristic values. The algorithm continues until a goal node is reached.

In a graph with cycles, multiple paths will be found to the same node, and the first path found may not be the shortest. When a shorter path to an open node is found, it is saved and the longer path discarded. When a shorter path to a closed node is found, the node is moved to the open list and the shorter path is saved. The main disadvantage of pure heuristic search is that it is not guaranteed to find optimal solutions.

Breadth-first search, uniform-cost search, and pure heuristic search are all special cases of a more general class of algorithm called 'best-first search'. In each cycle of a best-first search, a node that is best according to some cost function is expanded. These best-first algorithms differ only in their cost functions: the depth for breadth-first search, the total cost for uniform-cost search, and the heuristic function for pure heuristic search.

The A* Algorithm

The A* algorithm combines features of uniform-cost search and pure heuristic search to efficiently compute optimal solutions. A* is a best-first search in which the cost associated with a node n is $f(n) = g(n) + h(n)$, where $g(n)$ is the cost of the path from the initial state to node n, and $h(n)$ is the heuristic estimate of the cost of a path from node n to a goal. Thus, $f(n)$ estimates the lowest total cost of any solution path passing through node n. At each cycle, a node with lowest f value is expanded. Ties

among nodes of equal f value are broken in favor of nodes with lower h values. The algorithm terminates when a goal node is chosen for expansion.

A* finds an optimal path to a goal if the heuristic function h is admissible, meaning that it never overestimates actual cost. For example, since Manhattan distance never overestimates the actual number of moves required in the sliding-tile puzzles, A* using this evaluation function will find optimal solutions to these problems. In addition, A* makes the most efficient use of a given heuristic function in the following sense: among all shortest-path algorithms using a given heuristic function, A* expands the fewest number of nodes.

The main disadvantage of A*, and indeed of any best-first search, is its memory requirement. Since the open and closed lists must be saved, A* is severely space-limited in practice, and is typically no more practical than breadth-first search. For example, while it can be run successfully on the eight puzzle, it quickly exhausts available memory on the fifteen puzzle.

Iterative-Deepening A*

Just as depth-first iterative deepening solved the space problem of breadth-first search, iterative-deepening A* (IDA*) solves the space problem of A*, without sacrificing solution optimality. Each iteration of the algorithm is a depth-first search that keeps track of the cost, $f(n) = g(n) + h(n)$, of each node generated. When the cost of the last node on a path exceeds a threshold for that iteration, the path is pruned, and the search backtracks before continuing. The cost threshold is initialized to the heuristic estimate of the initial state, and in each successive iteration is increased to the total cost of the lowest-cost node that was pruned during the previous iteration. The algorithm terminates when a goal state is reached whose cost does not exceed the current threshold.

Since IDA* performs a series of depth-first searches, its memory requirement is linear in the maximum search depth. Furthermore if the heuristic function is admissible, IDA* finds an optimal solution. Finally, by an argument similar to that presented for DFID, IDA* expands the same number of nodes, asymptotically, as A* on a tree, provided that the number of nodes grows exponentially with the solution cost. These facts, together with the optimality of A*, imply that IDA* is asymptotically optimal in time and space over all heuristic search algorithms that find optimal solutions on a tree. In addition, IDA* is much easier to implement, and often runs faster, than A*, since it does not incur the overhead of managing the open and closed lists.

Depth-First Branch-and-Bound

For many problems, a maximum search depth is known in advance, or the search tree is finite. For example, the traveling salesman problem (TSP) is to visit each of a set of cities once, and return to the starting city, in a tour of shortest total distance. The natural problem space for this problem consists of a tree where the root node represents the starting city, the children of the root represent all the cities that could be visited first, the nodes at the next level represent all the cities that could be visited second, and so on. In this tree, the maximum depth is the number of cities, and all solutions occur at this depth. In such a space, a simple depth-first search guarantees finding an optimal solution using space that is only linear in the number of cities.

Depth-first branch-and-bound (DFBB) makes this search more efficient by keeping track of the best solution found so far. Since the cost of a partial tour is the sum of the costs of the edges traveled on it, whenever a partial tour is found whose cost equals or exceeds the cost of the best complete tour found so far, the branch representing the partial tour can be pruned, since all its descendents must have equal or greater cost. Whenever a lower-cost complete tour is found, the cost of the 'best' tour is amended to this lower cost. To increase the pruning, an admissible heuristic function, such as the cost of the minimum spanning tree of the remaining unvisited cities, can be added to the cost so far of a partial tour. Finally, by carefully ordering the children of a given node from smallest to largest estimated total cost, a lower-cost solution can be found more quickly, further improving pruning efficiency.

IDA* and DFBB exhibit complementary behavior. Both are guaranteed to return an optimal solution using only linear space, assuming that their cost functions are admissible. In IDA*, the cost threshold is a lower bound on the optimal solution cost, and increases in each iteration until it reaches the optimal cost. In DFBB, the cost of the best solution found so far is an upper bound on the optimal solution cost, and decreases until it reaches the optimal cost. While IDA* never expands a node whose cost exceeds the optimal cost, its overhead consists of expanding some nodes more than once. While DFBB never expands a node more than once, its overhead consists of expanding some nodes whose costs exceed the

optimal cost. For problems whose search trees are of bounded depth, or for which it is easy to construct a good solution, such as the traveling salesman problem, DFBB is the algorithm of choice for finding an optimal solution. For problems with infinite search trees, or for which it is difficult to construct a low-cost solution, such as the sliding-tile puzzles or Rubik's cube, IDA* is the best choice. For example, using appropriate admissible heuristic functions, IDA* can optimally solve random instances of the twenty-four puzzle and Rubik's cube.

TWO-PLAYER GAMES

A second major application of heuristic search algorithms in AI is to two-player games. One of the original challenges of AI was to build a program that could play chess at the level of the best human players. In May 1997, a computer called Deep Blue, evaluating about 200 million chess positions per second, defeated Gary Kasparov, the world champion, in a six-game tournament.

Minimax Search

The standard algorithm for two-player perfect-information games, such as chess, checkers or Othello, is minimax search with heuristic static evaluation. The algorithm searches forward to a fixed depth in the game tree, limited by the amount of time available per move. At this 'search horizon', a heuristic function is applied to the frontier nodes. In a two-player game, a heuristic evaluation is a function that takes a board position and returns a number that indicates how favorable the position is for one player relative to the other. For example, a simple heuristic evaluator for chess might count the total number of pieces on the board for one player, appropriately weighted by their relative strengths, and subtract the weighted sum of the opponent's pieces. Thus, large positive values would correspond to strong positions for one player, called Max, whereas large negative values would represent advantageous situations for the opponent, called Min.

Given the heuristic evaluations of the frontier nodes, values for the interior nodes in the tree are recursively computed according to the 'minimax rule'. The value of a node where it is Max's turn to move is the maximum of the values of its children, while the value of a node where Min is to move is the minimum of its children's values. Thus, at alternate levels of the tree, the minimum or the maximum values of the children are backed up. This continues until the values of the immediate children of the current position are computed, at which point a move is made to the child with the maximum or minimum value, depending on whose turn it is to move. Figure 5 shows an example of a completely evaluated minimax tree.

Alpha–Beta Pruning

One of the most elegant of all AI search algorithms is alpha–beta pruning. The idea, similar to branch-and-bound, is that the minimax value of the root of a game tree can be determined without examining all the nodes at the search frontier.

Figure 6 shows an example of alpha–beta pruning. At the square nodes Max is to move, while at the circular nodes it is Min's turn. The search proceeds depth first to minimize the memory required, and evaluates a node only

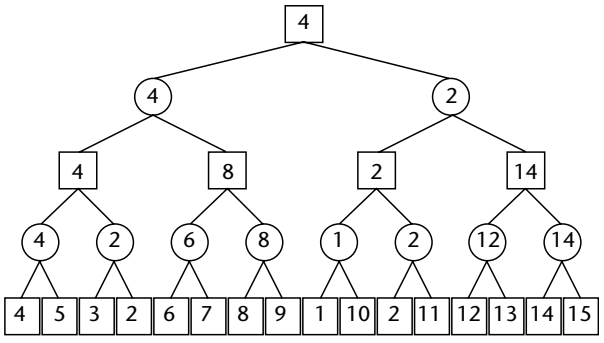

Figure 5. A minimax tree. At the square nodes it is Max to move; at the circular nodes, it is Min to move.

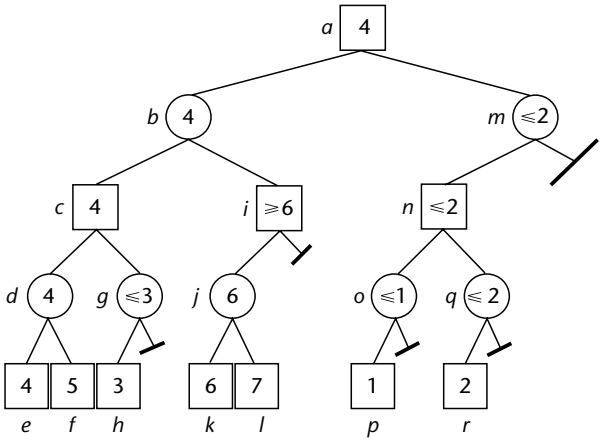

Figure 6. Alpha–beta pruning example.

when necessary. First, nodes e and f are statically evaluated as 4 and 5 respectively, and their minimum value is backed up to their parent node d. Node h is then evaluated as 3. The value of its parent node g must therefore be less than or equal to 3, since it is the minimum of 3 and the unknown value of its right child. The value of node c must then be 4, because it is the maximum of 4 and a value that is less than or equal to 3. Since we have determined the minimax value of node c, we do not need to evaluate or even generate the sibling of node h.

Similarly, after statically evaluating nodes k and l as 6 and 7 respectively, the backed-up value of their parent node j is the minimum of these values. This tells us that the minimax value of node i must be greater than or equal to 6, since it is the maximum of 6 and the unknown value of its right child. Since the value of node b is the minimum of 4 and a value that is greater than or equal to 6, it must be 4, and we have achieved another cut-off.

The right half of the tree shows an example of 'deep pruning'. After evaluating the left half of the tree, we know that the value of the root node a is greater than or equal to 4, the minimax value of node b. Once node p is evaluated as 1, the value of its parent node o must be less than or equal to 1. Since the value of the root is greater than or equal to 4, the value of node o cannot propagate to the root, and hence we need not generate the sibling of node p. A similar situation exists after the evaluation of node r as 2. At that point, the value of node o is less than or equal to 1 and the value of node q is less than or equal to 2, and hence the value of node n, which is the maximum of the values of nodes o and p, must be less than or equal to 2. Furthermore, since the value of node m is the minimum of the values of node n and its sibling, and node n has a value less than or equal to 2, the value of node m must also be less than or equal to 2. This inference allows the sibling of node n to be pruned, since the value of the root node a is greater than or equal to 4. Thus, we have computed the minimax value of the root of the tree to be 4, by generating only seven of sixteen leaf nodes.

Since alpha–beta pruning performs a minimax search while pruning much of the tree, its effect is to allow a deeper search with the same amount of computation. How much does alpha–beta improve performance? The best way to characterize the efficiency of a pruning algorithm is in terms of its 'effective branching factor'. The effective branching factor is the dth root of the number of frontier nodes that must be evaluated in a search to depth d, in the limit of large d.

The efficiency of alpha–beta pruning depends on the order in which nodes are encountered at the search frontier. In the worst case, alpha–beta will not perform any cut-offs at all. In that case, all frontier nodes must be evaluated and the effective branching factor is b, the brute-force branching factor.

On the other hand, in the best case of perfect ordering, every possible cut-off is realized. In that case, the effective branching factor is reduced from b to $b^{1/2}$, the square root of the brute-force branching factor. In other words, in the best case, one can search twice as deep with alpha–beta pruning as without, using the same amount of computation.

In between worst-possible ordering and perfect ordering is random ordering, which is the average case. Under random ordering of the frontier nodes, alpha–beta pruning reduces the effective branching factor to approximately $b^{3/4}$. This means that one can search 4/3 as deep with alpha–beta; that is, one can achieve roughly a 33% improvement in search depth.

In practice, however, the effective branching factor of alpha–beta is closer to the best case of $b^{1/2}$ because of 'node ordering'. Instead of generating the tree from left to right, we can reorder the tree based on static evaluations of the interior nodes. In other words, the children of Max nodes are expanded in decreasing order of their static values, while the children of Min nodes are expanded in increasing order of their static values.

CONCLUSION

We have examined search algorithms for two different classes of problems. In the case of single-agent problems, the task is to find a sequence of operators that map an initial state to a desired goal state. Much of the work in this area has focused on finding optimal solutions to such problems, often making use of admissible heuristic functions to speed up the search without sacrificing solution optimality. In the case of two-player games, finding optimal solutions is infeasible, and research has focused on algorithms for making the best possible move decisions given a limited amount of computing time. While these two types of problem are different, similar ideas, such as brute-force searches and heuristic evaluation functions, can be applied to both.

CONTENTS

A semantic network is a graphic notation for representing knowledge in patterns of interconnected nodes and arcs.

INTRODUCTION

A *semantic network* or *net* is a graphic notation for representing knowledge in patterns of interconnected nodes and arcs. Computer implementations of semantic networks were first developed for artificial intelligence and machine translation, but earlier versions have long been used in philosophy, psychology, and linguistics.

What is common to all semantic networks is a declarative graphic representation that can be used either to represent knowledge or to support automated systems for reasoning about knowledge. Some versions are highly informal, but other versions are formally defined systems of logic. The following are six of the most common kinds of semantic network, each of which is discussed in detail in this article:

1. *Definitional networks* emphasize the *subtype* or *is-a* relation between a concept type and a newly defined subtype. The resulting network, also called a *generalization* or *subsumption* hierarchy, supports the rule of *inheritance* for copying properties defined for a supertype to all of its subtypes. Since definitions are true by definition, the information in these networks is often assumed to be necessarily true.
2. *Assertional networks* are designed to assert propositions. Unlike definitional networks, the information in an assertional network is assumed to be contingently true, unless it is explicitly marked with a modal operator. Some assertional networks have been proposed as models of the *conceptual structures* underlying natural language semantics.
3. *Implicational networks* use implication as the primary relation for connecting nodes. They may be used to represent patterns of beliefs, causality, or inferences.
4. *Executable networks* include some mechanism, such as marker passing or attached procedures, which can perform inferences, pass messages, or search for patterns and associations.
5. *Learning networks* build or extend their representations by acquiring knowledge from examples. The new knowledge may change the old network by adding and deleting nodes and arcs or by modifying numerical values, called *weights*, associated with the nodes and arcs.
6. *Hybrid networks* combine two or more of the previous techniques, either in a single network or in separate, but closely interacting, networks.

Some of the networks have been explicitly designed to implement hypotheses about human cognitive mechanisms, while others have been designed primarily for computer efficiency. Sometimes, computational reasons may lead to the same conclusions as psychological evidence.

Network notations and linear notations are both capable of expressing equivalent information, but certain representational mechanisms are better suited to one form or the other. Since the boundary lines are vague, it is impossible to give necessary and sufficient conditions that include all semantic networks while excluding other systems that are not usually called semantic networks. The last section of this article discusses the syntactic mechanisms used to express information in network notations and compares them to the corresponding mechanisms used in linear notations.

DEFINITIONAL NETWORKS

The oldest known semantic network was drawn in the third century AD by the Greek philosopher Porphyry in his commentary on Aristotle's categories. Porphyry used it to illustrate Aristotle's method of defining categories by specifying the *genus* or general type and the *differentiae* that distinguish different subtypes of the same supertype. Figure 1 shows a version of the *Tree of Porphyry*, as it was drawn by the logician Peter of Spain circa 1329. It illustrates

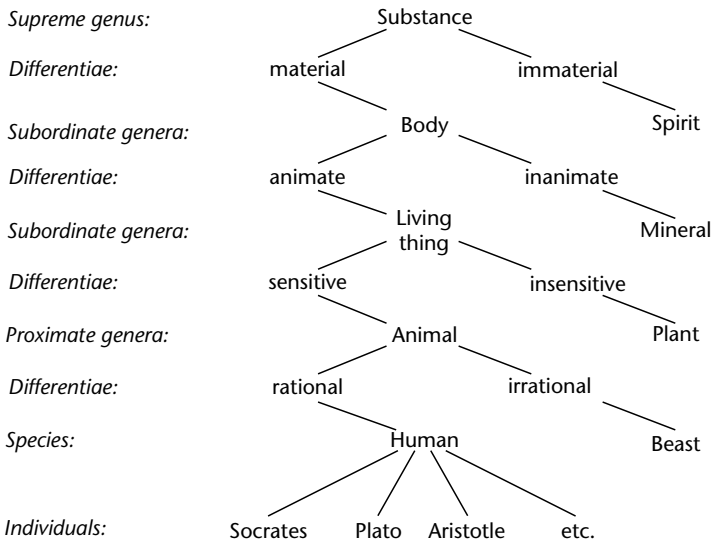

Figure 1. Tree of Porphyry, as drawn by Peter of Spain (1329).

the categories under Substance, which is called the *supreme genus* or the most general category.

Despite its age, the Tree of Porphyry represents the common core of all modern hierarchies that are used for defining concept types. In Figure 1, the genus Substance with the differentia material is Body and with the differentia immaterial is Spirit. The modern rule of *inheritance* is a special case of the Aristotelian syllogisms, which specify the conditions for inheriting properties from supertypes to subtypes: Living Thing inherits material Substance from Body and adds the differentia animate; Human inherits sensitive animate material Substance and adds the differentia rational. Aristotle, Porphyry, and the medieval logicians also distinguished the categories or *universals* from the individual instances or *particulars*, which are listed at the bottom of Figure 1. Aristotle's methods of definition and reasoning are still used in artificial intelligence, object-oriented programming languages, and every dictionary from the earliest days to the present.

The first implementations of semantic networks were used to define concept types and patterns of relations for machine translation systems. Silvio Ceccato (1961) developed *correlational nets*, which were based on 56 different relations including subtype, instance, part-whole, case relations, kinship relations, and various kinds of attributes. He used the correlations as patterns for guiding a parser and resolving syntactic ambiguities. Margaret Masterman's system at Cambridge University (1961) was the first to be called a semantic network. She developed a list of 100 primitive concept types such as Folk, Stuff, Thing, Do, and Be. In terms of those primitives, her group defined a conceptual dictionary of 15 000 entries. She organized the concept types into a lattice, which permits inheritance from multiple supertypes.

Among current systems, the *description logics* include the features of the Tree of Porphyry as a minimum, but they may also add various extensions. They are derived from an approach proposed by Woods (1975) and implemented by Brachman (1979) in a system called Knowledge Language One (KL-ONE). As an example, Figure 2 shows a KL-ONE network that defines the concepts Truck and TrailerTruck as subtypes of Vehicle.

Figure 2 has nine ovals for concept nodes and nine arrows which represent different kinds of links. The white ovals represent *generic concepts* for the types, as distinguished from the shaded oval, which is an *individual concept* for the instance 18. The oval marked with an asterisk* indicates that Integer is a built-in or primitive type. The concepts Truck and TrailerTruck are defined in Figure 2, but Vehicle, Trailer, WtMeasure, and VolMeasure would have to be defined by other KL-ONE diagrams.

The double-line arrows represent subtype–supertype links from TrailerTruck to Truck and from Truck to Vehicle. The arrows with a squared circle in the middle represent *roles*. The Truck node has four roles labeled UnloadedWt, MaxGrossWt, CargoCapacity, and NumberOfWheels. The TrailerTruck node has two roles, one labeled HasPart and one that restricts the NumberOfWheels role of Truck to the value 18. The notation *v/r* at the target

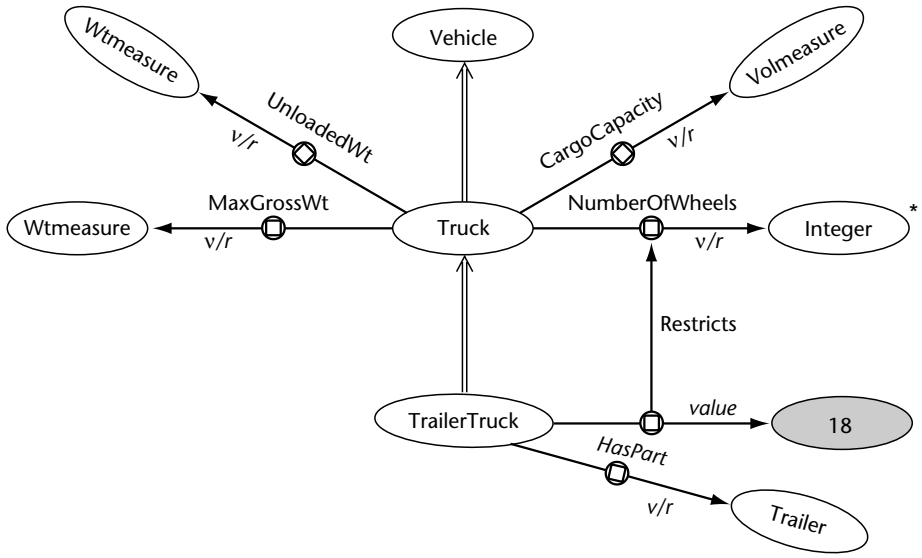

Figure 2. Truck and TrailerTruck concepts defined in KL-ONE.

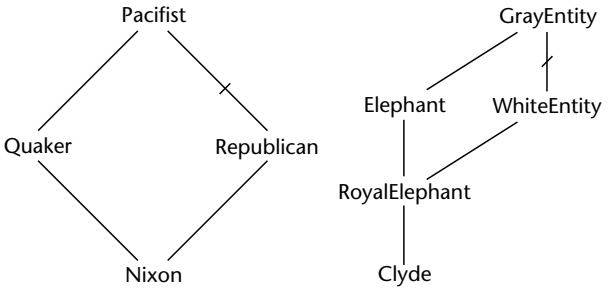

Figure 3. Conflicting defaults in a definitional network.

end of the role arrows indicates *value restrictions* or type constraints on the permissible values for those roles.

The Tree of Porphyry, KL-ONE, and many versions of description logics are subsets of classical first-order logic (FOL). They belong to the class of *monotonic logics*, in which new information monotonically increases the number of provable theorems, and none of the old information can ever be deleted or modified. Some versions of description logics support *non-monotonic reasoning*, which allows *default rules* to add optional information and *canceling rules* to block inherited information. Such systems can be useful for many applications, but they can also create problems of *conflicting defaults*, as illustrated in Figure 3.

The *Nixon diamond* on the left shows a conflict caused by inheritance from two different supertypes: by default, Quakers are pacifists, and Republicans are not. Does Nixon inherit pacifism along the Quaker path, or is it blocked by the negation on the Republican path? On the right is another diamond in which the subtype RoyalElephant cancels the property of being gray, which is the default color for ordinary elephants. If Clyde is first mentioned as an elephant, his default color would be gray, but later information that he is a RoyalElephant should cause the previous information to be retracted. To resolve such conflicts, many developers have rejected local defaults in favor of more systematic methods of *belief revision* that can guarantee global consistency.

Although the basic methods of description logics are as old as Aristotle, they remain a vital part of many versions of semantic networks and other kinds of systems. Much of the ongoing research on description logics has been devoted to increasing their expressive power while remaining within an efficiently computable subset of logic. Two recent description logics are DAML and OIL, which are intended for representing knowledge in the *semantic web* – a giant semantic network that spans the entire Internet.

ASSERTIONAL NETWORKS

Gottlob Frege (1879) developed a tree notation for the first complete version of first-order logic – his *Begriffsschrift* or *concept writing*. Charles Sanders Peirce (1880, 1885) independently developed an algebraic notation which, with a change of symbols by Peano, has become the modern notation for predicate calculus. Although Peirce invented the algebraic notation, he was never fully satisfied with it. As early as 1882, he was searching for a

graphic notation, similar to the notations used in organic chemistry, that would more clearly show 'the atoms and molecules of logic'. Figure 4 shows one of his *relational graphs*, which represents the sentence '*A Stagirite teacher of a Macedonian conqueror of the world is a disciple and an opponent of a philosopher admired by Church Fathers*.'

Figure 4 contains three branching *lines of identity*, each of which corresponds to an existentially quantified variable in the algebraic notation. The words and phrases attached to those lines correspond to the relations or predicates in the algebraic notation. With that correspondence, Figure 4 can be translated to the following formula in predicate calculus:

$$(\exists x)(\exists y)(\exists z)(\text{isStagirite}(x) \wedge \text{teaches}(x,y) \wedge \text{isMacedonian}(y) \wedge \text{conquersTheWorld}(y) \wedge \text{isDiscipleOf}(y,z) \wedge \text{isOpponentOf}(y,z) \wedge \text{isAdmiredByChurchFathers}(z))$$

As this formula illustrates, a relational graph represents only two logical operators: the conjunction $\wedge$ and the existential quantifier $\exists$. Other operators, such as negation $\sim$, disjunction $\vee$, implication $\supset$, and the universal quantifier $\forall$, are more difficult to express because they require some method for demarcating the *scope* – that part of the formula that is governed by the operator. The problem of representing scope, which Peirce faced in his graphs of 1882, also plagued the early semantic networks used in artificial intelligence 80 years later.

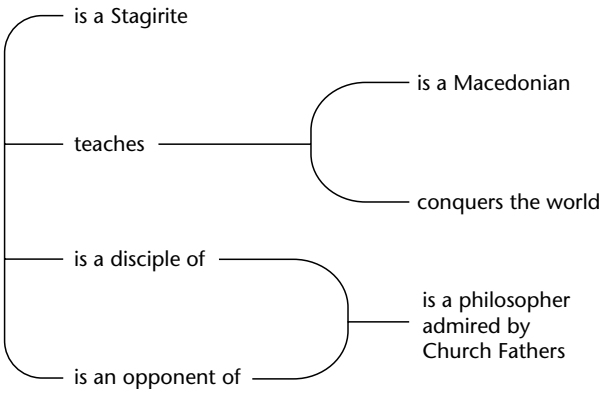

Figure 4. A relational graph.

In 1897, Peirce made a simple but brilliant discovery that solved all the problems at once: he introduced an oval that could enclose and negate an arbitrarily large graph or subgraph. Then combinations of ovals with conjunction and the existential quantifier could express all the logical operators used in the algebraic notation. That innovation transformed the relational graphs into the system of *existential graphs* (EG), which Peirce called 'the logic of the future'. The implication $\supset$, for example, could be represented with a nest of two ovals, since $(p \supset q)$ is equivalent to $\sim(p \wedge \sim q)$. At the left of Figure 5 is an existential graph for the sentence '*If a farmer owns a donkey, then he beats it*.'

The outer oval of Figure 5 is the antecedent or *if* part, which contains *farmer*, linked by a line representing $(\exists x)$ to *owns*, which is linked by a line representing $(\exists y)$ to *donkey*. The subgraph in the outer oval may be read *If a farmer x owns a donkey y*. The lines x and y are extended into the inner oval, which represents the consequent, *then x beats y*. Figure 5 may be translated to the following algebraic formula:

$$\sim (\exists x)(\exists y)(\text{farmer}(x) \wedge \text{donkey}(y) \wedge \text{owns}(x,y) \wedge \sim \text{beats}(x,y))$$

This formula is equivalent to

$$(\forall x)(\forall y)((\text{farmer}(x) \wedge \text{donkey}(y) \wedge \text{owns}(x,y)) \supset \text{beats}(x,y))$$

For comparison, the diagram on the right of Figure 5 is a *discourse representation structure* (DRS), which Hans Kamp (Kamp and Reyle, 1993) invented to represent natural language semantics. Instead of nested ovals, Kamp used boxes linked by arrows; and instead of lines of identity, Kamp used variables. But the logical structures are formally equivalent, and the same techniques for

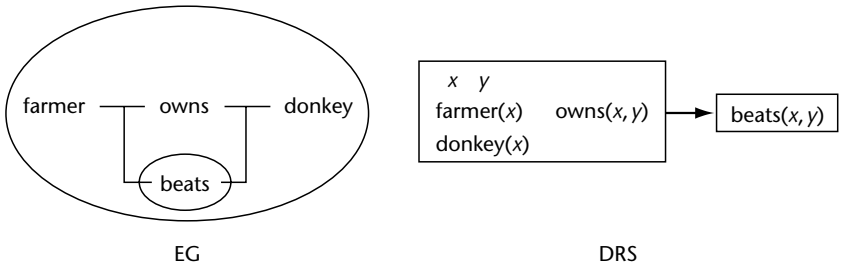

Figure 5. EG and DRS for 'If a farmer owns a donkey, then he beats it.'

representing logic in natural language can be adapted to either notation.

In linguistics, Lucien Tesnière (1959) developed graph notations for his system of *dependency grammar*. Figure 6 shows one of his graphs for the sentence '*L'autre jour, au fond d'un vallon, un serpent piqua Jean Fréron*' (The other day, at the bottom of a valley, a snake stung Jean Fréron). At the top is the verb *piqua* (stung), from which the words that depend directly on the verb are hanging: the subject (*serpent*), the object (*Jean*), and two prepositional phrases. The bull's-eye symbol indicates an implicit preposition (*à*). Every word other than *piqua* is hanging below some word on which it depends.

Tesnière has had a major influence on linguistic theories that place more emphasis on semantics than on syntax. The dependency theories have also been strongly influenced by *case grammar* (Fillmore, 1968), which provides a convenient set of labels for the arcs of the graphs.

Roger Schank adopted the dependency approach, but shifted the emphasis to concepts rather than words (Schank, 1975). Figure 7 shows a *conceptual dependency graph* for the sentence '*A dog is greedily eating a bone*.' Instead of Tesnière's tree notation, Schank used different kinds of arrows for different relations, such as ⇔ for the agent–verb relation or an arrow marked with *o* for object. He replaced the verb *eat* with one of his primitive acts *ingest*; he replaced adverbs like *greedily* with adjective forms like *greedy*; and he added the linked arrows marked with *d* for direction to show that the bone goes from some unspecified place into the dog (the subscript 1 indicates that the bone went into the same thing that ingested it). Conceptual dependencies were primarily suited to representing information at the sentence level, but Schank and his colleagues later developed notations for representing larger structures, in which the sentence-level dependencies occurred as nested substructures. To learn or discover the larger structures automatically, *case-based reasoning* has been used to search for commonly occurring patterns among the lower-level conceptual dependencies (Schank *et al*., 1994).

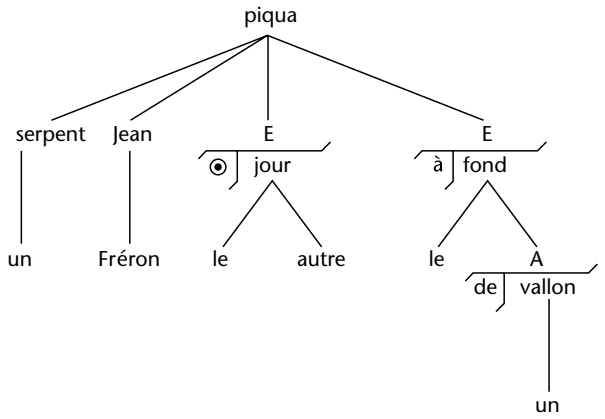

Figure 6. A dependency graph in Tesnière's notation.

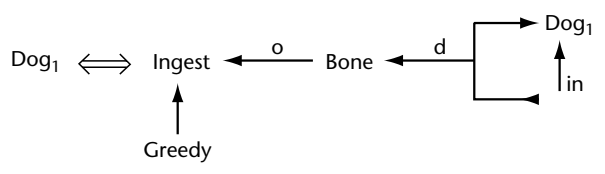

Figure 7. Schank's notation for conceptual dependencies.

Logically, Tesnière's dependency graphs have the same expressive power as Peirce's relational graphs of 1882: the only logical operators they can represent are conjunction and the existential quantifier. Even when those graphs have nodes marked with other logical operators, such as disjunction, negation, or the universal quantifier, they fail to express their scope correctly. During the 1970s, various network notations were developed to represent the scope of logical operators. The most successful approach was the method of adding explicit nodes to show propositions. Logical operators would connect the propositional nodes, and relations would either be attached to the propositional nodes or be nested inside them. By those criteria, Frege's *Begriffsschrift*, Peirce's existential graphs, and Kamp's discourse representation structures could be called *propositional semantic networks*. In Figure 5, for example, the two EG ovals and the two DRS boxes represent propositions, each of which contains nested propositions.

The first propositional semantic network to be implemented in artificial intelligence (AI) was the MIND system, developed by Stuart Shapiro (1971). It later evolved into the *Semantic Network Processing System* (SNePS), which has been used to represent a wide range of features in natural language semantics (Shapiro, 1979). Figure 8 shows the SNePS representation for the sentence '*Sue thinks that Bob believes that a dog is eating a bone*.' Each of the nodes labeled M1 through M5 represents a distinct proposition, whose relational content is attached to the propositional node.

The proposition M1 states that Sue is the experiencer (Expr) of the verb *think*, whose theme (Thme) is another proposition M2. For M2, the experiencer is Bob, the verb is *believe*, and the theme is a

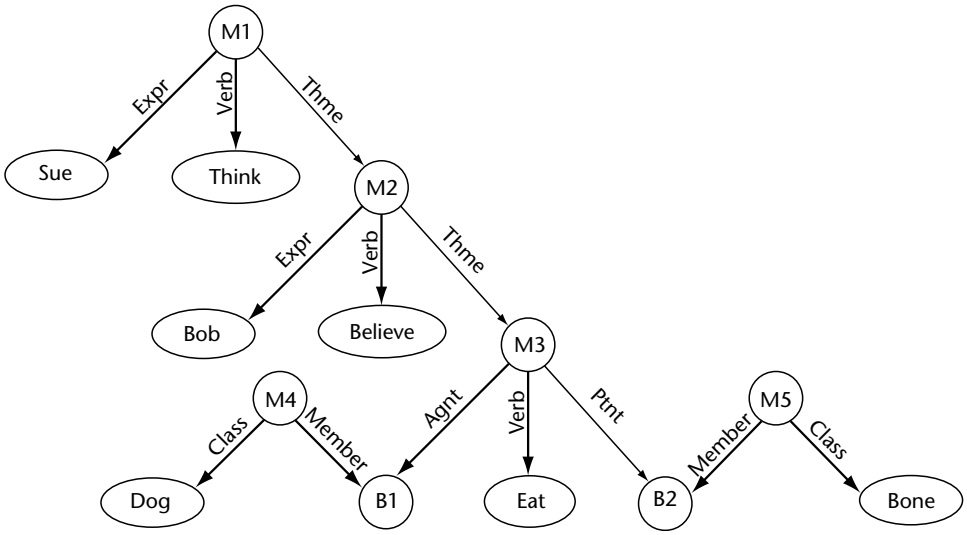

Figure 8. Propositions represented in SNePS.

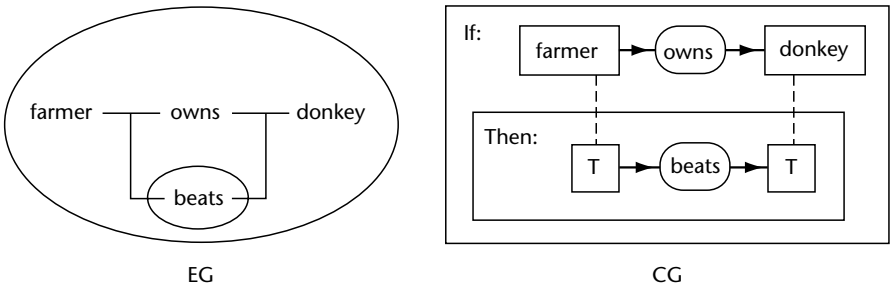

Figure 9. Comparison of the EG from Figure 5 with a CG for the same sentence.

proposition M3. For M3, the agent (Agnt) is some entity B1, which is a member of the class Dog, the verb is *eat*, and the patient (Ptnt) is an entity B2, which is a member of the class Bone. As Figure 8 illustrates, propositions may be used at the metalevel to make statements about other propositions: M1 states that M2 is thought by Sue, and M2 states that M3 is believed by Bob.

Conceptual graphs (Sowa, 1984, 2000) are a variety of propositional semantic networks in which the relations are nested inside the propositional nodes. They evolved as a combination of the linguistic features of Tesnière's dependency graphs and the logical features of Peirce's existential graphs with strong influences from the work in artificial intelligence and computational linguistics. Figure 9 shows a comparison of Peirce's EG from Figure 5 with a conceptual graph (CG) that represents the sentence '*If a farmer owns a donkey, then he beats it*.'

The most obvious differences between the EG and the CG are cosmetic: the ovals are squared off to form boxes, and the implicit negations in the EG are explicitly marked *If* and *Then* for better readability. The more subtle differences are in the range of quantification and the point where the quantification occurs. In an EG, a line of identity represents an existential quantifier ($\exists x$) or ($\exists y$), which ranges over anything in the domain of discourse; but in a CG, each box, called a *concept*, represents a quantifier ($\exists x$:Farmer) or ($\exists y$:Donkey), which is restricted to the *type* or *sort* Farmer or Donkey. In the CG, the arcs with arrows indicate the arguments of the relations (numbers are used to distinguish the arcs for relations with more than two arguments). Nodes such as [T] represent the pronouns *he* or *it*, which are linked to their antecedents by dotted lines called *coreference links*. As another example, Figure 10 shows the CG that corresponds to the SNePS diagram in Figure 8.

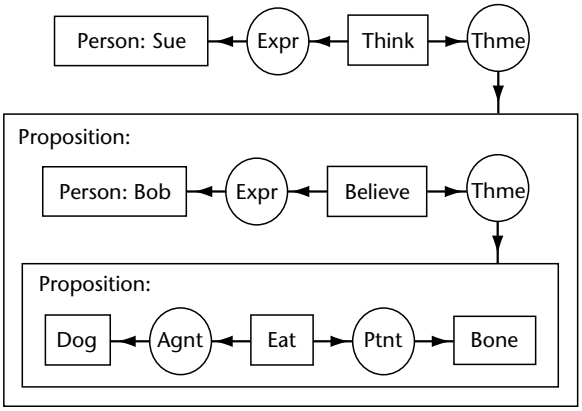

Figure 10. A conceptual graph that corresponds to Figure 8.

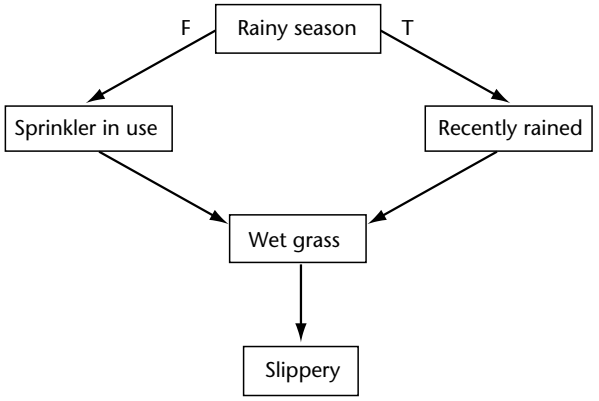

Figure 11. An implicational network for reasoning about wet grass.

Figures 8 and 10 both represent the sentence '*Sue thinks that Bob believes that a dog is eating a bone*'. The SNePS proposition M1 corresponds to the entire CG in Figure 10; M2 corresponds to the concept box that contains the CG for the nested proposition *Bob believes that a dog is eating a bone*; and M3 corresponds to the concept box that contains the CG for the more deeply nested proposition *A dog is eating a bone*. Each concept box in a CG could be considered a separate proposition node that could be translated to a complete sentence by itself. The concept [Dog] could be expressed by the sentence '*There exists a dog*', which corresponds to the SNePS proposition M4. The concept [Person: Sue] expresses the sentence '*There exists a person named Sue*'. By such methods, it is possible to translate propositions expressed in SNePS or CGs to equivalent propositions in the other notation. For most sentences, the translations are nearly one-to-one, but sentences that take advantage of special features in one notation may require a more roundabout paraphrase when translated to the other.

Different versions of propositional semantic networks have different syntactic mechanisms for associating the relational content with the propositional nodes, but formal translation rules can be defined for mapping one version to another. Peirce, Sowa, and Kamp used strictly nested propositional enclosures with variables or lines to show coreferences between different enclosures. Frege and Shapiro attached the relations to the propositional nodes (or lines in Frege's notation). Gary Hendrix (1979) developed a third option: *partitions* that enclose the relational content, but with the option of overlapping enclosures if they have common components. Formally, Hendrix's solution is equivalent to Shapiro's; but as a practical matter, it is not possible to draw the partitions on a plane sheet if multiple enclosures overlap in complex ways.

IMPLICATIONAL NETWORKS

An implicational network is a special case of a propositional semantic network in which the primary relation is implication. Other relations may be nested inside the propositional nodes, but they are ignored by the inference procedures. Depending on the interpretation, such networks may be called *belief networks, causal networks, Bayesian networks*, or *truth-maintenance systems*. Sometimes the same graph can be used with any or all of these interpretations. Figure 11 shows possible causes for slippery grass: each box represents a proposition, and the arrows show the implications from one proposition to another. If it is the rainy season, the arrow marked T implies that it recently rained; if not, the arrow marked F implies that the sprinkler is in use. For boxes with only one outgoing arrow, the truth of the first proposition implies the truth of the second, but falsity of the first makes no prediction about the second.

Suppose someone walking across a lawn slips on the grass. Figure 11 represents the kind of background knowledge that the victim might use to reason about the cause. A likely cause of slippery grass is that the grass is wet. It could be wet because either the sprinkler had been in use or it had recently rained. If it is the rainy season, the sprinkler would not be in use. Therefore, it must have rained.

The kind of reasoning described in the previous paragraph can be performed by various AI systems. Chuck Rieger developed a version of *causal networks*, which he used for analyzing problem descriptions in English and translating them to a network that could support metalevel reasoning.

Benjamin Kuipers, who was strongly influenced by Rieger's approach, developed methods of *qualitative reasoning*, which serve as a bridge between the symbolic methods of AI and the differential equations used in physics and engineering. Judea Pearl, who has developed techniques for applying statistics and probability to AI, introduced *belief networks*, which are causal networks whose links are labeled with probabilities.

Different methods of reasoning can be applied to the same basic graph, such as Figure 11, sometimes with further annotations to indicate truth values or probabilities. Following are two of the major approaches:

- *Logic*. Methods of logical inference are used in *truth-maintenance systems* (TMS). A TMS would start at nodes whose truth values are known and propagate them throughout the network. For the case of the person who slipped on the grass, it would start with the value T for the fact that the grass is slippery and work backwards. Alternatively, a TMS could start with the fact that it is now the rainy season and work forwards. By combinations of forward and backward reasoning, a TMS propagates truth values to nodes whose truth value is unknown. Besides deducing new information, a TMS can be used to verify consistency, search for contradictions, or find locations where the expected implications do not hold. When contradictions are found, the structure of the network may be modified by adding or deleting nodes; the result is a kind of non-monotonic reasoning called *belief revision*.
- *Probability*. Much of the forward and backward reasoning used with a TMS can also be adapted to a probabilistic interpretation, since truth can be considered a probability of 1.0 and falsity as 0.0. The continuous range of probabilities from 1.0 to 0.0, however, raises the need for more subtle interpretations and more complexity in the computations. The most detailed study of probabilistic reasoning in causal or belief networks has been done by Pearl. For Figure 11, a two-valued {T, F} interpretation is only a rough approximation, since it doesn't rain every day in a rainy season and a sprinkler might not be used even in a dry season. Pearl analyzed various techniques for applying Bayesian statistics to derive a causal network from observed data and to reason about it.

In both the logic-based and the probabilistic systems, the relational information that was used to derive the implications is ignored by the inference procedures. Doyle developed the first TMS by extracting a subgraph of implications from the rules of an expert system. Martins and Shapiro extracted a TMS from SNePS by analyzing only the Boolean connectives that link propositional nodes. Similar techniques could be applied to other propositional networks to derive an implicational subgraph that could be analyzed by logical or probabilistic methods.

Although implicational networks emphasize implication, they are capable of expressing all the Boolean connectives by allowing a conjunction of inputs to a propositional node and a disjunction of outputs. Gerhard Gentzen (1935) showed that a collection of implications in that form could express all of propositional logic. Following is the general form of an implication written in Gentzen's *clause form*:

$$p_1, \ldots, p_n \Rightarrow q_1, \ldots, q_m$$

The ps are called the *antecedents* of the implication, and the qs are called the *consequents*. The generalized rule of modus ponens states that when every one of the antecedents is true, at least one of the consequents must be true. In effect, the commas in the antecedent have the effect of *and* operators, and the commas in the consequent have the effect of *or* operators. Doyle's original TMS allowed only one term in the consequent; the resulting form, called *Horn-clause logic*, is widely used for expert systems. To support full propositional logic, later versions of TMS have been generalized to allow multiple *or* operators in the consequent.

EXECUTABLE NETWORKS

Executable semantic networks contain mechanisms that can cause some change to the network itself. The executable mechanisms distinguish them from networks that are static data structures, which can change only through the action of programs external to the net itself. Three kinds of mechanisms are commonly used with executable semantic networks:

1. *Message passing* networks can pass data from one node to another. For some networks, the data may consist of a single bit, called a *marker, token*, or *trigger*; for others, it may be a numeric *weight* or an arbitrarily large *message*.
2. *Attached procedures* are programs contained in or associated with a node that performs some kind of action or computation on data at that node or some nearby node.
3. *Graph transformations* combine graphs, modify them, or break them into smaller graphs. In typical theorem provers, such transformations are carried out by a program external to the graphs. When they are triggered by the graphs themselves, they behave like chemical reactions that combine molecules or break them apart.

These three mechanisms can be combined in various ways. Messages passed from node to node may

be processed by procedures attached to those nodes, and graph transformations may also be triggered by messages that appear at some of the nodes.

An important class of executable networks was inspired by the work of the psychologist Otto Selz (1913, 1922), who was dissatisfied with the undirected associationist theories that were then current. As an alternative, Selz proposed *schematic anticipation* as a goal-directed method of focusing the thought processes on the task of filling empty slots in a pattern or *schema*. Figure 12 is an example of a schema that Selz asked his test subjects to complete while he recorded their verbal protocols.

The expected answers for the empty slots in Figure 12 are the supertypes of the words at the bottom: the supertype of Newspaper and Magazine is Periodical, and the supertype of Periodical and Book is Publication. This task is actually more difficult in German than in English: Selz's subjects tried to find a one-word supertype for *Zeitung* (Newspaper) and *Zeitschrift* (Magazine), but the correct answer in German is the two-word phrase *periodische Druckschrift*.

The similarity between Selz's method of schematic anticipation and the goal-directed methods of AI is not an accident. Two of the pioneers in AI, Herbert Simon and Allen Newell, (1972) adopted Selz's method of protocol analysis for their study of human problem solving. Their student, Ross Quillian, combined Selz's networks with the semantic networks used in machine translation. Quillian's most significant innovation was the *marker passing* algorithm for *spreading activations*, which was adopted for later systems, such as NETL by Scott Fahlman (1979) and the *massively parallel* algorithms by Hendler (1992).

The simplest networks with attached procedures are *dataflow graphs*, which contain passive nodes that hold data and active nodes that take data from *input nodes* and send results to *output nodes*. Figure 13 shows a dataflow graph with boxes for the passive nodes and diamonds for the active nodes. The labels on the boxes indicate the data type (Number or String), and the labels on the diamonds indicate the name of the function (+, ×, or convert string to number).

For numeric computations, dataflow graphs have little advantage over the algebraic notation used in common programming languages. Figure 13, for example, would correspond to an assignment statement of the following form:

$$X = (A + B)^* S2N(C)$$

Graphic notations are more often used in an *Integrated Development Environment* (IDE) for linking multiple programs to form a complete system. When dataflow graphs are supplemented with a graphic method for specifying conditions, such as *if-then-else*, and a way of defining recursive functions, they can form a complete programming language, similar to *functional programming languages* such as Scheme and ML.

Petri nets, first introduced by Carl Adam Petri, are the most widely-used formalism that combines marker passing with procedures. Like dataflow diagrams, Petri nets have passive nodes, called *places*, and active nodes, called *transitions*. In addition, they have a set of rules for marking places with dots, called *tokens*, and for executing or *firing* the transitions. To illustrate the flow of tokens, Figure 14 shows a Petri net for a bus stop where three tokens represent people waiting and one token represents an arriving bus.

At the upper left of Figure 14, each of the three tokens represents one person waiting at the bus stop. The token at the upper right represents an arriving bus. The transition labeled *Bus stops*

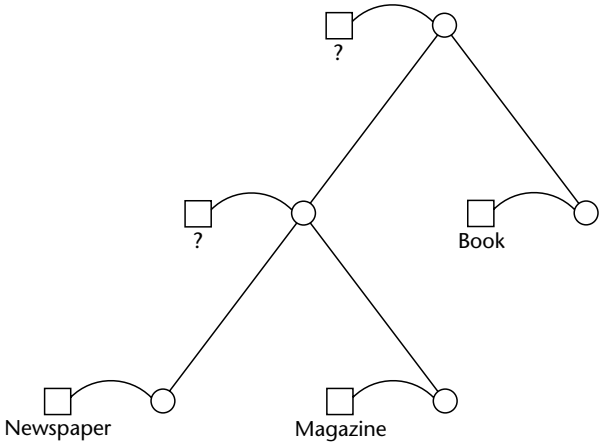

Figure 12. A schema used in Otto Selz's experiments.

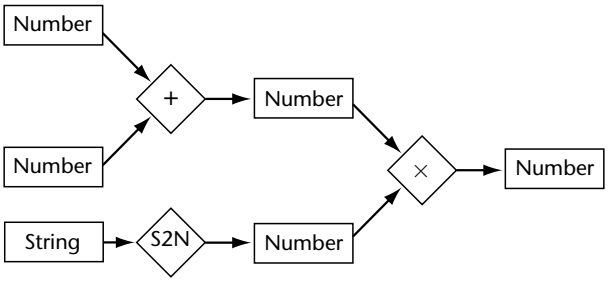

Figure 13. A dataflow graph.

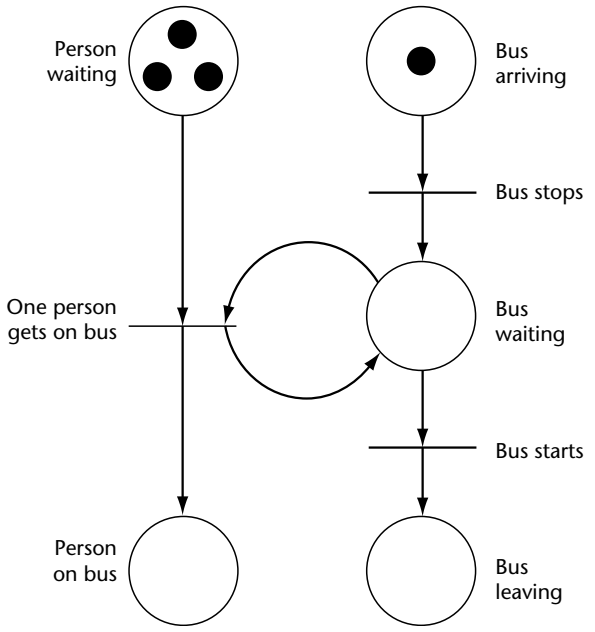

Figure 14. Petri net for a bus stop.

represents an event that fires by removing the token from the arriving place and putting a token in the waiting place. When the bus is waiting, the transition labeled *One person gets on bus* is *enabled* because it has at least one token in both of its input places. It fires by first removing one token from both of its input places and putting one token in both of its output places (including the *Bus waiting* place from which one token has just been removed). As long as the bus is waiting and there are more people waiting, that transition can keep firing. It stops firing when either there are no more people waiting or the *Bus starts* transition fires by removing the token for the waiting bus and putting a token in the place for *Bus leaving*.

Each place in a Petri net represents a precondition for the transitions that use it as an input and a postcondition for the transitions that use it as an output. A token in a place asserts that the corresponding condition is true. By removing a token from each input place, the firing of a transition retracts the assertions of its preconditions. By adding a token to each output place, the firing asserts that each of the postconditions has become true. Petri nets can be used to model or simulate physical events, as in the example of Figure 14. They can also be used to model processes that take place in computer hardware and software; they are especially useful for designing and modeling distributed parallel processes. In Figure 14, each token represents a single bit of information, but an extension, called *colored Petri nets*, can associate an arbitrary amount of data with each token. With such extensions, Petri nets can represent arbitrarily many dataflow graphs running in parallel or simulate the various marker-passing algorithms used in semantic networks in the Quillian tradition.

Although dataflow graphs and Petri nets are not usually called semantic networks, similar techniques have been implemented in *procedural semantic networks* (Levesque and Mylopoulos, 1979). Their systems incorporate definitional networks for defining *classes*, assertional networks for stating facts, and procedures similar to the *methods* of object-oriented programming languages. For conceptual graphs, Sowa allowed some relation nodes to be replaced by *actors*, which are functions that form the equivalent of a dataflow graph.

Besides markers and procedures, the third method for making networks executable is to let them grow and change dynamically. Peirce and Selz could also be considered pioneers of that approach. Peirce said that the inference operations on existential graphs could be considered 'a moving picture of thought'. For schematic anticipation, Selz considered a schema to be the cause of the neural activity that generates a solution to a problem. Formally, transformations on networks can be defined without reference to the mechanisms that perform the transformations. In Petri nets, for example, the definition states that a transition may 'fire' when each of its input nodes contains a token; the mechanism that performs the firing could be internal or external to the transition. For a computer implementation, it may be convenient to treat the networks as passive data structures and to write a program that manipulates them. For a cognitive theory, however, the transformation could be interpreted as network operations initiated and carried out by the network itself. Either interpretation could be found consistent with the same formal definitions.

LEARNING NETWORKS

A learning system, natural or artificial, responds to new information by modifying its internal representations in a way that enables the system to respond more effectively to its environment. Systems that use network representations can modify the networks in three ways:

1. *Rote memory*. The simplest form of learning is to convert the new information to a network and add it without any further changes to the current network.
2. *Changing weights*. Some networks have numbers, called *weights*, associated with the nodes and arcs. In an implicational network, for example, those weights

might represent probabilities, and each occurrence of the same type of network would increase the estimated probability of its recurrence.

3. *Restructuring*. The most complex form of learning makes fundamental changes to the structure of the network itself. Since the number and kinds of structural changes are unlimited, the study and classification of restructuring methods is the most difficult, but potentially the most rewarding if good methods can be found.

Systems that learn by rote or by changing weights can be used by themselves, but systems that learn by restructuring the network typically use one or both of the other methods as aids to restructuring.

Commercially, rote memory is of enormous importance, since the world economy depends on exact record keeping. For such applications, information is sometimes stored in tables, as in relational databases, but networks are also used. Either representation could be converted to the other. For better efficiency and usability, most database systems add indexes to speed up the search, and they support query languages, such as SQL, which perform transformations to extract and combine the information necessary to answer a request. Since a learning system must be able to distinguish common features and exceptions among similar examples, another feature is essential: the ability to measure *similarity* and to search the database for networks that are similar, but not identical to any given example.

Neural nets are a widely used technique for learning by changing the weights assigned to the nodes or arcs of a network. Their name, however, is a misnomer, since they bear little resemblance to actual neural mechanisms. Figure 15 shows a typical neural net, whose input is a sequence of numbers that indicate the relative proportion of some selected features and whose output is another sequence of numbers that indicate the most likely concept characterized by that combination of features. In an application such as optical character recognition, the features might represent lines, curves, and angles, and the concepts might represent the letters that have those features.

In a typical neural network, the structure of nodes and arcs is fixed, and the only changes that may occur are the assignments of weights to the arcs. When a new input is presented, the weights on the arcs are combined with the weights on the input features to determine the weights in the *hidden layers* of the net and ultimately the weights on the outputs. In the learning stage, the system is told whether the predicted weights are correct, and various methods of *back propagation* are used to adjust the weights on the arcs that lead to the result.

Rote memory is best suited to applications that require exact retrieval of the original data, and methods of changing weights are best suited to pattern recognition. For more versatile and creative kinds of learning, some way of restructuring the network is necessary. But the number of options for reorganizing a network is so vast that the full range of possibilities is largely unexplored. Here are some examples:

1. Patrick Winston (1975) used a version of relational graphs to describe structures, such as arches and towers. When given positive and negative examples of each type of structure, his program would generalize the graphs to derive a definitional network for classifying all the types that were considered.
2. Haas and Hendrix (1983) developed the NanoKlaus system that would learn definitional networks by being told. Unlike Winston's system, which required

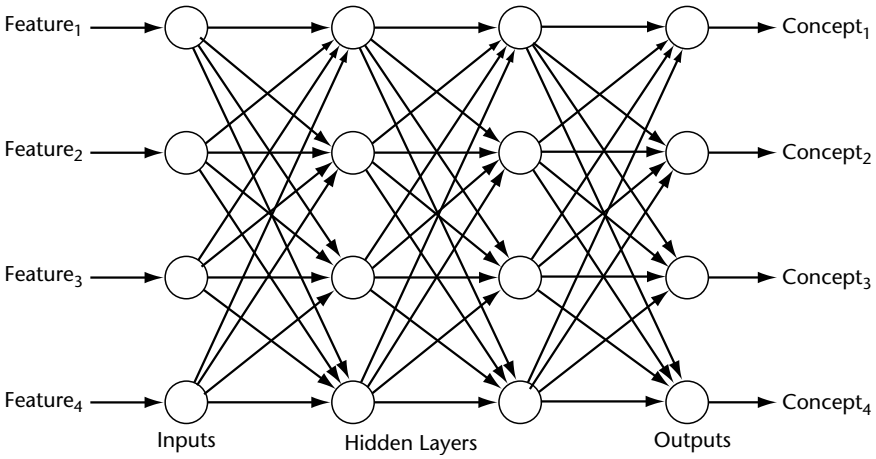

Figure 15. A neural net.

a set of examples that included all significant features, NanoKlaus would carry on a dialogue until the features it had been told were sufficient to distinguish all the specified types.

3. George Lendaris (1988) developed a two- stage learning system that combined conceptual graphs with neural networks. Both stages used a neural network with back propagation, but in the first stage, the inputs were features, and the outputs were concepts, as in Figure 15. In the second stage, each input represented a conceptual graph constructed from the concepts recognized by the first stage, and the outputs represented complex scenes described by those graphs. The two-stage system had a significantly reduced error rate and a faster learning rate than networks that matched features to scenes directly.
4. In *case-based reasoning* (Schank *et al*., 1994), the learning system uses rote memory to store various cases, such as medical diagnoses or legal disputes. For each case, it stores associated information, such as the prescribed treatment and its outcome or the legal argument and the court judgment. When a new case is encountered, the system finds those cases that are most similar to the new one and retrieves the outcome. Crucial requirements for the success of case-based reasoning are good similarity measures and efficient ways of searching for similar cases. To organize the search and evaluate similarity, the learning system must use restructuring to find common patterns in the individual cases and use those patterns as the keys for indexing the database.
5. Basili *et al*. (1996) developed methods of learning semantic patterns from a corpus of natural-language text. They started with a syntactic parser supplemented with a lexicon that had a limited amount of semantic information about the lexical patterns expected for each word. Then they used the parser to analyze the corpus and derive more detailed networks that represented the semantic patterns that occurred in the text. The system generalized those patterns to hypothesize better definitions of the lexical semantics for the words, which a linguist would verify before adding them to the lexicon. The system could then use the revised lexicon to reparse the corpus and further refine the definitions.
6. Robert Levinson (1996) developed a general system for learning to play board games such as chess or checkers. For each kind of game, the system was given the rules for making legal moves, but no further information about which moves are good or bad and no information about how to determine whether a game is won or lost. During the learning phase, the system would play games against a tutor (usually another program that plays very well, such as Gnu Chess). At the end of each game, the tutor would inform the system of a win, loss, or draw. For the learning phase, Levinson used a combination of rote learning as in case-based reasoning; restructuring to derive significant generalizations; a similarity measure based on the generalizations; and a method of back propagation to estimate the value of any case that occurred in a game. For playing chess, the cases were board positions represented as graphs. Every position that occurred in a game was stored in a generalization hierarchy, such as those used in definitional networks. At the end of each game, the system used back propagation to adjust the estimated values of each position that led to the win, loss, or draw. When playing a game, the system would examine all legal moves from a given position, search for similar positions in the hierarchy, and choose the move that led to a position whose closest match had the best predicted value.

These examples don't exhaust all the ways of using restructuring, but they illustrate its potential for learning sophisticated kinds of knowledge.

HYBRID NETWORKS

Many computer systems are hybrids, such as a combination of a database system for storing data, a graphics package for controlling the user interface, and a programming language for detailed computation. For knowledge representation, the Krypton system (Brachman *et al*., 1983) was a hybrid of a definitional network based on KL-ONE with an expert system that used a linear notation for asserting rules and facts. By the criteria used for calling Krypton a hybrid, most object-oriented (O-O) programming languages could be considered hybrids: the C++ language, for example, is a hybrid of the procedural language C with a definitional language for defining types or *classes*. Systems are usually called hybrids if their component languages have different syntaxes. Conceptual graphs, for example, include a definitional component for defining types and an assertional component that uses the types in graphs that assert propositions. But CGs are not usually considered hybrids because the syntax of the definitional component is the same as the syntax of the assertional component.

The most widely used hybrid of multiple network notations is the *Unified Modeling Language* (UML). Although UML is not usually called a semantic network, its notations can be classified according to the categories of semantic networks discussed in this article:

- Central to UML is a definitional network for defining object types. It includes the basic features of the Tree of Porphyry shown in Figure 1: type–subtype links, type–instance links, attributes that serve as differentiae for distinguishing a type from its supertype, and the inheritance of attributes from supertype to subtype.

- UML includes two kinds of executable networks that can be considered special cases of Petri nets: *statecharts*, which are special cases of Petri nets that do not support parallelism; and *activity diagrams*, which are almost identical to Petri nets, except that they do not use tokens to fire the transitions.
- The other networks in the UML family can be considered versions of relational graphs that are specialized for representing metalevel information. They include, for example, a version of entity-relation diagrams which are relational graphs designed for expressing the cardinality constraints and parameter types of relations.
- The most general of all the UML notations is a linear notation called the *Object Constraint Language* (OCL). It is a version of first-order logic with a notation that has syntactic features similar to some of the O-O programming languages. As an example, the following OCL statement says that all parameters of an entity have unique names:

```
self.parameter -> forAll (p1, p2 |
  p1.name = p2.name implies p1 = p2).
```

In OCL, *self* refers to the current entity being defined, and the names of functions are written after the entity to which they apply. In predicate calculus, the order would be interchanged: p1.name would be written name(p_1). Following is a translation of the OCL statement to predicate calculus with the symbol #self representing the current entity:

$$
\begin{aligned}
&(\forall p_1)\ (\forall p_2) \\
&\quad (\ (p_1 \in \texttt{parameter (\#self)} \\
&\quad \wedge\ p_2 \in \texttt{parameter (\#self)} \\
&\quad \wedge\ \texttt{name}\ (p_1) = \texttt{name}\ (p_2)\ ) \\
&\qquad \supset p_1 = p_2)
\end{aligned}
$$

This formula says that for every p_1 and p_2, if p_1 is a parameter of self and p_2 is a parameter of self and the name of p_1 is equal to the name of p_2, then p_1 is equal to p_2.

UML has been criticized for its lack of a formal definition, which has resulted in inconsistencies between its various notations. Work is currently underway to redesign UML with formal definitions for all the notations. One approach would be to extend OCL with sufficient features to define all the other notations. Another possibility would be to design a propositional semantic network that was equivalent to full first-order logic plus metalevel extensions, and use it to define everything in UML.

GRAPHIC AND LINEAR NOTATIONS

Graph notations and linear notations can express logically equivalent information, but with different syntactic conventions. The relational graph in Figure 4 and its translation to a formula in predicate calculus illustrate the differences between the two kinds of notations:

1. Both notations have seven occurrences of relation names, such as *isStagirite* or *teaches*.
2. They both have three occurrences of existential quantifiers, represented by three branching lines in the graph and by ($\exists x$), ($\exists y$), and ($\exists z$) in the formula.
3. The major difference lies in the way the connections from the quantifiers to the relations are shown: each line is directly connected to the relations, but 13 occurrences of the variables x, y, and z are scattered throughout the formula.

The chief advantage of graph notations is the ability to show direct connections. Linear notations must rely on repeated occurrences of variables or names to show the same connections.

As another example, Petri nets, which are usually expressed in a graphic notation, are formally equivalent to a notation called *linear logic*. Although Petri nets and linear logic were independently developed by different researchers for different purposes, a commonly used version of Petri nets happens to be isomorphic to a commonly used version of linear logic. Following is a translation of the Petri net of Figure 14 to that version of linear logic:

```
BusStops:
  BusArriving ⇒ BusWaiting

OnePersonGetsOnBus:
  PersonWaiting & BusWaiting ⇒
  PersonOnBus & BusWaiting

BusStarts:
  BusWaiting ⇒ BusLeaving

InitialAssertions:
  PersonWaiting. PersonWaiting.
  PersonWaiting. BusArriving.
```

Each arrow ($\Rightarrow$) in this example represents one of the transitions in the Petri net. The feature of linear logic that distinguishes it from classical first-order logic is the treatment of implication. For comparison, following is an application of modus ponens in classical FOL, its replacement in linear logic, and the rule for firing a transition in Petri nets:

- *Classical FOL*. Given propositions p and q and an implication $p \wedge q \supset r \wedge s$, conclude r and s. Everything that was previously true remains true.
- *Linear logic*. Given propositions p and q and an implication $p \wedge q \Rightarrow r \wedge s$, conclude r and s and retract the truth of p and q.
- *Petri nets*. Given tokens in the places p and q and a transition $p, q \rightarrow r, s$, add one token to each of the places

r and *s* and erase one token from each of the places *p* and *q*.

When the presence of a token in a place of a Petri net is interpreted as meaning the truth of the corresponding proposition, the rule for firing a transition is equivalent to using an implication in linear logic. Therefore, any collection of implications and assertions in linear logic can be represented by a Petri net, and any proof in linear logic corresponds to an execution of the Petri net.

One of the major arguments for graphic notations is human readability, but proponents of linear notations often argue that their notations are also highly readable. Each rule in linear logic, for example, is quite readable, but the relationships between rules are not as immediately readable as the direct connections in the Petri net.

As an example, consider the proposition Bus Waiting, which is represented by a single place in the Petri net, which has two inputs and two outputs. That fact can be seen immediately from Figure 14, but a reader would have to search through all of the rules in the linear logic example to verify that the name *BusWaiting* occurs four times. As examples become larger, any notation becomes more difficult to read, but the graphic notations still have an advantage over linear notations. Petri nets have been implemented with many thousands of nodes, but it is always possible to look at any node and see immediately how many inputs and outputs it has and where they are linked.

Besides readability, graphic notations often have heuristic value in helping human readers (either students or researchers) to discover patterns that would be difficult or impossible to see in the linear form. The reason why Peirce called his existential graphs 'the logic of the future' was not so much their readability as the direct insight they provided into the structure of proofs. With EGs, Peirce invented the simplest and most elegant rules of inference ever developed for any version of logic. Peirce's rules, which he discovered in 1897, are a simplification and generalization of the rules of *natural deduction* that Gentzen (1935) re-invented many years later. Even today, Peirce's rules lead to insights that have eluded logicians for many years.

SHRDLU

Introductory article

Nigel Ward, University of Tokyo, Tokyo, Japan

CONTENTS

SHRDLU was an integrated artificial intelligence system which could make plans and carry on simple conversations about a set of blocks on a table.

INTRODUCTION

SHRDLU, created by Terry Winograd, was a computer program that could understand instructions and carry on conversations about a world consisting of some toy blocks on a table. For example:

Person: '*Pick up a big red block.*'
Computer: 'OK.' (In the display, SHRDLU's animated robot hand does this.)
Person: '*Grasp the pyramid.*'
Computer: 'I DON'T UNDERSTAND WHICH PYRAMID YOU MEAN.'
Person: '*Find a block which is taller than the one you are holding and put it into the box.*'
Computer: 'BY "IT", I ASSUME YOU MEAN THE BLOCK WHICH IS TALLER THAN THE ONE I AM HOLDING.'
Computer: 'OK.' (Does it.)
Person: '*What does the box contain?*'
Computer: 'THE BLUE PYRAMID AND THE BLUE BOX.'
...

SHRDLU was perhaps the first integrated artificial intelligence (AI) system. It incorporated modules for parsing, planning, question-answering, dialog management, etc., which worked together to perform a complete task.

PLANNING

SHRDLU controlled a simulated robot hand with which to arrange the blocks as the user requested. This was not trivial, since the robot could directly perform only three actions: `MOVETO` (a location), `GRASP` (the block currently under the hand) and `UNGRASP` (the block currently in the hand). Thus SHRDLU, which accepted high-level commands, such as 'put a red block on the green block', had to discover sequences of basic actions that would achieve its goals. It did this with the 'Planner' program.

The key idea, as in many planning systems, was a technique now called backward chaining or means-ends analysis. For example, if the goal was to have 'a red block on the green block', the Planner would first check to see if this was true already, and if not, it would try to find a way to achieve it. To find a way, it would search through the various operations in its knowledge base. In this example, this would yield `UNGRASP` as a possible way to satisfy the goal, provided that three preconditions held: (1) the green block had nothing on top; (2) the hand was holding a red block; and (3) the hand was over the green block. The Planner would then check to see if these preconditions were true, and if not, develop sub-plans to achieve each precondition. For example, if the green block had something on top, the Planner would proceed to find an operation or plan to achieve the 'nothing-on-green' goal. The concatenation of all the operations found in this process gave the sequences of actions needed to achieve the final goal.

SHRDLU also kept track of these chains of reasoning, so that if the user later asked, for example, 'Why did you pick up the brown pyramid?', SHRDLU could give an answer like 'SO THAT THE GREEN BLOCK WOULD BE CLEAR SO I COULD PUT THE RED BLOCK ON IT'.

SHRDLU was also able to backtrack when a partial plan turned out to be infeasible. That is, it was able partially to undo some line of reasoning, and start looking for an alternative sub-plan without having to start again from scratch.

PROCEDURAL SEMANTICS

Planner used a special internal representation. Thus, 'a red block in the box' would be represented as something like

```
(THGOAL (#IS ?X #BLOCK)) (THGOAL
(#COLOR $?X #RED)) (THGOAL (#IN $?X
:BOX))
```

With some familiarity with the conventions of logic, and a little imagination, it should be possible for an intelligent reader to see what this means. However, for this to be meaningful for a program requires something more, Winograd noted. SHRDLU needed to be able to reason about the basic concepts such as #RED and #IN. At the time, the representation of reasoning as theorem-proving, in which formal procedures manipulated logical symbols without using any knowledge of what the symbols 'meant', was prevalent. Winograd, however, argued for a 'procedural' view of semantics. In a vivid illustration of this approach to meaning, Winograd showed how the concept CLEARTOP, corresponding to the English phrase 'clear off', can be expressed as a procedure:

1. Start.
2. Does X support an object Y? If not, go to 5.
3. Move Y off X.
4. Go to 2.
5. Assert that X is CLEARTOP.

Similarly, the meaning of 'a red cube which supports a pyramid' can be described as a procedure for looping through all pairs of blocks on the table while checking their dimensions, colors, and relations to each other. This viewpoint, called 'procedural semantics', sparked excitement at the time: it seemed that this fresh perspective, inspired by practical programing considerations, would allow AI to resolve or bypass the messy problems that had troubled philosophers of meaning for centuries. In practice, however, most of the procedural knowledge in SHRDLU was represented as simple declarative facts, goals, or operators, and a sharp distinction between procedural and declarative approaches turned out to be both elusive and unimportant.

Building SHRDLU involved a lot of clever programming, not just the implementation of a mathematical or psychological theory. For this reason, SHRDLU is a landmark 'hacker' AI system. Even today, a lecture about SHRDLU is a common way to excite and inspire computer science undergraduates. However, the 'hacker' approach tends to lead to messy programs and confused models, and modern AI researchers are generally more careful to distinguish between the systems-building and the theory-building aspects of AI.

ANALYZING THE INPUT

Since SHRDLU's inputs were English sentences, it first had to parse them: to work out where the noun phrases began and ended, which words went with with which, and so on.

In designing the language analysis model, Winograd looked beyond purely practical considerations. Reasoning that in a psychologically realistic grammar, syntax and semantics were interdependent, he chose to base SHRDLU's grammar on systemic grammar. Winograd thus denied the claim, common in linguistics that it is possible or desirable to have an autonomous theory of syntax, formulated without regard to meaning.

SHRDLU also embodies a highly 'interactionist' view of the relation between syntactic and semantic processing. For example, consider the command 'Put the blue pyramid on the block in the box', which is ambiguous (as to whether 'on the block' describes the current location of the pyramid or its desired location). For this sentence, SHRDLU would first recognize that 'the blue pyramid' was a syntactically possible noun phrase, then immediately check to see if this interpretation made sense semantically. Because SHRDLU knew about the locations of all the blocks, it could determine whether there was a unique blue pyramid. If so, the parser would know that the rest of the sentence, 'on the block in the box', had to be a single prepositional phrase, specifying where to put the pyramid. If, on the other hand, there was more than one blue pyramid, the parser would deduce that 'on the block' was part of the noun phrase; then SHRDLU would perform another semantic check, to make sure that 'the blue pyramid on the block' was a valid description of a unique object. (*See* **Natural Language Processing, Disambiguation in**)

In this way, SHRDLU used syntactic and semantic information in concert to efficiently arrive at the correct interpretation of the input: by using semantic information early, it avoided wasting time considering interpretations which were syntactically possible but actually impossible given the configuration of the blocks. Thus SHRDLU demonstrated that an AI system with multiple modules could be tightly integrated, for the sake of both cognitive plausibility and efficiency. At the same time, SHRDLU was a fairly modular system, with the different kinds of data structures and processing algorithms neatly separated into components, in

accordance with general software engineering principles, making the system easier to develop, debug, and extend. Of course, there is something of a trade-off between integration and modularity, and dealing with this was a central concern of the new sub-field of 'AI architectures' for many years.

RESEARCH STRATEGY

In 1972 SHRDLU was an amazing achievement. It succeeded partly because it worked in a 'micro-world', that is a limited domain, consisting of some colored blocks on a table. It could only understand sentences about blocks, only make plans about blocks, and only ask questions about blocks. This may seem like a retreat from real-world complexities, but Winograd argued that it was a reasonable first step. After all, small children play with blocks before going on to more complex things. Similarly, AI should perhaps start by developing systems for various microworlds. Each system would be a simple but complete application. As time went on, more complex microworlds would be tackled, and the inventory of AI knowledge and techniques would grow, and ultimately all would be combined into a fully intelligent system. This approach is not universally accepted, and many have argued that AI for the real world cannot be developed by this strategy. Nevertheless, today all useful AI systems operate in microworlds. Indeed, the successful deployment of AI techniques is known to require the identification of some domain of expertise (such as engine diagnosis, chess playing, or answering payroll questions) that can be dealt with in isolation from the unbounded complexity of the 'real world'.

SHRDLU's microworld allowed direct mappings from lexical categories (in the input sentences) to meaning elements, and from syntactic structures to rules for combining meaning elements, as seen in table 1. Of course language is more complex than this in general: for example, '*destruction*' is a noun, but refers to an activity, not an object; and '*fake gun*' does not refer to the subset of guns that are fake.

DIALOG MANAGEMENT

Perhaps the most appealing aspect of SHRDLU was that it could hold a reasonably involved conversation and not lose the thread – something that is not trivial even for people. For example, in the dialog above SHRDLU deals with words like 'it' and 'that' which refer back to things it heard or did or said earlier. SHRDLU was also able to formulate follow-up questions if the input was ambiguous. As such, it was probably the first system to incorporate what is now called a 'dialog manager' and face up to the problems that arise when dealing with discourse, not just individual sentences.

IMPACT AND LIMITATIONS

SHRDLU was one of the first AI systems to perform a realistic task. Although moving colored blocks around on tables is not a commercially important activity, SHRDLU-like dialogs are very plausible when querying databases. Thus SHRDLU inspired, in the early 1970s, one of the periodic rushes to commercialize AI. There were several efforts to build 'natural language interfaces' to databases, so that people could get the information they wanted (for example, 'a list of all single women in zip code 94705 with cats' or 'a list of all people who earn more than their managers') without having to write programs or arcane database queries.

This turned out to be easy to achieve for certain hand-chosen inputs, but not for the sorts of things that real users input. To build a natural language interface for a new domain, such as a shoe shop inventory database, would require months of effort tuning the lexicon, grammar and code, and even then users tended to lapse into a narrow subset of English after discovering that fragmentary, idiomatic or unusual phrasings were seldom understood correctly. The nail in the coffin for natural language interfaces was the invention of graphical user interfaces (GUIs). Most users prefer GUIs, with on-screen views of the data and with the available commands laid out in buttons and menus, over natural language. Today, however, there is a revival of interest in natural language interfaces for spoken language interaction: for example, to get airline flight information over the telephone. Systems capable of carrying on rudimentary con-

Table 1. Some semantic interpretation rules exploited in SHRDLU

Language	*Meaning*
noun	object
adjective	a property of an object
'*the*'	expect to find a unique object
verb	action
'*it*'	the most recent topic of conversation
question mark	compute the answer
adjective–noun	a subset: all members of the set that have the specified property
verb–noun phrase	perform the action on the set of objects specified by the noun phrase

versations about such information are now becoming common.

SHRDLU was also one of the first AI systems to capture the popular imagination. Winograd's style of research, taking inspiration from linguistics and psychology and using low-level programming tricks, was in accordance with the intellectual climate of the time. The view he propounded – that programming considerations can tell us how a human reasoning system might work, and conversely, that knowledge of human cognitive processing could inform AI system development – implied that AI researchers, linguists and psychologists could achieve great things if they worked together. This excitement helped to stimulate the new field of cognitive science.

Situated Cognition

Intermediate article

Kevin O'Connor, University of Wisconsin, Madison, Wisconsin, USA
Arthur M Glenberg, University of Wisconsin, Madison, Wisconsin, USA

CONTENTS

Theories of situated cognition maintain that intelligent human action has evolved within and is shaped by and adapted to the specific forms of activity within which it occurs, and that cognition must therefore be understood and studied as an aspect of embodied practical activity.

INTRODUCTION

Situated cognition is an evolving interdisciplinary project to describe the relationship between embodied agents and the social, semiotic, and material settings of their activity. Contemporary theories of situated cognition have arisen and taken shape largely against the background of traditional cognitivist perspectives in psychology and artificial intelligence, which have tended to conceive of cognition in terms of abstract and disembodied reasoning processes taking place in the heads of individuals. While many of the topics addressed within situated cognition – such as the nature of knowledge and cognitive processes, and the relationship between knowledge and intelligent action – are shared with cognitivist approaches, the ways in which these topics are understood and studied diverge fundamentally from cognitivism. Theories of situated cognition maintain that intelligent human action has evolved within and is shaped by and adapted to the specific forms of activity within which it occurs, and that cognition must therefore be understood and studied as an aspect of embodied practical activity. Situated cognition is not just a type of cognition that can be distinguished from 'non-situated' cognition; rather, theories of situated cognition claim that human cognition is inherently situated, and that attempting to study cognition apart from the specific settings of activity within which it takes place destroys the phenomenon being studied.

TRADITIONAL COGNITIVISM AND A CARTESIAN SEPARATION FROM THE WORLD

Traditional cognitivist approaches in psychology and artificial intelligence are ultimately based on Cartesian ideas about, on one hand, an objective external world whose character is determinate and independent of human knowledge and concerns, and on the other hand, the human mind as a rational instrument that is able to discover and use the principles according to which the external world is structured. Cognitivism has developed these tenets into a number of assumptions about the nature of the mind and its relationship to action. (*See* **Descartes, René**; **Mind–Body Problem**)

First, the mind and the world are viewed as fundamentally separate from and impenetrable to one another. The world is taken to have an objective and stable character, and the mind is understood as capable of knowing the world by representing it in explicit and formal symbolic terms.

Second, according to cognitivism, this explicit and formal knowledge about the world underlies and is necessary for action; thus, action can only be properly understood in terms of symbolic mental representations of the world and rules for manipulating them. (*See* **Symbol Systems**)

Third, mental representations are taken to involve abstraction from the particularities of specific situations: the more abstract the representation is, the more generally applicable it is across situations; thus, greater abstraction is a mark of greater potential for intelligent action.

Fourth, the proper level of explanation for cognition involves descriptions of the processing of abstract symbols. Thus, the details of the realization of symbols in the brain are taken to be irrelevant to cognitive explanation: it is on this basis that

computers, despite their physical differences from the human brain, are understood to provide a potential model for human intelligence. Moreover, the body is understood not to be involved in symbol processing in any fundamental way; its role is limited to one of providing input to the cognitive system, through perceptual processes, and output, through motor actions.

The cognitivist analysis of the mind and its relation to action is evident in its view of action as the outcome of a process of problem-solving (e.g. Newell and Simon, 1972). According to this view, action in the world results from a process involving several discrete steps. First, a situation in the external world is symbolically represented in the mind as a problem to be solved. The mind then performs rule-based operations on the problem to produce a different symbolic representation – a solution to the problem. This solution then produces some action in the world. Note that the relevant context in the problem-solving process is not the world, but a mental representation of it – the problem – which is, in principle, fully specifiable in terms of formal symbolic structures. Thus, action in the world is caused by underlying cognitive processes. The proper focus of study, then, is not action in the world but rather the underlying knowledge, the mental representations and rules for manipulating them, that cause action. (*See* **Problem Solving**; **Newell, Allen**; **Simon, Herbert A.**)

Influenced by this analysis of action, cognitivists have tended to focus on, and indeed have been quite successful at modeling, problem-solving in situations that lend themselves to description in terms of the manipulation of abstract symbols. Two common types of problem used in cognitivist research can serve to illustrate this. One type of problem, of which the well-known 'tower of Hanoi' is an example, is intended to provide a window to purportedly general cognitive processes by examining problem-solving in simple abstract situations, which often bear little resemblance to the kinds of activities people pursue in much of their everyday life. Another type of problem is drawn from activities, such as chess, that are chosen because they are suitable for producing formalizable cognitive tasks with clear criteria for determining appropriate solutions.

SITUATED ACTIVITY THEORY

Beginning around the 1980s, a number of theoretical and practical difficulties with the cognitivist paradigm, along with empirical observations that were anomalous from the cognitivist point of view, led researchers to explore alternatives to the traditional emphasis on cognition as the purely mental manipulation of abstract symbolic representations. Work in this new perspective, a loose convergence of a variety of anti-Cartesian traditions, placed primary emphasis upon activity situated in its everyday contexts.

Some of this work pointed to a theoretical problem associated with the cognitivist assumption that symbols are manipulated solely on the basis of their abstract form, and suggested that cognitivism provides no account of how symbols ultimately come to take on meaning in human action and experience. The abstract symbols (e.g. nodes in a semantic network) are equivalent to the zeros and ones in a computer. What differentiates one concept from another is solely the set of relations among the symbols corresponding to the two concepts. Thus, one symbol is defined solely in terms of other symbols. In contrast, Harnad (1990), Searle (1980) and others have argued that meaning (e.g. what concepts are about) cannot, in principle, arise from such a system. For example, Harnad asks us to consider how we could understand a sentence written in a foreign language using only a dictionary for that language. We would look up in the dictionary the first word in the sentence (the first abstract symbol) and see that it is defined in terms of relations to other abstract symbols. On looking up the first word in the definition, we find only more abstract symbols. Clearly, we will never be able to discover the meaning of the first word in the sentence, let alone the meaning of the sentence. Yet abstract symbol theory claims just this: that meaning arises from the relations among the symbols. If abstract symbols are to be meaningful, they must be grounded in the world through perception and action. But Hilary Putnam has formally proved that starting just from a set of abstract symbols, there is an infinite number of exactly corresponding objects and relations in the world, so it is impossible to ground the abstract symbols under these conditions (Lakoff, 1987, pp. 229–259). (*See* **Symbol-grounding Problem**; **Meaning**; **Chinese Room Argument, The**)

Others have suggested that the cognitivist requirement that the world be represented in explicit symbolic terms presents a further theoretical difficulty. Among the major practical limitations of the cognitivist tradition is its difficulty in modeling common-sense knowledge. While cognitivism has been very successful at modeling certain kinds of highly formalized cognitive tasks, modeling some very basic forms of everyday human intelligence has proved to be much more problematic.

Consider, for example, a pedestrian deciding when to cross a street. There is a simple rule: wait for a green crossing light. But this rule needs to be modified to fit almost every conceivable situation: if you are in a great hurry, then cross against the light, except if traffic is extremely heavy, in which case wait, except if it is a real emergency, in which case cross anyway, except if traffic is extremely heavy, in which case wait, except if the traffic is moving slowly, in which case cross, except if you have a twisted ankle, and so on. Some researchers have argued that this practical difficulty is a reflection of the impossibility in principle of explicitly modeling common-sense knowledge (e.g. Dreyfus, 1979). Dreyfus, drawing on phenomenology and the later philosophy of Wittgenstein, takes issue with the cognitivist assumption that explicit symbolic representation of the world is necessary to produce action, and argues that action in the everyday world depends on an enormous body of background knowledge, combined with perception of affordances (Gibson, 1979), that is, how a particular type of body constrains actions occurring in a particular situation and structured in part by particular goals. Given that the affordances for action will change with momentary changes in bodily abilities (such as adrenaline surges) and with changes in the goals, no set of rules can be constructed to guide actions in situations treated as members of abstract categories such as 'street-crossing situation'. Since all situations are unique, abstract rules cannot be constructed to ensure the adequacy of action in the situation in general. In this view, then, even if the explicit models offered by cognitivism are able to provide insight into certain aspects of cognition, these insights are strictly limited to formalizable aspects of cognition and do not provide us with a plausible general model of human cognition. (*See* **Phenomenology**; **Perception: The Ecological Approach**; **Wittgenstein, Ludwig**; **Gibson, James J.**)

These weaknesses and limitations of cognitivism, along with others to be discussed below, have led some researchers to conclude that the complexity of the relationship between the mind and its environment is such that considering them separately involves unjustifiable oversimplification, and that primary analytical emphasis should instead be placed on cognition as it occurs in situated activity. While not all researchers would commit themselves equally to each of the following points, theories of situated cognition have proposed several possible alternative assumptions about the nature of cognition and its relationship to action:

- The mind and the world are fundamentally interconnected with one another. The character of the world is not given, but is instead dependent upon construal by agents in the course of activity. These construals, furthermore, are both enabled and constrained by the structure of the brain, by the body, and by their occurrence in specific physical and social contexts.
- Representations of the world are not abstract, disembodied, and detached from the world, but arise in the course of situated activity.
- Knowledge is located in the evolving relationships between people and artifacts in culturally evolved systems of activity.
- Cognition is mediated by artifacts and distributed across people in systems of activity.
- Cognition is opportunistic and improvized. Successful participation in everyday activity, rather than engagement in tasks based on formal logic, is the primary phenomenon to be explained.

BODY, ENVIRONMENT AND SOCIAL CONTEXT

This shift in focus from abstract and logical thinking to successful participation in everyday activity has led to a corresponding shift of attention towards phenomena that have been considered by cognitivists to be of marginal importance. For example, whereas cognitivism treats sensorimotor processes as peripheral to and separate from the cognitive system, theorists of situated cognition have begun, in various ways, seriously to study the consequences of physical embodiment for the nature of cognitive processing. (*See* **Embodiment**)

One area of research has focused on individual cognition, and has attempted to identify universal aspects of cognition that are grounded in the nature of the human body and its capacity to act in a physical environment. This work argues that cognitive processes, even symbolic processes, are not abstract and are intimately linked to the embodied nature of the organisms carrying out those processes. Other researchers emphasize the fact that physical bodies are a part of the physical world in which they act, and claim that this locatedness requires alternative ways of thinking about cognition.

Recent research in cognitive psychology and cognitive linguistics, while retaining a primary focus on the cognitive processes of individuals, has attempted to understand how cognition has evolved and how it functions in the service of embodied organisms who act in a physical environment. In this work, symbolic mental representations have remained at the center of studies of cognition. However, instead of being viewed as abstract or

amodal (that is, as bearing only an arbitrary connection to experience in the world) symbols are viewed as inherently perceptual in that they modally or analogically replicate some aspect of experience. Thus, this work takes representational units to develop within activity and to remain linked to activity. Lakoff (1987) suggests that even our most abstract concepts – logical rules, such as '*p* or *q* but not both' – arise from experience in the world. For example, our experience with containers and containment provides just the structure for the rule: something can be in the container (*p*) or not in the container (*q*), but not both. Barsalou (1999) has demonstrated that the representations of many concepts have components related to the way the corresponding objects are perceived and acted upon, rather than consisting of amodal abstract symbols. (*See* **Cognitive Linguistics**)

Glenberg and Robertson (2000) demonstrate that understanding simple sentences requires a consideration of how human actions can combine. Thus, people find sentences such as 'Bill stood on the tractor to paint the top of the barn wall' much more sensible than sentences such as 'Bill stood on the hammer to paint the top of the barn wall'. From the point of view of abstract symbols, the two sentences are virtually identical: tractors and hammers are both inanimate concrete nouns, both are tools, and both are unrelated to painting in past experience. The difference is that knowledge of how people can interact with objects – even when used in atypical and never-before-encountered ways – allows people to determine which sentence is sensible and which is nonsense.

Recent work in artificial intelligence and robotics has contributed in a somewhat different way to an understanding of the importance of embodiment for cognition (e.g. Agre and Chapman, 1987; Brooks, 1991). This work has argued that situated activity by embodied agents in a complex physical environment is a nontrivial accomplishment, and one that must be viewed as central to intelligence. However, it has not been modeled successfully by approaches that are grounded in traditional artificial intelligence. Thus, some researchers have attempted to design agents that are able to respond effectively, in real time, to the demands of complex, unpredictable, and changing environmental conditions. An important strategy has been to replace the traditional cognitivist focus on perception, modeling, planning and action as discrete steps in a problem-solving process, by proposing a tight coupling of sensing and action. These embodied agents exploit features of the physical environment and their own relationship to it so as to avoid the need to form a complete and explicit representation of the environment before acting. Instead, they opportunistically exploit aspects of the structure of the environment that offer clues about how to proceed and when a task has been completed. (*See* **Situated Robotics**)

Similar opportunism and context-embeddedness has been demonstrated in research, largely inspired by the cultural–historical tradition begun by L. S. Vygotsky, that examines humans engaged in a wide variety of practical tasks. This work has led Sylvia Scribner to argue that the environment plays a 'constitutive role' in cognition. Scribner (1997, p. 329) argues that 'skilled practical thinking incorporates features of the task environment (people, things, information) into the problem-solving system. It is as valid to describe the environment as part of the problem-solving system as it is to observe that problem-solving occurs "in" the environment.' (*See* **Cultural Psychology**; **Vygotsky, Lev**)

This work challenges a number of ideas fostered by cognitivist models of problem-solving, including: that problems are given to the problem-solver in a complete form; that problems of the same logical class will be solved by the same sequence of operations on all occasions; and that learning involves increasing independence from the concrete particularities of a context. Instead, studies of problem-solving in a wide range of everyday activities have shown that what appear, in theory, to be formally identical problems are, in practice, flexibly formulated and solved by the problem solver according to the contingencies of the environment. For example, Scribner has shown that dairy workers reformulate abstract computational problems into problems that depend on the concrete physical array of the product they are working with. She has shown, in addition, that these reformulations differ depending on the nature of the activity (e.g. 'filling orders' versus 'inventory'), on the specific point in the flow of activity, and on the values and goals of the problem-solver. Similar claims have been made regarding the skilled practical thinking of shoppers, cooks, bartenders, street vendors, and participants in a range of other activities.

This work indicates that, compared with novices, experts in a domain of activity rely more, not less, on environmental sources of information. This movement towards increasing contextualization of practical thinking not only contradicts cognitivist claims suggesting that cognition should become more powerful as it becomes less contextualized; it also suggests that cognitivist models of thinking as a purely mental activity will find analysis of many

practical thinking problems intractable (Scribner, 1997). It is also important to note, lest one conclude that the cognition of what Lave (1988) ironically called 'just plain folks' represents an inferior and deficient mode of thought, that the very same kinds of context-embeddedness and opportunism have been demonstrated in careful studies of the work of those who, to cognitivists, represent the height of rationality, such as scientists, mathematicians, engineers, and medical diagnosticians (e.g. Goodwin, 1995; Latour, 1987; Norman and Brooks, 1997).

In addition to emphasizing the role of the environment in cognition, work in situated cognition has emphasized that it is necessary to understand several ways in which the social context influences cognitive processing. One of these is closely related to the opportunism and flexibility of practical problem-solving. When Scribner's dairy workers transformed abstract computational problems into problems that were tied to the physical environment in which they were situated, they did so by using materials (e.g. milk crates) designed for noncognitive purposes (e.g. holding milk bottles) to mediate their formulation and solution of a cognitive task. This is an instance of a more general capacity of human beings to modify their environment by creating mediating artifacts. These artifacts, moreover, can transform subsequent possibilities for activity by embodying 'partial solutions to frequently encountered problems' (Hutchins, 1995, p. 374) of an individual or group, and can preserve these solutions to be passed on to subsequent generations. In this sense, use of a mediating artifact situates its user within the cultural tradition that developed, transmitted, and continues to maintain that artifact.

A second, and closely related, way in which the social context is important in cognitive processing is connected with the idea that individual mental functioning has its origins in social interaction. A great deal of research, much of it again building on the ideas of Vygotsky, has demonstrated that social interaction provides the conditions within which skilled practical thinking is mastered by individuals. According to this work, other actors provide the individual with support in performing cognitive tasks that he or she would be unable to perform alone. Through this kind of 'apprenticeship' (Rogoff, 1990), individuals develop mental structures and processes that can be traced to their origins in social interaction. This is not to claim that forms of individual cognition directly copy processes found in social interaction: individuals transform cognitive structures and processes in the course of internalization, and cognition is opportunistically adapted by agents to their specific circumstances of activity (Wertsch, 1998). (*See* **Culture and Cognitive Development**)

Finally, some cognitive tasks are more properly viewed as carried out by social groups than by individuals, so the cognitive processes of individuals engaged in such tasks must be viewed in terms of their relationship to the larger cognitive system.

These points about the importance of the social context for cognitive processing have been of central importance in recent work on cognitive artifacts and distributed cognition.

COGNITIVE ARTIFACTS AND DISTRIBUTED COGNITION

Vygotsky's primary concern was with semiotic artifacts, or signs, and the ways in which they mediate higher mental functioning in humans. D. A. Norman, drawing on this emphasis within the cultural–historical tradition, introduced the idea of 'cognitive artifacts'. For Norman (1991, p. 17), cognitive artifacts are 'those artificial devices that maintain, display, or operate upon information in order to serve a representational function and that affect human cognitive performance'. Examples of cognitive artifacts include language, inscriptional systems for representing language, maps, lists, and calculators.

A well-known example can illustrate the importance of cognitive artifacts in mediating cognitive processes (Rumelhart *et al.*, 1986; Wertsch, 1998). Multiplication of multi-digit numbers – for example, multiplying 343 by 822 – represents a highly abstract conceptual problem. However, such a problem can be transformed by first arranging the digits in a spatial array and then carrying out a sequence of concrete operations on the digits, as shown in Figure 1.

Here, the spatial array serves as a cognitive artifact that transforms an abstract and difficult

```

Figure 1. An example of a cognitive artifact. An abstract and difficult problem (multiplying 343 by 822) is transformed into a relatively simple one by a process of arrangement of the digits and simple operations on them.

problem into a relatively simple one that most of us become very good at. It is important to note, however, that while an individual problem-solver must have knowledge of how to use this cognitive artifact, the knowledge required to solve this problem is not wholly a property of the individual. That is, much of the knowledge required for solving multi-digit multiplication problems is contained in the cognitive artifact, in the form of historically evolved ways of arranging and operating on digits. Moreover, while the cognitive processing involved in solving this problem does involve the manipulation of symbols, this symbol manipulation is not likely to be performed solely in the head, but will also depend on the use of materials in the world, such as paper and pencil. Indeed, as Wertsch (1998) points out, many individuals who are able easily to solve problems like this are unaware of the abstract principles involved in the cognitive artifact, and would in fact be unable to solve the problem if the use of the artifact were not possible – for example, without the use of paper and pencil in a noisy room.

Observations of this sort have led some theorists of situated cognition to propose that cognition is 'distributed – stretched over, not divided among – mind, body, activity, and culturally organized settings (which include other actors)' (Lave, 1988, p. 1). Theorists of distributed cognition argue that the study of cognition cannot involve only the study of what is in individual heads, but must extend 'beyond the skin' (Hutchins, 1995) to examine how individuals and groups of individuals use historically evolved artifacts in carrying out their activities. For example, Hutchins' study of the navigation team of a large naval vessel shows that, while there is a great deal of computation involved in the navigation of a large ship, this computation does not take place in the head of any individual, but in a coordination of the minds of different individuals with navigational artifacts, such as landmarks, maps, phone circuits, and organizational roles. The cognition of individuals often involves little more than what is involved in reading numbers or drawing lines. The symbol processing necessary for navigation is performed by the 'functional system' of a collection of individuals acting with cognitive artifacts.

Work in distributed cognition suggests that understanding how cognition is mediated by artifacts and realized in activity and social interaction leads ultimately to the study of how cognition is tied to and partially constitutive of cultural systems. Proponents of distributed cognition have called for a redefinition of the disciplinary boundaries of cognitive science, with a much more central role given to such fields as anthropology, sociology, and cultural psychology, whose methods and interests are well suited to the kinds of detailed 'cognitive ethnography' called for in the study of distributed activity systems.

Situated Robotics

Intermediate article

Maja J Matarić, University of Southern California, Los Angeles, California, USA

CONTENTS

Situated robotics is the study of robots embedded in complex, often dynamically changing environments. The complexity of the robot control problem is directly related to how unpredictable and unstable the environment is, to how quickly the robot must react to it, and to how complex its task is.

INTRODUCTION

Robotics, like any concept that has grown and evolved over time, has eluded a single, unifying definition. What was once thought of as a replacement for repetitive, manual labor has grown into a large field that includes applications as diverse as automated car assembly, space exploration and robotic soccer. Although robotics includes teleoperation, in which the robot itself may be merely a remotely operated body, in most interesting cases the system exists in the physical world, senses its environment, makes autonomous decisions, and acts on them, again in the physical world, typically in ways involving movement. Situated robotics focuses specifically on robots that are embedded in complex, challenging, often dynamically changing environments. 'Situatedness' refers to existing in, and having one's behavior strongly affected by, such an environment. Examples of situated robots include autonomous robotic cars on the highway or on city streets (Pomerleau, 1989), teams of interacting mobile robots (Matarić, 1995), and a mobile robot in a museum full of people (Burgard *et al*., 2000). Examples of unsituated robots, which exist in fixed, unchanging environments, include assembly robots operating in highly structured, strongly predictable environments. The predictability and stability of the environment largely determines the complexity of the robot that must exist in it; situated robots present a significant challenge for the designer.

Embodiment is a concept related to situatedness. It refers to having a physical body and interacting with the environment through that body. Thus, embodiment is a form of situatedness: an agent operating within a body is situated within it, since the agent's actions are directly and strongly affected by it. Robots are embodied: they must possess a physical body in order to sense their environment, and act and move in it. Thus, in principle every robot is situated. But if the robot's body must exist in a complex, changing environment, the situatedness, and thus the control problem, are correspondingly complex.

TYPES OF ROBOT CONTROL

Robot control is the process of taking information about the environment, through the robot's sensors, processing it as necessary in order to make decisions about how to act, and then executing those actions in the environment. The complexity of the environment, i.e., the level of situatedness, clearly has a direct relation to the complexity of the control (which is directly related to the task of the robot): if the task requires the robot to react quickly yet intelligently in a dynamic, challenging environment, the control problem is very hard. If the robot need not respond quickly, the required complexity of control is reduced. The amount of time the robot has to respond, which is directly related to its level of situatedness and its task, influences what kind of controller the robot will need.

While there are infinitely many possible robot control programs, there is a finite and small set of fundamentally different classes of robot control methodologies, usually embodied in specific robot control architectures. The four fundamental classes of control program are: reactive control ('don't think, react'), deliberative control ('think, then act'), hybrid control ('think and act independently in parallel'), and behavior-based control ('think the way you act').

Each of these approaches has its strengths and weaknesses, and all play important and successful roles in certain problems and applications. Different approaches are suitable for different levels of

situatedness, natures of the task, and capabilities of the robot, in terms of both hardware and computation. Robot control involves the following unavoidable trade-offs:

Thinking is slow, but reaction must often be fast. (1)

Thinking allows looking ahead (planning) to avoid bad actions. But thinking too long can be dangerous (e.g., falling off a cliff, being run over). (2)

To think, the robot needs potentially a great deal of accurate information. Information must therefore actively be kept up to date. But the world keeps changing as the robot is thinking, so the longer it thinks, the more inaccurate its solutions. (3)

Some robots do not 'think' at all, but just execute preprogrammed reactions, while others think a lot and act very little. Most lie between these two extremes, and many use both thinking and reaction. Let us review each of the four major approaches to robot control, in turn.

Reactive Control

'Don't think, react'. Reactive control is a technique for tightly coupling sensory inputs and effector outputs, to allow the robot to respond very quickly to changing and unstructured environments (Brooks, 1986). Reactive control is often described as its biological equivalent: 'stimulus–response'. This is a powerful control method: many animals are largely reactive. Thus, this is a popular approach to situated robot control. Its limitations include the robot's inability to keep much information, form internal representations of the world (Brooks, 1991a), or learn over time. The trade-off is made in favor of fast reaction time and against complexity of reasoning. Formal analysis has shown that for environments and tasks that can be characterized *a priori*, reactive controllers can be highly powerful, and, if properly structured, capable of optimal performance in particular classes of problems (Schoppers, 1987; Agre and Chapman 1990). But in other types of environments and tasks, where internal models, memory, and learning are required, reactive control is not sufficient.

Deliberative Control

'Think, then act.' In deliberative control, the robot uses all of the available sensory information, and all of its internally stored knowledge, to reason about what actions to take next. The reasoning is typically in the form of planning, requiring a search of possible state–action sequences and their outcomes. Planning, a major component of artificial intelligence, is a computationally complex problem. The robot must construct and then evaluate potentially all possible plans until it finds one that will tell it how to reach the goal, solve the problem, or decide on a trajectory to execute. Planning requires the existence of an internal representation of the world, which allows the robot to look ahead into the future, to predict the outcomes of possible actions in various states, so as to generate plans. The internal model, therefore, must be kept accurate and up to date. When there is sufficient time to generate a plan, and the world model is accurate, this approach allows the robot to act strategically, selecting the best course of action for a given situation. However, being situated in a noisy, dynamic world usually makes this impossible. Thus, few situated robots are purely deliberative.

Hybrid Control

'Think and act independently in parallel.' Hybrid control combines the best aspects of reactive and deliberative control: it attempts to combine the real-time response of reactivity with the rationality and efficiency of deliberation. The control system contains both a reactive and a deliberative component, and these must interact in order to produce a coherent output. This is difficult: the reactive component deals with the robot's immediate needs, such as avoiding obstacles, and thus operates on a very short timescale and uses direct external sensory data and signals; while the deliberative component uses highly abstracted, symbolic, internal representations of the world, and operates on a longer timescale. As long as the outputs of the two components are not in conflict, the system requires no further coordination. However, the two parts of the system must interact if they are to benefit from each other. Thus, the reactive system must override the deliberative one if the world presents some unexpected and immediate challenge; and the deliberative component must inform the reactive one in order to guide the robot towards more efficient trajectories and goals. The interaction of the two parts of the system requires an intermediate component, whose construction is typically the greatest challenge of hybrid system design. Thus, hybrid systems are often called 'three-layer systems', consisting of the reactive, intermediate, and deliberative layers. A great deal of research has been

conducted on how to design these components and their interactions (Giralt *et al*., 1983; Firby, 1987; Arkin, 1989; Malcolm and Smithers, 1990; Connell, 1991; Gat, 1998).

Behavior-based Control

'Think the way you act.' Behavior-based control draws inspiration from biology, and tries to model how animals deal with their complex environments. The components of behavior-based systems are called behaviors: these are observable patterns of activity emerging from interactions between the robot and its environment. Such systems are constructed in a bottom-up fashion, starting with a set of survival behaviors, such as collision avoidance, which couple sensory inputs to robot actions. Behaviors are added that provide more complex capabilities, such as wall following, target chasing, exploration, and homing. New behaviors are introduced into the system incrementally, from the simple to the more complex, until their interaction results in the desired overall capabilities of the robot. Like hybrid systems, behavior-based systems may be organized in layers, but unlike hybrid systems, the layers do not differ from each other greatly in terms of the timescale and representation used. All the layers are encoded as behaviors, processes that quickly take inputs and send outputs to each other.

Behavior-based systems and reactive systems share some similar properties: both are built incrementally, from the bottom up, and consist of distributed modules. However, behavior-based systems are fundamentally more powerful, because they can store representations (Matarić, 1992), while reactive systems cannot. Representations in behavior-based systems are stored in a distributed fashion, so as to best match the underlying behavior structure that causes the robot to act. Thus if a robot needs to plan ahead, it does so in a network of communicating behaviors, rather than using a single centralized planner. If a robot needs to store a large map, the map is likely to be distributed over several behavior modules representing its components, like a network of landmarks (Matarić, 1990), so that reasoning about the map can be done in an active fashion, for example using message passing within the landmark network. Thus, the planning and reasoning components of the behavior-based system use the same mechanisms as the sensing and action-oriented behaviors, and so operate on a similar timescale and representation. In this sense, 'thinking' is organized in much the same way as 'acting'.

Because of their capability to embed representation and plan, behavior-based control systems are not an instance of 'behaviorism' as the term is used in psychology: behaviorist models of animal cognition involve no internal representations. Some argue that behavior-based systems are more difficult to design than hybrid systems, because the designer must directly take advantage of the dynamics of interactions rather than minimize interactions through traditional system modularity. However, as the field is maturing, expertise in complex system design is growing, and principled methods of distributed modularity are becoming available, along with behavior libraries. Much research has also been conducted in behavior-based robot control.

COMPARISON AND DISCUSSION

Behavior-based systems and hybrid systems have the same expressive and computational capabilities: both can store representations and look ahead. But they work in very different ways, and the two approaches have found different niches in mobile robotics problem and application domains. For example, hybrid systems dominate the domain of single robot control, unless the domain is so time-demanding that a reactive system must be used. Behavior-based systems dominate the domain of multiple-robot control, because the notion of collections of behaviors within the system scales well to collections of such robots, resulting in robust, adaptive group behavior.

In many ways, the amount of time the robot has (or does not have) determines what type of controller will be most appropriate. Reactive systems are the best choice for environments demanding very fast responses; this capability comes at the price of not being able to look into the past or the future. Reactive systems are also a popular choice in highly stochastic environments, and environments that can be properly characterized so as to be encoded in a reactive input–output mapping. Deliberative systems, on the other hand, are the best choice for domains that require a great deal of strategy and optimization, and in turn search and planning. Such domains, however, are not typical of situated robotics, but more so of scheduling, game playing, and system configuration, for instance. Hybrid systems are well suited to environments and tasks where internal models and planning can be employed, and the real-time demands are few, or sufficiently independent of the higher-level reasoning. Thus, these systems 'think while they act.' Behavior-based systems, in

contrast, are best suited to environments with significant dynamic changes, where fast response and adaptivity are necessary, but the ability to do some looking ahead and avoid past mistakes is required. Those capabilities are spread over the active behaviors, using active representations if necessary (Matarić, 1997). Thus, these systems 'think the way they act.'

We have largely treated the notion of 'situated robotics' here as a problem: the need for a robot to deal with a dynamic and challenging environment it is situated in. However, it has also come to mean a particular class of approaches to robot control, driven by the requirements of situatedness. These approaches are typically behavior-based, involving biologically-inspired, distributed, and scalable controllers that take advantage of a dynamic interaction with the environment rather than of explicit reasoning and planning. This body of work has included research and contributions in single-robot control for navigation (Connell, 1990; Matarić, 1990), models of biological systems ranging from sensors to drives to complete behavior patterns (Beer *et al*., 1990; Cliff, 1990; Maes, 1990; Webb, 1994; Blumberg, 1996), robot soccer (Asada *et al*., 1994; Werger, 1999; Asada *et al*., 1998), cooperative robotics (Matarić, 1995; Kube and Zhang, 1992; Krieger *et al*., 2000; Gerkey and Matarić, 2000), and humanoid robotics (Brooks and Stein, 1994; Scassellati, 2001; Matarić 2000). In all of these examples, the demands of being situated within a challenging environment while attempting to safely perform a task (ranging from survival, to achieving the goal, to winning a soccer match) present a set of challenges that require the robot controller to be real-time, adaptive, and robust.

The ability to improve performance over time, in the context of a changing and dynamic environment, is also an important area of research in situated robotics. Unlike in classical learning, where the goal is to optimize performance over a typically long period of time, in situated learning the aim is to adapt relatively quickly, achieving greater efficiency in the light of uncertainty. Models from biology are often considered, and reinforcement learning models are particularly popular, given their ability to learn directly from environmental feedback.

This area continues to expand and address increasingly complex robot control problems. There are several good surveys on situated robotics which provide more detail and references (e.g. Brooks, 1991b; Matarić, 1998).

CONTENTS

Skill acquisition is the process whereby a learner progresses from slow, deliberate, memory-intensive, error-prone performance on a task, to rapid, automatic, near-error-free performance. The process applies to activities ranging from simple perceptual–motor tasks, such as pushing a button whenever a light comes on or shifting gears in a car, to complex cognitive tasks, such as playing chess or diagnosing diseases.

AUTOMATICITY AND THE POWER LAW OF PRACTICE

Automaticity is an essential aspect of skill acquisition. Skills are thought to consist largely of collections of automatic processes. Automatic processing often occurs without attention. It is often fast, effortless, stereotypic, autonomous, and unavailable to conscious awareness (Shiffrin and Schneider, 1977). (*See* **Automaticity**; **Attention**; **Attention, Models of**; **Consciousness and Attention**)

Skill acquisition is thought to proceed through three stages (Fitts, 1964; Fitts and Posner, 1967; Anderson, 1982). The first stage is the cognitive stage, in which the learner remembers a set of declarative facts (e.g., instructions and cue–feedback relations) relevant to the skill and uses domain-general problem-solving methods to perform the task. For instance, a novice skier might need to recall and even rehearse the ski instructor's instructions about how to turn and stop. While turning, the skier must carefully monitor and adjust his or her stance so as to achieve the desired result. Errors at this stage can result from misinterpreted instructions, failure to correctly recall instructions, and the relatively long time required to recall and interpret the instructions and carefully monitor task execution. (*See* **Implicit Learning**; **Implicit Learning Models**; **Implicit and Explicit Representation**)

In the second stage, called the associative stage, declarative facts are gradually transformed into procedural knowledge, which often represents a strengthened, direct link from perceptual stimuli to appropriate actions and therefore is much more efficient. In addition, general-purpose problem-solving methods are replaced by domain-specific procedures. For instance, when a person first learns a new card game, the person must try to remember all the rules and carefully consider how each possible card might affect the desired goal; but in the associative stage, the player would much more quickly select an appropriate move in any given situation.

The final stage in skill acquisition is the autonomous stage, in which performance becomes increasingly automated and rapid. As skill improves in this stage, cognitive involvement decreases, and the learner often loses the ability to verbally describe how he or she does the task. For instance, if an experienced touch typist is asked to fill in a blank typewriter keyboard with all the letters, he may need to imagine typing words in order to recall where the letters are located. Likewise, once someone becomes proficient at skiing, she may need to carefully observe herself turning in order to tell a novice how to turn. (*See* **Motor Control and Learning**; **Motor Control: Models**; **Memory: Implicit versus Explicit**)

It is generally accepted that automaticity and skill acquisition result from practice. A robust empirical finding in skill acquisition is that the time to perform a task is a power function of the amount of practice on the task. This is known as the *power law of practice*. Formally:

$$T = aP^{-b} \quad (1)$$

where T is the time to do a task, P is the amount of practice, and a and b are constants. This power law of practice is also called the log–linear learning law because the above equation can be transformed into

$$\ln T = a - b \ln P \quad (2)$$

indicating that there is a linear relationship between the logarithm of the time and the logarithm of the amount of practice. It has been shown that the power law of practice is universally valid in a wide range of human tasks, including both perceptual–motor and cognitive tasks (Newell and Rosenbloom, 1981; Anderson and Schooler, 1991).

Various different models of automaticity and skill acquisition have been proposed. This article will describe several of these models and their relationship to the three levels of skill acquisition and the power law of learning.

MATHEMATICAL MODELS OF AUTOMATICITY

Schneider and Shiffrin's (1977; Shiffrin and Schneider, 1977) model of automaticity assumes that automaticity is automation of attentional processes in terms of automatic encoding and automatic response. Their model was mainly based on the findings of different effects of consistent and varied mapping conditions in memory search tasks. In a memory search task, subjects are presented with a list of one or more letters (e.g. A, E, K, T), called the memory set, followed by a probe (e.g. E), and are instructed to make a timed response to indicate whether the probe is in the memory set (e.g. Kristofferson, 1972). Probes not in the memory set are called *distracters* (e.g. Q in the above example), whereas those in the memory set are called *targets*. The typical result for a memory search task is that the time it takes to locate a target in a memory set increases with the number of items in the set. In the consistent mapping condition, the items used as targets are never used as distracters in any trials. For example, as E is a target in the example above, E would never appear as a distracter in any other trial. In contrast, in the varied mapping condition, target items on one trial are also used as distracters on other trials. For example, probe T is a target in a trial for memory set (T, M, X, U) but a distracter in another trial with memory set (A, H, W, D). The basic finding in the consistent mapping experiments is that after enough practice the search time for a target does not increase with the number of items in the memory set, that is, the search time is a flat function of the number of items. In varied mapping conditions, however, the search time for a target still increases with the number of items in the memory set even after considerable practice. Based on such results, Schneider and Shiffrin argued that attentional processes were automated in the consistent mapping condition through automation of encoding and automation of responses. In the varied mapping condition, encoding and responses could not be automated because of the inconsistency of targets and distracters from trial to trial.

Schneider and Shiffrin's model of automaticity has been challenged by several researchers. For example, Hirst *et al*. (1980) showed that people could learn to perform two complex tasks simultaneously without automation of encoding and response in either task.

A more serious challenge for Schneider and Shiffrin's model is Logan's instance theory (Logan, 1988). Instead of relating automaticity to attention in terms of encoding and response, Logan's theory relates automaticity to memory retrieval. Specifically, it argues that performance is automatic when it is based on direct memory retrieval of past solutions from memory, whereas performance is not automatic when it is based on general-purpose algorithms or procedures. A novice starts with general algorithms. As he or she gains experience with practice, specific solutions are learned and remembered. When these specific solutions are later directly retrieved from memory to solve problems, the performance becomes automatic. Therefore, 'automatization reflects a transition from algorithm-based performance to memory-based performance' (Logan, 1988, p. 493). Compared to Fitts's stage model, solving problems using general algorithms corresponds to the cognitive stage, and solving problems using direct memory retrieval roughly corresponds to the associative and autonomous stages. Logan's theory assumes that whenever a stimulus is encountered, it is encoded, stored, and retrieved separately as an instance. It is this accumulation of specific episodic instances with practice that is behind the algorithm-to-memory transition and makes automaticity possible. In particular, the chances of solving a problem by direct memory retrieval are higher later in practice because of the greater number of acquired candidate instances.

The instance theory is consistent with the power law of practice. There is a race between memory and the algorithm; whichever finishes first controls the response. With practice, memory comes to

dominate the algorithm because more and more instances enter the race, and the more instances there are, the more likely it is that at least one of them will win the race. This model naturally yields the power law of practice.

Crossman (1959) proposed a theory of skill acquisition in terms of a trial-and-error method. Specifically, a novice performs a task by randomly selecting a method from a pool of possible methods and noting its speed of performance. Different methods have different speeds. If a method proves to be faster, its probability of being selected increases. In the long run, the fastest method would have the highest probability of being selected. This theory, though different from Logan's, is also consistent with the power law of practice: it is easier to improve the performance by finding a faster method early in practice than later.

CHUNKING IN SOAR

The mechanism of chunking was first proposed by Newell and Rosenbloom (1981), and is fully developed in Soar, a unified theory of cognition (Newell, 1991). Chunking is one of a class of learning mechanisms for converting declarative knowledge into procedural knowledge, a process called 'knowledge compilation'. Chunking models the transition from the cognitive stage to the associative stage by automatically converting multiple cognitive processing steps for achieving a goal into a single production rule, called a chunk, that represents procedural knowledge for achieving the goal. For instance, according to this theory, if a learner initially adds 2 and 3 by starting with 2 and then counting up three numbers to arrive at 5, that person will then acquire a rule that directly produces the answer 5 when presented with the goal of adding 2 and 3. The chunking theory also includes simple mechanisms that can produce a general rule from a single task instance. For example, Soar can learn a chunk that encodes '$m + 0 = m$' by solving a single instance such as '$5 + 0 = 5$'. (*See* **Soar**; **Learning Rules and Productions**)

Chunking produces power-law speed-up for tasks that can be decomposed into smaller, frequently recurring subtasks. For example, if Soar first solves '$112 + 112$' by using counting to add the two digits in each decimal place, then it would acquire three chunks: '$2 + 2 = 4$', '$1 + 1 = 2$', and '$112 + 112 = 224$'. The third chunk is specific to a single problem, so it has no effect on the speed of solving other problems; however, the first two chunks will speed up any problems in which either two ones or two twos must be summed. As Soar solves additional problems, it will quickly acquire chunks for other pairs of digits. Eventually, speed-up may be due to quickly solving problems by applying more specific rules, such as '$112 + 112 = 224$'.

Chunking is somewhat similar in spirit to Logan's instance theory. Both theories bypass processing by directly using stored answers to previously solved problems. However, Soar stores only one instance, in the form of a production rule, whereas, Logan's theory stores an instance, as a declarative memory trace, each time the problem is solved. Furthermore, in Soar there is never a race between chunks and algorithms for solving a problem: if a chunk is available Soar always uses it. Finally, chunking can produce general chunks (such as '$m + 0 = m$'), which apply to more than one instance of a task.

LEARNING IN ACT-R

ACT-R is a cognitive architecture that accounts for a wide range of cognitive phenomena, including perceptual–motor tasks, memory, and problem-solving (Anderson and Lebiere, 1998). ACT-R contains five learning mechanisms to account for the progression of skill from the cognitive to the autonomous stage. ACT-R's knowledge compilation mechanism is production compilation. It produces procedural knowledge (in the form of production rules) by summarizing and generalizing one or more problem-solving steps based on a declarative representation of the learner's understanding of how one state of problem-solving led to a subsequent state. For example, suppose that ACT-R discovers that it can add 5 and 2 on a calculator by typing the keys `5 ENTER 2 +`. To learn procedural knowledge from this example, ACT-R must set the goal of building a declarative representation that links the goal of adding 5 and 2 to typing `5 ENTER 2 +`. This representation includes the goal, the solution, and the fact that + is a symbol for addition. The result is a production rule of the form: 'If the goal is to perform a mathematical operation on two numbers n_1 and n_2, and o is a symbol for that operation, then type n_1 `ENTER` n_2 o.' This mechanism is similar to Soar's chunking; but Soar's mechanism works automatically and continuously, whenever a goal is achieved, whereas ACT-R's mechanism requires an explicit goal to understand how one problem-solving state led to another. (*See* **ACT**)

ACT-R models continuous improvement from the associative to the autonomous stage through the speed-up of declarative fact retrieval and two

rule-tuning mechanisms (discussed below). Research on human memory shows that the time to retrieve a declarative fact follows a power law. ACT-R contains two mechanisms for speeding up the retrieval of declarative facts from memory: base-level learning and associative strength learning. The time taken to retrieve a declarative fact in ACT-R is proportional to its activation, which depends on two quantities: its base-level activation, which is determined by its retrieval history, and activation it receives from other facts in working memory. A fact's base-level activation reflects the prior probability that it will be retrieved. In general, facts that are more frequently and more recently retrieved have higher activation. A fact's activation is adjusted (either upwards or downwards) by means of associative links with facts already in working memory. Associative links are unidirectional and have a strength that reflects the conditional probability that a fact will be needed, given that an associated fact is in working memory. The equations that govern activation growth and decay directly produce power-law response curves.

The activation of a declarative fact also affects the probability of its retrieval in ACT-R. Some facts may have such low activation that they will never be retrieved. In addition, ACT-R can model retrieval errors. Suppose that a child has two contradictory facts, '$5+4=9$' and '$5+4=8$', where '$5+4=8$' has been retrieved half as often as the correct fact. Since activation controls the probability of retrieval, the child will occasionally recall the incorrect fact.

The time taken to execute a rule in ACT-R is determined by the rule's strength, which reflects the probability that the rule will be needed based on the rule's past history of use. The equation governing this value is identical to that for base-level activation. As a result, the time taken to execute a rule is a power function of its frequency of execution.

The mechanisms described above lead to faster response times, but skill acquisition also involves learning to select an appropriate action. ACT-R models this using two mechanisms that estimate a production rule's cost and probability of success based on previous experience. These estimates are then used to select from among competing production rules by estimating an expected gain for each rule. Rules with higher expected gains have higher probabilities of selection. The expected gain is $PG-C$, where P is the probability of eventual success, G is the value of achieving the goal (typically specified as the number of seconds one is willing to spend to achieve the goal), and C is the cost of achieving the goal using the selected action. For example, when children are first learning to add, they often begin by counting on their fingers, then gradually shift to retrieving the sum from memory. ACT-R models this using two competing production rules: one that says to count to determine the sum and another that says to retrieve the sum from memory. Suppose that at an early stage a child's past experience indicates that counting is successful 95% of the time and takes 5 seconds, whereas memory retrieval is successful 75% of the time and takes 1 second. Suppose further that the child is willing to spend up to 30 seconds to correctly add the two numbers. In this example, the expected gain from counting is $0.95 \times 30 - 5 = 23.5$, whereas the expected gain from recalling the sum is $0.75 \times 30 - 1 = 21.5$. In this case, ACT-R predicts that the child would favor counting over memory recall. As the child experiences more success with recall, the expected gains will shift in its favor, causing the child to shift to direct recall.

NEURAL NETWORKS

Artificial neural networks, or connectionist models, have also been used to model a range of cognitive processes including learning, memory, and problem-solving (Rumelhart and McClelland, 1986). Instead of serial and symbolic computation, a neural network model employs parallel distributed processing, whereby processing occurs in parallel across a large number of simple units. Neural networks are capable of learning. The essence of learning in a neural network is to tune the connection strengths (weights) between units so that multiple constraints from the environment and the network structure can be simultaneously satisfied. Thus the network gradually achieves more efficient computations. In supervised learning (or learning from examples), where for every input the desired output is provided by an external teacher, a network learns by seeking to minimize the difference between its actual output and the desired output. In unsupervised learning, where no information about the desired output is available, the network has to discover for itself the best way to respond. This discovery may involve extracting the correlation among the inputs, or satisfying constraints, such as only one unit being allowed to fire for any given input (competitive learning). Both types of learning can be used to model human skill acquisition. (*See* **Backpropagation**)

A neural network is trained with a limited number of examples, in the hope that it will

generalize from them and achieve good performance on novel inputs. The performance of a neural network is typically indicated by the error, a measure of the difference between desired outputs and actual outputs. When the expected error is plotted against the number of training examples, a learning curve results. Both theoretical calculations (e.g. Seung *et al*., 1992) and experimental results (e.g. Cortes *et al*., 1994) have shown that the learning curves of layered feedforward neural networks typically follow a power function.

REINFORCEMENT LEARNING

Reinforcement learning (a term borrowed from the field of animal learning) is a learning model in which a system learns a mapping from situations to actions, by interacting with the environment and attempting to maximize the reward (reinforcement) from the environment (Sutton and Barto, 1998). Reinforcement learning is different from supervised learning in that the learner is not told the desired action. Reinforcement learning is also different from unsupervised learning in that the learner does receive a feedback for the action it performs. The feedback is evaluative, and may be delayed. The learner has to discover the actions that yield the greatest long-term reward through trial and error. It has been shown that reinforcement learning captures several fundamental concepts underlying human skill acquisition, including learning from interaction, trial and error, and temporal credit assignment. Reinforcement learning has been applied in many arenas, including robot learning and game playing. (*See* **Reinforcement Learning: A Computational Perspective**; **Reinforcement Learning: A Biological Perspective**)

OTHER COMPUTATIONAL FRAMEWORKS FOR SKILL ACQUISITION

Posner *et al*. (1997) have studied the brain mechanisms of skill acquisition. They claim that skill acquisition represents circuitry change in the brain. Specifically, there are four mechanisms that work together to generate skill acquisition. Firstly, automaticity is a result of an increase in the links between previously isolated subsystems. Secondly, when skills are acquired, the size or the number of brain areas involved increases. As a result, the computation within modules is improved. Thirdly, skill acquisition could be due to the replacement of the initial components by other more efficient components. Finally, certain brain areas can start performing tasks formerly implemented by different areas, indicating circuit change. All four mechanisms have been found using sophisticated brain imaging techniques. (*See* **Reward, Brain Mechanisms of**)

Anderson and Schooler (1991) provide evidence that the power law of learning reflects an optimal adaptation to the environment. They analyzed information access and retrieval in a variety of natural settings and found that the probability of a specific fact recurring is a power function of its past frequency of use. For example, they found that the probability that a word would appear in the 101st utterance of a speaker was a power function of the word's frequency of use in the speaker's last 100 utterances. They found similar patterns when studying electronic mail messages, and newspaper headlines. (*See* **Rational Models of Cognition**)

Wixted and Ebbesen (1991, 1997) suggest that the power function best describes the process of forgetting. (But see Anderson and Tweney (1997) for a different view.) (*See* **Memory Distortions and Forgetting**)

APPLICATIONS IN EDUCATION

Skill acquisition models have several important uses in education. The models often suggest ways to structure educational material so as to maximize learning. To achieve the greatest speed-up, knowledge compilation theories suggest that tasks should be hierarchically decomposed into subtasks and then taught by starting with the more general tasks and working towards more specific tasks. ACT-R's theory of knowledge compilation through understanding suggests ways to structure examples that might help the learner achieve better performance. For instance, for ACT-R to properly acquire a rule (namely, '$m+0=m$') from the example '$5+0=5$', it must note that 0 is a special case, otherwise it would induce the rule '$m+n=m$'. ACT-R's theory of production rule speed-up and memory retrieval suggests that each rule and each declarative memory fact follows the power law of learning, so that continued practice on all rules and facts used in a task is necessary to improve performance or maintain skill. (*See* **Learning Aids and Strategies**; **Education, Learning in**)

Skill acquisition models can also be used to construct models of specific learning tasks. Once constructed, these models can guide instructional design or be used as part of an intelligent tutoring system that monitors student progress and

presents appropriate examples to enhance learning. By including specific erroneous knowledge and rules in such models, an intelligent tutoring system can detect incorrect learning and propose appropriate intervention.

TYPES OF LEARNING

The three stages of skill acquisition proposed in Fitts's model can help us to understand the relevance of a model to the overall acquisition process, regardless of the model's particular mechanism. An alternative, and equally useful, way to view skill acquisition models is in terms of the type of learning they support. Based on salient features of the task, learning can be classified into different categories, including supervised and unsupervised, deductive and inductive, and symbolic and subsymbolic (or neural). The latter distinction is particularly important, because symbolic and neural models seem to be suited to very different kinds of learning tasks. Symbolic learning models are good at learning abstract rules from one example, but these rules are often not resistant to noisy data. Neural models require many learning trials, but result in networks that can handle noisy and incomplete data. Accordingly, many researchers have proposed hybrid symbolic–neural learning models of skill acquisition that incorporate neural networks for classifying perceptual information and symbolic learning systems for the overall control of problem-solving (Sun and Alexandre, 1997).

Soar

Intermediate article

Frank E Ritter, Pennsylvania State University, Pennsylvania, USA

CONTENTS

Soar is a unified theory of cognition, and a cognitive architecture, realized as a production system, a type of expert system. It is designed to model human behaviour on multiple levels.

UNIFYING COMPUTATIONAL MECHANISMS TO FORM A THEORY OF COGNITION

Soar is a unified theory of cognition (UTC) realized as a computer program. It can be considered in three mutually complementary ways. First, it can be seen as a theory of cognition realized as a set of principles and constraints on cognitive processing: a cognitive architecture (Newell, 1990). In this respect, Soar provides a conceptual framework for creating models of how people perform tasks, typically assisted by the corresponding computer program. In this view Soar can be considered as an integrated architecture for knowledge-based problem solving, learning, and interacting with external environments. It is thus similar to other unified theories in psychology, such as ACT-R, EPIC, PSI, and CAPS. (*See* **Skill Acquisition: Models**; **Learning and Memory, Models of**)

Second, Soar can be seen as the computer program that realizes a particular theory of cognition. There are debates as to whether and how the theory is different from the computer program, but it is fair to say that they are at least highly related. It is generally acknowledged that the program implements the theory, and also that there are commitments that are not in the theory but that must be made in the program to create a running system. In this way it is similar to other cognitive theories realized as computer programs, such as ACT-R, and connectionist models of specific tasks realized as programs.

Third, Soar can be seen simply as a specialized AI programming language. In this view, what matters is only that it performs the task in an intelligent way. In this respect it is similar to expert system tools such as OPS5 and CLIPS. (*See* **Expert Systems**)

The deliberate combination of these approaches to understand intelligence has been fruitful. Researchers interested in creating cognitive models have used Soar primarily to model human behaviour in detail, to suggest new uses of existing mechanisms to create behaviour, and to propose improvements to the Soar programming interface. Researchers interested in creating AI programs have contributed to the efficiency, functionality, and generality of Soar as a programming language and provided information on the functional requirements of working systems.

SOAR AS A UNIFIED THEORY OF COGNITION

Soar was proposed by Newell (1990) as a candidate UTC. Newell presents a full description of the virtues of unification. Three of the most important are: coherence in theorizing ('it is one mind that minds it all'); bringing to bear multiple constraints from empirical data; and reducing the number of theoretical degrees of freedom. (*See* **Unified Theories of Cognition**)

Being a UTC does not mean that there is only a single mechanism for each task or behaviour, although in most places in Soar there is only one. It does mean that the set of unifying principles and mechanisms must work together to support all of cognition: there is not a big switch or a set of disjoint modules (Newell, 1992). ACT-R is another unified theory, although the set of mechanisms it proposes to account for all of human behaviour is longer. (*See* **ACT**)

Unified theories represent a grand vision. None of them can yet provide even a verbal explanation

for all of human behavior in terms of architectural mechanisms, let alone provide implemented models, and few have yet covered more than a small set of regularities. This name may even be a misnomer, for they are attempting to unify all of behavior, not just cognition. Their intention is to cover larger amounts of data than have been covered before, and to bind the different areas of cognition together through a common set of mechanisms. A common and unproductive criticism is that an architecture is wrong because all areas are not yet covered. All theories suffer from this limitation. A much more valid and valuable criticism would be that an important aspect of a given area cannot be accounted for by the current architecture.

GOAL-DIRECTED SEARCH IN HIERARCHICAL PROBLEM SPACES BASED ON PRODUCTION RULES

Soar – as a theory, as a cognitive modeling language, and as an AI programming language – incorporates problem spaces as a single framework for all tasks and subtasks to be solved, production rules as the single representation of permanent knowledge, objects with attributes and values as the single representation of temporary knowledge, automatic subgoaling as the single mechanism for generating goals, and chunking as the single learning mechanism. Specifically, Soar provides a general scheme for control – deciding what to do next – that is hypothesized to apply to all cognition. These mechanisms can be used in different ways, however. For example, chunking can be used to learn both declarative and procedural knowledge.

Soar can be viewed at three levels. At the highest level, it approximates a knowledge-level system (Newell, 1982). This is an abstract level where a system is described in terms of its knowledge, and which is only approximated by any realized system, including Soar. The two lower levels are the problem space level and the symbol level. These work together to support learning.

The Problem Space Level

Figure 1 illustrates the two lower levels. These are similar to Marr's lower two level of analysis. The higher of these levels is the problem space level, where behaviour is seen as occurring in a problem space made up of goals, problem spaces, states, and operators. Note that these terms refer to specialized constructs in Soar, which are related to, but not strictly equivalent to, their usual meanings in cognitive science. (*See* **Computer Modeling of Cognition: Levels of Analysis**)

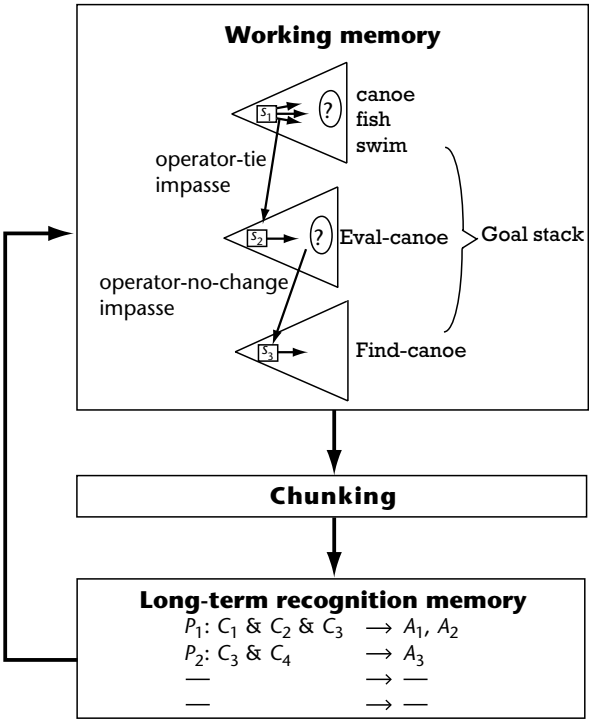

Figure 1. Structures in Soar.

A problem space is a set of representations for a problem, the structures for states, and all the operators relevant to those representations. The operators may be implicit and shared with other spaces. There can be several problem spaces active at any one time. A state may lack some required knowledge and have a state created to help it find the knowledge it needs, and similarly be providing knowledge itself. In figure 1 this state relationship is shown in the states S_1, S_2, and S_3. The main reason for organizing knowledge into problem spaces is that it reduces the search for information. This approach has also been used successfully as a software design technique.

While solving a problem there is a current state structure that specifies the situation of the problem solver in each problem space. For example, in a blocks world, the state might be 'block A is on top of block B, and block B is on the table'.

Fluent, expert behavior consists of a repeated cycle on the problem space level in which an operator is selected and is applied to the current state to produce a new (modified) current state. The process of choosing and applying a new operator (or creating a new state) is called a decision cycle. So in the example above, we could have applied an operator to move block A onto the table, after which

the current state would include the fact that block A and block B are both on the table.

The Symbol Level

The problem space level is realized by a lower level, a symbol level. At this level of analysis long-term recognition memory, realized as production rules, is compared to the current set of contexts. Rules (shown as P_1 and P_2 in figure 1) will have their conditions (C_1, C_2, etc.) matched to the current context. Their actions (A_1, A_2, etc.) will act on the problem space level to generate operators, propose how to choose between operators, implement operators, or augment the state with known inferences. Each cycle of rule application is called an elaboration cycle. There may be several elaboration cycles in each decision cycle. All rules whose conditions are satisfied are allowed to apply. If they make conflicting suggestions, the architecture sorts them out using an impasse (see below).

The rules are structured to match objects in the architecture. The rules can test the contents of states, and test for operators by name and by their contents. The rules' outputs are constrained to be in terms of the problem space structures. These constraints on the representation of the rules are part of what makes the system a cognitive architecture and not simply a free-form programming language.

Soar uses a modified RETE algorithm to apply the production rules. The time this algorithm takes to match a rule set is proportional to the number of memory elements that change, not the number of rules. This leads to very little slowdown as larger rule sets are used (but requires more computer memory). The largest systems created have had over a million rules with little or no slow down with additional rules (Doorenbos, 1995; Doorenbos *et al*., 1992).

Learning and Chunking

But what happens if something prevents the process of operator application from continuing smoothly? For example, perhaps the current knowledge in the Soar model cannot propose any operators to apply to the current state. Or the model may know of several applicable operators, but has no knowledge of how to choose between them. In such cases, the Soar model encounters an *impasse*. There is a limited number of types of impasse defined by the architecture, which primarily arise through a lack of knowledge (inability to apply or select an operator) or through inconsistent knowledge (conflict among operator proposals).

When Soar encounters an impasse in context level 1, it sets up a subcontext, a subgoal, at level 2, which has associated with it a new state, which may end up with its own problem space and operators. Note that the operators at level 2 could well depend upon the context at level 1. The goal of the level 2 context is to find knowledge sufficient to resolve the higher impasse, allowing processing to resume there. For example, we may not have been able to choose between two operators, so the level 2 subgoal may simply try one operator to see if it solves the problem, and if not, try the other operator.

The processing at level 2 might itself encounter an impasse, set up a subgoal at level 3, and so on. The problem solver usually has a stack of such levels, each generated by an impasse in the level above. Each level can have its own state, problem space, and operators.

In Figure 1, there were several operators proposed for the pond, including canoeing and fishing, and no knowledge was available to choose between them, so a new context was created to allow the architecture to consider this problem explicitly in a selection problem space, through what is called an 'operator-tie impasse'. Knowledge was available in that space, which suggested testing the canoeing operator and seeing how it would play out. The operator `Eval-canoe` was attempted, but nothing happened, so another impasse (an 'operator-no-change' impasse) was declared and an operator could be proposed in an evaluation problem space.

Whenever processing in the subgoal generates results that allow a higher level to continue, for example, if the operator `Find-canoe` allows `Eval-canoe` to continue, the architecture notices this, and automatically generates a new rule (also called a chunk) to summarize this problem solving. This rule's conditions are based on backtracking through the problem solving to find out what aspects of the initial situation were used, and the rule's actions are the output of `Find-canoe` that removed the higher-level impasse. In this case it would probably be a change to the `Eval-canoe` operator or to its state.

The next time such a condition occurs, the rule will match and update the operator or state, and the impasse will be avoided. This is the basic learning mechanism in Soar. This approach provides a strong theory of when and how learning and transfer will occur.

Chunking has been used to create a wide range of higher-level learning – including explanation-based learning, declarative learning, instruction

taking, and proceduralization – by varying the type of impasse and the knowledge used to resolve it.

THE HISTORY OF SOAR

The intellectual origins of Soar can be found in the seminal work of Newell and Simon on human problem solving. This builds upon work on production system architectures in the 1970s onwards, particularly Newell's work on the problem space as a fundamental category of cognition (Newell, 1980). Soar as a unified theory of cognition has some of its theoretical roots in the Model Human Processor (Card *et al*., 1983).

The first implementation of Soar was built by Laird, modifying Rosenbloom's XAPS architecture. Impasses were introduced in Soar 2, a reimplementation of Soar in OPS5, which allowed rules to fire in parallel and included the problem space decision mechanism. The original motivation was both functional (to create an architecture that could support problem solving using many different weak methods arising from the knowledge that was available) and structural (to create an architecture that integrated problem spaces and production systems). 'SOAR' was originally an acronym for 'state operator and result', but it is no longer recognised as being an acronym because the theory is more complex.

A major watershed in the development of Soar was Newell's William James lectures at Harvard (Newell, 1990). These lectures defined what a unified theory in psychology should include, proposed Soar as a candidate unified theory, and extended the Soar theory, providing some detailed examples. (*See* **Newell, Allen**)

The recent development of Soar has been driven by applications. Soar models have been applied to real-time domains such as flying simulated aircraft (Jones *et al*., 1999). Analyses of running models showed that the state and problem space in the original Soar theory were not being used as had been initially imagined: in most cases they did not vary and were simply reiterations of the goal. Later versions of Soar have dropped problem spaces and states as explicit reserved structures but allowed the modeller to represent them in the goal. This has led to faster systems that allow several models on a single computer to interact in real time, performing complex tasks. Because these context slots were not being used by models, their removal did not lead to changes in behavior.

Architectural work on Soar is currently focused on improving its interface, introducing new learning algorithms built upon the chunking mechanisms, tying Soar to external worlds (including behaviour moderators like stress), and the implications of interaction for problem solving and learning. Future work could include reviving the Neuro-Soar project (Cho *et al*., 1991). This project showed that it was possible to realize the symbol level of Soar with a connectionist network, although modelling so many theoretical levels made it slow.

MATCHING HUMAN PERFORMANCE IN DIVERSE DOMAINS

One of the strengths of Soar is that it predicts the action sequences and times to perform tasks (Newell, 1990). The parameters chosen by Newell have been gradually refined. The Soar philosophy has been to retain the same constraints from problem to problem, rather than having numerous parameters that can be adjusted for a specific task or data set.

For cognitive modelling, Soar is most effective at modelling deliberate cognitive human behavior at timescales greater than 50 ms. Published models include human–computer interaction tasks, typing, arithmetic, categorization, video game playing (i.e., rapid interaction), natural language understanding, concept acquisition, learning by instruction, verbal reasoning, driving, job shop scheduling, and teamwork.

Soar has also been used for modelling learning in many of these tasks, many of which involve interaction with external environments. Soar does not yet have a standard model for low-level perception or motor control, but two systems that could be integrated, EPIC-Soar (Chong and Laird, 1997) and Sim-eyes and Sim-hands (Ritter *et al*., 2000), have been created. Learning adds significant complexity to the structure of the model, however. (*See* **Learning Rules and Productions**)

One of the signature data regularities modeled in Soar is the learning curve. The learning curve predicts that the time to do a task decreases according to a power law (or perhaps an exponential decay). Soar's prediction of the power law of practice for a task arises from how models in Soar do the task and what they learn.

The first, and probably the simplest, way in which the power law of learning has been modelled in Soar is for the Seibel task. This simple task is to push the buttons on a panel corresponding to lights that are on. There are ten lights, therefore 1023 possible patterns of lights where at least one light is on. The model proposes two operators to do a left and a right subregion. If these are not individual lights, then an impasse occurs, and each subregion

gets two operators. This continues until a single light is a subregion. The model can then return a chunk that does both subregions, initially, two lights. Early trials generate two-light patterns that occur often and are useful. Later trials can build larger patterns, with more lights, that occur less often but save more time.

The Seibel model was one of the first learning models in Soar, and represents probably the simplest approach to learning in Soar. It does not represent more complex and accurate learning methods. Current models include learning by instruction, learning by following others, modeling transfer between tasks, and learning category knowledge. We are now at the point where, if we can model performance on a task in Soar, we expect to be able to model learning. Nearly all of the cognitive models in Soar are models that learn, and a majority of these have been compared with data.

SOAR AS AN EXPERT SYSTEM DEVELOPMENT ENVIRONMENT

Soar has also been used to create a variety of classification expert systems, that is, systems that classify situations. These including lift planning, production scheduling, diagnosis, robotic control, and computer configuration. It has been used in the Sisyphus knowledge elicitation comparisons.

Perhaps the greatest success for Soar expert systems has been in a procedural domain, flying simulated aircraft in a simulated hostile military environment. In one experiment Soar flew all of the US aircraft in an international 48-hour simulation exercise (Jones *et al*., 1999). The simulated pilots talked with each other and with ground control, and carried out over 700 sorties with up to 100 planes in the air at once.

For building artificial intelligence (AI) and expert systems Soar's strengths are in: integrating knowledge; planning; the ability to react quickly by modifying its internal state or changing its goal stack; search; and learning within a very efficient architecture. It also has the ability, used in a model that plays Quake®, to create a state mirroring its opponent's state, and consider what the opponent will do by considering what it would do itself in the same situation.

CHALLENGES FOR SOAR AND OTHER UTCs

Like any unified theory of cognition realized as a program, Soar faces major challenges. Work continues on applying Soar to a wider range of tasks and including learning and interaction in these models. Meanwhile, usability is becoming increasingly important as Soar moves out of the academic world into the world at large.

Soar has been developed and used by a community of researchers. Keeping a group of up to 100 researchers together intellectually has been difficult. Explicit mechanisms are necessary, such as repositories of papers and programs, regular meetings, mailing lists, frequently asked question lists (FAQs), and websites.

SUMMARY

There are a number of relatively unique capabilities that arise out of the combination of the structures and mechanisms in Soar. First, problem solving and learning are tightly intertwined: chunking depends on the problem solving, and most problem solving would not work without chunking. Secondly, interruptibility is available as a core aspect of behaviour. Rules are matched against the whole context stack. Processing can thus proceed in parallel on several levels. If the situation changes, rules can fire quickly, suggesting new operators at the level most appropriate for dealing with the change. Thirdly, it is possible to create large rule systems because they can be organized in problem spaces; and the architecture makes them fast to build and to run. Fourthly, planning can be integrated with reacting as well as with dynamic decomposition of tasks.

It takes effort to learn Soar. More practice is needed than for other, simpler, systems. Those projects that have used Soar successfully have often been able to solve problems that were previously unsolvable or unmodellable, but not without hard work on the part of the modellers.

Soar is, perhaps uniquely, appropriate for creating large cognitive models or expert systems, or for projects where learning or interaction (or both) are important.

Sparse Distributed Memory

Intermediate article

Tim A Hely, University of Edinburgh, Edinburgh, UK

CONTENTS

The sparse distributed memory is a mathematical technique for storing and retrieving large random binary patterns. The memory has been used in simple visual and linguistic applications, and has been proposed as a model of cerebellum function.

BACKGROUND

In 1988, Pentti Kanerva outlined a simple and mathematically elegant formulation for an associative memory called the 'sparse distributed memory' (SDM) (Kanerva, 1988). The SDM has been used in a wide range of studies and applications, and numerous extensions to the original model have been developed. It displays many of the characteristics of human memory, such as content-addressability and the association of closely related concepts when presented with a single input pattern. Furthermore, the architecture of the memory can be mapped onto that of the cerebellar cortex.

OVERVIEW

The SDM is a generalized random-access memory. In simple terms, it is a 'pattern computer'. All memories, including the SDM, have a large number of 'locations' where information can be stored. In the SDM, memory locations are randomly distributed in the input space (the set of all possible input patterns). The address of a memory location is a long binary pattern (e.g. 1000 bits) which has the same form as the input patterns presented to the memory. Input patterns may be presented to the memory to be stored (writing to memory), or to access information from parts of the memory (reading from memory). Like other networks, such as the Hopfield network (see below), the SDM works best when the input pattern consists of random zeros and ones.

A binary input consisting of only 2 bits can represent 4 possible patterns: `00`, `01`, `10`, and `11`. This input can also represent the coordinates of one of the $4 = 2^2$ corners of a 2-dimensional square: {(0,0), (0,1), (1,0), (1,1)}. Pairs of points that differ by only 1 bit lie closer together than pairs that differ by 2 bits. The number of bits that are different in two binary words (of the same length) is known as the Hamming distance. A 3-bit input can represent one of the $8 = 2^3$ corners of a 3-dimensional cube. Similarly, the number of different patterns that can be generated by a binary word 1000 bits long is 2^{1000}, and these form the corners of a 1000-dimensional hypercube. (The number of atoms in the universe is about 2^{250}.)

It is not feasible to assign a memory location to each possible input, as the storage requirements are too great. Instead, in the SDM a large number of binary patterns (e.g. a million) are chosen randomly as the addresses of the memory locations (also called 'hard locations'). This gives a representative sample of the input space; however, the probability that a random input will correspond exactly to a memory location is effectively zero (a million divided by 2^{1000} is about 10^{-295}). Rather, the addresses are distributed amongst multiple locations, some of which will probably be close to the input.

The SDM model depends fundamentally on subtle, nonintuitive properties of high-dimensional metric spaces and random distributed representations. It is not so important that the dimensions are binary.

CONTENT-ADDRESSABLE MEMORY

In a conventional computer, a memory location is accessed by its address, not by its contents. However, in the SDM, the input patterns can serve both as addresses to the memory locations and as the

data to be stored. This feature gives rise to a form of content-addressability, which is a characteristic of human memory. For example, to find out where the quote 'to be or not to be' comes from, a conventional computer program would have to search all the files stored in the computer until it found a matching string. But in the SDM, an input pattern is stored in the region of memory where similar information has previously been stored, and the quote directly triggers the play 'Hamlet'.

HOW THE SDM WORKS

In the SDM, each hard location consists of an N-bit address, which corresponds to a point in the memory space, and a sequence (or row) of signed integer 'counters' to store data. An input to the memory consists of two binary vectors: an 'address vector', which determines which locations are accessed, and a 'data vector', which is stored in the counters of the hard locations. The lengths of the address and data vectors may be different. When storing data in the SDM, first of all the Hamming distance between the input address vector and the address of each hard memory location is calculated. A copy of the input data vector is added to the data already contained in the memory counters of all locations where this distance is less than or equal to a preset value (the 'activation radius'). In this way, similar data are stored at locations that have similar addresses. If the input data vector to be stored is the same as the input address vector, the SDM functions as an autoassociative memory.

In the original SDM, the locations have integer counters initially set at 0 (i.e. storing no information). At each memory counter of a location that has been selected in a write operation, a 1 in the corresponding position of the input data vector increments that counter value by 1, and a 0 decrements it by 1. Figure 1 (adapted from Rogers (1988)) is a representation of how the pattern is stored in the SDM. It shows the state of the SDM after only one write to the memory, when the counters are storing only a single item of data. (The diagram also shows the operation of reading from the memory.)

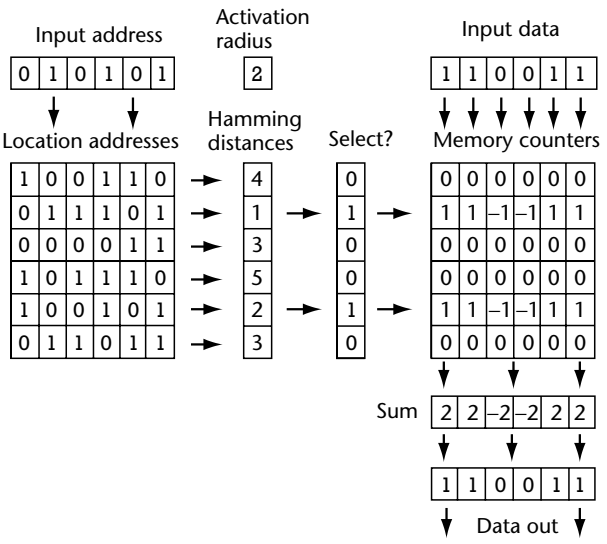

Figure 1. Writing to and reading from the SDM. (Adapted from Rogers (1998).)

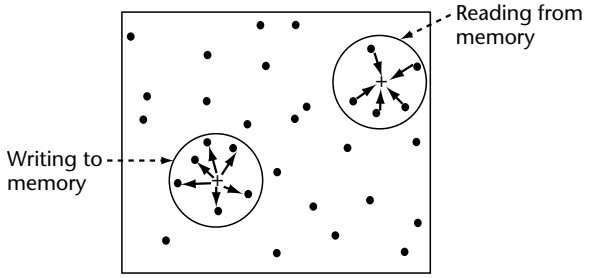

Figure 2. Writing to and reading from the SDM. The box represents the entire memory space (all possible addresses or cues). Each dot is the address of a memory location. The cross represents an address cue. When writing to memory, the system adds the contents of the input vector to all locations within the activation radius of the cue. When reading from memory, the system pools the contents of all locations within the activation radius of the cue.

The Write Operation

The word written to the memory is stored at those locations that lie sufficiently close to the input address vector. In Figure 1 the activation radius has been set to 2. For a location to be selected, the Hamming distance between the input address and the location address must be less than or equal to this value. (In the figure, these locations have a value of 1 in the 'Select?' column.) The counters of these memory locations are then updated with the input data pattern. In Figure 1, just one item of data has been stored, so the counters store only that item. Note that the input address pattern can be different from the input data pattern.

Figure 2 gives an alternative representation of the write and read processes. In the write process, the data are distributed to all locations within the activation circle.

The Read Operation

The word that is read from the memory at the reference address is the average of the contents of

all locations lying within a certain Hamming distance from it. The selection process is the same as for the write operation; however, the counters are not altered. The activated vectors of counters are added to produce an overall sum. At each position in the sum, a negative value sets the output bit to 0, while a nonnegative value sets the output bit to 1.

When the write process is repeated, the contents of a particular memory location will consist of the sum of all previous inputs. New input data are simply added to the existing values of the counters. As old patterns are not removed when a new word is written to the memory, the SDM stores copies of every data pattern presented to it.

If random binary data are stored in the memory, the probabilities of a counter value increasing by 1 or decreasing by 1 are equal. However many patterns a location may store, the statistical expectation of each counter will be zero. Figure 3 shows an SDM where three input data vectors **x**, **y** and **z** have been written to locations within the activation radius of input address points **A**, **B** and **C** respectively. (Note that points **A**, **B** and **C** do not correspond to any hard memory locations.)

In Figure 3, 10 copies of each of the patterns **x**, **y** and **z** have been stored around points **A**, **B** and **C** respectively. Reading from **A** will then retrieve the 10 copies of the original signal **x** plus 3 copies each of **y** and **z**, which make up the noise term. Pooling the data results in a pure signal term from the original input and a noise term due to other neighboring inputs. If random patterns are being stored, the noise term tends to be relatively small. It is only

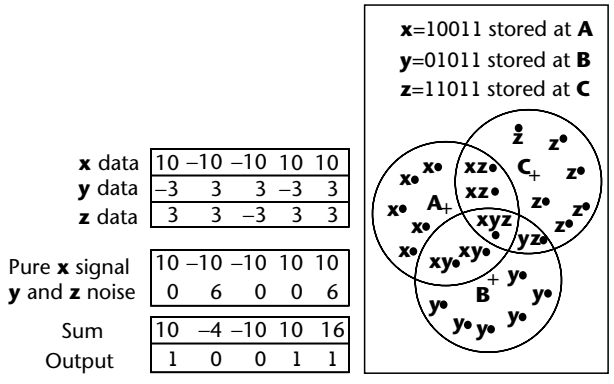

Figure 3. Retrieving a signal subject to noise. Reading at **A**, within the activation radius there are 10 locations storing **x**, 3 locations storing **y** and 3 locations storing **z**. Despite the noise due to the **y** and **z** signals, the original signal **x** is correctly retrieved.

when this noise term has a value opposite to and greater than the signal that an error will occur. Kanerva (1988) showed that this method results in the retrieval of the correct word, for appropriate values of the activation radius, with statistical reliability.

Before using the SDM, we must select a value for the activation radius. The memory performs best when the read and write radii are the same. In choosing the radius, there is a trade-off between obtaining a good signal over a reasonable range of uses and minimizing the noise. It turns out that a radius that selects slightly less than the square root of the total number of locations is a good solution. (The optimum probability of a 'hit' is $(2MT)^{-1/3}$ when T patterns are stored in a memory of M locations (Kanerva, 1993, p. 60).) The radius can also be set dynamically at each write or read operation to ensure that approximately the same number of locations are accessed each time.

ATTRACTORS IN THE SDM

When random input patterns are originally stored in an empty SDM, the point of each pattern in input space may be considered as an attractor (which is embedded in the particular set of memory locations to which the data are written). Reading data from nearby points will also retrieve the target pattern. This will not work if the memory is saturated (i.e. storing too many patterns), or if many almost identical copies of a pattern have previously been stored. (In practice, the latter situation is unlikely to occur unless the input patterns are low-dimensional or nonrandom.) If noisy versions of the same input pattern are stored in the memory, the attractor may actually represent a 'clean' version of the original pattern, as the noise can cancel out across the set (Kanerva, 1993).

An interesting situation can occur when the SDM is used as an autoassociative memory and multiple patterns have been stored in the network. If a noisy input pattern is fed into the SDM, the resulting output can be iteratively fed back into the memory until the network converges on a stable solution. Kanerva showed that the original target pattern is obtained if the Hamming distance between the input and target patterns initially decreases as the output is fed back into the network. However, if the Hamming distance initially increases, the memory will converge to a different attractor. Kanerva described this as a 'self-propagating search' and noted a similarity between this convergence process and the 'tip of the tongue' memory phenomenon.

RELATED MODELS

The SDM architecture can be mapped onto a standard 'two-layer' feedforward neural network design. Traditionally the input layer is not counted. The input units convey patterns to the memory. The weights of the hidden units store the hard locations and the weights of the output units store the memory contents. Other related associative memory models include the Willshaw and Hopfield networks (summarized below) and the Kohonen self-organizing network, which is usually used to map high-dimensional input data onto a one- or two-dimensional output. (*See* **Connectionism**)

The Willshaw network (Willshaw *et al*., 1969) has one of the simplest learning rules. In the fully connected network with binary inputs of length M and data of length N, there are $M \times N$ binary weights W_{ij} ($1 \leq i \leq M$, $1 \leq j \leq N$), initially all set to 0. On presentation of a pattern pair (**A**, **B**), W_{ij} is set to 1 if $A_i = B_j = 1$, where A_i is the i^{th} bit of input **A**. This is related to Hebbian learning, where coincidental firing of both presynaptic (input) and postsynaptic (output) cells is required to modify a synapse. Once activated, however, a weight remains on (set to 1) forever. This network performs best under sparse activity conditions (much fewer ones than zeros), otherwise it quickly saturates. A 'winner takes all' approach can be used to retrieve the output pattern. Calculate the dendritic sum, $d_i = \sum_j W_{ij}A_j$. Then select the required number of output units with the highest dendritic sums. The associative network has 69% of the capacity of a random access store with no associative capability. The network works well under sparsely connected conditions, and has been proposed as an abstract model of the hippocampus, which also has sparse connectivity (Graham and Willshaw, 1995). (*See* **Synapse**; **Hebb Synapses: Modeling of Neuronal Selectivity**; **Hippocampus**)

The Hopfield network (Hopfield, 1982) has N fully connected units with values of $\pm$ 1 and a (symmetric) weight update rule given by $W_{ij} = (\sum_n A_i^n A_j^n)/N = W_{ji}$, where the A_i^n represent p input patterns ($1 \leq n \leq p$), and $1 \leq i, j \leq N$. Usually there is a training phase, in which the weights are allowed to change, followed by a test phase, in which the weights remain fixed. In the test phase, the network can be used as an autoassociative, content-addressable memory. Stored patterns can be dynamically retrieved by asynchronously updating units (randomly choosing one at a time) according to the rule $A_i = \text{sgn}(\sum_j W_{ij}A_j)$ (where sgn $(x) = 1$ if $x \geq 0$, -1 otherwise) (cf. the dendritic sum in the Willshaw network above). If the test pattern is close enough to (a small Hamming distance away from) one of the stored patterns, the network will converge on the correct pattern, which acts as an attractor in a manner analogous to Kanerva's 'self-propagating search'. The Hopfield network has been the focus of extensive research. The maximum information density of the network that allows (random) patterns to be stored and dynamically retrieved in this way is $0.138N$.

To summarize, the SDM and the Willshaw and Hopfield associative networks use different methods to store (and retrieve) multiple copies of the input pattern. In the SDM, data are stored at those units closest to the input address; in the Willshaw network, the data are stored at all simultaneously active units; and in the Hopfield network, each data pattern is stored across the entire memory.

EXTENSIONS TO THE SDM

There have been many variations of the original SDM model (see Kanerva (1993) for a comprehensive summary). Many of these models aim to improve the theoretical capacity of the original memory which was calculated by Chou (1989). Rogers (1988, 1989) used a method called 'data tagging' to improve the efficiency of the SDM, but this method requires a greater storage capacity and takes longer to run. Jaeckel (1989a, 1989b) developed several sparsely connected versions of the SDM, including the 'selected coordinate' and 'hyperplane' designs. In a selected coordinate design with, say, 1000-bit binary addresses, only 10 of the 1000 bits might be 'set' to 0 or 1. The other 990 bits are not involved in the activation process. A location is activated only when all 10 of its selected bits match the corresponding bits in the input address vector. The hyperplane design uses a similar approach but with fewer selected bits, perhaps 3. This works well with nonrandom or skewed data, e.g. when there are on average 100 ones and 900 zeros in a 1000-bit address. Both designs are less computationally intensive than the original SDM and can perform better than it in certain circumstances.

Ryan and Andreae (1995) have extended the SDM to overcome some of the difficulties associated with storing and retrieving nonrandom input data. When reading data from the memory, they use a variable threshold for the values in the sum, which reflects the actual ratio of ones and zeros in the data set. If there are an equal number of ones and zeros, the threshold is 0, as before. However, if

there are more (or fewer) ones than zeros, the threshold is increased (or decreased) commensurably, resulting in an improved performance. To overcome some of the problems associated with a fixed activation radius, an alternative approach was developed by Hely *et al*. (1997). In this approach, the input signal 'propagates' throughout the memory, and its strength is attenuated as it encounters memory locations further from the input address.

Much recent research on the SDM has been carried out at the Swedish Institute of Computer Science, using sparse address patterns. Karlsson (1995) has developed a fast variant of the Jaeckel hyperplane design which makes it possible to simulate large SDMs in standard computer architecture. A more efficient way of reading the SDM memory using implicit information to remove noise has been developed by Sjoedin (1996). Kristoferson (1998) has shown that SDM performance does not scale up in the original SDM (the ability to tolerate noise in the retrieval cue decreases with memory size), but does scale up if sparse input address vectors are used.

The original SDM architecture has been used in many simple memory applications. These have included two-dimensional character recognition (Kanerva and Olshausen, 1989) and speech recognition (Prager and Fallside, 1989). In the character-recognition model, 16 $\times$ 16-pixel black-and-white images were converted into 256-bit binary patterns. These patterns were then stored and accessed using the normal operation of the SDM. Other applications have included converting text into phonemes: the address of a location corresponded to the text pattern, while the counters stored the phonemes associated with that word (Joglekar, 1989).

COMPARISON BETWEEN THE SDM AND THE CEREBELLUM

In the early 1970s, Kanerva noted the similarity between the SDM circuits and those of the cerebellar cortex. The cerebellum is involved in coordinating movements, and is located behind and below the cerebral hemispheres. Its highly regular design and repetitive architecture make it an ideal subject for theoretical analysis. It consists of the cerebellar cortex and deep cerebellar nuclei (the latter will not be discussed further here). The cerebellar cortex is organized into two layers: the inner or granular layer, and the outer or molecular layer. The principal cell and fiber types are shown in Figure 4 (adapted from Kanerva (1988)). (*See* **Cerebellum**)

Caution should always be exercised in attempting a one-to-one comparison between an abstract high-level model, such as the SDM, and the human brain, whose complexity is far from understood. However, it is instructive to summarize the functions of the cells and fibres in the cerebellum alongside the interpretation developed by Kanerva within the SDM framework.

Mossy Fibers

Mossy fibers originate from cells outside the cerebellar cortex. They form synapses with the granule cells.

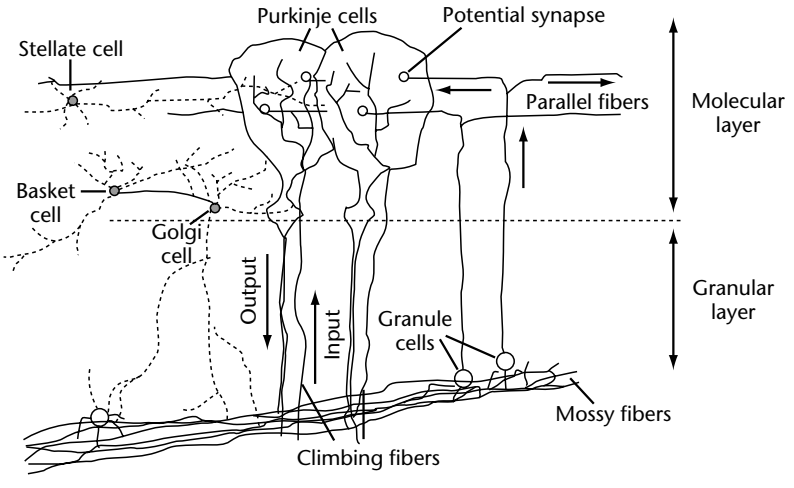

Figure 4. Simplified structure of the cerebellar cortex of the brain. Horizontal lines are continuations of parallel fiber axons. Single-headed arrows indicate direction of information flow (direction of action potential propagation along the axon).

In the SDM interpretation, they act as address lines to transmit the input address vectors or cues to the memory.

Granule Cells

Granule cells are the most abundant kind of neuron in the nervous system (there are as many as 10^{11} in humans). They occupy the inner layer, and receive input from the mossy or granular fibers and the Golgi cells.

In the SDM interpretation, their dendrites and bodies correspond to the hard memory address locations. The firing of a granule cell can be considered equivalent to the activation of a location in the SDM model.

Parallel Fibers

Parallel fibers are the axons of granule cells. They form synapses with the Purkinje cells, and also with the other cell types of the cerebellum. A single parallel fiber passes through between 200 and 450 of the Purkinje cells' dendrite planes.

In the SDM interpretation, the row of counters for a memory location is found along a parallel fiber and is activated by it. The synapse between a parallel fiber and a Purkinje cell acts as the counter for a given bit position. The other interneurons use the parallel fiber input to provide negative feedback when adjusting the thresholds of the Purkinje cells.

Purkinje Cells

The Purkinje cell axon provides the only output from the cerebellar cortex. The dendrite system of one Purkinje cell intersects as many as 400 000 parallel fibers and forms synapses with some or all of them. It has inputs from the stellate and basket cells and the climbing fibers, and weak connections with other Purkinje cells.

In the SDM interpretation, the Purkinje cell pools data for a single bit of output. The cell sums the inputs from parallel fibers and fires if the sum is over the threshold.

Stellate and Basket Cells

The stellate and basket cells are known as interneurons, and they reside in the outer layer. Both types of cell receive input from the parallel fibers, and their output has an inhibitory effect on the Purkinje cells. Albus (1971) hypothesized that synaptic weakening occurs at the parallel fiber synapses on basket and stellate dendrites. This effectively provides both positive and negative training. Positive adjustments occur by weakening excitatory synapses on inhibitory interneurons, and negative adjustments by weakening excitatory synapses on the Purkinje output cells.

In the SDM interpretation, these cells adjust the thresholds of the Purkinje cells to decide whether zeros or ones are more frequent in the pooled data.

Climbing Fibers

A Purkinje cell receives input from a single climbing fiber which branches extensively throughout the Purkinje dendritic tree. The firing of a climbing fiber guarantees the firing of the Purkinje cell output.

In the SDM interpretation, these are the data-input lines. They pair with the outputs (Purkinje cells) and they go to the vicinity of the bit locations (the Purkinje cell joins synaptically with the parallel fibers). In the microcircuit model (see below), the climbing fibers indicate when learning is to take place. Coincident parallel-fiber and climbing-fiber activity indicates where learning is to occur.

The granule cells, mossy fibers and climbing fibers are excitatory. The Purkinje, Golgi, basket and stellate cells are inhibitory. Kanerva does not discuss the functioning of the Golgi cells in relation to the SDM. A more generalized version of the SDM (the 'microcircuit architecture' model) has been developed, which also incorporates cerebellar interneurons (Miles and Rogers, 1993). In the microcircuit model, the basket cells also connect correlated cells responding to conditioned and unconditioned stimuli, facilitating learning.

THE SDM AS A MODEL OF HUMAN MEMORY

Like other neural network models, the SDM shares many features with human memory at the conceptual level: it is massively parallel; it is content-addressable; it degrades smoothly as storage locations are gradually removed; it can handle noisy or corrupt input patterns; and it processes high-dimensional data. In addition, information is widely distributed, and each memory location in the SDM encodes for multiple stored data patterns.

Although recent neurophysiological evidence supports the hypothesis that the cerebellum learns from experience, the cerebellum is not generally considered as a memory area of the brain. Indeed, the SDM was never intended as a biologically plausible model of short-item ('working') or long-term

memory, and the analogy should not be pushed too far. The SDM has, however, been considered alongside the theoretical work of Marr (1969) and Albus (1971) on the cerebellum. Interestingly, Kanerva (1993) has shown that the models of Marr and Albus can both be represented in terms of a slightly modified SDM architecture, and together they form the basis for a general theory of the cerebellum. (*See* **Working Memory, Computational Models of**; **Hippocampus**; **Neural Basis of Memory: Systems Level**; **Encoding and Retrieval, Neural Basis of**; **Learning and Memory, Models of**; **Semantic Memory: Computational Models**)

SUMMARY

The SDM was originally developed by Pentti Kanerva as a robust method for storing and retrieving large binary patterns. Later, the similarity between the architecture of the SDM and the cerebellar cortex was noted. There have been many applications and extensions to the original SDM, to handle nonrandom data, continuous variables, sparse connectivity, and so on; but many possible extensions and revisions remain to be explored. These include improved methods for avoiding memory saturation ('forgetting'), embedding multiple SDM architectures within a single framework, and storing spatio-temporal patterns. It is likely that the SDM will continue to inspire new memory architectures which will combine features of conventional computer and biological memories.

Spatial Representation and Reasoning

Advanced article

Jerry R Hobbs, Artificial Intelligence Center, SRI International, Menlo Park, California, USA
Srini Narayanan, Artificial Intelligence Center, SRI International, Menlo Park, California, USA

CONTENTS

Spatial representation and reasoning is a way of representing the facts about spatial properties and relationships, contiguity, dimensionality, shape, and motion, in a way that is convenient for a computer to reason about them.

INTRODUCTION

A robot moving through an environment, an interface to a geographical database, and a natural language program for giving directions all need means for representing and reasoning about spatial properties and relations. These include shape, size, distance, orientation, and relative location. The most precise and highly developed system of spatial representation is the mathematics of Euclidean space. But very often this is too precise for the purposes at hand. We may not have exact information and we may not need precise answers. For example, if we are telling someone how to get to the post office, we do not need to be more precise than the streets to follow. For this reason, much work in artificial intelligence has focused on *qualitative* spatial representation and reasoning.

Indeed, studies of human problem-solving and language understanding (Talmy, 1983; Herskovits, 1986; Langacker, 1987; Lakoff, 1987; Tversky, 1993; Landau and Jackendoff, 1993) indicate that we draw fairly subtle and important qualitative spatial distinctions. It is accepted that a topological description of the environment is central to building a cognitive map which is developmentally prior to a metrical description. Infants have been shown (Landau *et al.*, 1992) to be sensitive to shape distinctions and invariants very early in childhood, suggesting that some qualitative representation of space precedes, or at least coexists, with a more metrical one.

Research in primate vision (Ungerleider and Mishkin, 1982; Milner and Goodale, 1995) further suggests the existence of two separate pathways for visual information processing: a dorsal pathway which projects from the visual cortex to the posterior parietal cortex and a ventral pathway which projects into the inferotemporal cortex. The dorsal pathway is referred to as the 'where' system and is suggested as primarily computing task-related spatial information (such as location in egocentric coordinates or hand pre-shaping for a grasping task) while the ventral or 'what' pathway is suggested as computing primarily object-related characteristics (such as shape or other visual features). While there seems to be robust evidence (including double dissociation evidence) of these two different pathways, it is also clear that there are complex interactions through multiple cortico-cortical connections between them. Based on these findings, Landau and Jackendoff (1993) suggest the existence of related subsystems in language; a 'where' system corresponding to spatial predications (such as prepositions) and a 'what' system corresponding to object naming and nouns.

From a computational perspective, the most general and most challenging problem in spatial representation and reasoning is route planning. What paths can an object of a given shape, size and location follow through an environment with obstacles of particular shapes, sizes, locations, and trajectories? Most researchers have studied restricted versions of this problem. For example, the problem may be merely to place an object within

an environment and not to move it. Or the size and shape of an object may be viewed as negligible as it moves through the environment.

Thus, the first broad problem that must be addressed is to devise ways for representing and reasoning about relations and measures between objects at a range of granularities, from the purely topological to fully metric. The second problem is how to represent and reason about shape in two and three dimensions, again at a range of granularities. Finally, there is the problem of how to represent and reason about objects of particular shapes when they are moving.

LEVELS OF STRUCTURE

Spatial and other quantities can be represented at a range of granularities. The coarsest level in common use is what is known as the 'sign algebra' (e.g. Forbus, 1984); the real line is divided into the negative numbers, zero, and the positive numbers, and what is known about a quantity is only which of the three regions it lies in. This has proven very useful in qualitative physics for reasoning about increases and decreases in quantities and direction of flow. A more refined structure can be imposed by dividing the real line into further intervals, with ordering relations between them. For example, for a pot of water sitting on a stove, we might want to distinguish the intervals between the freezing point, the boiling point, and the temperature of the stove, as well as the transition points themselves. Moreover, 'landmarks' can be set during the reasoning process. For example, to determine whether an oscillation is damping, we should compare successive maxima; these would be the landmarks (Kuipers, 1986).

Some work has been done on providing logarithmic structure to scales. This is known as order-of-magnitude reasoning (Raiman, 1991). We may not know whether Los Angeles is closer to San Diego or Santa Barbara, but we certainly know that it is closer to both than it is to Chicago, because these distances are of different orders of magnitude. Most work in order-of-magnitude reasoning has sought to exploit the fact that quantities at lower orders of magnitude can be ignored in operations involving higher orders of magnitude. Thus, we know that adding a stamp to a letter will not increase its weight enough that more postage will be required.

A very fine-grained representation of space is one that places ϵ-neighborhoods around points and considers points indistinguishable if they are within the same ϵ-neighborhood (Roberts, 1973).

More generally, the level of structure we want to view space at will depend on functionality. If we are planning a land trip and are only concerned with getting the right visas, then we can view countries as nodes in a graph, regardless of their size, where each country is connected by an arc to each of its neighbors. When we are traveling in the country, we need a finer-grained view.

DIMENSIONALITY

The most important feature that distinguishes space from other quantitative domains is the fact that it has more than one dimension. The minimal condition that is required before a notion of dimensionality makes sense is that there must be two or more scales where the order of elements on one scale cannot be determined by their order on the other scales. We cannot infer from the fact that Chicago is east of Denver which of the two is farther north. The scales need not be fully numeric. A spatially represented bar graph may have a numeric vertical dimension while its horizontal dimension is a discrete space of alphabetically ordered named entities. The dimensionality of an entity is dependent on perspective. A road, for example, may be viewed as one-dimensional when we are planning a trip, two-dimensional when we are driving on it, and three-dimensional when we hit a pothole.

When one admits several dimensions, problems arise involving objects of different dimensions. For example, can we have an object consisting of a volume and a line segment? Does the boundary of an object have a lower dimension, and is it part of the object? These problems are related to more general problems concerning open and closed sets. Galton (1996) has developed an interesting solution to these problems. In his system, an object cannot be *part* of an object of a different dimension, but objects are *bounded* by objects of lower dimension.

Where there are dimensions, there must be frames of reference for describing locations in each of the dimensions. In human cognition, as evidenced by language, there are a number of frames of reference characterized by how they are anchored (Carlson and Irwin, 1993). There is the self-anchored frame of reference, right-left-front-back, and the world-anchored frame of reference, north-south-east-west. There can be frames of reference anchored on the vehicle one is in, port-starboard-bow-stern, or one's geographical region – the Hawaiian language has prepositions for 'toward the center of the island' and 'toward the

ocean'. There can be frames of reference determined by the forces that are acting on one, such as windward-leeward and upriver-downriver. Neurobiologists have also shown the existence of multiple reference frames including ones anchored on specific joints (Rizzolatti *et al*., 1997).

REGIONS

In recent years, there has been a good deal of research in purely qualitative representations of space (Randall *et al*., 1992; Gotts *et al*., 1996; Gotts 1996; Cohn, 1997; Lemon and Pratt, 1997; Cohn and Hazarika, 2001). Much of this work attempts to build axiomatic theories of space that are predominantly topological in nature and based on taking *regions* rather than *points* as primitives. Topological relationships between regions in two-dimensional space have been formalized, with transitivity inferences, similar to those used in temporal reasoning, identified for vocabularies of relations (Randall *et al*., 1992; Cohn, 1997). The basic primitive is a notion of two regions x and y being connected if the closures of x and y share at least one point.

This primitive `connect(x,y)` has been shown to be extremely powerful and has led to the development of a rich calculus of spatial predicates and relations referred to as RCC (Region Connection Calculus). It has been shown (Gotts *et al*., 1996; Gotts, 1996) how RCC can describe and distinguish between complicated objects such as loops, figure-of-8s and doughnuts with degenerate holes. However, this expressiveness is costly and reasoning with the general RCC calculus is undecidable (Cohn, 1997; Lemon and Pratt, 1997). There has been some work on tractable subclasses. The best known is based on identifying a pairwise disjoint, jointly exhaustive set of eight spatial relations called the RCC8 calculus. The RCC8 calculus is able to describe the relations *inside (touching the boundary or not), outside, touching, overlapping* for objects describable as *regular sets*; regular sets cannot have holes. The RCC8 subset also has a well-founded semantics (unlike the RCC calculus) based on Euclidean geometry (Lemon and Pratt, 1997) and has been shown to be complete under this interpretation.

ORIENTATION

In Euclidean geometry, the representation of orientation is straightforward. There is a fixed set of axes, and a direction corresponds to a vector, normalized to length 1, from the origin to some point in the space. That vector can be specified by projecting its endpoint onto the axes.

Qualitative representations of orientation can be inherited from qualitative representations on the axes. For example, if the structure of each of the two axes in a two-dimensional system is $\{+, 0, -\}$, then the corresponding representation of orientation maps the direction into one of eight values – along one of the four axes or in one of the four quadrants.

A finer structure on the axes yields a finer structure on orientations. For example, if each axis has regions corresponding to 'slightly positive' and 'slightly negative', then it will be possible to define the notion of angles being 'slightly acute' (Liu, 1998).

SHAPE

Shape is one of the most complex phenomena that must be dealt with in the qualitative representation of space. There is a range of possibilities. In topology, a circle, a square, and an amoeba-shaped blob are all equivalent, as long as they do not have holes in them. In Euclidean geometry, a large square and the same square with a slight nick in one side are different. Shape is very important in common-sense reasoning because very often the shape of an object is functional. The shapes of objects and obstacles determine possible paths. It is important for a door and a doorframe to be the same shape, and the fact that they are the same shape is the reason doors must be open for things to pass through them.

One form of representation for shape is the use of *occupancy arrays* that encode the location of an object in a 2-D or 3-D grid (Funt, 1980; Glasgow *et al*., 1995). These representations have a number of attractive properties including ease of visualization and a natural parallel implementation of operations such as intersection, translation, and computing spatial relations between objects. However, occupancy arrays are inflexible and cannot express abstractions and partial knowledge.

Another way to characterize shapes is by the shapes of their boundaries. In one approach (Hoffman and Richards, 1982), the sides of a complex figure are classified as straight or curving in or out, and the vertices as angling in or out. Boundary information can be combined with qualitative length information so that we can distinguish between 'thin' and 'fat' rectangles, for example, or between rectangles that are wider than they are tall and ones that are taller than they are wide. Boundary information can also be combined with

theories of orientation, so that we can get qualitative measures of angles between sides.

Another representation of shape is in terms of its 'bounding box', or smallest containing quadrangle, or in terms of its convex hull. These representations are useful in moving objects through an environment. To determine whether a car will fit through a garage doorway, you need to take the side mirrors into account, but not the cavities due to open windows.

A commonly used representation for complex three-dimensional objects is the cylinder (Davis, 1990). This representation is subject to variations in granularity. For example, a human being can be represented at a very coarse grain as a cylinder. At a finer grain, the person is resolved into a cylinder for the torso, cylinders for each arm and leg, and a cylinder for the neck and head. At even finer grains, there are cylinders for the upper and lower arms or for individual fingers.

MOTION

For any quantity or quality that can be represented at an instant in time, we can also imagine it changing across time. Topological relations between entities can change as the entities move. The distance between two objects, the orientations of two lines, the shape of two objects, can all change with time.

In general, given any qualitative theory of a spatial feature and any qualitative theory of time, we can develop a qualitative theory of how the spatial feature changes with time. In most instances, this will involve transforming what is a continuous motion in Euclidean space into a motion of discrete jumps in the qualitative space, as when an entity suddenly crosses the boundary between region A and region B of a plane. Various qualitative theories impose various constraints on the possible motions, or possible changes of state. Thus, we cannot go from positive to negative without passing through zero. Representing the behavior as a transition graph (fully qualitative or with metric information attached to the nodes), allows for algorithms that generate and recognize behaviors using a variety of analytic and simulation techniques. Modeling spatially distributed motion is more complex and some efforts have attempted to use spatial aggregation based on motion field invariants and other methods from computer vision to represent qualitative structures of fluid motion (Yip, 1995) and geometric features in phase space (Zhao, 1994).

IMAGISTIC AND PROPOSITIONAL REPRESENTATIONS

There is a long-standing debate among researchers in spatial representation and reasoning about whether representations of spatial relationships should be imagistic or propositional, that is, more like pictures or more like linguistic descriptions (Pylyshyn, 1981; Shepard and Cooper, 1982; Kosslyn, 1994). Proponents of propositional representations argue that imagistic representations reduce to propositional ones, but impose constraints on what situations can be represented, which make them of very limited use (Lemon and Pratt, 1997).

On the other hand, imagistic representations are common in models of human spatial reasoning. In human communication, imagistic representations such as sketches, maps and figures are commonly used to communicate information about shape, size, routes, and spatial arrangements. Images and diagrams are also commonly used to communicate and comprehend abstract structures ranging from data structure visualizations and process flow diagrams to corporate hierarchies. Reasoning with imagistic representations has often been argued to be fundamental in human cognition (Kosslyn, 1994; Farah, 1995). It has been shown that infants, very early, perhaps pre-attentively, do grouping based on similarity of shapes, orientations and sizes (Julesz, 1984) as well as shape closure (Treisman, 1982, 1985). There is evidence that even symbolic tasks such as language understanding may use imagistic representations (Langacker, 1987; Lakoff, 1987). A computational model of the role of such representations in the acquisition of spatial prepositions can be found in Regier (1992).

There is growing evidence that acquiring, storing and reasoning with spatial concepts requires the coordinated use of heterogeneous representation and inferential processes that involve both propositional and imagistic components (qualitative and metric) (Glasgow *et al*., 1995), and much of current research is exploring how this can be accomplished computationally.

Speech Perception and Recognition, Theories and Models of

Intermediate article

Dominic W Massaro, University of California, Santa Cruz, California, USA

CONTENTS

Multiple sources of information are exploited to perceive and understand spoken language.

INTRODUCTION

It is not unusual to have the impression that foreign languages are spoken much more rapidly than our own, and without silent periods between the words and sentences. Our own language, on the other hand, is perceived at a normal pace (or even too slowly at times) with clear periods of silence between the words and sentences. In fact, languages are spoken at approximately the same rate, and these experienced differences are solely due to the perceptual and memory structures and psychological processes involved in speech perception. Thus we define speech perception as the process of imposing a meaningful perceptual experience on an otherwise meaningless speech input. The empirical and theoretical investigation of speech perception has become an active interdisciplinary endeavor, including the fields of psychophysics, neurophysiology, sensory perception, psycholinguistics, linguistics, artificial intelligence, and sociolinguistics.

PSYCHOPHYSICS OF SPEECH PERCEPTION

In any domain of perception, one goal is to determine the stimulus properties responsible for perception and recognition of the objects in that domain. The study of speech perception seems to be even more challenging than other domains of perception because there appears to be a discrepancy between the stimulus and the perceiver's experience of it. For speech, we perceive mostly a discrete auditory message composed of words, phrases, and sentences. The stimulus input for this experience, however, is a continuous stream of sound (and facial and gestural movements in face-to-face communication) resulting from the speech production. Somehow, this continuous input is transformed into a more or less meaningful sequence of discrete events.

One long-standing issue in research has been whether there is an invariance between the speech signal and its category membership. One of the most obvious perceptual categories for speech is the phoneme. Phonemes are the minimal units in speech that can change the meaning of a word. The word *ten* has three phonemes: we can change the /t/ to /d/ to make *den*, the /e/ to /æ/ to make *tan*, and the /n/ to /l/ to make *tell*. If phonemes were invariant perceptual categories, we would expect to find an orderly relationship between properties of the speech signal and phoneme categories. We would expect to find some constant characteristic in the speech signal for a given phoneme. However, this appears not to be the case. Figure 1 gives a visual representation of the sounds /di/ and /du/. Given that /d/ is the first phoneme of both sounds, we might expect to see the same signal at the beginning. However, we do not. The second visible band of energy from the bottom (the second formant) rises in /di/ and falls in /du/. One of the original arguments for the special nature of speech perception implicated this uncertain relationship between properties of the speech signal and a given phonemic category. It was emphasized that, in contrast to other domains of pattern recognition, one could not delineate a set of acoustic properties that uniquely defined a phoneme.

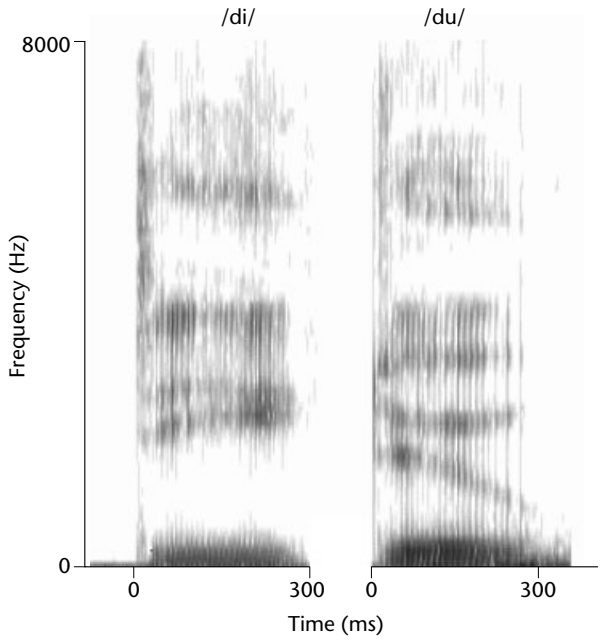

Figure 1. Spectrograms of the syllables /di/ and /du/, illustrating the lack of invariance between the acoustic signal and the phoneme. The second visible band of energy from the bottom (the second formant) rises in /di/ and falls in /du/, illustrating that the same phoneme /d/ has different acoustic characteristics in the different vowel contexts.

Not only is there a lack of invariance between the phoneme and the speech signal, but it does not at first seem to be possible to isolate the phoneme in the speech signal. Consider the syllable /da/: it has two phonemes, /d/ and /a/. If we listen to this syllable in isolation, we hear /da/. Now if we repeatedly shorten the syllable by removing short segments from the end, we should eventually hear just /d/. But this is not what happens. Our percept changes from /da/ to nonsense, not from /da/ to /d/. Therefore, some 'magic' must be involved in hearing both /d/ and /a/ given the syllable /da/.

One way to instate some systematicity between the speech signal and perception is to postulate a somewhat larger unit of speech perception. Open syllables are defined as V, VC or CV items, where V is a vowel and C can be either a single consonant or a consonant cluster. There is evidence that these items might function as units of perception. Subjects can easily identify shortened versions of V, VC and CV syllables when most of the vowel portion is eliminated. Although there are clearly contextual effects on the signal properties of these syllables, the influences are much more minor than those on the phoneme. Some support for the relative invariance of the open syllable comes from concatenative speech synthesis systems that use diphones (pairs of adjacent phonemes) rather than phonemes as units that are concatenated. Based on psychological research, synthesis would be even better if units for synthesis were open syllables.

Regardless of the units that are used for perception, there is still controversy over the ecological properties of the speech input that are actually functional in speech perception. One issue, revived by recent findings, is whether the functional properties in the signal are static or dynamic (changing with time). Static cues (such as the location of formants (bands of energy in the acoustic signal related to vocal tract configuration), the distribution of spectral noise as in the onset of *saw* and *shawl*, and the mouth shape at the onset of a segment) have been shown to be effective in influencing speech perception. Dynamic cues (such as the transition of energy between a consonant and the following vowel) have also been shown to be important. For example, recent research has shown that the second formant (F2) transition, defined as the difference between the F2 value at the onset of a consonant–vowel transition and the F2 value in the middle of the following vowel, is a reliable predictor of the category describing place of articulation (Sussman *et al.*, 1998).

Controversy arises over the type of cue on which speech perception primarily depends. For example, investigators recently isolated short segments of the speech signal and reversed the order of the speech within each segment (Saberi and Perrott, 1999). In this procedure, a sentence is divided into a sequence of successive segments of a fixed duration, such as 50 ms. Each segment is time-reversed and these new segments are recombined in their original order, without smoothing the transitions between the segments. Thus, the sentence could be described as locally time-reversed. Saberi and Perrott claimed that the speech was still intelligible when the reversed segments were relatively short (about 50 to 65 ms). Their conclusion was that our perception of speech was primarily dependent on higher-order dynamic properties rather than the short static cues assumed by most current theories. However, most successful research in psychology is better framed within the framework of *ceteris paribus* (other things being equal). There is good evidence that perceivers exploit many different cues in speech perception, and attempting to isolate a single functionally sufficient cue is futile.

There is now a large body of evidence indicating that multiple sources of information are available to support the perception, identification, and interpretation of spoken language. Auditory and visual

cues from the speaker, as well as the situational, social, and linguistic context contribute to understanding. There is an ideal experimental paradigm that allows us to determine which subset of the many potentially functional cues are actually used by human observers, and how these cues are combined to achieve speech perception (Massaro, 1998). The experiment involves the independent manipulation of two or more sources of information in a factorial or expanded factorial design. This systematic variation of the properties of the speech signal and quantitative tests of models of speech perception allow the investigator to interpret the psychological validity of different cues. This paradigm has already proven to be effective in the study of audible, visible, and bimodal speech perception (Massaro, 1998). It addresses how different sources of information are evaluated and integrated, and can identify the sources of information that are actually used.

AMBIGUITY IN SPEECH PERCEPTION

When listening to speech, we have the impression of perceiving discrete categories. This fact has contributed to the development of the popular 'categorical perception' hypothesis, that listeners can discriminate syllables only to the extent that they can recognize them as different phoneme categories. This hypothesis was quantified in order to predict discrimination performance from the identification judgments. Many researchers concluded that discrimination performance was fairly well predicted by identification. However, discrimination performance is consistently better than predicted by identification, contrary to the predictions of the categorical perception hypothesis (Massaro, 1987).

In many areas of inquiry, a new experimental paradigm enlightens our understanding by helping to resolve theoretical controversies. Rating experiments were used to determine if perceivers indeed have information about the degree of category membership. Rather than ask for categorical decisions, perceivers are asked to rate the stimulus along a continuum between two categories. A detailed quantitative analysis of the results indicated that perceivers have reliable information about the degree of category membership (Massaro and Cohen, 1983). Although communication forces us to partition the inputs into discrete categories for understanding, this does not imply that speech perception is categorical. To retrieve a toy upon request, a child might have to decide between *ball* and *doll*; however, the child can have information about the degree to which each toy was requested.

Although the categorical perception hypothesis has been refuted, it is often reinvented under new guises. Recently, the 'perceptual magnet effect' hypothesis has generated a great deal of research (Kuhl, 1991; Iverson and Kuhl, 2000). The idea is that the discriminability of a speech segment is inversely related to its category goodness. Ideal instances of a category are supposedly very difficult to distinguish from one another relative to poor instances of the category. If we understand that poor instances of one category will often tend to be at the boundary between two categories, then the perceptual magnet effect hypothesis is more or less a reformulation of the categorical perception hypothesis. That is, discrimination is predicted to be more accurate between categories than within categories. In the perceptual magnet effect framework, it is also necessary to show how discrimination is directly predicted by a measure of category goodness. We can expect category goodness to be related to identification performance. Good category instances will tend to be identified equivalently, whereas poor instances will tend to be identified as instances of different categories. Lotto *et al*. (1998) found that discriminability was not poorer for vowels with high category goodness, in contrast to the predictions of the perceptual magnet effect hypothesis. They also observed that category goodness ratings were highly context-sensitive, because they changed systematically with changes in the task context. This reliable context-sensitivity is a problem for the perceptual magnet effect hypothesis. If category goodness is functional in discrimination, it should be reasonably stable across different contexts.

It was once commonly believed that speech is perceived categorically. Current research suggests, however, that speech is perceived continuously and not categorically (Massaro, 1987, 1998). These results challenge views of language acquisition that attribute to the infant and child discrete speech categories (Eimas, 1985; Gleitman and Wanner, 1982). Most importantly, the case for the special nature of speech perception is weakened considerably, because of its dependence on the assumption of categorical perception (Liberman and Mattingly, 1985). Several neural network theories, such as single-layer perceptrons, recurrent network models, and interactive activation, have been developed to predict categorical perception (Damper, 1994; Damper and Harnad, 2000), and its probable nonexistence poses great problems for these models.

Given the existence of multiple sources of information in speech perception, each perceived

continuously, a new type of theory is needed. The theory must describe how each of the many sources of information is evaluated, how the many sources are combined or integrated, and how decisions are made. A promising theory has evolved from sophisticated experimental designs and quantitative model testing to understand speech perception and pattern recognition more generally. A wide variety of results have been accurately described within the fuzzy-logical model of perception (FLMP).

THE FUZZY-LOGICAL MODEL OF PERCEPTION

The three processes involved in perceptual recognition are illustrated in Figure 2. They are evaluation, integration, and decision. These processes make use of prototypes stored in long-term memory. The evaluation process transforms these sources of information into psychological values, which are then integrated to give an overall degree of support for each speech alternative. The decision operation maps the outputs of integration to some response alternative. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely. The assumptions central to the model are: (1) each source of information is evaluated to determine the continuous degree to which that source specifies various alternatives; (2) the sources of information are evaluated independently of one another; (3) the sources are integrated to provide an overall continuous degree of support for each alternative; and (4) perceptual identification and interpretation follows the relative degree of support among the alternatives. The FLMP appears to be a universal principle of perceptual cognitive performance that accurately models human pattern recognition. People are influenced by multiple sources of information in a diverse set of situations. In many cases, these sources of information are ambiguous and no one source specifies completely the appropriate interpretation.

MULTIMODAL SPEECH PERCEPTION

Speech perception has traditionally been viewed as a unimodal process, but in fact appears to be multimodal. This is best seen in face-to-face communication. Experiments have shown conclusively that our perception and understanding are influenced by a speaker's face and accompanying gestures, as well as by the actual sound of the speech (Massaro, 1998). Consider a simple syllable

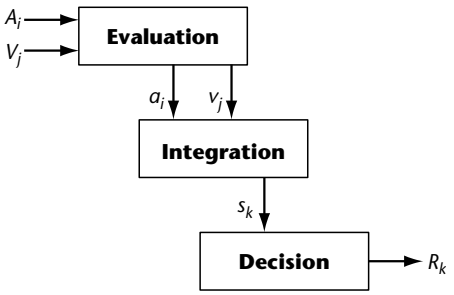

Figure 2. Schematic representation of the three processes involved in perceptual recognition. The three processes are shown proceeding from left to right (in time) to illustrate their successive but overlapping operation. These processes make use of prototypes stored in long-term memory. Sources of information are represented by upper-case letters. Auditory information is represented by A_i and visual information by V_j. The evaluation process transforms these sources of information into psychological values (indicated by lower-case letters a_i and v_j). These sources are then integrated to give an overall degree of support s_k for each speech alternative k. The decision operation maps the outputs of integration into some response alternative R_k. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely.

identification task. Synthetic visible speech and natural audible speech were used to generate the consonant-vowel syllables /ba/, /va/, /ða/, and /da/. Using an expanded factorial design, the four syllables were presented audibly, visibly, and bimodally. Each syllable was presented alone in each modality for $4 \times 2 = 8$ unimodal trials. For the bimodal presentation, each audible syllable was presented with each visible syllable for a total of $4 \times 4 = 16$ unique trials. Thus, there were 24 types of trial. Of the bimodal syllables, 12 had inconsistent auditory and visual information. The 20 participants in the experiment were instructed to watch and listen to the talking head and to indicate the syllable that was spoken.

Figure 3 shows the accuracy for unimodal and bimodal trials when the two syllables were consistent with one another. Performance was more accurate given two consistent sources of information than given either one presented alone. Consistent auditory information improved visual performance about as much as consistent visual information improved auditory performance. Given inconsistent information from the two sources, performance was poorer than observed in the unimodal conditions. These results show a strong influence of both modalities on performance, with a stronger influence from the auditory than from the visual source of information.

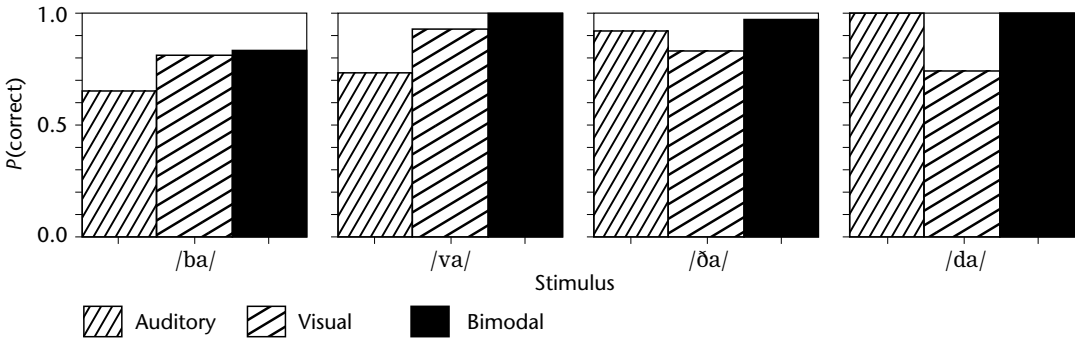

Figure 3. Probabilities of correct identification of syllables in unimodal (auditory and visual) and bimodal consistent trials for the four test syllables /ba/, /va/, /ða/ and /da/.

Although the results demonstrate that perceivers use both auditory and visible cues in speech perception, they do not indicate how the two sources are used together. There are many possible ways the two sources might be used. We first consider the predictions of the FLMP.

In a two-alternative task with /ba/ and /da/ alternatives, the degree of auditory support for /da/ can be represented by a_i, and the support for /ba/ by $(1 - a_i)$. Similarly, the degree of visual support for /da/ can be represented by v_j, and the support for /ba/ by $(1 - v_j)$. The probability of a response to the unimodal stimulus is simply equal to the feature value. For bimodal trials, the predicted probability of a response $P(/\mathrm{da}/)$ is

$$P(/\mathrm{da}/) = \frac{a_i v_j}{a_i v_j + (1 - a_i)(1 - v_j)} \quad (1)$$

In previous work, the FLMP has been contrasted against several alternative models, including a weighted averaging model (WTAV), which is an inefficient algorithm for combining the auditory and visual sources. For bimodal trials, the predicted probability of a response $P(/\mathrm{da}/)$ is

$$P(/\mathrm{da}/) = \frac{w_1 a_i + w_2 v_j}{w_1 + w_2} = w a_i + (1 - w) v_j \quad (2)$$

where W_1 and W_2 are the weights and $W = \frac{W}{W_1 + W_2}$.

The WTAV predicts that two sources can never be more informative than one. In direct comparisons, the FLMP has consistently and significantly outperformed the WTAV (Massaro, 1998).

Furthermore, the results are well described by the FLMP, an optimal integration of the two sources of information (Massaro and Stork, 1998). A perceiver's recognition of an auditory–visual syllable reflects the contribution of both sound and sight. For example, if the ambiguous auditory sentence, *my bab pop me poo brive* is paired with the visible sentence *my gag kok me koo grive* the perceiver is likely to hear *my dad taught me to drive*. Two ambiguous sources of information are combined to create a meaningful interpretation (Massaro and Stork, 1998).

Recent findings show that speechreading, or the ability to obtain speech information from the face, is not compromised by oblique views, partial obstruction or visual distance. Humans are fairly good at speechreading even if they are not looking directly at the talker's lips. Furthermore, accuracy is not dramatically reduced when the facial image is blurred (because of poor vision, for example), when the face is viewed from above, below, or in profile, or when there is a large distance between the talker and the viewer (Massaro, 1998).

CONTEXTUAL, HIGHER-ORDER, OR TOP-DOWN INFLUENCES

There is now a substantial body of research showing that speech perception is influenced by a variety of contextual sources of information. Bottom-up sources have a direct mapping between the sensory input and the representational unit in question. Top-down sources, or contextual information, come from constraints that are not directly mapped to the unit in question. An example of a bottom-up source would be the stimulus presentation of a test word after the presentation of a top-down source, a sentence context. A critical question for both integration and autonomous (modularity) models is how bottom-up and top-down sources of information work together to achieve word recognition. For example, an important question is how early contextual information can be integrated with acoustic and phonetic information. A large body of research shows that several bottom-up sources are evaluated in parallel and integrated to achieve recognition (Massaro, 1987, 1994). Another important question is whether

top-down and bottom-up sources are processed in the same manner. A critical characteristic of autonomous models might be described as the language user's inability to integrate bottom-up and top-down information. An autonomous model must necessarily predict no perceptual integration of top-down with bottom-up information.

Pitt (1995) studied the joint influence of phonological information and lexical context in an experimental paradigm developed by Ganong (1980). A speech continuum is made between two alternatives, and the contextual information supports one alternative or the other. The initial consonant of a CVC syllable was varied, taking six values between /g/ and /k/ inclusive. The following context was either /Ift/ or /Is/. The context /Ift/ supports initial /g/ because *gift* is a word whereas *kift* is not. Similarly, the context /Is/ supports initial /k/ because *kiss* is a word whereas *giss* is not.

The lines in Figure 4 give the predictions of the FLMP. The model generally provides a good description of the results of this study. For each of these individuals, the model captures the observed interaction between phonological information and lexical context: the effect of context was greater to the extent that the phonological information was ambiguous.

The model tests establish that perceivers integrate top-down and bottom-up information in language processing, as described by the FLMP. This means that sensory information and context are integrated in the same manner as are several sources of bottom-up information. These results pose problems for autonomous models of language processing.

CONNECTIONIST MODELS

In connectionist models, information processing occurs through excitatory and inhibitory interactions

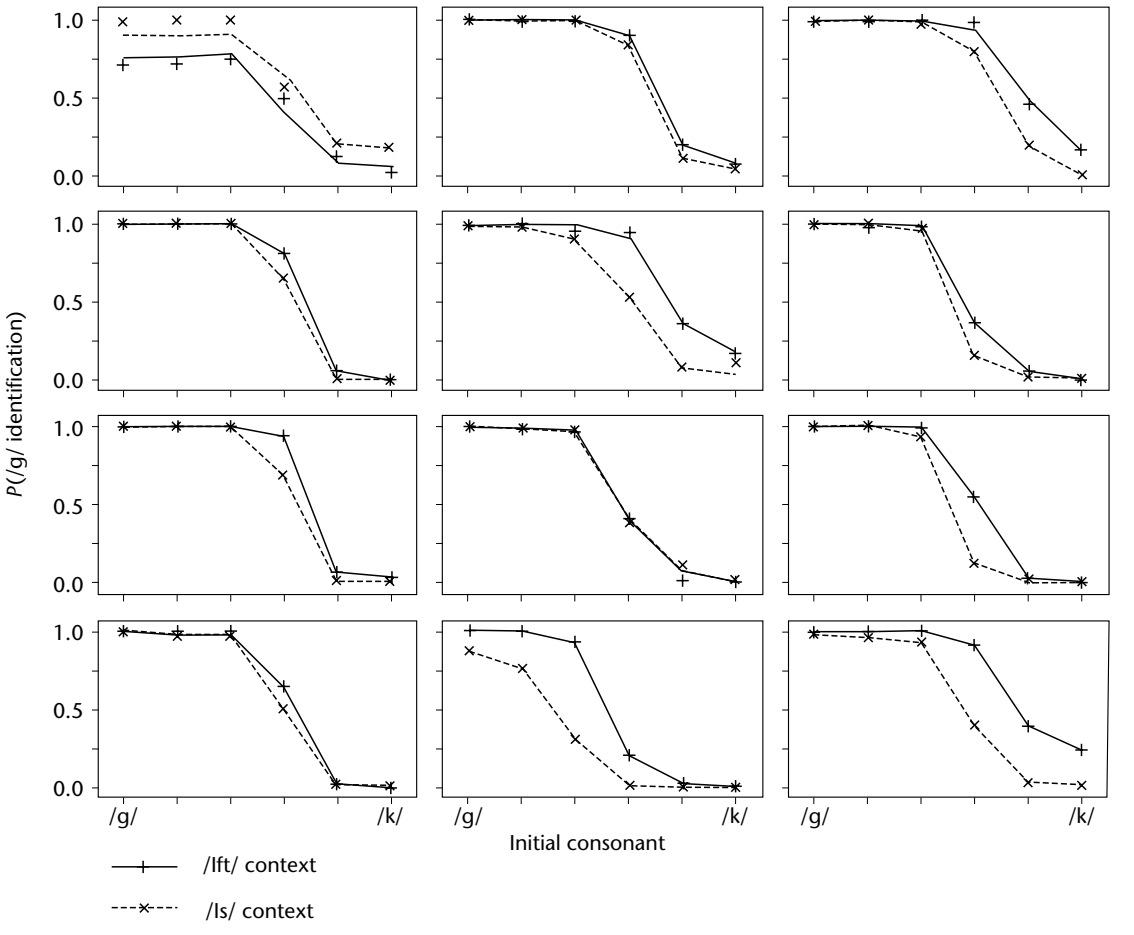

Figure 4. Observed probabilities (points), and FLMP's predictions (lines), of /g/ identifications for /Ift/ and /Is/ contexts as a function of the speech information of the initial consonant which ranges from /g/ to /k/. Results for 12 subjects from Pitt (1995).

among a large number of simple processing units. These units are meant to represent the functional properties of neurons or neural networks. Three levels or sizes of units are used in the TRACE model of speech perception (McClelland and Elman, 1986; McClelland, 1991): feature, phoneme, and word. Features activate phonemes which activate words, and activation of some units at a given level inhibits other units at the same level. In addition, an important assumption of interactive activation models is that activation of higher-order units activates their lower-order units; for example, activation of the /b/ phoneme would activate the features that are consistent with that phoneme.

In the TRACE model, word recognition is mediated by feature and phoneme recognition. The input is processed online in TRACE, all words are activated by the input in parallel, and their activation is context-dependent. In principle, TRACE is continuous, but its assumption about interactive activation leads to categorical-like behavior at the sensory (featural) level. In the TRACE model, a stimulus pattern is presented and activation of the corresponding features sends more excitation to some phoneme units than others. Given the assumption of feedback from the phoneme to the feature level, the activation of a particular phoneme feeds back and activates the features corresponding to that phoneme (McClelland and Elman, 1986, p. 47). This effect enhances sensitivity around category boundaries, exactly as predicted by the categorical perception hypothesis. Evidence against phonemes as perceptual units and against the categorical perception hypothesis is, therefore, evidence against the TRACE model.

PHONEMIC RESTORATION

In the original type of phonemic restoration study (Warren, 1970), a phoneme in a word is removed and replaced with some other stimulus, such as a tone or white noise. Subjects perceive the word as relatively intact and have difficulty indicating what phoneme is missing. This illusion has been taken to support interactive activation: the lexical information supposedly modifies the sublexical auditory representation. This interpretation contrasts with that given by the FLMP, in which the lexical context simply provides an additional source of information. There is no reason to assume that the auditory representation was modified. In terms of signal detection analysis, the lexical influence is one of bias and not sensitivity. Several experimenters have addressed this issue. Although Samuel (1981) concluded that his results favored interactive activation, the changes in top-down context were confused with different stimulus conditions (Massaro, 1989).

Repp (1992) carried out a systematic set of experiments to clarify the locus of the phonemic restoration phenomenon. Essentially, he asked the question whether the restoration was localized at the auditory level or at a higher linguistic level. Within the framework of the FLMP, the effect is attributed to the independent contribution of lexical constraints, with no top-down influence on the auditory level. Subjects were asked to judge the perceived pitch (timbre, brightness) of the extraneous noise that replaced the speech sound. If restoration involved auditory processing, we would expect these pitch judgments to be influenced by lexical context. The overall results of five experiments were negative: auditory effects were not observed, even though phonemic restoration did occur. Repp concludes that perceivers' reports of what they are hearing cannot be taken as an index of auditory process or representation (the McGurk effect). A positive influence of a top-down constraint on perceptual report does not necessarily mean that the representation of the bottom-up influences has been modified. Thus there is no evidence for top-down activation of a lexical representation on a lower-level auditory representation.

HIDDEN MARKOV MODELS

Hidden Markov Models (HMMs) are used in speech recognition when we conceptualize the signal in speech as a sequence of states (Rabiner, 1989; Jurafsky and Martin, 2000). The goal is to determine which model best accounts for the observed sequence of states. For example, the states might correspond to a sequence of phonemes or to a sequence of smaller segments, and the goal is to determine which word best accounts for the observed sequence. A pedagogical example involves an observation of a series of coin tosses, such as HHTHHTTTH. We know there are many possible models that could generate these observed results. The most obvious (and parsimonious) model would be to assume that only a single (possibly biased) coin was being tossed. This is an observable model, and the only parameter needed to completely specificy the model is the bias value. In another model, one could assume that two different coins are being tossed. In this case, it is necessary to specify both the biases of the two coins and how the system moves from state to state (coin to coin). A

third model assumes three biased coins, and choosing among the three on the basis of some probabilistic event. The three models vary in the number of free parameters: the first model requires only a single free parameter; the second model requires four free parameters; and the third model requires nine free parameters. Given that the goal is simply speech recognition accuracy rather than psychological validity, it is not a problem that larger HMMs will necessarily provide a better description of the observed sequence of events. The only limitation on the size of the HMMs is computational complexity.

The three basic problems to solve given HMMs are: (1) computing the probability of an observed sequence for a given model; (2) choosing a state sequence that is optimal given the observation sequence and the model; and (3) determining how the model's parameters are adjusted to maximize the probability of an observed sequence for a given model. What are the fundamental assumptions in using HMMs? It is assumed that the observations are independent, so that the sequence of observations can be written as a product of individual observations. Furthermore, the probability of being in state t depends only on the state at time $t-1$. Finally, the distributions of individual observation parameters can be represented by a mixture of Gaussian or autoregressive densities.

HMMs have found limited application in psychology perhaps because they are not easily applied to empirical studies of speech perception, they are not grounded in psychological processes, and they may not be falsifiable.

CONCLUSION

The study of speech perception is an interdisciplinary endeavor, which involves a varied set of experimental and theoretical approaches. It includes the fundamental psychophysical question of what properties of spoken language are perceptually meaningful and how these properties signal the message. Independent variation of several properties, along with a quantitative theoretical analysis, is a productive paradigm to address not only the psychophysical question but also the issue of how multiple cues are used together for perception and understanding. Spoken language consists of multiple sources of information from several modalities, and people have continuous information from these many sources. In addition to these bottom-up sources, higher-order context is exploited in speech processing. There are several productive theoretical approaches to the complex question of how we so easily communicate with one another.

Spreading-activation Networks

Introductory article

Lokendra Shastri, International Computer Science Institute, Berkeley, California, USA

CONTENTS

Spreading-activation networks are networks of 'active' nodes that compute by propagating activation levels along links. Such network models are inspired by the idea that meaning can be expressed via associations between concepts. They have been used to model cognitive phenomena ranging from low-level vision to common-sense reasoning and language understanding.

INTRODUCTION

Spreading-activation networks derive their inspiration from associationism – the idea that meaning can be expressed via associations between concepts. This idea can be traced through the writings of John Locke, David Hume, William James, and Donald Hebb. But the notion of associative representations came into its own when modern computers allowed it to be articulated and realized in the form of computational models. Today, spreading-activation network models exist for the full range of cognitive phenomena: from low-level vision to reasoning and language understanding.

Much of the early work on spreading-activation network models was motivated by a desire to model common-sense knowledge and common-sense reasoning. A simple example from this domain will illustrate certain aspects of spreading-activation networks. Figure 1 represents a semantic memory encoding the following knowledge: Sylvester is a cat, Tweety is a canary, canaries are birds, cats and birds are animals, canaries are yellow, cats move around by walking, and birds move around by flying. Note that concepts (instances, categories, and attribute values) are represented as nodes, and relations between concepts are encoded by labeled links. For example, `Sylvester` is linked to `Cat` by a link labeled `instance-of`, indicating that Sylvester is a cat; `Cat` is linked to `Animal` by a link labeled `is-a`, indicating that cats are animals, and `Cat` is linked to `Walking` by a link labeled `has-mode-of-transportation`, indicating that cats move around by walking.

The network depicted in Figure 1 may be viewed as a graphical notation (or language) for expressing knowledge. In this view, the network is a passive data structure, and the retrieval of knowledge encoded in the network involves the traversal of this data structure by a program (or interpreter). For example, to answer the question 'What is the mode of transportation of *X*?' (where *X* is a concept), the interpreter examines the links emanating from *X* and looks for a link labeled `has-mode-of-transportation`. If it finds such a link it follows it and retrieves the answer from the node at the end of the link. If it does not find such a link, it traverses the `instance-of` or `is-a` links emanating from *X*, and looks for a `has-mode-of-transportation` link emanating from concepts reached from *X* by traversing these links. For example, to answer the question 'What is the mode of transportation of Tweety', the program visits `Tweety`, `Canary` and `Bird`, and finds the answer `Flying` at the end of the `has-mode-of-transportation` link emanating from `Bird`.

Similarly, to answer the question 'What is yellow and flies?', the interpreter marks the node `Yellow` with a tag `a`, and the node `Flying` with a different tag `b`. Next, it traverses all links that terminate at `Yellow` and have the label `has-color`, and marks nodes at the tails of these links with the tag `a`. Similarly, it traverses all links that terminate at `Flying` and have the label `has-mode-of-transportation`, and marks nodes at the tails of these links with the tag `b`. Thereafter, it propagates tags `a` and `b` by traversing `is-a` and `instance-of` links in the reverse direction, and marks nodes at the tails of these links with the tags marking the heads of these links. Any node marked by both `a`

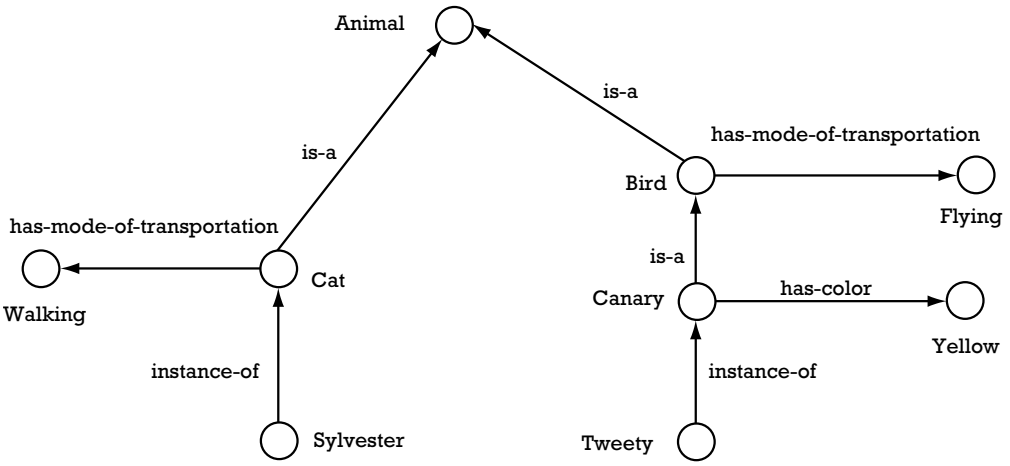

Figure 1. A graphical representation of a small domain of semantic knowledge.

and `b` tags constitutes an answer to the question. Given the domain depicted in Figure 1, the interpreter will identify `Canary` and `Tweety` as the answers to the question 'What is yellow and flies?'.

Note that in finding answers to the two questions discussed above, the system essentially computes set intersections and transitive closures of `is-a` and `instance-of` relations (and their inverses) by traversing a network.

SPREADING ACTIVATION AS A BASIS OF RETRIEVAL AND INFERENCE

A little reflection suggests a more efficient way of realizing the retrieval process described above. In this realization, each node in the graph corresponds to an active processing unit, and each link in the graph corresponds to a physical connection between nodes. A node receives messages along incoming connections, performs some simple operations on the received messages, and propagates the outcome of these operations as messages along outgoing connections. Such a device could perform the sorts of retrieval operations discussed above by a parallel propagation of messages among active processors.

For such a parallel realization to be effective, however, the messages exchanged by nodes and the operations performed by nodes must be simple. This preference for simplicity is motivated by basic computational considerations as well as by the desire to fashion nodes and links after neurons and synapses. (*See* **Connectionism**)

One can trace the idea of such parallel spreading-activation networks to a model of semantic memory proposed by M. Ross Quillian in 1968. Quillian's model represents 'word concepts' in terms of their associations with other word concepts, and finds common properties of two word concepts A and B by propagating discrete 'activation tags' starting at A and B and identifying nodes where tags originating from A and B intersect. Since Quillian's work on semantic memory, spreading-activation networks have been proposed for a wider range of cognitive tasks including semantic memory, word-sense disambiguation, language understanding, speech recognition, speech production, visual object recognition, reading, inference, and problem-solving. (*See* **ACT**; **Semantic Networks**)

Spreading-activation models can be broadly classified into 'marker-passing' networks and 'activation-passing' networks. In marker-passing networks, nodes propagate and store discrete markers, and perform Boolean operations on stored markers. In activation-passing networks, nodes propagate graded levels of activity, and links may have weights associated with them. These weights can be positive (excitatory) or negative (inhibitory). A node typically computes the weighted sum of its inputs (i.e., it multiplies the weight of each incoming link by the output of the node at the source of the link, and computes the sum over all incoming links), and produces an output activity determined by a simple, though often nonlinear, function of that weighted sum. Two such functions that are commonly used are the step function (output activity equals 1 if the weighted sum of inputs exceeds a threshold and zero otherwise) and the sigmoid function (output activity is a monotonically increasing function of the weighted sum of inputs and varies smoothly between -1 and $+1$ in the shape of an S). A node's output function in an

activity-passing system can be viewed as an 'evidence combination function' which performs a graded integration of evidence incident on the node.

MARKER-PASSING NETWORKS

The NETL system proposed by Scott Fahlman in 1979 is an example of a marker-passing system. It consists of a parallel network of simple processors and a serial central computer that controls the operation of the parallel network. Each node can store a small number of markers and perform Boolean operations on stored markers in response to commands issued by the central controller. Nodes can also propagate markers along links in parallel under the supervision of the central controller. Thus NETL performs parallel marker passing and effectively computes transitive closures and set intersections. Consequently, it can rapidly answer inheritance questions (such as 'Do sparrows fly?') and categorization questions (such as 'Which animal lives in Africa and has large ears?').

One limitation of a marker-passing network such as NETL is that markers and operations on markers are discrete ('yes or no'). Consequently, such a network cannot support evidential (or probabilistic) inference. In particular, such a network has no notion of 'best match' or of 'partial match'. Finding a concept that matches a given description amounts to finding a concept that has all the properties specified in the description.

A different type of marker-passing network has been proposed by Engene Charniak and James Hendler. These networks use complex messages that also encode information useful for controlling marker propagation. Typically, such a message contains path information, which can be stored at a node and used to detect loops, extract paths traced by a marker, and evaluate the relevance of these paths. Consequently, nodes in such networks are fairly complex.

ACTIVATION-PASSING NETWORKS

An early activation-passing network incorporating parallelism, graded activation, and evidence combination is the 'interactive activation model' proposed by James McClelland and David Rumelhart in 1981 for the perception of words and letters in visually presented stimuli.

The model consists of three layers of nodes, corresponding to visual letter features, letters, and words (see Figure 2). The letter features consist of horizontal, vertical, and diagonal bars similar to the ones used in some electronic alphanumeric displays. Feature and letter nodes are replicated four times, once for each position in a word, to enable the network to represent words of length up to four. The activity level of a node indicates the belief in the hypothesis that the node stands for. For example, the activation level of the node standing for the letter T in position 2 indicates the network's belief that the presented stimulus has a T in its second position.

Nodes representing mutually consistent hypotheses support one another, and hence are connected via excitatory links. Thus a feature node is connected via excitatory links to letter nodes representing letters that contain that feature. Similarly, a letter node (e.g. T in position 1) is connected via excitatory links to word nodes representing words containing that letter in the appropriate position (e.g. 'TAKE').

Nodes representing mutually inconsistent hypotheses are connected via inhibitory links. Thus all word nodes inhibit one another, all letter nodes for a given position inhibit one another, a feature node inhibits all letter nodes representing letters that do not contain that feature, and a letter node inhibits all word nodes representing words that do not contain that letter in the appropriate position.

Additionally, there are reciprocal (feedback) connections from a word node to all letter nodes that comprise the word (e.g. from 'TAKE' to the node for T in position 1, the node for A in position 2, and so on). These connections allow bottom-up perceptual processing to be reinforced by top-down expectations.

A visual input is presented to the model by activating feature nodes corresponding to it. The activation emanating from feature nodes excites and inhibits appropriate letter nodes. Activated letter nodes inhibit other letter nodes, and excite and inhibit appropriate word nodes. Activated word nodes, in turn, inhibit other word nodes, and excite appropriate letter nodes. Thus activation propagates through the network and results in a consistent set of letter nodes and a word node becoming highly active and forming a 'stable coalition'.

The model supports perceptual completion and disambiguation. For example, given an input consisting of the letters W, O, and R in positions 1, 2, and 3 respectively, and a partial input in position 4 consistent with both R and K, the network determines that the ambiguous letter in position 4 is K, and the word being presented is 'WORK'. An informal explanation of how this happens is as

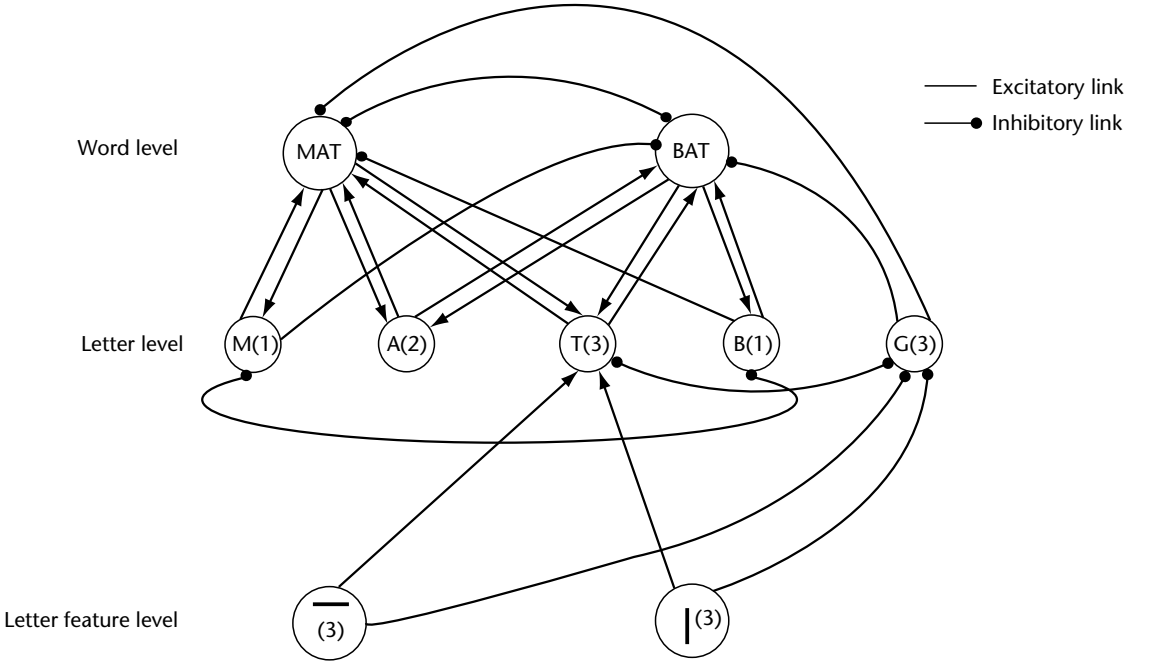

Figure 2. A fragment of a network showing the connectivity of the interactive activation model for word perception. The numbers in parentheses indicate the position of a letter or feature within an input word. The feature nodes depict the visual features of the letter T.

follows. The input provided to the feature nodes leads to the strong activation of letter nodes W, O, and R in positions 1, 2, and 3 respectively, and the weak activation of letter nodes K and R in position 4. All other letter nodes are inhibited. The activity of letter nodes leads to a strong activation of the 'WORK' node since this is the only word consistent with the ongoing activity of letter nodes. The 'WORK' node therefore dominates the activity in the word level, and sends excitatory feedback to letter nodes W, O, R, and K in the appropriate positions. This additional activity received by K in position 4 raises its activation level above that of R in position 4. Given the inhibitory link from R to K, the stronger activity of K suppresses the activity of R, resulting in the ambiguous and partial input being interpreted by the system as 'WORK'.

The model also explains psychological findings such as the ease of processing words and pronounceable non-words compared with other non-words, and the 'word superiority effect', whereby subjects are better at detecting a letter when the letter is presented as part of a word than when the letter is presented in isolation.

Applications to Language and Speech

The spreading-activation networks described above deal only with static inputs: the complete input is available at one time, and stays constant during processing. The treatment of time-varying signals is problematic in such a network. The TRACE model of McClelland and Jeffrey Elman shows how spreading-activation networks can be extended to process a time-varying signal such as speech. The model consists of three layers, corresponding to acoustic features, phonemes, and words. Feature and phoneme nodes are replicated several times to account for their occurrences in different temporal positions within an utterance. Moreover, since phonemes and words extend over time, inputs to phoneme and word nodes span multiple time slices.

Most words have multiple senses, but we are able to exploit contextual and syntactic (e.g. word-order) information to disambiguate them. Spreading-activation networks have modeled such disambiguation. For example, David Waltz and Jordan Pollack have developed a network that disambiguates between the 'celestial object' and 'famous personality' senses of the word 'star' in 'the astronomer married the star'. Similarly, Garrison Cottrell and Steven Small's network assigns correct senses to 'ball' and 'threw' in the sentences 'John threw a ball' and 'John threw a ball for charity'. These networks incorporate several representational levels, such as word, word-sense, and

thematic-role levels, and excitatory and inhibitory interconnections to express support and conflict.

Gary Dell has proposed a spreading-activation network for converting a sequence of words into a sequence of phonemes. The network consists of a word layer and a phoneme layer. Each word node has excitatory connections to nodes representing its phonemes, and each phoneme node has excitatory connections to all word nodes containing that phoneme. The word node corresponding to the current word in a sequence is activated to a high level, and word nodes corresponding to upcoming words in the same phrase as the current word are activated to a low level. This leads to the formation of a stable coalition of mutually consistent word and phoneme nodes. This network explains empirical findings about speech errors such as phoneme anticipation errors (e.g. pronouncing 'deal back' as 'beal back'), phoneme exchange errors (e.g. pronouncing 'deal back' as 'beal dack'), and the lexical bias effect (e.g. pronouncing 'dean bad' as 'bean bad' is more likely than pronouncing 'deal back' as 'beal back' because both 'bean' and 'bad' are words, whereas 'beal' is not a word).

NETWORKS WITH DYNAMIC BINDINGS

Consider the following simple narrative: 'John fell in the hallway. Tom had cleaned it. He got hurt.' Upon hearing this narrative, most of us would infer that Tom had cleaned the hallway, John fell because he slipped on the wet hallway floor, and John got hurt because of the fall. These inferences allow us to establish causal and referential coherence among the events and entities involved in the narrative. They help us to explain John's fall by means of plausible inferences, that the hallway floor was wet as a result of Tom cleaning the hallway, and that John fell because he slipped on the wet floor. They help us to causally link John's hurt to his fall, and help us to determine that 'it' in the second sentence refers to the hallway, and 'he' in the third sentence refers to John and not to Tom. Our ability to draw such inferences during language understanding suggests that we are capable of performing a wide range of inferences rapidly, spontaneously, and without conscious effort. This remarkable human ability poses a challenge for cognitive science: How can the brain represent a large body of common-sense knowledge and perform a wide range of inferences with the requisite speed?

The sort of reasoning described above is particularly difficult to model using spreading-activation networks because it requires the representation of relational structures and a solution to the binding problem. Consider the representation of the event 'John gave Mary a book'. Call this event *E*. *E* is a specific instance of a relation in which John, Mary, and book play specific roles. It cannot be represented by simply activating the conceptual roles 'giver', 'recipient', and 'given object' and the entities 'John', 'Mary', and 'book'. Such a representation would be identical to that of 'Mary gave John a book'. An unambiguous representation of *E* requires the representation of bindings between the roles of *E* (e.g. 'giver') and the entities that fill these roles in the event (e.g. 'John'). Furthermore, inferring that Mary has the book as a result of John giving the book to her involves rapidly establishing additional bindings between the role 'owner' and 'Mary' and between the role 'owned object' and 'book'. Thus reasoning about events and situations also requires a solution to the problem of propagating bindings.

None of the spreading-activation models discussed above solves the dynamic binding problem. For example, the TRACE model requires multiple banks of letter (or phoneme) nodes because it cannot dynamically bind a letter (or phoneme) to a position.

It is straightforward to represent role–entity bindings using additional nodes and links (e.g., using 'binder' nodes encoding conjunctions of roles and entities). But while it is feasible to use additional nodes and links to encode long-term knowledge, it is implausible that binder nodes could be recruited for representing large numbers of dynamic bindings arising rapidly during language understanding and visual processing. In standard computing, bindings are expressed using variables and pointers, but these techniques have no direct analogue in spreading-activation networks.

Activation-passing network modelers have devised several solutions to the binding problem. One solution, proposed by John Barnden and Kankanahalli Srinivas, makes use of the relative positions of active nodes and the similarity of their firing patterns to encode bindings. Another solution, proposed by Trent Lange and Michael Dyer and by Ron Sun, assigns a distinct activation pattern (a signature) to each entity, and propagates these signatures to establish role–entity bindings. In 1989, Venkat Ajjanagadde and Lokendra Shastri proposed a biologically plausible solution for expressing and propagating role–entity bindings. They suggested that, for example, the role–entity binding `John=giver` be expressed by the synchronous firing of `John` and `giver` nodes. The

use of synchrony for binding perceptual features during visual processing had been suggested earlier by Christoph von der Malsburg, but the Shruti model of Shastri and Ajjanagadde offered a detailed account of how synchronous activity can be harnessed to represent complex relational knowledge, and to carry out rapid inference with respect to such knowledge.

The Shruti model encodes relational knowledge using 'focal node clusters' (see Figure 3). The focal cluster of a relation such as `fall` consists of a `+:fall` node, whose activity indicates that the network is making an assertion about a fall, a `?:fall` node, whose activity indicates that the network is seeking an explanation about a fall, and role nodes – one for each role associated with `fall`. Links between the '+' and '?' nodes of a focal cluster enable the network to automatically seek explanations for active assertions. The focal cluster of an entity also contains a '+' node and a '?' node.

The event 'John fell in the hallway' is represented by the synchronous firing of the nodes `+:John` and `fall-patient`, the synchronous firing of the nodes `+:Hallway` and `fall-location`, and the sustained firing of the node `+:fall`.

From Simple Associations to Systematic Reasoning

A systematic mapping between relations (and other rule-like knowledge) is encoded by high-efficacy links between focal clusters (see Figure 3). For example, the rule-like knowledge 'If one slips, one is likely to fall' is encoded by bidirectional links between the patient roles of `slip` and `fall` and between the object roles of `slip` and `fall`, and by directed links from `+:slip` to `+:fall` and from `?:fall` to `?:slip`. Since each link has a weight associated with it, and since each node uses a graded activation combination function to generate its output based on its inputs, Shruti can encode evidential rules and perform evidential (probabilistic) reasoning.

Given the connectivity shown in Figure 3, the activity encoding 'John slipped in the hallway' automatically evolves so that `+:fall` starts firing, the 'patient' role of `fall` starts firing in synchrony with the 'patient' role of `slip` (and hence, with `+:John`), and the 'object' role of `fall` starts firing in synchrony with the 'object' role of `slip` (and hence, with `+:Hallway`). The resulting pattern of activity encodes not only 'John slipped in the hallway' but also the inferred event 'John fell in the hallway' (see Figure 4). Similarly, the pattern of activity encoding 'John fell in the hallway' automatically evolves to a pattern of activity that also encodes 'Did John slip in the hallway?'.

Inference in Shruti occurs automatically as a result of the propagation of rhythmic activity across interconnected focal clusters. There is no interpreter or central controller that manipulates symbols or applies rules of inference. The network encoding is best viewed as an internal model of the environment. When the nodes in this model are

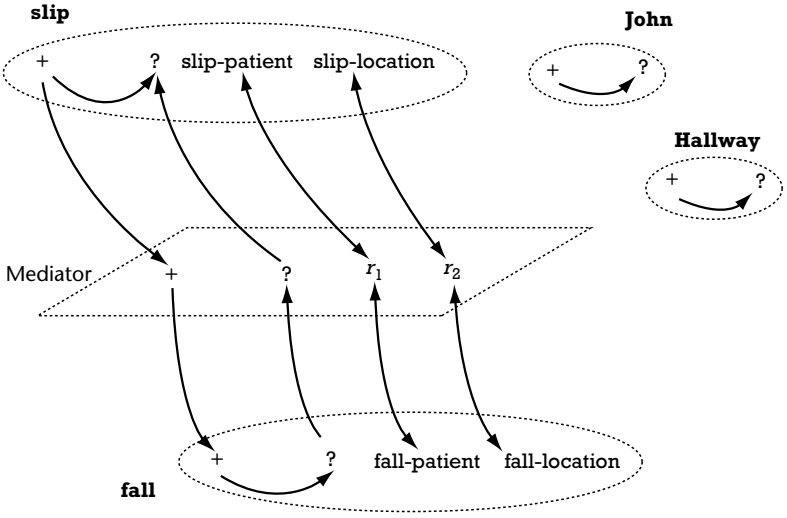

Figure 3. A network fragment illustrating Shruti's encoding of the causal rule-like knowledge 'if one slips, one is likely to fall'. Each ellipse encloses a focal node cluster associated with a relation. Labels within such a cluster denote nodes. The activity of a '+' node indicates an assertion and that of a '?' node indicates a search for an explanation. Other nodes within a focal cluster are role nodes (e.g. slip-patient and slip-location).

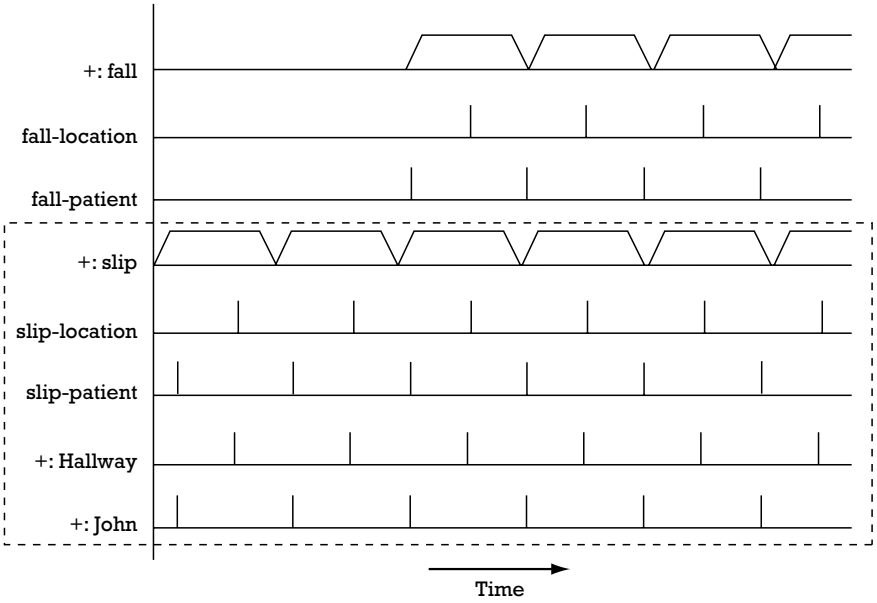

Figure 4. Rhythmic node firings in Shruti. The boxed activities correspond to the encoding of the input sentence 'John slipped in the hallway'. Bindings are encoded by the synchronous firing of role and entity nodes. This activity evolves to include the activation-based encoding of 'John fell in the hallway'.

activated to reflect a given state of affairs, the model spontaneously simulates the behavior of the external world, and in doing so, finds explanations, makes predictions, and draws inferences.

In addition to the representational machinery described above, Shruti can also encode episodic and semantic facts. These facts are 'coincidence' and 'coincidence error' detector circuits situated between the '?' and '+' nodes of focal clusters. A fact becomes active, and enables the flow of activity from the '?' to the '+' node of the associated relational focal cluster, whenever the bindings encoded in the fact match the dynamic bindings expressed in the ongoing flux of activity. Finally, during inference, Shruti can also instantiate new entities, unify multiple entities by merging their phases of firing, and exhibit priming effects by rapid changes in link weights.

With all the above machinery in place, Shruti can rapidly draw a wide range of inferences in parallel, including bridging inferences such as 'Tom had cleaned the hallway', 'John fell because he slipped on the wet hallway floor', and 'John got hurt because of the fall', in response to the input: 'John fell in the hallway. Tom had cleaned it.'

An Enriched Notion of Spreading-activation Networks

In the representational context of events and situations, the operative representational unit in a spreading-activation network is often a circuit of nodes rather than a node. Only some of the nodes in such a circuit correspond to cognitively meaningful entities; other nodes perform a processing function or serve an ancillary representational role. For example, the persistent encoding of the event *E* ('John gave a book to Mary') involves not only nodes corresponding to 'John', 'Mary', 'book', 'giver', 'recipient', and 'given object', but also functional nodes, such as a node for asserting belief in *E*, a node for querying *E*, binder nodes for encoding role–entity bindings in *E*, and nodes for linking *E* to perceptual–motor schemas for the 'give' action.

CURRENT RESEARCH

Spreading-activation networks provide a natural and computationally effective framework for encoding complex evidential interactions. These networks have grown in their sophistication and representational power to encompass not only perceptual and associative phenomena, but also high-level cognitive activities such as reasoning, language understanding, and problem-solving. A promising development has been the blending of spreading-activation models with connectionist models that are explicitly guided by behavioral, biological, and computational constraints. Having resolved some difficult representational problems, the focus of the field is shifting towards the study of structured adaptive networks grounded in perception and action.

Story Understanding

Intermediate article

Erik T Mueller, IBM Thomas J Watson Research Center, Yorktown Heights, New York, USA

CONTENTS

Story understanding researchers have built computer programs that read and answer questions about simple stories. They have proposed a number of knowledge structures and processing mechanisms useful for this task.

INTRODUCTION

The field of story understanding is concerned with building computer programs that can understand stories. It also investigates how people understand stories. Thus far, the field has dealt mainly with short stories a few paragraphs long, rather than full-length novels, which represent a much harder problem. By 'understanding' it is usually meant that the program should be able to answer questions about a story it reads. It should also be able to generate summaries.

STORY GRAMMARS

An early formalism for stories was the story grammar (Rumelhart, 1975). A story grammar consists of a context-free grammar, with semantic rules associated with each rule of the context-free grammar. An example of a simple story grammar is:

Story → Setting + Episode
Setting → State (Setting ALLOWS Episode)
Episode → Event + Emotion (Event CAUSES Emotion)
Event → Event + Event (Event CAUSES Event)
Event → Episode
Event → Action (1)

Consider the story:

1. Althea was in the playroom.
2. She sat on the balloon.
3. It popped.
4. She was pleased. (2)

The story grammar can be used to parse the story as follows:

Story ⇒
Setting ALLOWS Episode ⇒
State ALLOWS Episode ⇒
1 ALLOWS Episode ⇒
1 ALLOWS (Event CAUSES Emotion) ⇒
1 ALLOWS ((Event CAUSES Event) CAUSES Emotion) ⇒
1 ALLOWS ((Action CAUSES Action) CAUSES Emotion) ⇒
1 ALLOWS ((2 CAUSES 3) CAUSES 4) (3)

The complete parse of the story is:

Althea was in the playroom ALLOWS ((She sat on the balloon CAUSES It popped) CAUSES She was pleased) (4)

This parse can then be used to answer questions:

Why did the balloon pop? Because she sat on it. (5)

Why was she pleased? Because she sat on the balloon and it popped. (6)

The problem with story grammars is that they tie together form and content. According to the above story grammar, the form `Event1 + Event2` corresponds to the content `Event1 CAUSES Event2`. Yet it is quite possible that `Event1 + Event2` instead corresponds to `Event2 CAUSES Event1`, as in the text

The balloon popped. She sat on it. (7)

Although story grammars are useful for capturing the structure of certain story forms such as folk tales, they do not account for the content of a story. They fail to address how an understander is able to make sense of a story despite the variety of

ways of expressing the story. The ingredient missing from story grammars is the understander's knowledge about the way the world works.

KNOWLEDGE-DRIVEN STORY UNDERSTANDING

Stories do not specify everything down to the last detail. Rather, to understand a story one must 'fill in the blanks' and make inferences. Given the text

Althea shook the piggy bank. Three dimes fell out. (8)

a reader easily infers that the dimes fell out because Althea shook the piggy bank, even though this was not explicitly stated. This inference can be made because the reader knows that coins are often stored in piggy banks, that piggy banks have a slot through which coins and other small objects can pass, that shaking helps those objects pass through that slot, and that unsupported objects fall. Such information, known to the reader but not contained in the text, is variously referred to as 'world knowledge', 'general knowledge', 'common-sense knowledge', or simply 'knowledge'.

Much research has focused on identifying the types of knowledge required for story understanding, representing that knowledge within a computer program, and building programs that make use of the knowledge.

Demons

Early work on story understanding (Charniak, 1972) used a single mechanism, called 'demons', for representing and applying knowledge. A demon consists of a test and an action. The test specifies a condition to await. The action specifies an action to perform when the condition becomes true. The following demon allows a program to make the correct inference regarding the piggy bank:

Test : Person *P* shakes piggy bank *B* and money *M* comes out of *B*.
Action : Assert that *M* comes out of *B* because *P* shakes *B*. (9)

That is, this demon generates the inference:

Three dimes fell out BECAUSE Althea shook the piggy bank. (10)

Using a large number of demons, a story understanding program will be able to make a large number of inferences. However, demons can go off on a tangent, generating inferences of doubtful relevance to a story:

The dimes were in the piggy bank BEFORE they fell out. (11)

The dimes were somewhere else BEFORE they were in the piggy bank. (12)

The dimes were minted BEFORE they were somewhere else. (13)

Althea picked up the piggy bank BEFORE she shook the piggy bank. (14)

Althea was somewhere else BEFORE she picked up the piggy bank. (15)

and so on. A type of knowledge structure, called 'scripts', was therefore proposed (Schank and Abelson, 1977) for capturing the relevant inferences in a typical situation.

Scripts, Plans, and Goals

Scripts are bundles of information about situations or activities that are common in a given culture, such as eating at a restaurant, attending a birthday party, or taking the subway. Scripts consist of roles, props, settings, entry conditions, results, and scenes. Here is a short version of the restaurant script:

Roles: customer *C*, waiter *W*
Props: table *T*, menu *M*, food *F*, bill *B*, money *D*
Settings: restaurant *R*
Entry conditions: *C* is hungry, *C* has *D*
Results: *C* is satiated
Scenes:
1. Entering: *C* goes to *R*, *C* sits at *T*
2. Ordering: *C* reads *M*, *C* chooses *F*, *W* comes to *T*, *C* requests *F* from *W*
3. Eating: *W* brings *F* to *C*, *C* eats *F*
4. Exiting: *W* brings *B* to *C*, *C* gives *D* to *W*, *C* leaves *R*

This script may be used to fill in missing information. Told that someone went to a restaurant, ordered lobster, paid the bill, and left, the listener infers (unless told otherwise) that the person ate the lobster.

Of course, the above is not the only possible sequence for eating in a restaurant. Certain types of variations can be accommodated by scripts. A script may have several 'tracks'. The restaurant script has a fast food track, a cafeteria track, and a fancy restaurant track. In the fast food track, the customer pays for the food before eating and may eat the food inside or outside the restaurant. A script may contain alternative paths. If the service is poor, the customer leaves a smaller tip.

However, suppose the story begins:

Suzy was hungry. She went to the Zagat website. (16)

Though the restaurant script mentions hunger, it does not mention visiting a particular website. Knowledge structures for plans and goals were therefore proposed (Schank and Abelson, 1977) to deal with story events that do not follow an existing script. A person has a goal to reduce hunger, and one plan for achieving this goal is toeat at a restaurant. Another plan is to eat at home. A subgoal of eating at a restaurant is to go to the restaurant. A subgoal of going to the restaurant is to know the address of the restaurant. One plan for knowing the address of a restaurant is to read a restaurant guide. Another plan is to ask a friend. One plan for reading a restaurant guide is to read it online. Zagat is a restaurant guide. There are many other plans and subgoals for many other goals. (*See* **Natural Language Processing: Models of Roger Schank and his Students**)

Knowledge of these plans and goals may be used to explain why Suzy went to the Zagat website, namely, in order to read the Zagat guide, so that she could know the address of a restaurant, so that she could go to the restaurant, so that she could eat, so that she could satisfy her hunger.

Themes

Scripts, plans, and goals allow a reader to connect up elements of a story locally. But stories usually have some overall point, moral, or theme. That is, stories are coherent globally. Researchers have proposed a number of related knowledge structures for capturing the point of a story: thematic organization packets, story points, plot units, thematic abstraction units, and planning advice themes.

Consider a story about a man who loses his job, runs out of money, and then happens to save a wealthy person who gives him a large reward. The essence of this story is captured by the story point called 'fortuitous solution' (Wilensky, 1982):

Person *P* is in a negative state.
An incidental event *E* occurs.
E results in a positive state for *P*. (17)

Plot units (Lehnert, 1982) also capture the essence of stories. Plot units are graphs consisting of linked positive events, negative events, and mental states. For example, the 'retaliation' plot unit describes any story in which person *A* causes a negative event for person *B*, which motivates *B* to cause a negative event for *A* (see Figure 1).

Space and Time

Recent approaches to story understanding (Duchan *et al*., 1995) stress the importance of the reader's immersion in the story world. Readers imagine they are inside stories and vicariously experience them. As a story unfolds, the reader keeps track of the shifting 'where', 'when', 'who', and 'what' of the story.

Two-dimensional grids have been proposed (Mueller, 1998) for representing typical locations such as a grocery store, theatre, or hotel room, and for keeping track of the 'where' in a story understanding program. Given the text

Jim was in his hotel room. (18)

an imagined view from above is represented as a square grid in which certain cells are assigned to the various elements of the room: bed, door, minibar, wall, phone, table, and Jim.

Grids allow a story understanding program to make inferences regarding the distance between objects, the relative position of objects (left, right, front, back), whether story characters can see or hear each other, and whether there is a path from one location to another. The program answers questions by consulting the grid:

Was Jim near a bed? Yes. (19)

The 'when' of a story can be represented using absolute timestamps (e.g. '11 a.m. GMT on 12 January 1997') or relations on time intervals (e.g. '*A* happened before *B*', '*A* happened during *B*').

One possible organizational structure for the 'where' and 'when' is the scenario participant map (Dyer, 1983). This is a graph consisting of settings (such as the elevator or hotel room where the story action takes place) connected by transitions (such as walking through the hallway to get to the hotel room).

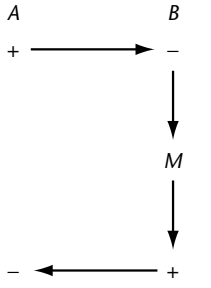

Figure 1. The 'retaliation' plot unit. Person *A* causes a negative event for person *B*, which motivates *B* (via mental state *M*) to cause a negative event for *A*.

USING SCRIPTS, PLANS, GOALS, STORY POINTS, AND PLOT UNITS

A story understanding program builds representations of knowledge structures such as scripts, plans and goals while reading a story. Those representations can then be used for question answering, paraphrasing, and summarization. Table 1 lists some of the story understanding programs that have been built over the years. Some of these programs can be downloaded from the internet (see 'Further Reading').

Script Application

The 'script applier mechanism' or SAM program (Cullingford, 1978) uses scripts to understand stories as follows. Suppose the first sentence of a story is

Fred went to a restaurant. (20)

SAM must activate the restaurant script. Script headers are attached to scripts to assist in script activation. In the above case, a locale header activates the restaurant script because the text mentions that a story character (Fred) went to the setting of the script (restaurant). A precondition header activates a script when the text mentions the main entry condition of a script, as in *Fred was hungry*. A direct header activates a script when the text simply states that the script occurred, as in *Fred ate at a restaurant*. A script is also activated when the text mentions an event of the script.

Alternatively, script activation may be viewed as a text categorization problem and handled using statistical natural language processing techniques. The task is to assign a segment of text to one of many scripts.

When the restaurant script is activated, 'Fred' is assigned to the customer role and 'restaurant' is assigned to the restaurant setting. SAM's representation of the story after reading the first sentence is:

restaurant script, $C =$ 'Fred', $R =$ 'restaurant'
last matched event = 'C goes to R' (21)

As further sentences of the story are read, they are matched to events of the script and additional assignments are made as necessary. For example, given *he ordered lobster*, the representation is updated to:

restaurant script, $C =$ 'Fred', $R =$ 'restaurant', $F =$ 'lobster'
last matched event = 'C requests F from W' (22)

In order to answer a question about the story, the program tries to locate an event of an active script that both matches the question and occurs in the script at or before the last matched event. (Later events have not yet happened in the story.) The script event 'C chooses F' matches the question *What did Fred choose?* and occurs before the last matched event. The variables C and F in the event are replaced by their values, resulting in the answer *Fred chose lobster*.

Several scripts can be active in SAM at a time, and the program can also handle certain deviations from a script, such as being served a burnt hamburger.

Tracking Plans and Goals

Since human behavior is to a large extent goal-directed, tracking the plans and goals of story characters is essential to understanding. If one is told that someone is making marinara sauce, one assumes the person has the goal of eating and is in the middle of preparing a meal.

Given observations of the behavior of story characters, the process of plan recognition (Kautz, 1991) produces explanation graphs such as that shown in Figure 2.

Table 1. Representative story understanding programs

Program	*Year*	*Knowledge structures and mechanisms*
Ms Malaprop	1977	frames
SAM	1978	scripts
PAM	1978	plans, goals
BORIS	1982	scripts, plans, goals, emotions, themes, integration
AQUA	1989	asking and answering questions while reading, explanation
DISCERN	1991	scripts, architecture of subsymbolic networks
TACITUS	1993	axioms, weighted abduction
AbMaL	1994	emotions
SNePS/Cassie	1995	propositional semantic networks, beliefs
ThoughtTreasure	1998	plans, goals, emotions, grids, simulation

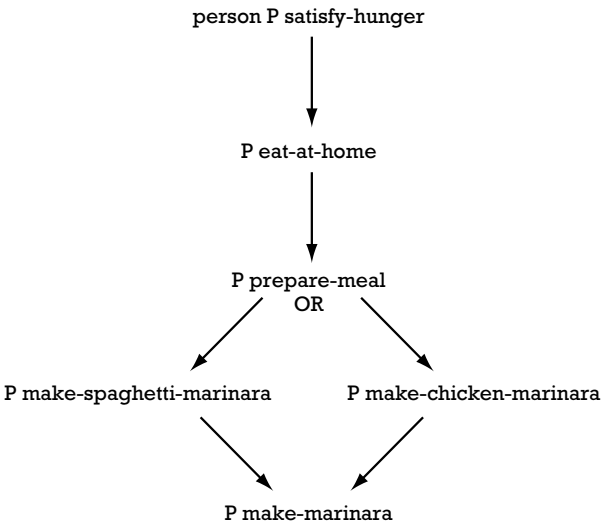

Figure 2. An explanation graph for the information that someone is making marinara sauce.

Since two recipes known to the understander use marinara sauce, the explanation graph contains these alternatives. The top-level goal is to satisfy hunger. In order to satisfy this goal, a subgoal of eating at home is activated. This in turn activates a subgoal to prepare a meal, which activates a subgoal to prepare spaghetti marinara or chicken marinara (the understander does not know which), which activates a subgoal to make marinara sauce. Producing such graphs requires a library of common plans.

Stories often mention states leading to goals. The program thus creates links from states to goals activated by those states:

$$\texttt{P hungry} \rightarrow \texttt{P satisfy-hunger} \quad (23)$$

Emotions are intertwined with goals, and stories often mention the emotional reactions of story characters (Dyer, 1983). Goal successes result in positive emotions, while goal failures result in negative emotions. The program therefore tracks goal outcomes, and creates links from goal outcomes to their resulting emotions:

$$\texttt{P obtain-employment} \rightarrow \texttt{P happy (succeeded)} \quad (24)$$

The program answers questions about a story by consulting the explanation graphs:

Why was Joan making marinara sauce?
She was hungry and wanted to eat. (25)

Why was Jim happy? Because he was hired for a job. (26)

Using Story Points and Plot Units

Story points and plot units are derived from explanation graphs, extended with further goal situations. Goal conflict is the situation in which several goals of a single character interfere with each other. Goal competition is the situation in which the goals of several characters interfere. Goal concord is the situation in which the goals of several characters are compatible. Goal subsumption is the situation in which one goal continually enables satisfaction of another goal.

Plot unit graphs map to explanation graphs as follows. Positive events correspond to goal successes or positive mental states, negative events correspond to goal failures or negative mental states, and mental states correspond to active goals. Named plot units are recognized by building plot unit graphs and matching those graphs to a library of named plot units such as retaliation or fortuitous problem resolution.

Themes such as story points and plot units are useful for predicting what might come next in a story. If a sufficiently large portion of a theme is recognized, the program anticipates the events predicted by the remainder of that theme.

Themes are also useful for producing remindings. If a story is recognized as being an instance of a given theme, the understander may be reminded of another story with that theme.

Finally, themes are useful for summarization. The retaliation plot unit leads to the summarization template:

Because *A* caused a negative event for *B*,
B later caused a negative event for *A*. (27)

For example, a summary that might be produced from the above template is:

Because Harrison turned Debra down for a date, she later turned him down when he changed his mind. (28)

INTEGRATING SENTENCE ANALYSIS WITH STORY UNDERSTANDING

As a story understanding program reads a text, it must incorporate new information into its existing representation of the story. There are two ways this might be performed. In batch interpretation, the program updates its representation after reading each sentence. In incremental interpretation, the program updates its representation after reading each word. The incremental approach is valid from a cognitive standpoint since people appear

to be able to interpret words in real time as they are read (Just and Carpenter, 1980).

There are two ways the story understanding program might be structured: as a series of modules with distinct responsibilities, or as one large process. The trend is towards modular processing, because it is easier to build and understand modular programs, and some self-contained modules for natural language tasks such as part-of-speech tagging now exist.

Modular processing has often been associated with batch interpretation, though this need not be the case. For example, syntactic and semantic parsing modules may cooperate to produce an interpretation incrementally (Mahesh *et al*., 1999).

Let us adopt a modular, batch approach in order to sketch out a complete story understanding program. The first module of a story understanding program is the sentence boundary detector, which segments an input text into sentences. The next module is the entity recognizer. This module segments a sentence into words, phrases, and other entities such as places, numbers, dates, and times. The next module is the tagger, which assigns a part of speech to each entity. The next module is the syntactic parser, which takes a stream of tagged entities and produces syntactic parses such as:

```
[S
  [NP [Name Jim]]
  [VP
    [V set]
    [NP [Det the] [N milk]]
    [PP [Prep on] [NP [Det the]
    [N table]]]]]
```

The next module is the semantic parser, which takes syntactic parse trees and converts them into logical formulae such as:

```
set(Jim,milk,on(table))        (29)
```

Ambiguities are recognized by each module and passed along to the next module. For example, a word may have several possible parts of speech, and a sentence may have several possible syntactic and semantic parses. (*See* **Natural Language Processing**; **Natural Language Processing, Disambiguation in**; **Parsing**; **Parsing: Overview**)

The understanding modules include a script applier, a plan recognizer, and a theme recognizer. Logical formulas from the semantic parser are fed to the understanding modules, which then update their representation or understanding of the story. The understanding modules must agree among themselves how to resolve the ambiguities that were introduced by previous modules, as well as any newly encountered ambiguities.

The question answerer and summarizer take questions from the semantic parser, and examine representations produced by the understanding modules to produce answers and summaries. They use a generator to convert representations into natural language.

The capabilities that have been proposed by various researchers as necessary for story understanding include: to extract themes and morals; to go back and reread; to look for hidden messages; to model naive physics; to model physical objects, devices, and settings; to model the minds of story characters (theory of mind); to pose questions during reading and answer them; to read according to some goal for reading; to read creatively and invent new explanatory frames; to recognize a typical situation (scripts); to reconcile conflicting interpretations; to revise an interpretation; to track emotions of story characters; to track plans and goals of story characters; to track temporal relationships; to track the shifting 'where', 'when', 'who', and 'what'; to use discourse markers; to use imagery or visual representations; to use past experiences to guide understanding; to zoom in on detail; and to zoom out from detail. This list does not include capabilities normally assumed in natural language processing, such as syntactic parsing and anaphora resolution.

The processing mechanisms used in various story understanding programs include: abduction (inference to the best explanation); backward chaining; constraint satisfaction; demons; discrimination nets; finite-state automata; forward chaining; indexing; logic; neural networks; pattern matching; plan recognition; production systems; simulation; society of agents; spreading activation or marker passing; and working memory. These vary in scope. For example, it has been claimed that all levels of natural language processing, including syntax, semantics, and pragmatics, can be handled using abduction.

SPREADING ACTIVATION AND CONNECTIONIST APPROACHES

Dissatisfaction with strictly symbolic mechanisms has led some researchers to experiment with mechanisms inspired by the physiology of the brain and experimental results in psychology such as those from priming experiments. (*See* **Syntax and Semantics, Neural Basis of**; **Connectionism**; **Priming**)

Spreading Activation

Consider the text

> Suzy wanted to eat dinner. She got in her car. (30)

One way to relate these two sentences is to conduct two simultaneous searches through the plan library. One search starts from `eat-dinner` while the other starts from `enter-car`. When one search meets the other, a path has been found from `eat-dinner` to `enter-car`, as shown in Figure 3.

This method is known as 'spreading activation' or 'marker passing' (Charniak, 1986). Once a path is found, it must be verified for correctness. It must be checked, for instance, that the person who wants to eat dinner is the same person who got in the car. Marker passing with verification is one method for doing plan recognition to produce an explanation graph.

Connectionist Approaches

So far we have discussed symbolic representations of knowledge structures such as scripts, plans, and goals. An alternative kind of representation is a subsymbolic, or connectionist, one, in which concepts are represented not as discrete entities but by the pattern of activity in a neural network.

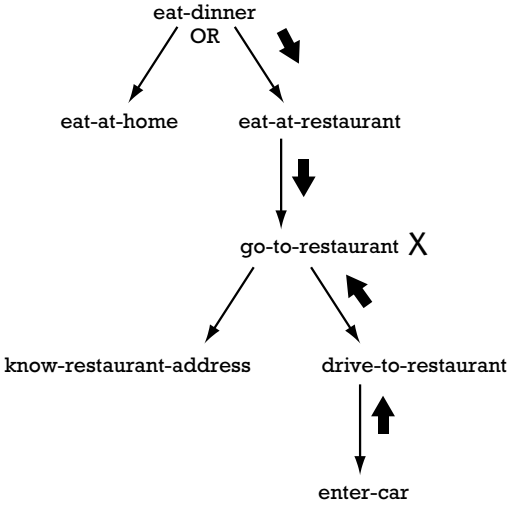

Figure 3. The statements 'Suzy wanted to eat dinner' and 'she got in her car' can be related by conducting two simultaneous searches through the plan library, one from `eat-dinner` and the other from `enter-car`. These are shown by the downward- and upward-facing stubby arrows, respectively. The point of intersection is marked by the 'X'.

The connectionist approach has several advantages. Firstly, neural networks are neurally inspired, so a story understanding program implemented in neural networks is more likely to model how understanding is actually implemented in the brain. Secondly, neural networks can be trained on a set of examples in order to learn representations and make generalizations automatically, reducing the need for a programmer to specify knowledge structures. Thirdly, the performance of neural networks generally degrades in a steady fashion.

On the other hand, the connectionist approach has several disadvantages. Firstly, neural networks have difficulty with novel inputs, since they need to be trained on a large number of examples of their inputs. Secondly, it is difficult to implement in neural networks certain operations such as role assignment and composition that are easy to implement in symbolic programs.

Miikkulainen (1993) used the connectionist approach to build a complete program called DISCERN that reads and answers questions about script-based stories. The program is built from independent connectionist modules that communicate using distributed representations. The modules are: lexicon, episodic memory, sentence parser, sentence generator, story parser, story generator, cue former, and answer producer.

The episodic memory stores and generalizes script-based stories. It is organized by the programmer into a fixed three-level architecture. The top level represents the script class, the middle level represents the script track, and the bottom level represents the script roles. The neural networks at each level are self-organized by training on an artificially generated set of stories involving the restaurant, shopping, and travel scripts. In testing, the distributed representation of an input story, which may contain missing role bindings, is fed to the episodic memory. The episodic memory is able to fill in any missing role bindings using the generalizations it made during training. The cue former retrieves answers to questions about input stories from the episodic memory.

DISCERN can only handle one script per story and is unable to handle deviations from a script. Thus it is not as sophisticated as SAM, one of the early symbolic story understanding programs.

ASSESSMENT

Since the 1970s, we have learned much about story understanding. Yet it is still not known how to scale up a story understanding program so that it can understand more than 'toy' stories. The problem

does not appear to be what symbolic or subsymbolic mechanism is used for processing – probably a number of mechanisms will do the job – but how to get a story understanding program to work at the human level at all.

It is hardly surprising that story understanding is a difficult problem. It is a task that calls the entire mind into play. All of the explanatory frames, skills, and mechanisms used to deal with everyday life can be invoked in story understanding. A story can be about almost anything, from picking up and holding an apple (motor skills) to observing the subjective redness of the apple (consciousness). (*See* **Language Comprehension, Methodologies for Studying**; **Discourse Processing**)

Programmers have difficulty managing the complexity of building and debugging story understanding programs. Even if a library of common-sense knowledge is available (Cyc and ThoughtTreasure are attempts at building such libraries), it is still difficult to build processing mechanisms that apply the library in understanding. It appears that the knowledge library needs to be developed with the understanding program in mind, yet it is not clear how this can be done. Story understanding might take a cue from statistical language processing and information extraction. Success has been achieved in these fields by building modules that address well-defined subproblems, such as part-of-speech tagging or filling templates about terrorism news stories. By putting together many modules that address parts of the story understanding problem, it may be possible to reach a complete solution. (*See* **Natural Language Processing, Statistical Approaches to**)

It is easy to forget how ambiguous natural language is. A sentence has many possible interpretations. Many of those possibilities are implausible, but the program does not always know that. Furthermore, the possible interpretations of each sentence must be considered in light of the possible interpretations of previous sentences. So if there are two interpretations of the first sentence, there might be four after reading the second, eight after reading the third, and so on. Knowledge structures such as scripts were designed to prevent such problems, but in practice they do not always work.

It is a mystery how people are able to avoid this proliferation of possible interpretations and understand stories. Cognitive psychologists have conducted experiments investigating how inferences are made during narrative comprehension (Graesser *et al*., 1994). Cognitive neuroscientists are beginning to address discourse comprehension (Beeman and Chiarello, 1998). Someday it may be possible to use a brain scan with high spatial and temporal resolution to trace a behavior such as a verbal response to a question back to its causes during reading.

STRIPS

Introductory article

David Furcy, Georgia Institute of Technology, Atlanta, Georgia, USA
Sven Koenig, Georgia Institute of Technology, Atlanta, Georgia, USA

CONTENTS

STRIPS was the planning component of the agent architecture for the robot Shakey. Its representation language is still widely used for planning.

THE PROBLEM OF GOAL-DIRECTED ACTION

Intelligent agents, including humans, need to determine how to achieve their goals. Reasoning about how the execution of actions can change the current state of the world to a desired state is called 'planning'. How to automate this task has been a major focus of research in artificial intelligence (AI).

This article describes seminal work on planning in AI, and the influence of that work on current research. The 'Stanford Research Institute problem solver' (STRIPS) was developed by Fikes, Nilsson, Hart, Sacerdoti and their colleagues as the planning component of the agent architecture for the robot Shakey. Begun in the late 1960s, the Shakey project studied how to control a robot to push boxes from room to room. The project had a major influence on subsequent research on planning and plan execution in AI. For example, although current planners are able to solve planning problems that are much larger than those solved by Shakey, many of them use variants of the knowledge representation language originally used by STRIPS. (*See* **Robotics**)

We will first describe the representation language of STRIPS, and then its search strategy, called means–ends analysis, which had originally been developed by Newell, Simon and their colleagues in the context of the 'general problem solver'. Next, we will discuss other important components of the agent architecture of Shakey, including macro-operator learning, plan monitoring, and hierarchical planning. Finally we will briefly discuss how current planners use and extend the representation language of STRIPS. (*See* **Newell, Allen**; **Simon, Herbert A.**)

PROPOSITIONAL WORLD MODELS AND THE ROBOT NAVIGATION TASK

A planner needs to represent world states in order to reason about them. STRIPS represents world states as sets of propositions, called world models. Each proposition in a world model represents a fact that is true in the corresponding world state. STRIPS assumes that propositions that are not part of a world model correspond to facts that are false in the corresponding world state (the 'closed-world assumption'). STRIPS also represents the goal as a set of propositions. The objective of planning, then, is to change the current world model to one that includes all propositions of the goal (but may contain additional propositions). The goal thus represents a set of world models, one of which needs to be reached. (*See* **Knowledge Representation**)

We will use Shakey's environment to illustrate the representation language of STRIPS. Symbols, such as `Box1` or `Door1`, represent objects. Propositions represent either properties of objects, such as `Pushable(Box1)` and `Open(Door1)`, or relationships among two or more objects, such as `Connects(Door1,Room1,Room2)` or `In(Shakey,Room1)`. (We will refer to `Pushable`, `Connects`, and so on as the 'proposition names'.) Some propositions are part of all world models, for example because they encode background knowledge: examples are `Pushable(Box1)` and `Connects(Door1,Room1,`

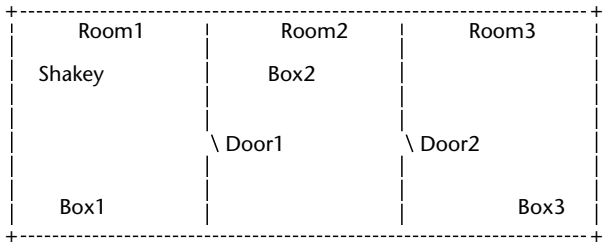

Figure 1. Diagram of a world state consisting of 3 rooms with 2 connecting open doors.

Room2). Other propositions encode facts that can change and are thus not part of all world models: examples are Open(Door1) and In (Shakey,Room1).

Imagine a world state with three rooms in a row, connected with two open doors (Figure 1). Each room contains a pushable box, and Shakey is in the first room. The corresponding world model is:

```
Open(Door1) and Open(Door2) and
Connects(Door1,Room1,Room2) and
  Connects(Door2,Room2,Room3) and
Connects(Door1,Room2,Room1) and
  Connects(Door2,Room3,Room2) and
Pushable(Box1) and Pushable(Box2)
  and Pushable(Box3) and
In(Shakey,Room1) and In(Box1,
  Room1) and In(Box2,Room2) and
  In(Box3,Room3)
```

A possible goal would be:

```
In(Box2,Room1)
```

This goal is satisfied by any world state where Box2 is in Room1.

The domain designer chooses which objects and propositions are used to represent world states. For example, we have not included the color of the boxes in the example, since this feature is irrelevant for pushing them. The representation language, together with the chosen objects and propositions, determines which planning problems a planner can solve and how quickly it can solve them. Many current planners use the propositional representation language presented here. STRIPS actually uses a slightly more expressive representation language. For example, it can represent in one short statement the fact that all boxes are pushable. However, its more expressive representation language requires it to use a theorem prover during planning, which increases the planning time.

PLANNING OPERATORS

A planner also needs to represent actions in order to reason about them. It needs to know, for example, in which world states they apply and which world states result from their execution. STRIPS assumes that each action execution instantaneously and deterministically transforms the current world state into another world state. STRIPS represents actions as operators. Each operator has a 'precondition list', an 'add list', and a 'delete list'. An operator can be applied in a world model if the world model contains all propositions of its precondition list. The world model that results from its application is obtained by deleting all propositions of its delete list from the current world model and then adding all propositions of its add list. Thus, the precondition list specifies which facts must be true in the current world state in order for an action to be executable. The add list specifies which facts its execution makes true; and the delete list specifies which facts its execution makes false. STRIPS assumes that the truth values of all other facts remain unchanged (the 'STRIPS assumption').

STRIPS actually uses operator schemata ('STRIPS rules') in order to represent actions concisely and reason about them in a general way. Operator schemata generalize operators, since they can use variables where operators use object symbols. The operators are then obtained by instantiating the operator schemata, that is, by replacing each variable within an operator schema with the same object symbol. Thus, an operator schema corresponds to several operators.

For example, the following operator pushes Box1 from Room1 through Door1 to Room2:

- Name: PUSHTHRU-Box1-Door1-Room1-Room2
- Precondition list: In(Shakey,Room1) and In(Box1,Room1) and Pushable(Box1) and Connects(Door1,Room1,Room2) and Open(Door1)
- Add list: In(Shakey,Room2) and In(Box1, Room2)
- Delete list: In(Shakey,Room1) and In(Box1,Room1)

The corresponding operator schema, which pushes any object from one room through some door to another room, is:

- Name: PUSHTHRU
- Parameter list: box, door, room1, room2
- Precondition list: In(Shakey,room1) and In(box,room1) and Pushable(box) and

Connects(door,room1,room2) and Open(door)
- Add list: In(Shakey,room2) and In(box, room2)
- Delete list: In(Shakey,room1) and In(box, room1)

(Note that object names start with a capital letter while variable names do not.) The following operator schema moves Shakey from one room through a door to another room:

- Name: GOTHRU
- Parameter list: door, room1, room2
- Precondition list: In(Shakey,room1) and Connects(door,room1,room2) and Open(door)
- Add list: In(Shakey,room2)
- Delete list: In(Shakey,room1)

PLANNING AS SEARCH

STRIPS takes as input the operator schemata, the initial world model, and the goal. Its objective is to output an operator sequence that transforms the initial world model into one that satisfies the goal. This is a difficult problem: in general, it is P-space complete to determine whether such an operator sequence exists. In principle, planning can be formulated as searching the state-space graph, whose vertices correspond to world models (states). An edge corresponds to an operator, and connects a world model in which the operator can be applied to the world model that results from its application. The objective of the search is to find a path from the vertex that corresponds to the initial world model to any vertex that corresponds to a world model that satisfies the goal. The high complexity of planning can be explained by the size of the state-space graph: the number of vertices is exponential in the number of propositions used to describe the planning problem. (*See* **Computability and Computational Complexity**)

Planners that search the state-space graph are called 'state-space' or 'situation-space' planners. The size of the graph makes uninformed searches of the graph intractable even for relatively small planning problems. STRIPS therefore searches the graph without representing all of it explicitly, using the structure of the world models and some heuristics to guide its search. (*See* **Search**)

PLAN GENERATION THROUGH MEANS–ENDS ANALYSIS

The following piece of pseudo-code shows the principle of means–ends analysis:

```
achieve-propositions(world-model
W1, propositions S)
{
  if S is a subset of W1, return the
    empty operator sequence;
  choose a proposition P such that P
    is part of S but not W1 (choice
    point);
  operator-sequence O1 := achieve-
    proposition(W1, P);
  world-model W2 := the world model
    that results from applying O1 in
    W1;
  operator-sequence O2 := achieve-
    propositions(W2, S);
  return the concatenation of O1 and
    O2
}
achieve-proposition(world-model
  W, proposition P)
{
  choose an operator O1 whose add
    list contains P (choice point);
  if no such operator exists,
    backtrack to the previous choice
    point;
  operator-sequence O2 := achieve-
    propositions(W, precondition
    list of O1);
  return O2 with O1 appended
}
```

STRIPS uses means–ends analysis as its search strategy. Means–ends analysis focuses on the propositions that need to be achieved (the ends) and the operators that can achieve them (the means). (*See* **Means–Ends Analysis**)

Initially, STRIPS calls achieve-propositions with the initial world model and all propositions that are part of the goal. It tries to achieve the desired propositions one after the other, combining forward and backward searches. If a desired proposition has not already been achieved, it chooses an operator that adds it and then tries to achieve the preconditions of the operator.

Later versions of means–ends analysis only choose operators whose main (primary) effects are to add the proposition. For example, moving the box is the main effect of the PUSHTHRU-Box1-Door1-Room1-Room2 operator. Moving Shakey is only a side effect.

Thus, means–ends analysis constructs plans by concatenating sub-plans, each of which achieves a desired proposition. However, a sub-plan can delete desired propositions that were achieved by earlier sub-plans in the sequence. Since there are planning problems where this happens no matter

the order in which means–ends analysis tries to achieve the propositions (Sussman anomaly), it might have to reachieve them. How to do this is a difficult problem, and means–ends analysis is not guaranteed to find an operator sequence that achieves the goal from the initial world model even if one exists.

PLAN GENERALIZATION

Since planning is time-consuming, STRIPS caches plans for later reuse. However, each cached plan can only be reused for one specific planning problem. Thus, a large number of plans need to be cached, which can make plan retrieval as time-consuming as planning itself (the 'utility problem'). To address this problem, STRIPS generalizes plans before caching them.

For example, the problem of the boxes in the three rooms, discussed above, is solved by the operator sequence `[GOTHRU(Door1,Room1, Room2), PUSHTHRU(Box2,Door1, Room2,Room1)]`. STRIPS first stores it in a triangle table, which is a compact way of recording the dependencies of the preconditions of each operator on the effects of the operators that precede it in the operator sequence. STRIPS then uses a theorem prover to generalize the operator sequence by replacing as many object symbols as possible with variables while maintaining the dependencies recorded in the triangle table. Maintaining the recorded dependencies guarantees that the preconditions of all operators are satisfied during the application of the operator sequence, no matter which object symbols the variables are replaced with.

This results in the generalized operator sequence `[GOTHRU(door1,room1,room2), PUSHTHRU(box,door2,room2,room3)]`. Finally, STRIPS could create a new operator (a 'macro-operator') (with a computer-generated name) that has the same effect as the operator sequence:

- Name: `FOO1653`
- Parameter list: `door1, door2, room1, room2, room3, box`
- Precondition list: `In(Shakey,room1)` and `In(box,room2)` and `Pushable(box)` and `Connects(door1,room1,room2)` and `Connects(door2,room2,room3)` and `Open(door1)` and `Open(door2)`
- Add list: `In(Shakey,room3)` and `In(box, room3)`
- Delete list: `In(Shakey,room1)` and `In(box, room2)`

This macro-operator could then be used like any other operator, allowing the program to achieve any proposition that is part of the add list of the macro-operator with only one operator application (instead of two, in our example). This reduces the number of recursive calls to `achieve-propositions`, and thus the number of choice points for backtracking.

In fact, STRIPS stores the triangle table instead of the macro-operator, so that it can reuse not only the generalized operator sequence, but also parts of it.

Unfortunately, the number of sub-sequences grows exponentially with the length of the operator sequence in a triangle table. Therefore, there is a trade-off between the number and size of stored triangle tables.

DYNAMIC MONITORING OF ACTIONS

The execution of plans can fail if STRIPS makes wrong assumptions. For example, if STRIPS were erroneously told that a door was open, or if the door were closed during plan execution, then the resulting plan might direct Shakey to pass through the door without opening it first. In this case, its execution would fail. Therefore, it is important that plan execution be monitored. Shakey's plan monitor, PLANEX, can change the operator sequence that Shakey executes. If this does not resolve the problem, PLANEX invokes STRIPS to find a different plan that achieves the goal from the current world state.

For example, if the preconditions of an operator are not satisfied, PLANEX can insert operators before it to ensure that the operator sequence can be applied and that it continues to achieve the goal. In our example, plan execution fails when Shakey tries to pass through a closed door. Therefore, PLANEX inserts an operator that opens the door and then proceeds to execute the operator sequence.

PLANEX also optimizes an operator sequence during execution. It uses a triangle table to find the shortest suffix of the operator sequence that achieves the goal, and executes it instead of the whole operator sequence. This allows PLANEX to skip operators if some of the operators returned by means–ends analysis are redundant or if their execution is unnecessary for some other reason. For example, Shakey might try to open a door that is already open because STRIPS was erroneously told that the door was closed. In this case, PLANEX removes the operator that opens the door from the operator sequence, and then proceeds to execute the sequence.

HIERARCHICAL PLANNING IN ABSTRIPS

Hierarchical planning can reduce the planning time by first finding a plan for a simplified version of the planning problem and then using it to speed up finding a plan for the more complex problem. ABSTRIPS is a hierarchical planner based on STRIPS. It was the first planner to demonstrate the computational advantages of hierarchical planning. It simplifies the planning problem by deleting details, then finds a plan for the more abstract planning problem, and finally refines it by filling in operators that achieve the deleted details.

For each proposition, ABSTRIPS stores a criticality value, which measures how easy it is to achieve the proposition. These values are determined by a combination of human input and automatic reasoning. For example, `Open(Door1)` has a low criticality value since closed doors can easily be opened once Shakey is next to them. `In(Room1)` has a higher criticality value since Shakey might have to traverse several rooms and open several doors in order to reach the room. ABSTRIPS first deletes all propositions with criticality values below a given threshold from all world models and operators. This makes the state-space graph significantly smaller, and therefore the planning problem easier to solve. ABSTRIPS then uses STRIPS to find a plan that solves this simplified planning problem. (In our example, this plan is a sequence of `GOTHRU` and `PUSHTHRU` operators.) It does not solve the original planning problem if the preconditions of some operators or some goal propositions are not satisfied, for example if it requires Shakey to go through closed doors. In such cases, ABSTRIPS might have to refine the plan. It uses STRIPS to find plans that achieve the unsatisfied propositions, and inserts each plan into the operator sequence where it is needed. (In our example, this adds the necessary `OPEN` operators to the operator sequence.) If the plan cannot be refined by inserting additional operators, ABSTRIPS attempts to find a different plan for the simplified planning problem (via backtracking) and refine it.

This planning scheme with two levels of abstraction can easily be generalized to multiple levels of abstraction with decreasing thresholds of criticality values. The resulting search strategy is called 'length-first' search, because it constructs a complete plan at each level of abstraction before it refines the plan at the next lower level of abstraction.

THE INFLUENCE OF STRIPS ON COMPUTER MODELS OF GOAL-DIRECTED ACTION

STRIPS had a major influence on subsequent research in AI planning. Research into topics such as plan representation, plan generalization and learning macro-operators, execution monitoring and replanning, and hierarchical planning, is continuing. For instance, the plan generalization method of STRIPS is an example of a class of machine-learning methods later called explanation-based learning. (*See* **Machine Learning**)

STRIPS trades off the expressive power of the representation language and the efficiency of reasoning. In principle, planning problems can be expressed in first-order logic (situation calculus) and solved with theorem provers. The designers of STRIPS decided to sacrifice some expressive power of the representation language to be able to plan more efficiently with specialized reasoning methods, such as means–ends analysis. STRIPS combined means–ends analysis with theorem proving; whereas many current planners use planning methods (without theorem proving) that work on the simplified propositional representation language presented here. This version of the STRIPS representation language allows one to represent simplified versions of many interesting planning problems, and retains the important property that the domain designers do not need to represent those facts that are not affected by action executions. (*See* **Frame Problem, The**)

However, few current planners use means–ends analysis as a search strategy. The success of some of them even casts doubt on a basic assumption behind means–ends analysis, namely, that planning has to use the structure of world models to be efficient. Some recent planners, for example, are based on techniques from heuristic search, constraint satisfaction, or model checking. Others do not even search the situation space. Planners that use hill-climbing methods from boolean satisfiability, for example, search the space of partial assignments of truth values to propositions; and partial-order planners search the space of incomplete plans. (*See* **Hill-climbing Search**)

However, most planners solve the same kind of problems as STRIPS, and make the same assumptions. They assume, for example, that planning problems have discrete world states and actions, that the goal can be expressed as a set of world states, that the goal is known in advance and does not change over time, that actions have known

effects and change the world state deterministically and instantaneously, that the agent always observes the current world state completely and executes actions sequentially, and that the states change only due to actions executed by the agent.

The representation language of STRIPS has been extended in various ways to relax some of these assumptions. For example, the 'planning domain definition language' is more general since it can model continuous resources, such as time or energy, and durative actions with continuous effects. There are also variants of STRIPS that can express planning problems where actions have nondeterministic effects or the current world state is only partially observable, in which case planners must decide when and what to sense and which actions to execute depending on the sensed information ('conditional planning').

SUMMARY

STRIPS was an early planner, consisting of a language that represents world states and actions, and a planning method that uses means–ends analysis to search the space of world models. It had a major influence on subsequent research in AI planning. Although current planners are more efficient and solve more realistic planning problems, the representation language of STRIPS is still widely used.

Supervenience

Intermediate article

Brian P McLaughlin, Rutgers University, New Brunswick, New Jersey, USA

CONTENTS

There is supervenience when a difference in one respect requires a difference in another respect. For example, the mental characteristics of individuals supervene on their physical characteristics if and only if two individuals cannot differ in respect of their mental characteristics without differing in respect of their physical characteristics.

INTRODUCTION

The notion of supervenience has been invoked in virtually every area of philosophy. It has been invoked to try to characterize the relationship between mental and physical properties, the relationship between moral and natural properties, and the relationship between aesthetic and natural properties, to name just a few. There have been attempts to formulate the doctrine of physicalism as a psychophysical supervenience thesis. And the positions of internalism and externalism in psychosemantics – the theory of meaning for mental representations – are usually characterized in terms of supervenience theses.

WHAT IS SUPERVENIENCE?

Sometimes one difference requires another. Two sets cannot differ in respect of their cardinalities without differing in respect of what members they contain; two elements cannot differ in respect of their chemical properties without differing in respect of their electronic shells; and two machines cannot differ in respect of what algorithms they can execute without differing in respect of what programs they can run. If one sort of difference, difference in *A*-respects, requires another sort of difference, difference in *B*-respects, then, and only then, *A*-respects supervene on *B*-respects (McLaughlin, 1995). For example, mental respects supervene on physical respects if and only if there cannot be a difference in mental respects without a difference in physical respects; aesthetic respects supervene on natural respects if and only if there cannot be a difference in aesthetic respects without a difference in natural respects.

Supervenience is a relation. As such it is reflexive and transitive, but it is neither symmetrical nor asymmetrical. Specifically, supervenience is the relation of dependent variation (McLaughlin, 1995). For *A*-respects supervene on *B*-respects just in case variation in *A*-respects *depends* on variation in *B*-respects. The dependency is purely modal: from the fact that *A*-respects supervene on *B*-respects it does not follow that something is the way it is in *A*-respects by virtue of its being the way it is in *B*-respects. Equivalently, in the relevant sense of independence, *A*-respects can vary independently of variation in *B*-respects if and only if it is possible to have variation in *A*-respects without variation in *B*-respects. So, for example, mental respects fail to supervene on physical respects if and only if mental respects can vary independently of variation in physical respects (Jackson, 1993). That is just to say that mental respects fail to supervene on physical respects when and only when it is possible to have variation in mental respects without variation in physical respects.

When A-respects supervene on B-respects, *A*-respects are *supervenient* relative to *B*-respects and *B*-respects are *subvenient* relative to *A*-respects (Kim, 1984). Given that it is impossible to have variation in supervenient *A*-respects without variation in subvenient *B*-respects, it follows that exact similarity in *B*-respects suffices for exact similarity in *A*-respects. For example, two sets exactly alike in respect of what members they contain must be exactly alike in respect of what cardinalities they have; two machines exactly alike in respect of what programs they can run will be exactly alike in respect of what algorithms they can execute; and two elements exactly alike in their electronic shells must be exactly alike in their chemical properties. In the first two cases, the 'must' is that of logical necessity; in the last, it is that of nomological necessity.

Call two things *A-twins* if and only if they are exactly alike in every *A*-respect. (Note that everything is trivially an *A*-twin of itself.) Then, *A*-respects supervene on *B*-respects if and only if *B*-twins cannot fail to be *A*-twins (McLaughlin, 1995). So, for example, mental respects supervene on physical respects just in case physical twins cannot fail to be mental twins. If physical twins can fail to be mental twins, then, and only then, mental respects fail to supervene on physical respects; for, then and only then, variation in mental respects is possible without variation in physical respects.

VARIETIES OF SUPERVENIENCE

Various definitions have been proposed that define determinates of the determinable relation of dependent variation, and so define various subcategories of supervenience.

Strong and Weak Supervenience

Quantifying over possible worlds, two much-discussed categories of supervenience can be defined as follows (Kim, 1987; McLaughlin, 1995):

Weak supervenience: *A*-respects weakly supervene on *B*-respects if and only if for any possible world w, *B*-twins in w are *A*-twins in w. (1)

Strong supervenience: *A*-respects strongly supervene on *B*-respects if and only if for any possible worlds w_1 and w_2 and any individuals x_1 and x_2, if x_1 in w_1 is a *B*-twin of x_2 in w_2 then x_1 in w_1 is an *A*-twin of x_2 in w_2. (2)

Strong implies weak, but not conversely. Weak supervenience is concerned with intraworld relations, with whether it is the case that in every world, *B*-twins are *A*-twins. Strong supervenience is concerned with interworld as well as intraworld relations, with whether any possible *B*-twins, from the same or different worlds, are *A*-twins within their respective worlds.

The range of possible worlds quantified over can be restricted; for example, it can be restricted to the causally possible worlds, or the nomologically possible worlds. These restrictions yield subcategories of weak and strong supervenience.

Modal Operator Supervenience

While the focus of this article is supervenience understood as the relation of dependent variation, other relations are sometimes called supervenience relations. Jaegwon Kim (1984, 1987) has attempted to define notions of supervenience using modal operators, rather than quantification over possible worlds. He offers the following definitions, where *A* and *B* are non-empty sets of properties:

Modal operator weak supervenience: *A* weakly supervenes on *B* if and only if necessarily, if anything has some property *F* in *A*, then there is at least one property *G* in *B* such that that thing has *G*, and everything that has *G* has *F*. (3)

Modal operator strong supervenience: *A* strongly supervenes on *B* if and only if necessarily, if anything has some property *F* in *A*, then there is at least one property *G* in *B* such that that thing has *G*, and necessarily everything that has *G* has *F*. (4)

Since definitions 3 and 4 differ only in that the latter contains one more occurrence of 'necessarily' than does the former, operator strong implies operator weak, but not conversely. Kim (1993) has argued that modal operator weak and strong supervenience are equivalent, respectively, to weak and strong supervenience for properties, when: (a) 'necessarily' is understood as equivalent to universal quantification over worlds; (b) the same worlds are quantified over in each occurrence of 'necessarily' within the respective definition, and (c) *A* and *B* are sets of properties closed under complementation, infinitary conjunction, and infinitary disjunction.

Consider (c). It is controversial whether the complement of a *B*-property is itself a *B*-property (Post, 1987). Descartes took having spatial extension to be a physical property, and maintained that minds lack spatial extension. It is odd to say that he was, thereby, committed to the view that minds have a physical property, namely, the property of lacking spatial extension (McLaughlin, 1995). It is, moreover, controversial whether complementation is even a property-forming operation; that is to say, whether if *P* is a property, then not-*P* is too. It is, furthermore, controversial whether even finitary disjunction (let alone infinitary disjunction) is a property-forming operation. Some metaphysicians would deny that if *P* and *Q* are both properties, then $P \vee Q$ is too (Armstrong 1978).

In any case, even if Kim's conclusion is true, it is not the case that weak and strong supervenience are equivalent, respectively, to modal operator weak and strong supervenience, when *A* and *B* are understood to be simply non-empty sets of properties. When *A* and *B* are so understood,

operator weak and strong supervenience imply weak and strong supervenience, respectively, but the converse implications fail. For both operator weak and operator strong imply that something cannot have a supervenient property without having a subvenient property, and neither weak nor strong supervenience has that implication. For example, one way in which two things can be exactly alike in respect of every *B*-property is by lacking any *B*-property whatsoever. For a dramatic example of the failure of equivalence, suppose that complementation is indeed a property-forming operation. Then property *P* strongly supervenes on property not-*P*, and conversely. For any individuals x_1 and x_2 and any worlds w_1 and w_2, x_1 in w_1 and x_2 in w_2 will be exactly alike in respect of property *P* if and only if they are exactly alike in respect of property not-*P*. But property *P* fails to either operator-weakly or operator-strongly supervene on not-*P* since if something has *P* then it is not the case that it has not-*P*. Thus weak and strong supervenience fail to imply, respectively, operator weak and strong supervenience. Indeed, strong supervenience fails even to imply modal operator weak supervenience. Strong supervenience and operator weak supervenience are thus logically independent: neither implies the other (McLaughlin, 1997a).

Unlike the definitions of weak and strong supervenience, the definitions of operator weak and operator strong supervenience do not define determinates of the determinable relation of dependent variation. Rather, they define what might be called dependence-determination relations: something's having any *A*-property depends on its having some *B*-property that determines that it has that *A*-property (McLaughlin, 1995). Dependence-determination relations are of interest in their own right. For example, realization requires a dependence-determination relation. Thus, the claim that *A*-properties are realized by *B*-properties implies that *A*-properties modal operator strongly supervene on *B*-properties.

Multiple Domain Supervenience

Sometimes two individuals *x* and *y* cannot differ in some *A*-respect without their differing in some *B*-respect. Then, there is single domain supervenience. The definitions of weak and strong supervenience are definitions of kinds of single domain supervenience. There is, however, also multiple domain supervenience (Kim, 1988). There is multiple domain supervenience when some *x* and *y* cannot differ in some *A*-respect without distinct things, *x** and *y**, that bear appropriate relationships to *x* and *y* respectively, differing in some *B*-respect. Consider clay statues. A reason for claiming that clay statues are not identical with the lumps of clay that compose them is that the statues and the lumps of clay can differ in their temporal properties; for example, the lump of clay might come into existence before the statue and continue to exist after the statue ceases to exist. And even if a lump of clay and a statue come into existence and cease to exist at the same time, lumps of clay and clay statues have different persistence conditions; and so, a clay statue and the lump of clay it is made of will still differ in their modal properties. For example, the lump of clay has the property of being capable of surviving flattening, while the statue may lack this property. For these reasons, it is often claimed that clay statues are not identical with lumps of clay, but only materially constituted by them. Suppose that this claim is correct. It would still be the case that two clay statues cannot differ in respect of their shapes without the lumps of clay that compose them differing in respect of their shapes, that clay statues cannot differ in their masses without the lumps of clay that compose them differing in their masses, and so on. If clay statues are indeed not identical with lumps of clay, then these are cases of multiple domain supervenience (McLaughlin, 1995).

Kim (1988) has formulated definitions of multiple domain weak and strong supervenience. Let D_1 and D_2 be two nonempty domains, and let *R* be a relation whose domain is D_1 and whose range is a subset of D_2. For any member *x* of D_1, let R/x denote the 'image' of *x* under *R* (that is, the set of all objects in D_2 to which *x* is related by *R*). For a world *w*, let the expression 'R/z in w' designate the image of *x* that *R* picks out in *w*. Multiple domain weak and strong supervenience can then be formulated as follows:

> *Multiple domain weak supervenience*: $\{A, D_1\}$ weakly supervenes on $\{B, D_2\}$ relative to relation *R* if and only if for any world *w* and for any *x* and *y* in D_1, if R/x and R/y in *w* are *B*-twins in *w* then *x* and *y* are *A*-twins in *w*. (5)

> *Multiple domain strong supervenience*: $\{A, D_1\}$ strongly supervenes on $\{B, D_2\}$ relative to relation *R* if and only if for any worlds w_1 and w_2 and for any x_1 and x_2 in D_1, if R/x_1 in w_1 is a *B*-twin of R/x_2 in w_2, then x_1 in w_1 is an *A*-twin of x_2 in w_2. (6)

When *R*, the coordinating relation, is identity, there

is single domain supervenience. But R need not be identity; it can, for instance, be the relation of material constitution, in which case there is multiple domain supervenience. Multiple domain supervenience is of interest when discussing dependent variation relations among properties of objects and the lumps of material that materially constitute them, or macrostructures (e.g. tables, trees, mountains) and the microstructures (e.g. structures of atoms) that materially constitute them.

Global Supervenience

So far, this article has focused on 'local' supervenience. Another much-discussed category of supervenience is global supervenience. Global property supervenience can be formulated as follows:

> *Global property supervenience*: A supervenes on B if and only if for any worlds w and w^*, if w and w^* have exactly the same worldwide pattern of distribution of B-properties, then they have exactly the same worldwide pattern of distribution of A-properties. (7)

This formulation raises the question of what is it for two worlds to have the same worldwide pattern of distribution of properties of a certain sort. In exploring this question, it is fruitful to appeal to the notion of there being an isomorphism between worlds, without actually specifying one. Let us say that an isomorphism I between two worlds w and w^* preserves B-properties if and only if for any x in w, x has a B-property F in w if and only if the image of x under I has F in w^* (McLaughlin, 1996, 1997a). Appealing to the notion of a property-preserving isomorphism between worlds, two kinds of global property supervenience can be distinguished (Stalnaker, 1996; McLaughlin, 1997a; Sider, 1999):

> *Weak global supervenience*: A-respects weakly globally supervene on B-respects if and only if for any worlds w and w^*, for every B-preserving isomorphism between w and w^*, there is an A-preserving isomorphism between them. (8)

> *Strong global supervenience*: A-respects strongly globally supervene on B-respects if and only if for any worlds w and w^*, every B-preserving isomorphism between w and w^* is an A-preserving isomorphism between them. (9)

Strong implies weak, but not conversely.

HISTORY

As McLaughlin (1995) notes:

> The term 'supervenience' has a vernacular use: Dr Samuel Johnson's *A Dictionary of the English Language* (1775), Vol 2 reports that 'supervene' derives from the Latin 'super', meaning 'on', 'above', or 'additional', and from the Latin verb 'venire' meaning 'to come'. And Dr Johnson's Dictionary defines 'supervene' as 'to come as an extraneous addition' and 'supervenient' as 'added, additional'. More recently, *Webster's New International Dictionary*, 3rd edition (1986), defines 'supervene' as 'coming or occurring as something additional, extraneous, or unexpected'.

The philosophical sense of 'supervenience' is different from its vernacular sense. It was introduced into the philosophy of mind in the following passage by Donald Davidson:

> Mental characteristics are in some sense dependent, or supervenient, on physical characteristics. Such supervenience might be taken to mean that there cannot be two events exactly alike in all physical respects but differing in some mental respect (Davidson, 1970).

Davidson has been reported as saying that he got the term 'supervenience', used in a related way, from R M. Hare (Hare, 1952). Hare (1984) reports that he did not himself introduce the term into philosophy, but that the term was being used at Oxford in the 1940s. There has been some speculation that the British philosopher–biologist Lloyd Morgan (1923) introduced the term 'supervenience' in something like its current philosophical sense in the context of emergent evolution (Kim, 1990). Morgan spoke of emergent phenomena as 'supervening' on the phenomena from which they emerge. This appears, however, to be the vernacular sense: emergent phenomena occur unexpectedly or unpredictably from the phemomena from which they emerge. This vernacular sense of 'supervenience' persisted in the philosophy of mind until the late 1950s (McLaughlin, 1997b).

As McLaughlin (1997b, pp. 41–42) notes:

> Harry Lewis (1985, p.159n) reports that [Peter] Geach suggested to him 'that the term "supervenient" entered our philosophical vocabulary by way of Latin translations of Aristotle's *Nichomachean Ethics* 1174B31-3'. The Greek at 1174B31-3 reads: 'hos epiginomenon ti telos, hoion toise akmaiois he hora'. Robert Grosseteste's Latin translation of this passage translated 'epiginomenon' as 'supervenire' [Gauthier, 1973]. Sir David Ross translated 'epiginomenon' as 'supervenient'. In Ross's English 1174B31-3 becomes: 'as an end which supervenes as the bloom of youth does on those in the flower of their age'. The passage

occurs in the context of Aristotle's talking of certain properties 'naturally following' from other properties.

This sense of the term 'supervenience' is related to Hare's sense in (Hare, 1952). Perhaps Hare encountered the term 'supervenience' at Oxford in the 1940s in discussions of the *Nichomachean Ethics*, a book that he frequently cites. In any case, as noted above, Hare's use of 'supervenience' inspired Davidson's related use.

While Davidson introduced the term 'supervenience' in its current philosophical sense into the philosophy of mind, it should be noted that psychophysical supervenience theses appear fairly early on in discussions of the mind–body problem. For example, in 1778 Joseph Priestley claimed: 'different systems of matter, organized exactly alike, must make different beings, who would feel and think exactly alike in the same circumstances'. Their minds, therefore, would be exactly 'similar', but 'numerically different' (Priestley 1819/1977, p. 47). Indeed, supervenience theses – claims of dependent variation – can be found in many areas of western philosophy throughout its history.

SUPERVENIENCE AND REDUCTION

Supervenience is usually taken not to imply reduction, so that *A*-respects can supervene on *B*-respects without reducing to *B*-respects. If reduction has an explanatory dimension, that is surely right. For the fact that *A*-respects supervene on *B*-respects does not imply that *A*-respects are in any sense explainable in terms of *B*-respects. Also, if reduction is irreflexive, then supervenience fails to suffice for reduction. Some hold, however, that both strong supervenience of one sort of property on another sort of property across all metaphysically possible worlds and strong global supervenience of one sort of property on another across all such worlds, imply reduction in a non-epistemic, ontological sense of reduction. Be this as it may, reducibility implies supervenience. If *A*-respects reduce to *B*-respects, then *A*-respects supervene on *B*-respects in even the strongest sense of supervenience defined above.

Given that supervenience is required for reducibility, one way to argue that *A*-respects fail to reduce to *B*-respects is by arguing that *A*-respects fail to supervene on *B*-respects. A single possible example of *B*-twins that are not *A*-twins will show that. Thus, supervenience theses provide a useful way of testing claims of reducibility. Consider, for example, the claim that intentional mental properties (such as believing that *P*, desiring that *Q*, etc.) reduce to neurophysiological properties. That claim implies that two individuals exactly alike in their neurophysiological properties cannot differ in their intentional properties. Some philosophers would appeal to a 'twin Earth' thought experiment of the sort designed by Hilary Putnam (1976) and Tyler Burge (1979) to argue that this supervenience claim is false since there can be neurophysiological twins that are not intentional twins. Arguments that attempt to refute claims of reducibility by offering counterexamples to the supervenience theses implied by the claims are called arguments by appeal to false implied supervenience theses.

SUPERVENIENCE AND COGNITIVE SCIENCE

The philosophy of mind is an area of cognitive science in which the notion of supervenience is frequently used. There have been various attempts to define physicalism as a psychophysical supervenience thesis. For example, appealing to the notion of a non-alien world (i.e., a possible world that has only the same perfectly natural properties found in the actual world), David Lewis (1983) has defined physicalism as follows: any two non-alien worlds that are indiscernible physically are indiscernible in every respect. And there have been other attempts to define physicalism by appeal to supervenience (see, for example, (Jackson, 1993) and (Chalmers, 1996)).

Whether any psychophysical supervenience thesis that counts as physicalism is true is, of course, a controversial question. Another controversial question is whether, in order to be justified in accepting a psychophysical supervenience thesis, there must be some explanation of why the thesis is true. It has been said that when a supervenience thesis is explainable, there is 'superdupervenience' (Horgan, 1993). The question is whether a justifiable physicalism would require a superdupervenience psychophysical claim.

Supervenience has also been invoked in one of the major debates in psychosemantics. Internalism in psychosemantics is the thesis that the meaning (or content) of any kind of mental representation strongly supervenes with metaphysical necessity on intrinsic properties of psychological subjects that possess mental representations of that kind. Externalism in psychosemantics, which is often defended by 'twin Earth' thought experiments, is the thesis that the meanings of certain kinds of mental representation fail to so supervene on intrinsic properties of psychological subjects that possess representations of that kind. Externalists

typically claim that the meanings of mental representations fail to even weakly supervene on intrinsic properties of psychological subjects.

Symbol-grounding Problem

Intermediate article

Stevan Harnad, University of Quebec, Montreal, Quebec, Canada

CONTENTS

The symbol-grounding problem is related to the problem of how words get their meanings, and of what meanings are. The problem of meaning is in turn related to the problem of consciousness, or how it is that mental states are meaningful.

WORDS AND MEANINGS

We know since Frege (1952/1892) that the thing that a word refers to (its referent) is not the same as its meaning. This is most clearly illustrated using the proper names of concrete individuals (but it is also true of names of kinds of things and of abstract properties): (1) 'Tony Blair', (2) 'the UK's current prime minister', and (3) 'Cherie Blair's husband' all have the same referent, but not the same meaning.

Some have suggested that the meaning of a (referring) word is the rule or features one must use in order to pick out its referent. In that respect, (2) and (3) come closer to wearing their meanings on their sleeves, because they seem to be explicitly stating a rule for picking out their referents (find whoever is the UK's current PM, or whoever is Cherie's current husband). But that does not settle the matter, because there is still the problem of the meaning of the components of the rule ('UK', 'current', 'PM', 'Cherie', 'husband'), and how to pick *them* out.

Perhaps 'Tony Blair' (or better still, just 'Tony') does not have this component problem, because it points straight to its referent, but how? If the meaning is the rule for picking out the referent, what is that rule, when we come down to non-decomposable components?

It is probably unreasonable to expect us to know the rule, explicitly at least. Our brains need to have the 'know-how' to follow the rule, and actually pick out the intended referent, but they need not know how they do it consciously. We can leave it to cognitive science and neuroscience to find out and then explain how.

THE MEANS OF PICKING OUT REFERENTS

So if we take a word's meaning to be the means of picking out its referent, then meanings are in our brains. If we use 'meaning' in a wider sense, we may want to say that meanings include both the referents themselves and the means of picking them out. So if a word (say, 'Tony-Blair') is located inside an entity, then its meaning consists of both the means that that entity uses to pick out its referent, and the referent itself: a big causal nexus between a head, a word inside it, an object outside it, and whatever 'processing' is required to connect the inner word to the outer object.

But what if the 'entity' in which a word is located is not a head but a piece of paper? What is its meaning then? Surely all the (referring) words on this page, for example, have meanings, just as they have referents.

CONSCIOUSNESS

Here is where the problem of consciousness rears its head. For there would be no connection at all between scratches on paper and any intended referents if there were no minds mediating those intentions, via their internal means of picking out those referents.

So the meaning of a word on a page is 'ungrounded', whereas the meaning of a word in a head is 'grounded' (by the means that cognitive neuroscience will eventually reveal to us), and thereby mediates between the word on the page and its referent.

COMPUTATION

What about the meaning of a word inside a computer? Is it like the word on a page or like the word in a head? This is where the symbol-grounding problem comes in. Is a dynamic process transpiring in a computer more like the static paper page, or more like another dynamical system, the brain?

There is a school of thought according to which the computer is more like the brain – or rather, the brain is more like the computer. According to this view, called 'computationalism', that future theory about how the brain picks out its referents, the theory that cognitive neuroscience will eventually arrive at, will be a purely computational one. A computational theory is a theory at the software level; it is essentially a computer program. And software is 'implementation-independent'. That means that whatever it is that a program is doing, it will do the same thing no matter what hardware it is executed on. The physical details of the implementation are irrelevant to the computation; any hardware that can run the computation will do (Pylyshyn, 1984).

THE TURING TEST

A computer can execute any computation. Hence once computationalism finds the right computer program, the same one that our brain is running when there is meaning transpiring in our heads, then meaning will be transpiring in that computer too. How will we know that we have the right computer program? It will have to be able to pass the Turing Test (TT) (Turing, 1950). That means it will have to be capable of corresponding with any human being for a lifetime as a pen-pal, without ever being in any way distinguishable from a real pen-pal.

SEARLE'S CHINESE ROOM ARGUMENT

It was in order to show that computationalism is incorrect that Searle (1980) formulated his celebrated 'Chinese Room Argument', in which he pointed out that if the Turing test were conducted in Chinese, then he himself, Searle (who does not understand Chinese), could execute the same program that the computer was executing without knowing what any of the words he was processing meant. So if there's no meaning going on inside him when he is implementing the program, there's no meaning going on inside the computer when it is the one implementing the program either, computation being implementation-independent.

How does Searle know that there is no meaning going on when he is executing the TT-passing program? Exactly the same way he knows whether there is or is not meaning going on inside his head under any other conditions: he understands the words of English, whereas the Chinese symbols that he is manipulating according to the program's rules mean nothing to him. And there is no one else in there for them to mean anything to. They are like the ungrounded words on a page, not the grounded words in a head.

Note that in pointing out that the Chinese words would be meaningless to him under those conditions, Searle has appealed to consciousness. Otherwise one could argue that there *would* be meaning going on in his head under those conditions, but he would simply not be aware of it. This is called the 'System Reply', and Searle rightly rejects it as simply a reiteration, in the face of negative evidence, of the very thesis that is on trial in his thought experiment: are words in a running computation like the ungrounded words on a page, meaningless without the mediation of brains, or are they like the grounded words in brains?

In this either/or question, the (still undefined) word 'ungrounded' has implicitly relied on the difference between inert words on a page and consciously meaningful words in our heads. And Searle is reminding us that under these conditions (the Chinese TT), the words in his head would not be consciously meaningful, hence they would still be as ungrounded as the inert words on a page.

So if Searle is right, that (1) the words on a page, and in any running computer program, including a TT-passing computer program, are meaningless in and of themselves, and hence that (2) whatever it is that the brain is doing to generate meaning, it cannot be just implementation-independent computation, then what *is* the brain doing to generate meaning (Harnad, 2001a)?

FORMAL SYMBOLS

To answer this question we have to formulate the symbol-grounding problem (Harnad, 1990). First we have to define 'symbol': a symbol is any object that is part of a symbol system. (The notion of symbol in isolation is not a useful one.) A symbol system is a set of symbols and rules for manipulating them on the basis of their shapes (not their meanings). The symbols are systematically interpretable as having meanings, but their shape is arbitrary in relation to their meaning.

A numeral is as good an example as any: numerals (e.g. '1', '2', '3') are part of a symbol system (arithmetic) consisting of formal rules for combining them into well formed strings. '2' means what we mean by 'two', but its shape in no way resembles 'two-ness'. The symbol system is systematically interpretable as making true statements about numbers (e.g. '$1 + 1 = 2$').

It is critical to understand that the symbol-manipulation rules are based on shape rather than meaning (the symbols are treated as primitive and undefined, insofar as the rules are concerned), yet the symbols and their rule-based combinations are all meaningfully interpretable. It should be evident in the case of formal arithmetic, that although the symbols make sense, that sense is in our heads and not in the symbol system. The numerals in a running desk calculator are as meaningless as the numerals on a page of hand calculations. Only in our minds do they take on meaning (Harnad, 1994).

This is not to deprecate the property of systematic interpretability: we select and design formal symbol systems (algorithms) precisely because we want to know and use their systematic properties; the systematic correspondence between scratches on paper and quantities in the universe is a remarkable and extremely powerful property. But it is not the same as meaning, which is a property of certain things going on in our heads.

NATURAL LANGUAGE AND THE LANGUAGE OF THOUGHT

Another symbol system is natural language. On paper, or in a computer, it too is just a formal symbol system, manipulable by rules based on the arbitrary shapes of words. In the brain, meaningless strings of squiggles become meaningful thoughts. I am not going to be able to say what had to be added in the brain to make them meaningful, but I will suggest one property, and point to a second.

One property that the symbols on static paper or even in a dynamic computer lack that symbols in a brain possess is the capacity to pick out their referents. This is what we were discussing earlier, and it is what the hitherto undefined term 'grounding' refers to. A symbol system alone, whether static or dynamic, cannot have this capacity, because picking out referents is not just a computational property; it is a dynamical (implementation-*de*pendent) property.

To be grounded, the symbol system would have to be augmented with non-symbolic, sensorimotor capacities – the capacity to interact autonomously with that world of objects, events, properties, and states that its symbols are systematically interpretable (by us) as referring to. It would have to be able to pick out the referents of its symbols, and its sensorimotor interactions with the world would have to fit with the symbols' interpretations (Cangelosi *et al*., 2000).

The symbols, in other words, need to be connected directly to (i.e. grounded in) their referents; the connection must not be dependent only on the connections made by the brains of external interpreters like us. The symbol system alone, without this capacity for direct grounding, is not a viable candidate for being whatever it is that is really going on in our brains (Cangelosi and Harnad, 2001).

ROBOTICS

The necessity of groundedness, in other words, takes us from the level of the pen-pal Turing test, which is purely symbolic (computational), to the robotic Turing test, which is hybrid symbolic/sensorimotor (Harnad, 2000). Meaning is grounded in the robotic capacity to detect, identify, and act upon the things that words and sentences refer to. (*See* **Categorical Perception**)

But if groundedness is a necessary condition for meaning, is it a sufficient one? Not necessarily, for it is possible that even a robot that could pass the Turing test, 'living' amongst the rest of us indistinguishably for a lifetime, would fail to have in its head what Searle has in his: it could be a zombie, with no one home, feeling feelings, experiencing meanings.

And that is the second property, consciousness, towards which I wish merely to point, rather than to suggest what functional capacities it must correspond to (I have no idea what those might be – I rather think it is impossible for consciousness to have any independent functional role except on pain of telekinetic dualism). Maybe robotic TT capacity is enough to guarantee it, maybe not. In any case, there is no way we can hope to be any the wiser (Harnad, 2001b).

Symbolic versus Subsymbolic

Intermediate article

CONTENTS

There are two competing approaches to computational modeling of cognition: the symbolic approach, based on language-like representations, and the subsymbolic (connectionist) approach, inspired by neuroscience.

INTRODUCTION

Explanations in cognitive science often take the form of computational models. Since the inception of the discipline in the 1950s, there has been a competition between two approaches to computational modeling: the symbolic approach, and the subsymbolic, connectionist, or 'artificial neural network' approach. These two approaches differ in their conception both of computation and of the representations that figure in computations. Not surprisingly, then, symbolic and connectionist explanations of cognitive behavior tend to be quite different.

HISTORY

Both approaches have a long pedigree. Indeed, both were advocated in talks on 11 September 1956 at the Symposium on Information Theory, which George Miller (1979) has identified as the birth event of cognitive science. Exemplifying the symbolic approach, Newell and Simon presented a paper describing a 'logic theory machine', while Rochester, Holland, Haibt, and Duda presented a connectionist implementation of Hebb's neuropsychological theory of cell assemblies.

Even in these prototypical instantiations, the symbolic and subsymbolic computational models are clearly distinct. Symbolic models typically employ syntactically structured representations and logic-like rules that are sensitive to those structures. Thus, Newell and Simon's model adopted the language of symbolic logic, and relied on algorithms that were sensitive to the logical operators in that language. Subsymbolic models, on the other hand, typically employ neuron-like units that excite or inhibit each other according to their current activation values.

However, specifying precisely what makes a computational model symbolic or connectionist is not easy. Before attempting this, it is helpful to examine how the two approaches have developed historically.

Historical Development of the Symbolic Tradition

The early history of the symbolic approach is one of successes. Not only did Newell and Simon's 'logic theorist' serve as an early existence proof that computers could be employed to model processes thought to require intelligence in humans, but shortly afterwards they developed an even more sophisticated artificial intelligence program called 'general problem solver' (GPS) that did more than just prove theorems. GPS was applied to a number of reasoning problems, including the Tower of Hanoi problem and problems of cryptoarithmetic. A central goal of this research was to model human reasoning, and GPS was able to provide a detailed 'trace' of state transitions that closely matched the verbal reports of a human working on the same problem (Newell and Simon, 1976b).

GPS and other early symbolic programs (of which several examples are presented in (Minsky, 1968) were applied to linguistically-posed problems, but there were also symbolist successes in other domains, such as interacting with physical objects. Around 1970, Terry Winograd developed a program called SHRDLU which functioned in a simulated world of blocks. The program responds to natural language queries about what blocks are present and how they are arranged, and it can carry

out simulated manipulations of the virtual blocks. Advocates claimed that the program seemed to understand its limited domain: it carries out appropriate actions based on commands, and responds correctly to questions about its environment. (For an argument that it did not really exhibit understanding, see (Dreyfus, 1972.)

These successes (albeit in limited domains such as logic and block worlds) led a number of researchers to begin developing general frameworks for symbolic cognitive modeling. Two early examples, which have been developed over the course of several decades, are John Anderson's ACT and ACT* (Anderson, 1983 and 1990), and Allen Newell's Soar (Newell, 1990). Both have, at their heart, a production system, that is, a system of 'if–then' (condition–production) rules that operate on syntactically structured symbolic representations stored in working memory.

The physical symbol system hypothesis

The early successes and seemingly unlimited promise of the symbolic approach led two of its early proponents, Newell and Simon (1976a), to propose what they called the physical symbol system hypothesis, according to which a physical symbol system has the necessary and sufficient means for general intelligent action.

According to Newell and Simon, a physical symbol system is subject to the laws of physics and operates on physical patterns. These patterns, or symbols, can be physically related so as to comprise expressions (symbol structures). The system itself is composed of such structures and a collection of processes that operate on these structures to produce other structures. With unlimited memory and unlimited time, physical symbol systems are capable of universal computation (Newell, 1990), just like the more famous Turing machine (Turing, 1950).

The physical symbol system hypothesis advances a very strong claim that (1) any intelligent system is a physical symbol system, and (2) any physical symbol system of 'sufficient size' can exhibit intelligence (Newell and Simon, 1976a). Newell (1990) also introduces the notion of a knowledge system. The symbols in such a system encode knowledge about that system's goals, actions and environment, and the relations between these. Knowledge systems are governed by a single law: take actions to attain goals using all of the knowledge available to the system. Newell's statement of the relation between knowledge systems and symbol systems is clear: symbol systems are supposed to 'realize knowledge systems by implementing representation laws so that the symbol structures encode the knowledge about the external world'. Newell's conclusion is that 'humans are symbol systems that are at least modest approximations of knowledge systems'. Thus, for the purposes of explaining cognition, a description in terms of a physical symbol system is a complete description and, also for these purposes, the fact that such a system might be implemented in a brain (i.e. a bunch of interconnected neurons) is irrelevant.

This view was widely accepted by many early cognitive scientists, for a number of reasons. Firstly, in computer science, universal computers had been proven to be able to compute all computable functions. If physical symbol systems are universal computers, and people don't compute noncomputable functions, then symbol systems have the computational resources necessary for exhibiting human intelligence. Secondly, in linguistics, Chomsky argued that grammars of natural languages required precisely that kind of computational power. Thirdly, in psychology and philosophy, the 'language of thought' hypothesis – the hypothesis that all thought is a language-like 'mentalese' and subject to a mental grammar – suggested that symbol processing was the basis of human cognition (Fodor, 1975). Lastly, such a picture of human function is consistent with our everyday folk psychology, which characterizes people's mental states as attitudes (e.g., beliefs, desires) towards propositions. If these very propositions are stored and operated on in symbolic models, then those models offer an explanation of why accounts of people's behavior in terms of beliefs and desires succeed much of the time.

Historical Development of the Subsymbolic Connectionist Approach

Even at its heyday, the symbolic approach was not the only one. One of the major early developers of the alternative, subsymbolic approach to understanding cognition was Frank Rosenblatt, the developer of a computational device called a 'perceptron' (Rosenblatt, 1958). This device consists of a grid of photocells, randomly connected to associators that collect and process the electrical impulses produced when objects are placed in front of the photocells. The associator units are, in turn, connected to response units by weighted connections. The weights determine how much each associator unit influences each response unit. These weights are modifiable by a learning procedure designed to correct any errors in the response

units. Rosenblatt (1962) proved the 'perceptron convergence theorem', which states that a certain learning procedure will succeed in finding weights that permit the network to produce correct responses, provided such weights exist. In fact, the device was successful at recognizing various letters of the alphabet, and provided an interesting alternative to symbolic models. However, excitement over this less logic-like approach soon diminished, mostly as a result of Minsky and Papert's (1968) demonstration that there are classes of computations that models of this kind can't perform. Rosenblatt knew that this problem could be overcome by inserting additional layers of trainable weights. However, he failed to develop a generalized learning rule for finding these weights.

It wasn't until the mid-1980s that a learning rule – back propagation – was developed that applied to multiple layers of connections. Around the same time, deep difficulties with the symbolic approach began to become apparent. Consequently, the subsymbolic approach began to attract more attention. Now known by a variety of names, including 'connectionism', '*artificial neural networks*', and 'parallel distributed processing', the subsymbolic approach has enjoyed its own history of successes (McClelland and Rumelhart, 1986; Bechtel and Abrahamsen, 1991). New and better models of language processing, object recognition, speech recognition, and motor control were proposed by connectionists. The stage was set for a conflict between computational paradigms.

THE CONFLICT BETWEEN THE SYMBOLIC AND CONNECTIONIST APPROACHES

Differences Between the Symbolic and Connectionist Approaches

The differences between these two approaches can be grouped under two headings: representational differences and computational differences.

Representational differences

In symbolic models, the basic units of representation (i.e., symbols) are semantically interpretable, and are often actually words in natural languages. By contrast, in the subsymbolic approach, the basic representational units are below the level of semantic interpretation (Smolensky, 1988). Only patterns of activation distributed over large populations of network units are semantically interpretable. (Such patterns are called vectors.) Moreover, any individual unit can be a constituent of many vectors, each of which has a different interpretation.

On occasion, the difference between symbolic and subsymbolic approaches is presented as a difference between continuous and discrete, or digital and analog representation. Paul Churchland has construed the difference in this way:

> So-called 'digital' or *discrete-state* computing machines are limited by their nature to representing and computing mathematical functions that range over the *rational* numbers. … This is a potentially severe limitation on the abilities of a digital machine. … Therefore, functions over real numbers cannot strictly be computed or even represented within a digital machine. They can only be approximated. (Churchland, 1995)

In fact, subsymbolic models almost always employ digital representations. There is nothing inherent in the 'digitalness' of these models that makes them only approximations of 'actual' subsymbolic models. Furthermore, there is evidence that biological networks do not employ continuous representations (Eliasmith, 2000). Thus, it is misleading and inappropriate to present the distinction between symbolic and subsymbolic systems as one between digital and analog representations.

Computational differences

Computational differences between symbolic and connectionist modeling can be understood as turning on the preferred metaphor for cognition. Symbolic theorists typically see cognizers as analogous to serial digital computers: there is a central processing unit (i.e., higher cognition), input systems (i.e., peripheral sensory systems), and output systems (i.e., motor systems) (see, for example (Newell, 1990)). Connectionists, by contrast, see cognizers as inherently brain-like: massively parallel processors that rely on uniform functional units. Thus, they claim that they work with a 'neurally inspired model of cognitive processes' (McClelland and Rumelhart, 1986), or with 'brain-style computation' (Rumelhart, 1989).

This apparent distinction is a result of a deeper distinction between the symbolic and subsymbolic approaches. Indeed, we could translate symbolic models to run on parallel computers. Such a translation is far from trivial since it requires decomposing a problem into independently solvable pieces and maintaining communication between parallel processors working on these pieces. However, there is a more basic difference: the kind of computation in a parallel instantiation of a symbolic program is not at all like that in a subsymbolic model. Computation in a symbolic system is governed by

many different, explicitly encoded rules (as in a production system). In subsymbolic models, computation is governed by one or a few mathematical rules that rely on numeric parameters to determine how the activation of one unit affects the activation of other units. Although in simple models these parameters might be predetermined, as models become more complex, researchers typically rely on learning rules to determine them. In addition, the set of possible computations a connectionist model can realize is governed by the overall design of the system (for example, what sets of nodes are connected to what other sets, and how densely). Generally, this system 'architecture' has been determined by the designer, but some connectionist models now rely on tools such as genetic algorithms to develop the pattern of connectivity in the model.

Connectionist Critiques of Symbolic Models

As noted above, by the 1980s some cognitive scientists had begun to feel frustrated by the perceived limitations of the symbolic approach, limitations which the subsymbolic connectionist alternative seemed able to overcome. The first limitation stemmed from the very fact that symbolic representations are generally sentential. Initially, this seemed to be a strength, since the problems that people solve are often easily represented linguistically.

However, many basic cognitive tasks, such as the classification of sensory stimuli (like taste, touch, smell, sound, and sight) are not presented linguistically. These tasks involve responding to statistical regularities in the environment, to which symbolic representations are generally not sensitive (Smolensky, 1995). Subsymbolic representations, on the other hand, are equally well suited to modeling representations in any modality, and have been successfully applied to visual (Qian and Sejnowski, 1988; Raeburn, 1993), olfactory (Skarda and Freeman, 1987), auditory (Lazzaro and Mead, 1989) and tactile problems. Moreover, Kosslyn (1980 and 1994) and others have convincingly argued that a large class of reasoning problems entail operations on images, which are a paradigmatically nonlinguistic representation (although symbolists such as Pylyshyn (1973, 1981) have argued for a propositional construal of visual images). Subsymbolic models are well suited to modeling this kind of perceptual processing.

Furthermore, symbolic systems tend to be brittle. Any degradation of a symbolic representation (such as a piece of computer code) can radically alter or destroy the whole system's functionality. Such brittleness is psychologically unrealistic. People often exhibit behavior that indicates partial retrieval of representations: 'tip of the brain' recall, prosopagnosia (loss of face recognition), and 'blindsight' are all instances in which mental representations are incomplete. Although such incomplete representations reduce performance, they generally don't completely destroy it or radically alter it. Human performance tends to degrade gradually as information is lost.

Subsymbolic connectionist models are not very brittle. Whereas minor damage to a symbolic conceptual network causes loss of entire concepts, damage to a connectionist network causes only a loss in accuracy, as observed in human subjects (Churchland and Sejnowski, 1992).

There are also difficulties in modeling learning in symbolic models. In general, learning in symbolic systems depends entirely on the current set of symbols in the system. The most common example of this kind of learning is 'chunking', in which many related symbols are grouped together and represented by another single symbol. Chunking can effectively capture some kinds of human learning, but is deficient for explaining how new primitive symbols themselves are learned. By contrast, learning in subsymbolic models involves strengthening or weakening connections, an approach which is well suited to modeling low-level perceptual learning: the kind of learning that may explain the development of new symbols.

Finally, symbolic systems suffer from their natural suitability for serial processing. Serial processing is quite compatible with the discrete, nonstatistical character of symbolic representations. If the relations between elements are irrelevant to their effect on cognition, then processing them one at a time makes sense. However, if the relations between elements are important for determining how they can or should be processed (i.e. if 'holistic' considerations are relevant) then parallel processing is more appropriate. Many cognitive problems involve soft constraints (constraints that ideally would all be satisfied, but some of which may have to be violated to arrive at the best solution). For example, generating analogies depends on the ability to match a current situation to another situation we have encountered before, where no previous situation is a perfect match.

In general, the representational and computational commitments of the subsymbolic connectionist approach have avoided many of the difficulties with the symbolic approach. Holistic processing,

handling of soft constraints, statistical sensitivity and gradual degradation are all more successfully incorporated into subsymbolic systems.

Symbolist Critiques of Connectionist Models

Many symbolists claim that, whatever the shortcomings of the symbolic approach, the cost of the subsymbolic connectionist approach is too high. Fodor and Pylyshyn (1988) argue that the failure to employ structured representations and structure-sensitive operations leaves subsymbolic models unable to explain truly cognitive phenomena.

Fodor and Pylyshyn focus on two features of cognition that they claim connectionist models cannot explain: productivity and systematicity. Productivity is the capacity to produce arbitrarily many expressions. This is achieved in symbolic systems by means of recursion (e.g. 'John told Sue who told Mary who told Bob …'). A physical symbol system can construct these sorts of structures since the rules used to compose representations employ (possibly recursive) processes defined over atomic elements (symbols). Fodor and Pylyshyn contend that by eschewing compositional rules and not recognizing the importance of syntactic structure, subsymbolic connectionist approaches fail to be productive.

Systematicity concerns the relations that exist between representations. Fodor and Pylyshyn note that anyone who has mastered English must admit all of the following as sentences: 'John loves the girl', 'the girl loves the girl', 'John loves John', and 'the girl loves John'. They claim that in order to explain the systematicity found both in language and thought, symbolists can appeal to syntactic structure. Structured schemas such as 'noun-phrase transitive-verb noun-phrase' can be applied to any noun-phrase and transitive-verb. Symbolic models routinely employ such structured representations and so can readily explain systematicity. However, since subsymbolic connectionist models do not employ this kind of representation, Fodor and Pylyshyn argue that they lack the resources needed to explain systematicity.

In characterizing the representational structures that can explain the systematicity and productivity of cognition, Fodor and Pylyshyn rely on the notion of a compositional syntax and semantics. They thereby emphasize that the particular syntactic rules that are employed are appropriate for ensuring semantic coherence. A compositional representation is one in which meaning is an additive function of the meaning of its components. Thus, in a sentence like 'the ball is red', the meaning of the structure can be derived from the meaning of each of the component lexical items (words). Furthermore, each lexical item makes the same semantic contribution to each expression in which it occurs. This, claims the symbolist, is typical of both language and thought. This 'compositionality' is a problem for subsymbolic connectionist models because population activation vectors, the semantic units for such models, have no particular structure. It is not clear how an activation vector that represents a sentence would be related to an activation vector that represents each of the words in the sentence. The sentence vector is not built up as a concatenation of word vectors. Connectionist models, then, will have difficulty accounting for some basic aspects of human cognition. All of the failings of the subsymbolic connectionist approach derive from the lack of structured representations.

New Kinds of Connectionist Model

Symbolic theorists have identified potential serious shortcomings of the subsymbolic connectionist approach. Connectionists cannot solve these problems merely by implementing a physical symbol system in a connectionist architecture. Such an implementation is in principle possible, since in both approaches it is possible to design universal computational systems (i.e. universal Turing machines). However, for a connectionist model merely to implement a symbolic one is for the connectionist to admit that subsymbols are themselves irrelevant for modeling cognition, and that nothing is gained by turning to subsymbols for a new and different understanding of cognition.

However, some theorists do think that an adequate response to the symbolist's challenge does require some appeal to symbolic systems. They advocate hybrid systems in which symbolic structures are implemented in subsymbolic structures in such a manner that the subsymbolic implementation plays a cognitive role. The goal in such hybrid systems is for the subsymbolic implementation to provide statistically sensitive processing, while allowing the implemented symbol system to provide structurally sensitive processing. Some researchers have developed interesting hybrid models (Barnden, 1995; Sun and Alexandre, 1997). But it is difficult to develop a principled means of determining the right combination of structurally sensitive and statistically sensitive processes.

Another, more purely subsymbolic, response to the symbolists' objections is to attempt to develop a

significant degree of structural sensitivity directly in subsymbolic models. Two such approaches have achieved some successes.

First, Pollack (1990) has developed 'recurrent auto-associative memory' (RAAM) networks for recursively creating compressed vectors of input vectors. If linguistic strings (structured representations) are employed as inputs, these networks can create representations that are not explicitly compositional, but from which the compositional structure of the input can be recovered. Moreover, other structurally sensitive operations (for example, transforming compressed representations of active sentences into compressed representations of passive sentences) can be performed directly on the compressed strings without first extracting the compositional structures. Since the compressed representations are not themselves syntactically structured but seem to perform tasks that require information about such structures, they are construed as functionally compositional (van Gelder, 1990).

A second way to account for productivity and systematicity in subsymbolic connectionist models employs distributed representation schemes based on vector products (Smolensky, 1990). Essentially, these schemes include operations for combining and extracting vectors. Two vectors, *A* and *B*, can be combined to produce a third vector *C*. From *C* either *A* or *B* can subsequently be extracted, given the other. This provides a way of building up structures in vector representations. Because of the generality of the defined operations, problems of systematicity no longer arise for this representational scheme. Productivity is achieved because these operations can be recursively applied.

In fact, these kinds of schemes have been successfully used to model high-level cognitive function. For example, Eliasmith and Thagard (2001) have proposed a model of analogy based on Plate's representational scheme (Plate, 1994). Analogical mapping is notoriously structurally sensitive and is a typically cognitive task (Gentner and Toupin, 1986; Holyoak and Thagard, 1995). This kind of model is thus an existence proof of the ability of the subsymbolic connectionist approach to handle structural sensitivity.

However, these subsymbolic attempts to account for productivity and systematicity do not provide for unlimited realizations of either of these features of cognition. For example, as longer strings are recursively supplied to a RAAM network, errors result. And the vector product approach restricts the size of the vectors. The product vector *C*, is not a concatenation of the vectors *A* and *B*. Rather, *A* and *B* are partially encoded into *C*. So the meaning of *C* is not a 'linear' function of the meanings of its component parts.

Whether those limitations mean that connectionists have failed to respond adequately to the symbolists' challenges depends on the nature of compositional human mental representations, and how productive and systematic human thought is. The suggestion that mental representations might be less compositional than symbolists claim is supported by examples taken from natural language, a typically symbolist source of data. The meanings of most colloquial expressions ('it's raining cats and dogs', 'what a couch potato', 'break a leg') are clearly not additive functions of the meanings of their components. Meanings are so flexible that, for example, the words 'unravel' and 'ravel' can mean the same thing despite opposite 'compositional' meanings. Given such examples, it is not so clear that lack of complete compositionality is a valid objection to the subsymbolic approach. Since compositionality is intended to explain productivity and systematicity, and since subsymbolic models only provide a measure of these properties to a degree, subsymbolic theorists prefer to ask just how much productivity and systematicity is needed to model human cognitive abilities.

SUMMARY

The symbolic and subsymbolic connectionist approaches provide distinct ways of modeling cognitive phenomena. Both have had significant successes at explaining certain aspects of human cognition. But both have been the subject of serious criticism, and neither approach obviously explains more aspects than the other. Although recent advances in connectionist models have made some headway into symbolist domains, it is not yet clear whether these advances achieve sufficient systematicity and productivity to model human cognition.

Syntax and Semantics: Formal Approaches

Advanced article

Glyn Morrill, Universitat Politècnica de Catalunya, Barcelona, Spain

CONTENTS

Syntax concerns the relations between words in sentences; semantics concerns the meanings of words and sentences.

INTRODUCTION

Language is a vehicle for the expression of meanings via forms: an association between forms and meanings. On the side of forms we could speak of phonetic form, phonological form, prosodic form, signifier, and so on, depending on the construal of the term and the detail targeted. Let us suppose that we have a set of vocabulary items or words; then forms will comprise at least a string of words together with a prosodic contour. For the purposes of this article we assume that they comprise only strings of words, and refer to them as 'expressions'.

Consider the set of all expressions over some vocabulary. Some will be sentences, some not; some will be verb phrases, some not; and so on. We can picture language as a family of subsets of this domain, one member of the family for each part of speech, with a distinguished member of sentences. There will be interrelations between the members of this family: for example, sentences that contain noun phrases, and noun phrases that contain sentences. Mathematically, we can look at the family of all sets of expressions as an algebra in which there are operations such as language concatenation or product:

$$L_1 \cdot L_2 = \{s_1 + s_2 | s_1 \in L_1 \text{ and } s_2 \in L_2\} \quad (1)$$

On the side of meanings we could speak of content, sense, logical form, semantic form, signifier, and so on, depending on the construal of the term and the detail targeted. Let us suppose that, whatever meanings are, they comprise at least truth conditions, and that those of sentences are related by logical consequence. For the purposes of this article we will consider meanings as just terms of higher-order logic, and refer to them as 'logical forms'.

Consider the set of all logical forms, which will be partitioned into different types: those that represent propositions for sentences, those that represent properties for verb phrases, and so on. Now we can picture language as a family of relations between expressions and logical forms. Such a view of language as (a family of) associations between forms (signifiers) and meanings (signifieds) derives from de Saussure (1916), wherein each association signifier–signified is called a 'sign'. Note that the association between forms and meanings can be one-to-many (ambiguity) and many-to-one (paraphrase).

Thinking just of forms, the following program suggests itself: to try to specify the class of expressions that are sentences of a language. Such a program of 'formal syntax' was launched by Chomsky (1957), instantiated by his 'transformational grammar'. Thinking also of meanings, the program would include: to try to specify in addition the logical forms of the expressions. Such a program of 'formal semantics' was launched by Montague (1974).

One methodological option would be to observe that since meaning is the less tangible dimension, and forms represent a hard enough challenge, we had better focus our sights on just syntax and in this way divide the task at hand. Another would be to observe that since the expression of meaning is the point of language, we had better attempt to pursue both tasks in parallel, for surely it is the expressive and communicative *raison d'être* of language that must guide us through the many alternatives that will present themselves and in which explanation for why things are so will reside.

This article illustrates some basic tools and methods of formal syntax and semantics and shows how they can work together. In the process it indicates various courses that can be and have been taken in formal syntax and formal semantics.

PHRASE STRUCTURE GRAMMAR

Let us assume some category symbols for different parts of speech as in Table 1.

We are picturing a language as a family of sets of expressions (strings of words) indexed by such category symbols: thus, S = {**John** + **runs, Mary** + **runs, John** + **loves** + **Mary,** …}, N = {**John, Mary**, …}, etc. Let there be lexical assignments w: A of words to categories, meaning that $w \in A$:

- **John**: N
- **Mary**: N
- **man**: CN
- **that**: C
- **runs**: VP
- **loves**: TV
- **gives**: TTV
- **thinks**: SV
- **that**: RELPRO

Then relations between categories can be expressed by rules of the form $A \rightarrow A_1 \ldots A_n$, meaning that $A_1 \cdot \ldots \cdot A_n \subseteq A$. For example:

- S → N VP
- CP → C S
- VP → TV N
- VP → TTV N N
- VP → SV CP
- CN → CN RELCLS

The lexicon together with the rules entail certain facts about the language model. For example, **John** ∈ N, **runs** ∈ VP, and N · VP ⊆ S entail that **John** + **runs** ∈ S. Such reasoning can be structured into derivation trees ('phrase markers') like those in Figure 1.

Table 1. Category symbols for parts of speech

Symbol	*Meaning*
S	declarative sentence
N	proper name
CN	count noun
C	complementizer
CP	complementizer phrase (complementized sentence)
VP	verb phrase
TV	transitive verb
TTV	ditransitive verb
SV	sentential verb
RELCLS	relative clause
RELPRO	relative pronoun

Such phrase markers are the syntactic structures of phrase structure grammar: concrete geometrical representations of the essential structure by which expressions are deemed to be grammatical.

Consider object relativization:

(a) man that$_i$ Mary loves e_i
(b) man that$_i$ John thinks that Mary loves e_i
(c) man that$_i$ Mary thinks that John thinks that Mary loves e_i (2)

The noun *man* modified by the relative clause is construed as the object of the transitive verb *loves*, which may be embedded arbitrarily far from the relative pronoun. Such unbounded dependencies were originally taken as motivating, in transformational grammar, transformations mapping from deep phrase markers, in which the left-extracted element appears at the extraction site, to surface phrase markers, in which it appears in its surface position, by means of 'movement'. However, Gazdar (1981) showed how a simple generalization of phrase structure grammar can characterize unbounded dependency.

Let the category indices include structured category symbols B/A where B and A are categories (read: B 'slash' A). Roughly, B/A means 'a B missing an A'. Add a 'metarule' for deriving rules from rules:

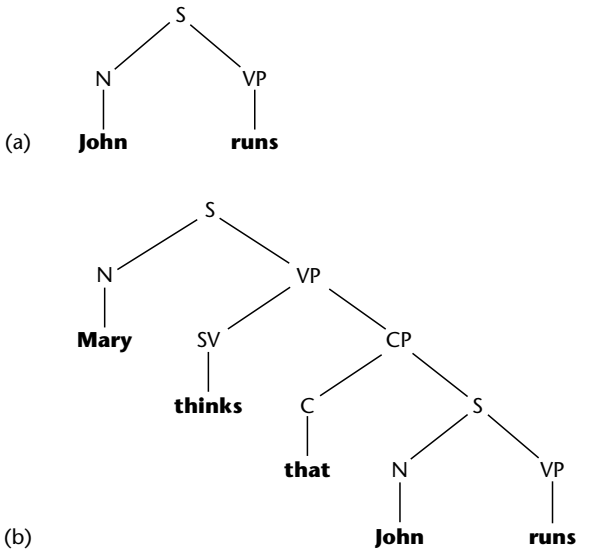

Figure 1. Examples of phrase markers. (a) Phrase marker for the sentence *John runs*. (b) Phrase marker for the sentence *Mary thinks that John runs*.

$$\frac{C \rightarrow \Gamma\ B}{C/A \rightarrow \Gamma\ B/A} \tag{3}$$

Add also rules for rewriting A/A as the empty string (after all, the empty expression is 'an A missing an A'), and a rule combining a filler with an S/N:

$$\mathrm{N/N} \rightarrow \varepsilon \tag{4}$$

$$\mathrm{RELCLS} \rightarrow \mathrm{RELPRO\ S/N} \tag{5}$$

Then example 2(b), and unbounded dependencies in general, are generated as illustrated in Figure 2.

The line of thought according to which perhaps, after all, transformations are not indispensable to unbounded dependencies, and phrase structure grammar might suffice, developed into 'generalized phrase structure grammar' (Gazdar *et al.*, 1985) and 'head-driven phrase structure grammar' (HPSG) (Pollard and Sag, 1987). (*See* **Construction Grammar**; **Phrase Structure Grammar, Head-driven**)

Another line of thought, according to which, for example, passivization is treated nontransformationally (by a lexical rule), led to 'lexical-functional grammar' (LFG) (Bresnan, 1982). Both HPSG and LFG make extensive use of the notion of 'unification', a device for treating universal quantification in automatic theorem proving, and central to logic programming languages such as PROLOG. Transformational grammar developed in the 1980s into 'government–binding theory' and in the 1990s into 'minimalism'. (*See* **Government–Binding Theory**; **Lexical-Functional Grammar**)

CATEGORIAL GRAMMAR

Consider the following operations in the algebra of sets of expressions (Lambek, 1958, 1988) (the first is just language concatenation):

$$A \bullet B = \{s_1 + s_2 | s_1 \in A \text{ and } s_2 \in B\} \tag{6}$$

$$A\backslash B = \{s | \text{ for all } s' \in A,\ s' + s \in B\} \tag{7}$$

$$B/A = \{s | \text{ for all } s' \in A,\ s + s' \in B\} \tag{8}$$

We read the operators $\bullet$, $\backslash$, and $/$ as 'product', 'under', and 'over', respectively. We assume some 'primitive types', for example S (declarative sentence), N (proper name), CN (count noun) and CP (complementizer phrase). We refer to the terms built over the primitive types by the operators as 'types'.

Let there be lexical assignments w: A of words to types, meaning that $w \in A$:

- **John**: N
- **Mary**: N
- **man**: CN
- **that**: CP/S
- **runs**: N\S
- **loves**: (N\S)/N
- **gives**: (N\S)/(N • N)
- **thinks**: (N\S)/CP
- **that**: (CN\CN)/(S/N)

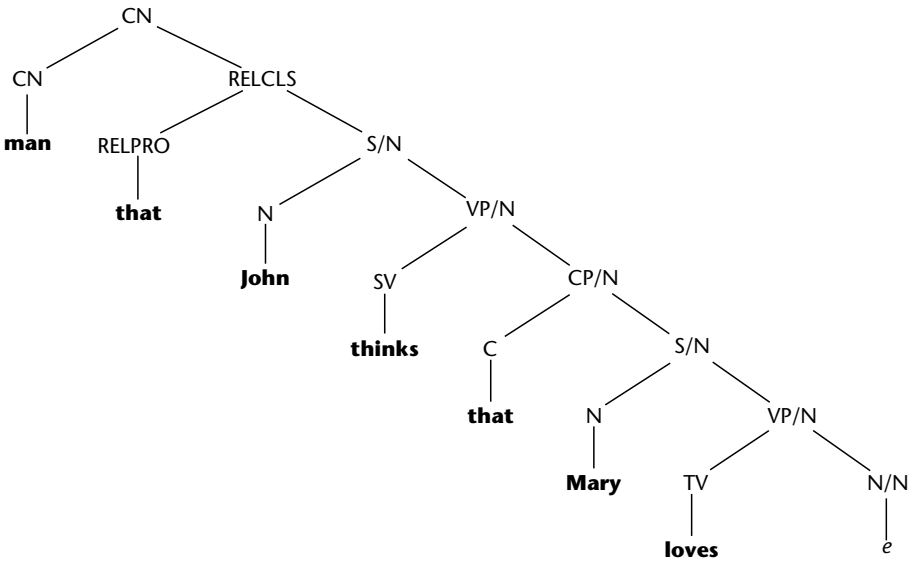

Figure 2. Phrase structure analysis of *man that$_i$ John thinks that Mary loves e$_i$*.

Then other facts are entailed. For example, from **John** $\in$ N and **runs** $\in$ N\S it follows that **John** + **runs** $\in$ S. Similarly, we have from the assignments above that **Mary** + **thinks** + **that** + **John** + **runs** $\in$ S. Note that in contrast to phrase structure grammar, the language model is determined solely by the lexicon (together with the meanings of the operators as operations): there are no syntactic rules in the definition. That is, categorial grammar is lexicalist whereas phrase structure grammar is nonlexicalist.

The grammar already generates the unbounded dependencies of example 2. Thus, sentence 2(b) is obtained because **John** + **thinks** + **that** + **Mary** + **loves** $\in$ S/N. Indeed the metarule of equation 3 is valid when we read 'slash' as 'over': if $\Gamma \cdot B \subseteq C$ then $\Gamma \cdot B/A \subseteq C/A$.

The syntactic structures of categorial grammar (i.e., the concrete geometrical representations of the essential structure by which expressions are deemed to be grammatical) are 'proof nets' (Roorda, 1991), which originated in linear logic (Girard, 1987). A 'polar type' is a type together with a 'polarity' – input ($^\bullet$) or output ($^\circ$). A 'polar type tree' is the result of unfolding a polar type into 'links' as shown in Figure 3.

For example, the polar type tree for (CN\CN)/(S/N)$^\bullet$ is shown in Figure 4.

To derive the theorem that words of types $A_1, \ldots, A_n$ constitute (in that order) an expression of type A, construct first the 'proof frame' comprising the sequence of polar type trees $A^\circ, A_1^\bullet, \ldots, A_n^\bullet$. A 'proof structure' is the result of connecting (by an 'axiom link') each leaf in a proof frame to exactly one other with the same primitive type of opposite polarity. A proof net is a proof structure that satisfies certain conditions. Examples of proof nets are shown in Figure 5.

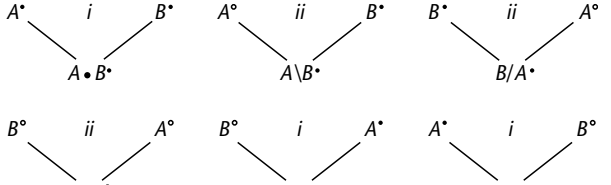

Figure 3. Unfolding a polar type into links.

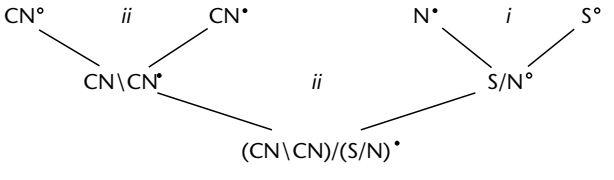

Figure 4. The polar type tree for (CN\CN)/(S/N)$^\bullet$, obtained by unfolding up to primitive leaves according to Figure 3.

Note that these proof nets are planar: that is, they can be drawn in the half-plane without crossing lines. Here, for a proof structure to be a proof net it must be planar; in addition, every cycle must cross both edges of some *i*-link, which is why we label links *i* or *ii*.

LAMBDA CALCULUS AND HIGHER-ORDER LOGIC

Given sets X and Y, the 'functional exponentiation' X^Y is the set of all functions from Y to X, and the 'Cartesian product' $X \times Y$ is the set of all ordered pairs comprising an element of X (first) and an element of Y (second).

Assume some set of primitive (semantic) types, for example o and e (for propositions and entities). The 'semantic types' are the terms that can be built over the primitive semantic types by the operators $\rightarrow$ and &. Given sets D_o and D_e associated to the primitive semantic types, a domain D_τ is associated to each semantic type τ as follows:

$$D_{\tau \rightarrow \tau'} = D_{\tau'}^{D_\tau} \tag{9}$$

$$D_{\tau \& \tau'} = D_\tau \times D_{\tau'} \tag{10}$$

Let there be a set of 'constants' and a set of 'variables' of each type, a 'valuation' mapping each constant of each type τ to an element of D_τ, and an 'assignment' mapping each variable of each type τ to an element of D_τ. Then the 'terms' ϕ of the 'typed lambda calculus' of each type τ and their denotations $[\![\phi]\!]_f^g \in D_\tau$ are defined as follows:

- If a is a constant of type τ, then a is a term of type τ and $[\![a]\!]_f^g$ is $f(a)$.
- If x is a variable of type τ, then x is a term of type τ and $[\![x]\!]_f^g$ is $g(x)$.
- If ϕ is a term of type $\tau \rightarrow \tau'$ and ψ is a term of type τ, then $(\phi\ \psi)$ is a term of type τ' and $[\![(\phi\ \psi)]\!]_f^g$ is $[\![\phi]\!]_f^g([\![\psi]\!]_f^g)$ (functional application).
- If x is a variable of type τ and ϕ is a term of type τ', then $\lambda x\phi$ is a term of type $\tau \rightarrow \tau'$, and $[\![\lambda x\phi]\!]_f^g$ is the function $h \in D_{\tau \rightarrow \tau'}$ such that $h(m) = [\![\phi]\!]_f^{g'}$, where g' is just like g but maps x to m (functional abstraction).
- If χ is a term of type $\tau \,\&\, \tau'$, then $\pi_1\chi$ is a term of type τ, $\pi_2\chi$ is a term of type τ', $[\![\pi_1\chi]\!]_f^g$ is $\mathrm{fst}([\![\chi]\!]_f^g)$, and $[\![\pi_2\chi]\!]_f^g$ is $\mathrm{snd}([\![\chi]\!]_f^g)$ (first and second projection).
- If ϕ is a term of type τ and ψ is a term of type τ', then (ϕ, ψ) is a term of type $\tau \,\&\, \tau'$ and $[\![(\phi\ \psi)]\!]_f^g$ is $\langle [\![\phi]\!]_g^f, [\![\psi]\!]_f^g \rangle$ (pairing).

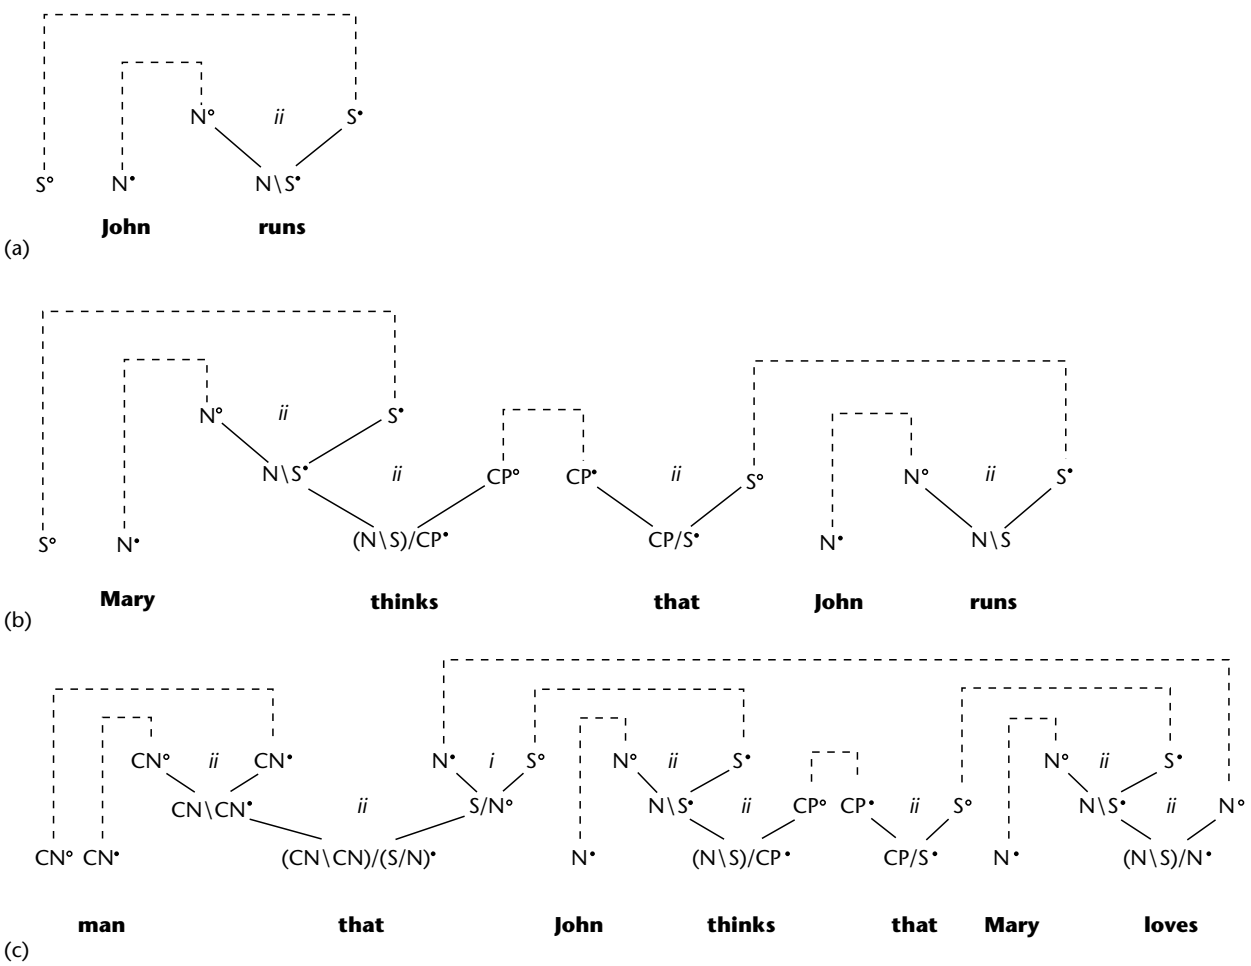

Figure 5. Examples of proof nets. (a) Proof net for *John runs*. (b) Proof net for *Mary thinks that John runs*. (c) Proof net for *man that*$_i$ *John thinks that Mary loves* e_i.

Let $\phi\{\psi/x\}$ be the result of substituting by ψ the free occurrences of x in ϕ; we say it is 'free' if and only if no variable becomes bound in the process of substitution. The following terms are equivalent (with respect to every valuation and assignment they share denotations):

- $\lambda x\phi \equiv \lambda y(\phi\{y/x\})$ if y is not free in ϕ and $\phi\{y/x\}$ is free (α-conversion)
- $(\lambda x\phi\ \psi) \equiv \phi\{\psi/x\}$ if $\phi\ \{\psi/x\}$ is free (β-conversion)
- $\lambda x(\phi\ x) \equiv \phi$ if x is not free in ϕ (η-conversion)
- $\pi_1(\phi, \psi) \equiv \phi$ and $\pi_2(\phi, \psi) = \psi$ (β-conversion)
- $(\pi_1\phi, \pi_2\phi) \equiv \phi$ (η-conversion)

We go from typed lambda calculus to higher-order logic by taking some of the constants to have denotational constraints (making them 'logical constants'). For example, if the elements of D_o are themselves sets, we might assume a logical constant AND of type $(o \& o) \rightarrow o$ which, rather than being assigned any function in this type, is assigned always the function of intersection on its arguments. And a consequence relation $\models$ is induced on the propositional terms: $\phi \models \psi$ if and only if $[\![\phi]\!]^g_f \subseteq [\![\psi]\!]^g_f$ for every f and g. In this way, terms of higher-order logic can be associated with expressions in an attempt to model their logical properties. For example, we might associate logical forms with expressions as follows. (*See* **Semantics and Pragmatics: Formal Approaches**)

(a) Mary thinks that John runs
(b) $((think\ (run\ j))\ m)$ (11)

(a) man that John thinks that Mary loves
(b) $\lambda z(\text{AND}\ ((man\ z), ((think\ ((love\ z)\ m))\ j)))$ (12)

The attempt to associate expressions of natural language systematically with such logical forms was initiated by Montague (1974), working with the notion of 'possible world' (Dowty *et al*., 1981); an alternative approach, centered on the notion of

'situation', was considered by Barwise and Perry (1983). Montague's focus was on semantics, and his syntax, though precise, was informal. Gamut (1991) dubbed the kind of grammar that associates logical forms to expressions 'logical grammar'.

LOGICAL GRAMMAR

We can develop a logical grammar associating logical forms with expressions by assigning semantic operations to each rule of a phrase structure grammar. Such a design, keying semantic interpretation on syntactic structure, is referred to as 'compositional'. First, we will need to fix a semantic type for each category. For example, we could use the associations in Table 2:

Lexical items will be associated with closed terms of the corresponding types. For example:

- **John** – j : N
- **Mary** – m : N
- **man** – *man* : CN
- **that** – λxx : C
- **runs** – *run* : VP
- **loves** – *love* : TV
- **gives** – *give* : TTV
- **thinks** – *think* : SV
- **that** – $\lambda x \lambda y \lambda z$(AND (($y$ z), (x z))) : RELPRO

Rules can be associated with semantic operations by assigning distinct variables to each daughter and assigning to the mother a term the free variables of which are those assigned to the daughters. For example:

- (y x): S $\rightarrow$ x: N y: VP
- (x y): CP $\rightarrow$ x: C y: S
- (x y): VP $\rightarrow$ x: TV y: N
- (x (y, z)): VP $\rightarrow$ x TTV y: N z: N
- (y x): CN $\rightarrow$ x: CN y: RELCLS

Then the examples in Figure 1 have the following derivations (we represent trees growing upwards, and lambda terms are simplified when possible):

$$\dfrac{\dfrac{\textbf{John}}{j\text{: N}} \quad \dfrac{\textbf{runs}}{run\text{: VP}}}{(run\ j)\text{: S}} \tag{13}$$

$$\dfrac{\textbf{Mary} \quad \dfrac{\textbf{thinks} \quad \dfrac{\dfrac{\textbf{that}}{\lambda xx\text{: C}} \quad \dfrac{\dfrac{\textbf{John}}{j\text{: N}} \quad \dfrac{\textbf{runs}}{run\text{: VP}}}{(run\ j)\text{: S}}}{(run\ j)\text{: CP}}}{(think\ (run\ j))\text{: VP}}}{((think\ (run\ j))\ m)\text{: S}} \tag{14}$$

The metarule annotated with semantics is:

$$\frac{\chi : C \rightarrow \Gamma\ y : B}{\lambda x \chi\{(z\ x)/y\} : C/A \rightarrow \Gamma\ z : B/A} \tag{15}$$

And:

$$\lambda xx : \text{N/N} \rightarrow \varepsilon \tag{16}$$

$$(x\ y)\text{: RELCLS} \rightarrow x\text{: RELPRO}\ y\text{: S/N} \tag{17}$$

Then example 2(b) is generated as in Figure 6.

The combination of semantics with syntax in categorial grammar is dubbed by Morrill (1994) 'type logical grammar' (Moortgat, 1997; Carpenter, 1997). (*See* **Categorial Grammar and Formal Semantics**)

Table 2. Semantic types associated with categories

Category	*Semantic type*
S	o
N	e
CN	e $\rightarrow$ o
C	o $\rightarrow$ o
CP	o
VP	e $\rightarrow$ o
TV	e $\rightarrow$ (e $\rightarrow$ o)
TTV	(e & e) $\rightarrow$ (e $\rightarrow$ o)
SV	o $\rightarrow$ (e $\rightarrow$ o)
RELCLS	(e $\rightarrow$ o) $\rightarrow$ (e $\rightarrow$ o)
RELPRO	(e $\rightarrow$ o) $\rightarrow$ ((e $\rightarrow$ o) $\rightarrow$ (e $\rightarrow$ o))

TYPE LOGICAL GRAMMAR

For categorial grammar the type map T from syntactic types to semantic types is such that:

$$T(A \bullet B) = T(A)\ \&\ T(B) \tag{18}$$

$$T(A\backslash B) = T(B/A) = T(A) \rightarrow T(B) \tag{19}$$

A mapping for primitive semantic types must be chosen – for example, $T(\text{S}) = \text{o}$, $T(\text{N}) = \text{e}$, $T(\text{CN}) = \text{e} \rightarrow \text{o}$, $T(\text{CP}) = \text{o}$.

When we include semantics, the categorial operations are over signs, which are pairs of forms and meanings:

$$A \bullet B = \{(s_1 + s_2, (m_1, m_2)) | (s_1, m_1) \in A \text{ and } (s_2, m_2) \in B\} \tag{20}$$

$$A\backslash B = \{(s, m) | \text{ for all } (s', m') \in A, (s' + s, m(m')) \in B\} \tag{21}$$

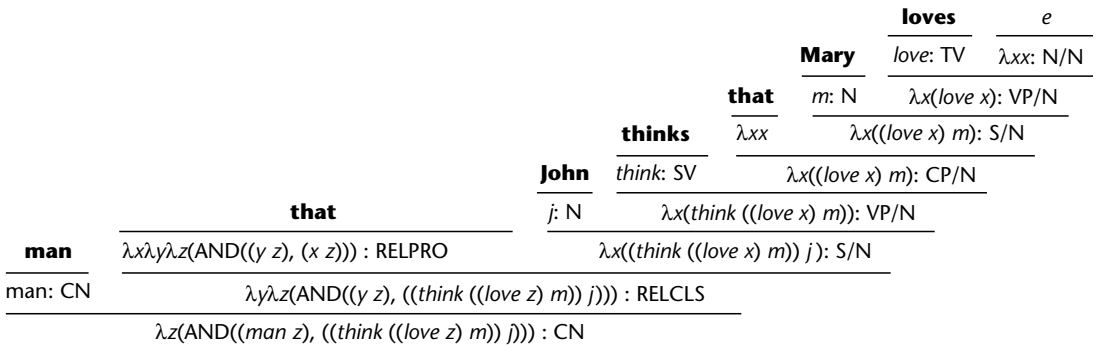

Figure 6. Logical analysis of *man that*$_i$ *John thinks that Mary loves* e_i.

$$B/A = \{(s,m) | \text{ for all } (s',m') \in A, \\ (s+s', m(m')) \in B\} \quad (22)$$

Lexical items are associated with closed semantic terms of the corresponding type, as for phrase structure logical grammar:

- **John** – j : N
- **Mary** – m : N
- **man** – *man* : CN
- **that** – λxx : CP/S
- **runs** – *run* : N\S
- **loves** – *love* : (N\S)/N
- **gives** – *give* : (N\S)/ (N • N)
- **thinks** – *think* : (N\S)/CP
- **that** – $\lambda x \lambda y \lambda z$ (AND ((y z), (x z))) : (CN\CN)/(S/N)

The semantics of derivation is contained in the proof net analysis. It is recovered by a deterministic semantic 'trip', which starts upwards at the output root of the proof net, visits each node twice, once traveling upwards and once traveling downwards, and finishes back down at its origin (de Groote and Retoré, 1996). The link of each $A\backslash B^\circ$ and B/A° mother-node is labeled with a distinct variable, then the semantics as a lambda term is generated by successive left-to-right production of its symbols during the trip, which is made according to the instructions shown in Figure 7.

Thus, the semantics extracted from Figure 5(a) is

$$(run\ j) \quad (23)$$

The semantics extracted from Figure 5(b) is

$$((think\ (\lambda xx\ (run\ j)))\ m) \quad (24)$$

which simplifies to

$$((think\ (run\ j))\ m) \quad (25)$$

The semantics extracted from Figure 5(c) is

$$((\lambda x \lambda y \lambda z(\text{AND}\ ((y\ z), (x\ z)))\ \lambda w((think \\ (\lambda xx\ ((love\ w)\ m)))\ j))\ man) \quad (26)$$

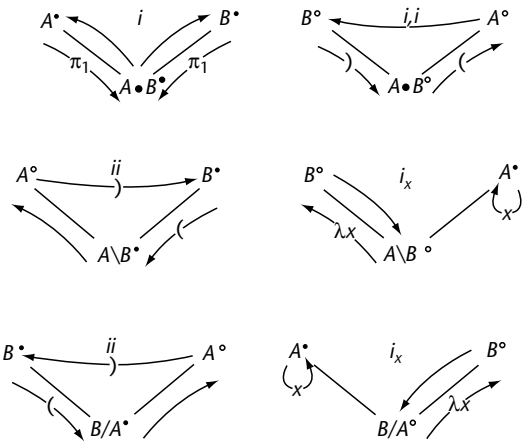

Figure 7. Instructions for a semantic 'trip' around a proof net that recovers the semantics of derivation. Travel starts upwards at the output root, follows the arrows at each link, picks up lexical semantics and bounces at input roots, and ends down backwards back at the output root.

which simplifies to

$$\lambda z(\text{AND}\ ((man\ z), ((think\ ((love\ z)\ m))\ j))) \quad (27)$$

CONCLUSION

We have looked at some approaches to formal grammar with reference to the 'action at a distance' of unbounded dependencies. To mention just one other phenomenon representing the challenge of mismatch between syntax and semantics, consider the quantification in a sentence like:

Everyone loves someone. (28)

The usual judgment is that the sentence is ambiguous, with one reading giving wide scope to the universal quantification (cf. 'everyone loves his mother') and another giving wide scope to the

existential quantification (cf. 'the queen is loved by everyone'). The puzzle is that if the architecture of grammar is compositional, that is, if semantics is determined by syntactic analysis, the sentence cannot be semantically ambiguous without having distinct syntactic analyses, and it is not obvious what syntactic alternation one should entertain.

Montague (1973) treated quantifier phrases as 'quantifying in' to sentences with variables in noun-phrase positions: different orders of quantifying in then yield different quantifier scopes. Cooper (1983) distinguishes from semantics proper a semantic 'quantifier store' from which quantifiers can be transferred at sentence nodes; again the order of transference effects alternative scopings. Treatments in contemporary phrase structure grammar and categorial grammar can usually be construed in one or other of these terms.

The range of phenomena that present themselves for syntactic and semantic study is truly vast, and this is hardly surprising: a huge part of our cognitive life, with all its subtlety and expanse, is linguistic, and we cannot expect a lot of easy answers. But formal syntax and formal semantics are good scientific programs, in that the nature of their failures, as well as the form of their successes, can reveal much about language and cognition.

Unified Theories of Cognition

Introductory article

Ronald S Chong, George Mason University, Fairfax, Virginia, USA
Robert E Wray, Soar Technology, Inc., Ann Arbor, Michigan, USA

CONTENTS

A collection of task-independent mechanisms that can be used to explain, through computational modeling, human cognitive behaviors such as problem solving, decision making, learning, memory, and interaction via perceptual and motor systems.

INTRODUCTION

In 1973, Allen Newell characterized the modus operandi of psychology as moving from phenomenon to phenomenon, producing vast numbers of studies and data either to formulate new theories or to support or refute existing theories. It appeared that the future of psychology would be a continuation of the same. Unlike physics, psychology had no practitioners pursuing the long-term goal of reconciling and synthesizing the various theories into a single unifying theory able to address all cognitive behavior.

Almost twenty years later, Newell, in his influential book *Unified Theories of Cognition*, called for psychology to begin the search for a unified theory of cognition (UTC). According to Newell, a UTC is 'a single set of mechanisms for all of cognitive behavior'. Examples of cognitive behaviors include problem solving, decision making, all forms of learning, skilled behavior, language, memory, perception, motor behavior, and perhaps even errors, motivation, emotions, imagining, and dreaming. Examples of behavior-independent mechanisms include memory systems, knowledge representation schemes, reasoning systems, perceptual and motor systems, and learning procedures.

Newell proposed several principles to guide the use and development of UTCs. The first is making a commitment to a UTC's mechanisms: new mechanisms must not be introduced just to address new phenomena. The reason for making a commitment is that it enforces parsimony and provides constraints on the modeling process, and hence leads to principled and informative models. Secondly, to accommodate UTC changes, Newell advocated 'listening to the architecture'. He believed that an architecture will indicate when it is wrong; i.e., when a phenomenon cannot plausibly be made to conform to the UTC's mechanisms. Only then should existing mechanisms be modified or new ones added. The final principle is that a UTC must be instantiated as a cognitive architecture. Newell proposed Soar as a candidate UTC. The remainder of this article will briefly describe Soar and two other computational architectures, ACT-R and EPIC.

SOAR

The Soar cognitive architecture, developed by Allen Newell, John Laird, and Paul Rosenbloom, has its roots in work that sought to understand human problem solving and decision making, or more generally, the nature of intelligent behavior. Soar is a production system which has been significantly extended to include mechanisms and structures believed to be functionally necessary for producing intelligent behavior. (*See* **Soar**; **Production Systems and Rule-based Inference**)

Soar incorporates a mechanism to automatically change the problem-solving context when a model reaches an 'impasse' – a point where progress towards accomplishing a goal cannot continue because of a lack of knowledge. In the new context, called a *subgoal*, processing is focused on resolving the impasse so that progress towards the initial goal can be resumed.

For example, if a Soar model of web browser use needs to display the bookmarks but does not know under which menu this command is located, the architecture would create a subgoal in which a 'search menus' method might be used to check each menu. When the menu item is found, the

impasse would be resolved and behavior can resume.

A by-product of resolving an impasse is the creation of new rules by 'chunking', Soar's sole learning mechanism. When processing in a subgoal succeeds in resolving an impasse, the chunking mechanism automatically compiles the processing in the subgoal into new productions. These learned rules could be applied the next time Soar is in the same or a similar situation: for example, it would remember how to get to the 'bookmarks' menu item. This single learning mechanism has been found to be sufficient for producing a variety of learning including concept learning, learning from instruction, and correcting faulty knowledge.

ACT-R

ACT-R, developed by John Anderson, grew out of an attempt to produce a computational theory of human memory. At the symbolic level, ACT-R is a production system. ACT-R also includes several subsymbolic mechanisms each of which addresses a specific form of cognitive adaptation. These mechanisms are justified by 'rational analysis' – the principle that cognition adapts to the structure of the environment. They modulate the availability of symbolic elements (declarative and procedural) during processing, as well as influencing the processing cycle time. (*See* **ACT**; **Symbolic versus Subsymbolic**)

One such subsymbolic mechanism assigns to each declarative memory element (DME) a number called an 'activation'. An activation learning mechanism varies the activation of each DME as a function of its frequency and recency of use. DMEs that are frequently or recently used will tend to have higher activations, and can be retrieved more quickly, than those less frequently or recently used. Any DME whose activation falls below a threshold ceases to be retrievable and is effectively forgotten.

For example, consider the situation of changing one's residence and having to learn a new phone number. Initially the new number may be difficult to recall, but as its use increases (by repeating the number to memorize it or giving it to friends), it becomes easier to recall. As the new number is being learned, the old number typically becomes harder to recall and may eventually be forgotten. ACT-R's activation learning mechanism can account for the gross aspects of this observation. As the use of the new-number DME increases, its initially low activation increases, causing it to be more readily recalled. At the same time, the high activation of the old-number DME decreases because of infrequent use, and in time may become inaccessible.

Another subsymbolic mechanism assigns an expected utility value to each production rule, and enables the system to learn which rules are best suited to accomplishing the goal that a model is currently trying to achieve.

EPIC

In *Unified Theories of Cognition*, Newell writes: '… one thing wrong with much theorizing about cognition is that it does not pay much attention to perception on the one side or motor behavior on the other. … The result is that the theory gives up the constraint on … cognition that these systems could provide. The loss is serious – it assures that theories will never … be able to tell the full story about any particular behavior.'

Unlike Soar and ACT-R, which are purely cognitive systems, EPIC, developed by David Kieras and David Meyer, addresses the full arc of behavior – from perception, to cognition, to motor behavior – with particular emphasis on the constraints provided by the perceptual and motor systems.

EPIC includes perceptual and motor mechanisms, each representing a synthesis of much empirical evidence. EPIC also contains a cognitive system, implemented using a production system. EPIC's cognitive system does not have any of the additional mechanisms found in Soar and ACT-R. This reflects the developer's commitment to parsimony: to avoid cognitive mechanisms or assumptions that may not be needed when perceptual and motor constraints are considered.

EPIC contains three perceptual systems: visual, auditory, and tactile. The visual system, the most highly developed, incorporates a representation of the eye's retinal regions. Consequently, the system accounts for the varying availability of an object's characteristics as a function of the object's eccentricity: for example, the color of an object is readily perceivable when the object is in the center of one's gaze, but is less so as it moves out to the periphery.

There are three motor systems: ocular, manual, and vocal. The two most developed processors, the ocular and manual motor processors, control the movement of a simulated eyeball and a pair of simulated hands, respectively.

The perceptual system conveys information about events and objects in a simulated task environment to the cognitive system. Using these inputs, the cognitive system then performs task-related

processing. When appropriate, it issues commands to the motor system to interact with a device in the simulated task environment.

Consider a very simple fictitious task where single text characters are sequentially presented at random locations on a screen and the user is to press a button when the '&' character appears. An EPIC model of this task would consist of productions that: first, send an ocular motor command to cause the eye to move to an object that just appeared; then, after the eye has moved to the object, think about the object to determine if it is an '&'; and finally, if it is an '&', send a manual motor command to cause the hand to press a button in the simulated task environment.

One of the advantages of incorporating perceptual and motor systems in a cognitive model is that they impose constraints such as the availability of perceptual information or the time it takes to perform a motor action. In the above example, the motor activity (eye movements and button presses) requires the same amount of time as observed in humans. Because of these and other constraints, more principled, informative, and predictive models can be developed.

EVALUATING UNIFIED THEORIES OF COGNITION

Newell outlines a method for evaluating UTCs in terms of cumulation: a UTC becomes more powerful as it explains more phenomena. A UTC would be 'better' than another if it could explain more phenomena while also enforcing more constraints.

This approach has suffered from two main problems. Firstly, most architectures provide little constraint on the creation of individual models, and thus offer little actual explanation. Furthermore, constraint is often imposed differently in different models, even within the same architecture. Some have argued that because all architectures can be made to exhibit any given phenomenon, the choice of one architecture over another must perhaps be made according to how easily the architecture explains some behavior, rather than empirical veracity alone.

A second problem concerning evaluation arises because UTCs are continually evolving. It is often unclear if the explanations and predictions of a model produced in an earlier version of an architecture remain valid in later versions. Anticipating this problem, Newell suggested that researchers build databases of models, so that previous models could always be validated in later architecture versions. However, this methodology has not been generally adopted. Thus, the cumulation of psychological evidence for UTC evaluation is not being undertaken in any rigorous way.

BENEFITS AND DANGERS OF UNIFIED THEORIES OF COGNITION

In *Unified Theories of Cognition*, Newell lists many benefits of UTCs: they provide unification in a wide-ranging field of research; they can increase the rate of cumulation of behavioral explanations; they can help constrain assumptions in models; they can help identify new areas for empirical investigations. UTCs have not yet provided all these benefits. However, another benefit of UTCs is their use in practical applications. Applications based on comprehensive cognitive models are used, for example in the evaluation of user interfaces, intelligent tutoring, and simulation of human actors for training.

UTCs also present dangers. Perhaps the most significant is the tendency to focus on cognition at the exclusion of other systems that are likely to impose strong constraints on cognition. Newell warns against the exclusion of perceptual and motor systems. The same warning might also apply to language, emotion, and even neurobiology. (*See* **Connectionism**)

CONCLUSION

Soar, ACT-R, and EPIC all satisfy the definition of a UTC in that they each make commitments to a small fixed set of mechanisms for producing a wide range of cognitive behavior. However, each of these architectures has traditionally had its own niche: Soar has mainly been used for modeling knowledge-level behavior and production learning via chunking; ACT-R for modeling the influence of memory on cognitive behavior via its subsymbolic mechanisms; and EPIC for modeling and explaining interactive behaviors via its perceptual and motor systems.

Note that these mechanisms are essentially orthogonal. One short-term approach to increasing both behavioral coverage and computational constraints is to combine established mechanisms from different architectures. An instance of this approach is the EPIC–Soar integrated architecture. This system merges Soar with the perceptual and motor mechanisms of EPIC and some of the subsymbolic mechanisms of ACT-R. Another instance of this approach is ACT-R/PM, an extension of ACT-R that incorporates some of the perceptual and motor systems of EPIC.

User Interface Design

Introductory article

Andrew Dillon, University of Texas at Austin, Texas, USA

CONTENTS

The design of computer interfaces that are usable and easily learned by humans is a non-trivial problem for software developers. As information technologies mediate many of the activities we now perform routinely, the process of human–computer interaction is of fundamental importance.

INTRODUCTION

Since much human–computer interaction (HCI) is cognitive in nature, involving perception, representation, problem-solving, navigation, query formulation and language processing, the theories and methods of cognitive science are directly relevant to it. Thus an applied cognitive science for software design has emerged.

Traditional cognitive science approaches to HCI and user interface design model the user as made up of three basic components: the psychomotor, perceptual, and cognitive subsystems. Recent treatments of HCI have extended this model to include the social system as an essential component of the user and have placed greater emphasis on group dynamics and social context in examining what users do with technology. Any full treatment of user psychology must embrace all these components, though cognitive issues dominate most research in HCI.

HUMAN–COMPUTER INTERACTION

The success of any computer application is dependent on it providing appropriate facilities for the task at hand in a manner that enables users to exploit them effectively. Whereas the provision of facilities is an issue of functionality, the user interface is the means by which the functionality can be used, and here we are directly concerned with usability.

For interaction to proceed, the human user must input a signal to the computer and perceive changes in the interface. Since most current interaction involves physical input and visual perception of output, any basic interactive device must incorporate an input device and a screen. However, to determine the appropriate input the user must have some representation of a goal or intention of an outcome to attain, necessitating the employment of memory, both short-term (to handle current status information) and long-term (to enable the planning and interpretation of the interactive sequence).

Information undergoes transformation at each stage of progression from a perceived stimulus (e.g. a visual change in the interface) to a comprehended cue (e.g. a recognized sign), leading to an active response (e.g. pushing a mouse button). All of this happens repeatedly and rapidly as the human interacts with the system. This process can be simply envisioned using a variant of Neisser's perceptual cycle model, whereby users engage in an ongoing cycle of information exchange involving exploration of a changing information environment (see Figure 1).

For example, an interface normally provides a response to user input which signals to the user that his or her input has caused an action. Through direct manipulation, users can select and move objects on screen, open and close windows with a mouse click, or jump from place to place within documents via hyperlinks. In each case, the user must initiate an action and the interface must communicate its change of state through appropriate feedback to the user. Where feedback is vague, too rapid or nonexistent, the user is likely to be confused. Ideally feedback communicates to the user that the system status has altered in the intended manner and that the user is closer to his or her goal as a result.

We can usefully understand HCI as a cognitive process by considering the human as possessing general knowledge structures (e.g. mental models or schemata) which organize the user's task-oriented information exploration and use. This

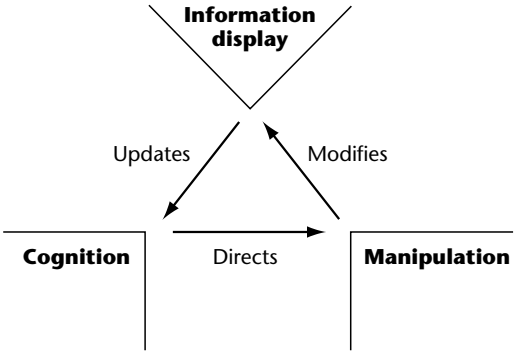

Figure 1. Human–computer interaction as an iterative process.

exploration, which may involve a variety of psychophysical actions such as key presses, scrolling, link selection, or command input, exposes the user to samples of the information space contained within the software, the perception of which must be interpreted and categorized, before it in turn can influence the subsequent actions of the user, and so on in an iterative fashion.

This is a very general portrayal of user psychology. Its purpose is to convey the active nature of cognition and show how humans select information on the basis of expectation and prior experience and how the selected information can itself modify the knowledge structures within the human. Thus, while the general model holds true, in the interface design context, each user is likely to have unique experiences and knowledge, which will influence the user's perception of, and interactions with, a computer. Software designers are now very aware of the effect that interface design has on users' experience of their products, and have sought guidance from cognitive scientists as to how best to design interfaces for usability and human acceptance.

The response from the cognitive science community has been threefold: the derivation of design guidelines to aid designers; the formulation of theoretical models to predict user response in specific instances; and the development of design methods and evaluation techniques to improve the process of user-centered design.

COGNITIVE DESIGN GUIDELINES

Since cognitive science has made important progress in understanding the mechanisms and processes underlying perception, memory, attention, categorization, decision-making, comprehension, and related processes and structures, it is reasonable to assume that such findings are relevant to practical design issues. For interfaces, we need to consider whether users will perceive actions and behaviors, how they will interpret them, what demands our designs place on their attention, and what knowledge they will need in order to interpret and respond in a manner acceptable to the software. There have been many attempts to bridge the gap between scientific findings and software design, and a full set of guidelines derived from studies of cognition would be very long. Much reinterpretation of cognitive science research has taken the form of general guidelines for designers to consider. Below are described several that have gained broad acceptance by most interface designers.

Screen Readability and Image Quality

To perform most information tasks with a computer, the user must be able to extract and process visual stimuli reliably and quickly. Early computer screens suffered from a variety of technological limitations that resulted in much slower reading of electronic text than of text on paper, or constrained the range of representations possible on screen. Current design guidance recommends the use of high-resolution screens with strong image polarity (preferably dark on light) to enhance human perception. Standard design advice is to produce all interfaces so that they can work in monotone and to add color sparingly to guide visual processing, attract attention, and aid chunking. As we interact more and more with screens, both large and small, the importance of readability becomes paramount. Poor visual ergonomics can prevent otherwise sophisticated software from being fully exploited.

Manipulation and Input Devices

While the typical computer of today is a desktop model with a keyboard and a mouse, there are many variants and alternatives, such as personal digital assistants and laptop computers, which are designed for mobility and use a stylus or trackpad as an input mechanism. Where once punched cards were the primary medium of interaction, the emergence of so-called 'direct manipulation' interfaces has advanced the exploitation of natural mappings between pointing and positioning found in the real world and the control of objects in a digital environment. 'Immersive' environments take this to the stage of creating a virtual world where users perform physical actions, much as in the real world, to produce responses from the software.

Studies of input devices have revealed that a mouse is fairly optimal for most standard point-and-click tasks, and that user reaching and target selection follow the basic principles of Fitt's law (a simple model of human psychomotor performance in rapid, aimed pointing tasks). However, where few on-screen selections are available, or where the use of a mouse would not work well (e.g. in a mobile application), touch screens with predefined tabbing zones have proven suitable, and there are claims of rapid input speeds with stylized input such as Graffiti (a simplified, single-stroke script designed for writing in a natural pen-based manner with the Palm series of devices). The qwerty keyboard remains dominant despite evidence that more efficient keyboard layouts could be designed, hinting at one important aspect of design that is beyond the control of science: the influence of precedent, habit, and market forces.

Supporting Accurate Mental Model Formation

Current work on HCI uses the concept of mental model extensively. The basic assumption is that users must try to understand what is happening with a system when they issue commands, and since much of the activity is hidden, they have to rely on inference. Depending on their knowledge of computing or the task being performed, users may infer correctly or incorrectly. Each user develops a personal image of the technology and how it works, though these images may be broadly similar across many users.

Research suggests that designers should regard models as 'mental scaffolding' upon which users hang their ideas about how the system works. The user's model is a personal, often idiosyncratic view of what the system does and how it does it. The designer should seek to make important aspects of the design transparent, coherent, and supportive. Another source of the user's mental model is prior experience, particularly with related products. If the user has worked with another system or an older version of the existing system then that experience is bound to influence the user's perception of the new technology since an existing schemata will be brought to bear on initial interactions. The user's experience of performing the tasks is also a contributing factor in the development of a personal model, and designers are advised to exploit the language, mappings, relationships among concepts, and procedures used by the target audience in creating an interface.

Use of Metaphors to Enhance Comprehension and Learning

Another generic aspect of human cognition that seems readily exploitable by designers is the reliance of human thinking on metaphors and analogies. Linked to the general tendency to model and learn by analogy, metaphors enable users to draw on their existing knowledge to act on a new domain.

There has been much discussion of the merits of the metaphor approach in dialogue design. It is argued that there are two dimensions relevant for understanding the information metaphors convey: scope and level of description. A metaphor's scope refers to the number of concepts to which it relates. A metaphor of broad scope in the domain of HCI is the 'desktop' metaphor common to many computing interfaces. Here, many of the concepts a user deals with when working on the system can be easily dealt with cognitively in terms of physical 'desktop' manipulations. The metaphor of the internet as an 'information superhighway' is also broad. The 'typewriter' metaphor that was often invoked for explaining word processors is far more limited in scope. It offers a basic orientation to using word processors (you can use them to create good-quality printouts) but is very limited beyond that as in many ways word processors do not behave like typewriters (e.g. typewriters do not save and store files, allow easy reformatting of text, or make instant copies of documents).

The metaphor's level of description refers to the type of knowledge it is intended to convey. This may be very high-level information, such as how to think about the task and its completion, or very low-level, such as how to think about particular command syntax in order to best remember it. Theorists in HCI distinguish four levels – task, semantic, lexical, and physical – which refer to different kinds of general question – 'can I do it?', 'what does this command do?', 'what does that term mean?', and 'what activities are needed to achieve that?', respectively.

Few, if any, metaphors convey information at all levels, but this does not prevent them being useful to users. Few users ever expect metaphors to offer full scope and all levels of description, so any metaphor employed should have its limitations and exceptions clearly pointed out. If the user cannot easily distinguish between the metaphorical aspects and functional relations that are and are not essential to its use, then the power of the metaphor will be greatly reduced. Of all the cognitive science

concepts used in HCI, metaphor has proved one of the most durable and accepted.

Learning by Doing

The most successful systems are those that enable a user to get something done as soon as possible. Users tend to be very resistant to reading any accompanying documentation and often want to get on with real tasks immediately rather than follow any training guides. Hence, error-free performance is not considered a real goal. Instead, cognitive scientists emphasize the importance of clear and informative feedback, and the ability to undo actions, to support the user through the learning process.

Having gained some knowledge by using one part of a system, users will expect to be able to apply this throughout the system. Particular attention should be paid to the consistent use of terms, colors, and highlighting techniques, and the positioning of task-related zones on the screen, so as to support generalization by the user. Consistency between systems can also be important to maintain – for example, between the old and the new versions. The benefits of a new system can easily be obscured if users feel that their existing knowledge is redundant and they must learn the new system from scratch.

Minimizing Attentional and Cognitive Load

Some theoretical insights into cognitive architecture emphasize the memory and attentional constraints of humans. These lessons have been learned by the HCI community who argue that interaction sequences should be designed to minimize the load on short-term memory (e.g. not asking a user to choose from an excessive number of menu items, or requiring the user to remember numbers or characters from one screen to another). Since recognition memory is superior to absolute recall, the use of menus is now the norm in design, as opposed to the command-line interfaces of the 1980s, which required users to memorize control arguments.

Another related contribution of cognitive science to user interface design has been in the area of task sequencing. User interface designers are encouraged to minimize the number of steps for which information must be retained by the user. Instead, designers are encouraged to provide all necessary information in the interface for the user to exploit as needed. The use of animation is recommended only where a process is being explained, although many designers deliberately exploit the natural human perceptual tendency to attend to movement by using animation to capture attention, particularly for advertisements in commercial internet sites.

Using Images and Icons

Screen 'real estate' is a limited commodity, so designers seek means of conveying concepts and actions through the medium of signs, images, and symbols. Another reason for iconic interfaces is their independence of language and their presumed ability to cross cultural boundaries.

Semiotic approaches to design have been invoked to help designers create appropriately comprehensible icons, but the results have been mixed. Current interfaces make extensive use of graphic capabilities and iconic representations but couple these with pop-up text labels that explain their meaning to users who find the representations difficult to decipher.

COGNITIVE THEORIES AND MODELS IN HCI

It is not yet possible to talk of a complete theory of human–computer interaction, given the many activities, processes, and tasks that computers support. However, to overcome the piecemeal approach that results from repeated empirical tests of evolving interface features, attempts have been made to produce stronger theoretical models to guide interface designers. This approach has worked best where it has been constrained to specific or localized interactive phenomena rather than the full range of user responses to information technology.

Interaction as Serial Information Processing

Cognitive scientists have derived many findings about human information processing, and this knowledge has been distilled in the area of HCI into a form of engineering model of the user that can be exploited by designers. Generally referred to as the 'model human processor', this cognitive model enables interface designers to predict the time a user will take to complete a task sequence given an analysis of the cognitive, perceptual, and psychomotor components that are applied at each step. For example, to determine how long it would take a user to complete the task sequence involving

saving a file to hard disk, consider the data in Table 1, derived from laboratory studies of humans.

To apply such a model, the designer would first list the basic steps a user must take with an interface. We can imagine a proposed design that requires the user to locate the mouse (*Th*), move the mouse to a menu (*Tp*), select the 'save' command ($Tp + Tk$), allow the system to respond with a prompt (*Tr*), input the filename ($Tk \times$ (number of letters)), and then hit a save button (*Tk*). The designer could quickly use the estimates from Table 1 to calculate how long a user would take to perform this sequence, and use these data to evaluate the proposed design.

The exact values of these estimates can be debated, but the principle of the model human processor is constant; i.e. decompose the task into its constituent actions and calculate the time involved in the serial processing of these actions. Multiple applications of this method have confirmed its value in estimating expert or error-free task completion times for repetitive, nondiscretionary tasks.

However, this model has its limitations. We cannot use it to estimate how long users will spend on tasks that are not highly practiced, or that require decision-making, planning, or learning. Similarly, where tasks involve parallel processing, it is easy to overestimate times by assuming simple serial processing of the task actions. However, as an applied model of cognition for a limited range of routine and well-practiced tasks, such a technique is clearly useful.

There have been several extensions of this approach, most notably to cover learning. Based on a production system analysis (describing the behavior a user must learn to complete a task in terms of a series of '*if–then*' rules of interactive sequences; e.g. 'if file is "new" then select menu option "new file" '), cognitive complexity theory enables calculation of the estimated time it would take a user to learn a new procedure. According to experimental findings, each new if–then rule production will take a typical user about 25 seconds to learn. Armed with such knowledge, designers could estimate, for example, the costs involved in changing procedures or violating consistency of interaction with new designs. This is obviously a gross estimate, but for many proceduralized tasks the data indicate the underlying regularity of human performance.

Table 1. Time estimates for completion of basic interactive tasks by a human operator

Label	*Action*	*Time estimate (seconds)*
Tk	Enter a keystroke	0.23
Th	Move hand to mouse	0.36
Tp	Point mouse	1.5
Tm	Retrieve from memory	1.2
Tr	Computer to respond	1.2

Sociocognitive Analyses of HCI: Activity Theory and Acceptance Models

An alternative application of cognitive theory has emerged as HCI researchers have become interested in user acceptance of computers and the exploitation of technology by groups of users. Such research draws less on the traditional base of laboratory findings within cognitive science and more on its social and anthropological traditions. These theories may be called 'sociocognitive' theories.

Activity theory aims to bring a closer reading of cultural forces to bear on our analyses of interaction. Users are seen as situated within a context that exerts strong forces on their actions. Furthermore, such users are dynamic, changing as their experience and application of technology changes. Taking an activity-theoretic approach to HCI, it is important to extend analyses of interface usability to cover the contexts in which the technology is used (or rejected).

Typical activity-theoretic approaches examine HCI in terms of the praxis, or situated context – e.g. a banking organization, a teaching scenario, or a medical process – in which the various levels of interaction can take place, from automatic individual operations to collective ventures or activities that define the group's purpose. The analysis and design of any technology needs to be grounded in such a broader perspective to ensure it is appropriate and usable by the intended user community. One can see activity theory as extending traditional cognitive approaches rather than replacing them.

Other socially-oriented approaches to HCI that consider cognition include the general class of acceptance theories that seek to predict whether a user, given a choice, will utilize a technology. Such models emphasize the perceived value that users place on the new technology, and measure the relationship between such ratings and subsequent behavior in context. For example, it is now known that if users perceive a new tool as having direct usefulness for them in their work, they will be more likely to choose it, and may tolerate a

certain difficulty of use for the sake of the power it affords them. Such perceptions by users seem to be formed very quickly, often within minutes of interacting for the first time. This means that early impressions due to aesthetics, implementation style, and related factors are particularly important.

Theoretical developments in HCI have not kept pace with developments in technology, partly because of the speed of technological change, but also because of the difficulty of translating cognitive science into rich theoretical models that predict human behavior in multiple contexts. Nevertheless, although some dismiss the theoretical approach as too limited for practical application, most HCI professionals are of the view that long-term progress is possible only with increased effort at deriving and applying cognitive science theories to the problems of user interface design.

DEVELOPING USER-CENTERED DESIGN METHODS

Where design guidelines and theoretical models of interaction fail to provide sufficient answers, designers resort to usability tests of their user interfaces. Cognitive scientists have contributed to this effort by providing the methodological and analytical perspective that informs evaluation practice.

Within HCI there are three basic evaluation methods: expert-based, model-based, and user-based. Expert-based methods assess an interface for compliance with known design principles and guidelines. Most of these guidelines are the products of research related to cognitive science. Model-based methods, including the methods mentioned above, are the application of theoretical models to specific design questions, and are almost always applied by those who have received some training in cognitive science. Both of these approaches are relatively fast and cost-effective, but they are limited in what they can predict.

User-based methods involve testing an interface with a sample of representative users in an appropriate context. There are as many variations on these methods as there are of methods of enquiry in cognitive science, ranging from controlled laboratory trials akin to psychology experiments, to field-based studies drawing on anthropological methods.

The pressures of design place demands on HCI professionals to produce fast answers, and cognitive scientists have worked on ways of improving the reliability and validity of test methods. There is a need for better expert-based evaluation methods to overcome the rather poor validity of most such methods. (Testers employing these methods tend to overestimate the number of problems users actually experience; that is, they label as 'problems' many aspects of interfaces that users subsequently perceive as acceptable.) Similarly, researchers have tried to package formal methods into tools that can be used effectively by non-specialists to predict usability. The aim of this approach is to develop software tools that designers could use to estimate learning effort or time to perform a task, without having to know the details of how such an estimate is derived. This would be analogous to the use engineers can make of the principles of physics. However, few such tools have yet made the transition from research laboratory to design practice.

CONCLUSION

User interface design is a complicated process that requires detailed analysis of human performance and preference. Furthermore, developments in technology require an understanding of emotional and 'trust' aspects of interaction that have yet to be studied in detail by cognitive scientists. As a form of applied cognitive science, interface design is a fruitful testing ground for a range of cognitive theories and methods.

Further developments in digital technologies will create new computing devices that will surround us at work, in leisure, and in our public and private lives. Cognitive scientists will be called on to help with the design and to study the impact of such technologies, and theory will meet practice in a manner that is likely to be important for our future wellbeing.

Vision, Early

Intermediate article

Carlo Tomasi, Duke University, Durham, North Carolina, USA

CONTENTS

Early vision algorithms in humans and computers process images from the eye and from electronic video cameras respectively. They infer the shape, appearance, and motion of objects in the world. Conventionally, the lack of semantic interpretation distinguishes between 'early' and higher levels of vision.

INTRODUCTION

The crystalline lens in the human eye focuses the entering light onto the array of receptors in the retina, forming an image of the world. This retinal image encodes the color and brightness of the light that surfaces in the world reflect from light sources into the eye. The retinal image changes over time as objects or light sources move relative to the observer. The human early vision system analyzes these changing patterns of color and brightness to determine the position, shape, motion, and appearance of objects in the world. Conventionally, vision is said to be 'early' when it implies little or no semantic interpretation of the scene. Early vision therefore excludes higher cognitive aspects like object recognition or event interpretation.

Computer vision systems make similar inferences from the images produced by electronic video cameras. The basic computational elements and the overall architecture of human and computer early vision systems differ greatly. However, the abstract nature of the computations they both perform does not depend on the mechanisms of their implementation in man or machine.

The first step in vision is the formation of images, either in a camera or in the eye. Thereafter, images are analyzed and summarized in terms of edges, colors and textures, in order to provide a description of images that is more compact and depends to a lesser extent on changes of lighting or viewpoint. When changes of an image over time are considered, the motion of points in the field of view provides valuable information about the world. Image motion results from both observer motion and the movements and deformations of objects in the field of view. Its analysis allows distinguishing foreground from background, reconstructing the geometry of the three-dimensional world, and computing the motion of the observer within the environment. Additional sources of information about the world's geometry are: stereoscopic vision, which employs two cameras or eyes; the variations in the shading of visible surfaces; and the analysis of how edges meet one another in simple scenes. Although effortless to humans, early vision is the very difficult task of forming a stable representation of the world from the variable images seen by a moving observer.

IMAGE FORMATION

In the 'pinhole camera' model of perspective projection, the rays of light passing through a point O in space intersect an image plane, which records the intensity and color of each ray. The point O represents the optical center of the eye or camera, and the image plane stands for the retina or the camera sensor. Let a point P on a visible surface in the world have coordinates (X, Y, Z) in a Cartesian reference system with origin at O and Z-axis orthogonal to the image plane. If the focal distance (the distance from O to the image plane) is f, the image p of P has coordinates $x = f\,X/Z$ and $y = f\,Y/Z$. These coordinates are measured in a Cartesian image reference system, whose origin is the image point nearest to O.

The pinhole camera model captures the essential property of image formation: each point on the image plane corresponds to a line in the world, called the projection ray of that point. This model

does not account for secondary properties of real lenses, such as their imperfections, their limited ability to form sharp images, or the dependency of image brightness on lens size.

To model the finite number of sensing elements in real vision systems, the image coordinates x and y are discretized into integer pixel values within a finite range: $i = q(x/s)$ and $j = q(y/s)$ $(-n \leq i, j \leq n)$, where $q(a)$ is the integer nearest to a, s is the size of a sensing element, and n is a positive integer. The function q captures the discrete nature of images, and the bound n on image coordinates accounts for the finite field of view of a real vision system. This model does not account for possible overlap between adjacent sensing elements, or for sensors not on a square grid.

In the human eye, two types of photoreceptors at pixel (i, j) encode the color and brightness of incoming light. The 'rods' are highly sensitive to all wavelengths in the visible spectrum, but cannot distinguish colors. The 'cones' are less sensitive, but exist in three types, responsive to different, (but overlapping) bands of the visible spectrum. In electronic color cameras, red, green, and blue filters are superimposed on three brightness sensors at each pixel. Black-and-white cameras have one sensor per pixel.

CONVOLUTION WITH LINEAR FILTERS

Convolution is a ubiquitous operation in early vision. Intuitively, it amounts to additively blending the pixel values of small image neighborhoods to form a new pixel value. For instance, the blurring of a lens can be described as a weighted average of neighboring pixels in an ideal, sharp image. In this case, the blurred image is the convolution of the sharp image with an operator that averages pixel values together. At a somewhat higher level, an edge can be detected by comparing neighboring image pixels with an edge template. This is, again, a convolution, between the input image and the template.

Another example of convolution is image smoothing. To reduce the effects of noise in images, it is often useful to replace each pixel in an image with a weighted average of the intensity values that surround it. This averaging operation can be described by saying that the image is convolved with an operator, or 'kernel', that contains the weights to use for the average. As a simple example, if we compute the average of a pixel and its eight immediate neighbors, the kernel is a 3-by-3 matrix all of whose elements are equal to 1/9. These nine numbers are multiplied by the nine pixels in question, and the products are added together to yield the output average value. This procedure is repeated everywhere in the image.

Formally, let $L(i, j)$ be a function of pixel coordinates (i, j), and let $I(i, j)$ be the output, say, of a rod or cone. The convolution J of I with L is defined as

$$J(i,j) = \sum_a \sum_b I(i-a, j-b)\ L(a,b) \tag{1}$$

where the sums are performed over the domain of definition of the 'filter kernel' L. Thus, the output J at (i, j) is a linear combination of the values of the input I in some neighborhood of (i, j) and the values of the filter kernel L provide the combination coefficients. Similarly, single or triple summations appear in the definitions of convolutions of functions of one or three variables with filter kernels of one or three variables respectively.

Convolution with a bell-shaped kernel smoothes the input. A well-known example of a smoothing kernel is the isotropic Gaussian function

$$G(i,j) = k\mathrm{e}^{-(i^2+j^2)/2} \tag{2}$$

and its one- and three-dimensional equivalents. 'Isotropic' here means that the function G is rotationally symmetric, that is, it has the same shape in all directions. For instance, an out-of-focus lens blurs in approximately the same way in all directions, and its output is often approximated by the convolution of an isotropic Gaussian with the input image.

Convolution with the derivative of G with respect to one of its arguments approximates the partial derivative of the input with respect to the corresponding variable. This operation is very useful for edge detection, described next.

EDGE DETECTION

Edges are curves in the image across which image brightness or color changes abruptly. They are caused by shadow boundaries, contours of objects, or changes in surface orientation or reflectance. Standard algorithms for edge detection convolve the brightness $I(i, j)$ of the input image separately with the two partial derivatives G_i and G_j of the Gaussian kernel G to approximate the spatial gradient (I_x, I_y) of I. Some algorithms (Canny, 1986) then define edges to be ridges in the magnitude of the gradient. Others (Marr and Hildreth, 1980) convolve again I_x with G_i and I_y with G_j and add the resulting images together to obtain the Laplacian of image brightness. Edges are then zero crossings of the Laplacian.

Noise in the sensing elements produces random fluctuations of perceived brightness, which can cause spurious edges to be detected. A single threshold on the gradient magnitude cannot be used to suppress these edges: if the threshold is too high, good edges are removed as well, and if it is too low, spurious edges persist. Some algorithms (Canny, 1986) require edges to contain some elements above a high threshold, but are then extended to all edge elements that are connected to the former and are above a lower threshold. Other algorithms link edge elements into curves, and preserve only those curves that are longer than a given length.

OPTICAL FLOW AND MOTION PERCEPTION

As a point in the world moves relative to the observer, so does its image. When specified for every visible point, this image motion is called the motion field. The true motion field cannot be determined unambiguously from measurements in a very small image neighborhood. For example, if the neighborhood straddles a vertical edge and the edge moves in any direction, one only sees the horizontal component of motion. The edge may also be moving up or down, but this motion cannot be seen in the small aperture of this neighborhood. This inability to observe the motion field directly is called, somewhat awkwardly, the aperture problem.

The *optical flow* is defined to be the smallest image motion that is consistent with local image measurements. In the example above, the optical flow along the edge is $(u, 0)$. This example shows that the optical flow is not always the same as the motion field: the latter is the true, projected motion; the former is the apparent motion.

In computer vision, approximate motion fields are computed by combining values of the optical flow over several neighboring pixels, assumed to share the same motion field (Lucas and Kanade, 1981), or by imposing smoothness constraints on the field itself (Horn and Schunck, 1981). The human visual cortex computes the motion field by comparing the outputs of filters tuned to different orientations in space-time, that is, to different sets of spatial and temporal frequencies and directions of motion. Accuracies of 5 percent for velocities between 2 and 15 degrees per second have been reported for humans (McKee and Welch, 1985).

If only the observer is moving, the motion field at as few as five points is sufficient in principle to compute both the translation and the rotation of the observer, except for an overall scale factor, as well as the distance of the five points in the world from the observer (Thompson, 1959). However, this computation is very sensitive to inaccuracies in the field measurements, and reliable results require more motion field values. This computation is called 'structure from motion'. Accuracies as good as one degree of visual angle for observer translation have been reported both in psychophysics and in computer vision, where algorithms have been proposed also for reconstruction from more than two images.

COLOR AND TEXTURE PERCEPTION

Color

The three types of cone in the human eye are sensitive to three different bands in the visible spectrum of light, between 370 and 730 nm. Sensitivities peak at about 440, 540 and 560 nm for the three types, with much overlap in particular between the latter two bands. The distribution of the approximately 5 million cones in each eye varies from about 160 000 mm^{-2} in the fovea to about 20 000 mm^{-2} at the periphery, with the short-wavelength receptors being about 10 times sparser than those of the other types, consistently with the greater amount of blurring that the crystalline lens introduces at shorter wavelengths. The density in the fovea corresponds to a separation between cones of about half a minute of visual angle.

The spectrum of light impinging on a set of cones is the product of the spectrum of the light source and the reflectance of the visible surfaces. Yet if the color of the light source is changed, humans perceive surface colors as if the change in the light source were only about half as much as the actual change. This ability of the human visual system to compensate for changes in the color of the light source is called color constancy. To achieve color constancy, the visual system must estimate the color of the light source at least approximately. Some theories (Land, 1986) propose that the visual system selects a color for the light source that corrects the average color perceived by all the cones to gray. Other theories (D'Zmura and Iverson, 1993) propose that the visual system detects specular reflections in the image, and takes them to reflect the color of the light source unchanged.

Both psychophysical and physiological evidence suggest that colors are perceptually organized into pairs of 'opponent' colors in the visual cortex. This scheme for color encoding posits three mechanisms, each responding to a pair of sensations considered to be opposite to each other: light and dark, red and green, and blue and yellow.

Texture

An image region has visual texture when the distribution of its brightness values exhibits periodicity, either deterministic or stochastic. For instance, tiles on a floor are deterministically periodic, and leaves on a tree are stochastically periodic. When a texture on a complex surface is projected to an image, the deformations caused by foreshortening and by the changing normal to the surface modulate the periodic components of the texture.

Psychophysics and psychology indicate that humans can recognize materials and objects based on visual texture (texture classification), discriminate image regions with different textural properties (texture discrimination), and infer the shape and slant of a surface in the world from the modulation of its texture (shape from texture). Statistical representations (Caelli and Julesz, 1978) describe visual textures by the first- and second-order distributions of image brightness values in small regions of the image. Brightness histograms have been used in computer vision to capture the complete first-order empirical distribution. Summaries of the second-order distribution have included co-occurrence matrices, the fractal dimension of the spatial distribution of brightness values, and the conditional densities of an underlying Markov random field model.

Structural representations describe visual textures as the repetition of a basic pictorial element, or *texton*, according to some placement rule. This rule can take the form of the description of a grid on which textons are arranged, or it can be a formal grammar, either deterministic or stochastic, that generates the grid points. For instance, the texton of a tiled floor could be a single tile, and the grammar is the description of a regular grid of squares.

Current models of human texture analysis favor filter-based representations of texture (Bergen and Adelson, 1988). These are derived from the responses of a bank of linear filters tuned to different sizes and possibly orientations of the image intensity patterns. The integral of the magnitude of these responses over a small image neighborhood measures the energy contents of that neighborhood at the sizes and orientations that characterize the filters. A final stage of computation groups neighborhoods that have similar energy responses.

If the texture on a surface in the world is uniform, the different distances and slants of different surface patches relative to the observer produce gradual variations of the corresponding image texture, as described by the equations of perspective projection. Shape from texture solves these equations for either distance or slant, and infers the three-dimensional shape of the surface.

REGION ANALYSIS AND SEGMENTATION

The technique of segmentation partitions an image into regions such that different parts of the same region are similar to each other in some sense. For example, gray-level segmentation may require that the greatest difference between two pixels in the same region be less than a fixed threshold. A good segmentation would then have regions that are as large as possible given this constraint. Similarly, segmentation can be based on color or texture features. The results of segmentation differ from those of edge detection, mainly because edges are generally open curves while regions are bounded by closed contours.

In computer vision, images are often segmented in the hope that the resulting regions belong to different objects, or to different parts of an object. This is, however, rarely the case, because the varied colors of objects, shadows, shading, and variations in lighting produce large variations within objects , while at the same time similar colors in adjacent objects are not uncommon. Even so, describing an image as a collection of disjoint regions can offer advantages for later stages of processing, at least in terms of computational complexity.

Several segmentation methods are based on repeated splitting or merging, and sometimes on a combination of both. In a splitting method, for instance, the whole image may initially be considered as a single region, to be split, say, in half if the region as a whole is not homogeneous enough. The same procedure is then applied recursively to the resulting regions, until all regions are sufficiently homogeneous. Merging methods proceed in the other direction, starting with each pixel being considered as its own region, to be merged with neighbors as long as the resulting region is homogeneous.

'Stochastic relaxation' has also been used for segmentation. The class of images of interest is modeled as a Markov random field, which specifies the probability that a pixel has a certain value given the values of its neighbors. Given a particular image, relaxation iteratively adjusts pixel values to maximize the likelihood of the image having being drawn from the class in question (Geman and Geman, 1984). For segmentation, the underlying Markov random field assigns highest probability to noisy piecewise-constant images. As a result, relaxation turns the input image into a

piecewise-constant one, whose discontinuities are the segmentation boundaries.

BINOCULAR STEREOPSIS

'Binocular stereopsis' computes distances (called 'depths') to the visible surfaces by comparing the images of the world seen by two eyes, in humans, or by two cameras, in computer vision. This computation assumes knowledge of the relative position and orientation of the eyes or cameras. First, a stereoptic correspondence module finds pairs of points in the two images that are projections of the same point in the world. Then, the depth for each pair is computed by triangulation.

Stereoptic Correspondence

Two matching points in the two images of a stereoptic pair are likely to look similar to each other. However, this is not always the case. For instance, a point on a glossy surface may have the color of the surface when viewed from one eye, but the color of the light source in the other eye because of a specular reflection. Furthermore similar points do not necessarily match. On a blank wall, for instance, many points look the same. Thus, similarity of appearance, the main criterion for matching two points, is neither necessary nor sufficient for a match. Correspondence is also complicated by the fact that points visible in one image may not be visible in the other because of an intervening occluding object, so that not every image point need have a match.

Yet the human visual system can establish correspondences effortlessly and on the basis of minimal information. Random-dot stereograms like the one in Figure 1 serve to demonstrate this ability, and show that no prior recognition is necessary for stereoptic correspondences to be established (Julesz, 1960).

Knowledge of the relative position and orientation of the two eyes, or cameras, restricts matches for any given point in one image to be on a known line in the other. This is because the two optical centres and any one point P in the world define a plane, the so-called epipolar plane of P. This plane intersects the two image planes at two lines called the epipolar lines, which pass through the two images of P. Hence the 'epipolar constraint': the match for any point on one epipolar line must be on the corresponding epipolar line. The angle formed by the projection rays of two matching points is called the disparity.

One way to establish correspondences is to compare small image patches along corresponding epipolar lines in the two images. Sums of squared differences can quantify the comparison between a small image patch P_L centered at (i_L, j_L) in the left image I_L and a patch P_R centered at (i_R, j_R) in the right image I_R:

$$s = \sum_a \sum_b [I_L(i_L + a,\ j_L + b) - I_R(i_R + a, j_R + b)]^2 \quad (3)$$

where the summation indices range over the patches.

Even for image pairs as ambiguous as those in Figure 1, and even with imperfect image measurements, a small value of s indicates a likely match, as long as the patches being compared are not too small. When these local comparisons fail to determine matches unambiguously, more global criteria must be invoked. For instance, matches may be required to correspond to smooth, or at least continuous, surfaces. In computer vision, these more

Figure 1. The images in this random-dot stereogram are identical, except that a central square in the right image has been shifted slightly to the right, and the resulting gap filled with random dots. When viewed with eyes crossed so as to fuse the two images into one, a square floating in front of a plane should appear after a few seconds.

global requirements have been enforced by the use of various techniques, including stochastic relaxation, dynamic programming, and network flow optimization methods.

Triangulation

The depth of a point in the world is easily computed from a pair of corresponding points. Let α be the angle that the left projection ray of point P forms with the optical center of the left camera. Let δ be the disparity, and let the baseline, that is, the distance between the two optical centers, be b. Then, a simple geometric construction shows that the distance between the left optical centre and point P is

$$\rho = b(\cos\alpha + \sin\alpha\cot\delta) \tag{4}$$

SHAPE FROM SHADING

The perceived brightness of a surface varies with the orientation of the surface relative to illumination and viewing directions, among other factors. As a consequence, the shading on a uniformly colored surface conveys some information about the shape of the surface itself. The locations of concavities and convexities are examples of qualitative information that can be gathered in this way, but the shape of the surface can be reconstructed even quantitatively if its reflectance map is known.

The reflectance map of a surface expresses surface brightness as a function of surface orientation for a particular distribution of the light sources. If the depth of a surface is represented as a function $z(x,y)$ of the image coordinates x and y, the two partial derivatives p and q of z encode the orientation of the surface, since the surface is orthogonal to the vector $(-p, -q, 1)$ everywhere. Therefore, the reflectance map can be expressed as a function $R(p,q)$ that gives the brightness of a surface patch with normal proportional to $(-p, -q, 1)$ in viewer coordinates. If the image at (x, y) has brightness $I(x,y)$, one thus obtains the equation

$$R(p,\ q) = I(x,\ y) \tag{5}$$

The two functions $R(p,\ q)$ and $I(x,\ y)$ are known (the former by assumption, the latter by measurement), and the unknown depth $z(x,\ y)$ appears through its partial derivatives p and q. The equation above is therefore a partial differential equation, which can be solved for z by numerical means.

Because the reflectance map combines information about light and surface, it is often hard to determine *a priori*. However, it is conceivable that one could learn approximate reflectance maps for surfaces of various materials and, say, known position of the sun in the sky.

LINE LABELING IN POLYHEDRAL SCENE ANALYSIS

The remarkable human ability to understand line drawings inspired early computer vision researchers to separate the image interpretation task into two stages. In the first stage, edge detection transforms an image into a line drawing, which the second stage then interprets.

In a world of polyhedral objects with no surface markings, a line segment in the drawing can only represent the convex or concave edge between two visible faces, or an edge that occludes some surface at a greater depth. Two or more line segments meet at junctions corresponding to vertices in the world. If the number of lines meeting at a junction is bounded (typically by a maximum of three), junctions can be classified into a finite taxonomy depending on the number and angles of the meeting lines. For instance, two lines form a V junction. In Y junctions, three lines meet at angles that are all smaller than 180° in the image; and in W junctions one of the three angles exceeds 180°.

A line drawing can then be interpreted by assigning labels – convex, concave, or occluding – to all line segments, making sure that no impossible junctions result. For instance, a concave edge cannot meet a convex edge at a V junction; and three occluding edges cannot meet at a W or Y junction. Remarkably, these rules usually restrict the interpretation of a line drawing to one or very few possibilities, assuming there are no accidental alignments of features. Huffman (1971) developed an elegant algorithm for finding a possible labeling of a line drawing, and started a very active area of investigation.

However, attempts to extend these results to complex images failed for several fundamental reasons. First, objects in the world are not always polyhedral. Second, an edge detector also detects surface markings, shadow contours, and other curves, for which simple consistency rules cannot be given. Third, edges computed from images are usually broken, and junctions are hard to pinpoint. Because of these difficulties, this line of research has been abandoned.

SIZE AND POSITION INVARIANCE

As an object moves relative to the viewer, the size and position of its projection on the image

change. However, objects are recognized in spite of these changes, and also in spite of changes of illumination or viewing angle. The methods for three-dimensional reconstruction described in the previous sections form one basis for explaining this invariance of recognition performance under changing stimuli. According to this explanation, the visual system would compute invariant representations of the image, such as three-dimensional object models in world coordinates.

An alternative explanation seems to be more consistent with physiological evidence, and posits instead the existence of mechanisms that compensate for variations in size, position, and other factors (Ito *et al*., 1995). Almost half of the neurons in the anterior part of monkey inferotemporal cortex seem to respond to the same object in the field of view under large changes in object size and position, although different cells respond within different ranges of variation. On the other hand, other neurons in the same area respond only when the object is presented in a narrow range of sizes and positions. Invariance in the former type of neuron may be achieved by convergence of multiple cells of the latter type.

These two explanations of perceptual invariance lead to entirely different theories of how the world is represented in the visual system. The proposal based on compensation is more consistent with pictorial representations of objects, in which images are transformed and aligned to achieve constancy, than the miniature world of the reconstruction-based approach. But the evidence is still insufficient to allow us to conclude definitely either way.

CONCLUSION

Some of the problems of early vision are problems of image processing or statistical estimation. For instance, edge detection amounts to template matching in the presence of noise; and geometric reconstruction estimates three-dimensional quantities from noisy measurements of image motion. However, vision is inherently a process of inference, and early vision is no exception: several assumptions must be made in order to reconstruct aspects of the three-dimensional world from its two-dimensional projections on eye or camera, and finding assumptions that are adequate in most situations is still a challenge to computer vision researchers. Vision is a form of cognition, and the study of early vision may be one of the best approaches towards understanding intelligence.

CONTENTS

The main functions of high-level vision are the recognition and categorization of visual objects and navigation guidance.

INTRODUCTION

The main functions of high-level vision are the recognition and categorization of visual objects and the guidance of navigation in the environment. It must be noted that these tasks are, however, not exclusively visual in nature. Object recognition can occasionally be based on olfactory (the recognition of a skunk) or auditory (the recognition of a seagull) or haptic (the recognition of tree bark) information. More significantly, in navigation and object manipulation navigation, the information conveyed by proprioceptors is essential.

This review discusses in detail object recognition and categorization, and only briefly vision-based navigation and object manipulation.

OBJECT RECOGNITION

Object recognition refers to the process whereby a previously seen object is identified in an input image, possibly under novel viewing conditions. Categorization is the assignment of a (possibly previously unseen) input object to a known object class. Of the two, recognition is better understood computationally. Recognition is in principle achieved by comparing input image data to a number of candidate internal object models, and selecting the model best matching the image data. There exist multiple sources of information in an image, and multiple pathways to recognition: an object can be recognized on the basis of its shape, texture, color, size, motion, or scene context. Only shape-based recognition is considered here.

Recognition proper must be preceded by two preparatory stages: visual selection and image segmentation.

Visual selection is the process whereby an object of interest is detected and localized in the input image. This represents a computationally difficult problem. One difficulty is that the location, scale and orientation of the sought object are unknown, resulting in a large search space. Another difficulty is that the target object may be only partially visible, being occluded by other objects in the scene.

The problem of selection has been studied in computer vision especially in connection with the detection of faces and people in images. In human vision research, visual selection refers to locating the *salient* regions of the input image, not to the detection of a target object. A salient image region is likely to contain a biologically relevant visual stimulus and consequently attracts visual attention. The salience of an image location is a measure of how different it is from the rest of the image in terms of features such as color, orientation, spatial frequency, etc. (*See* **Visual Attention**)

Segmentation is the grouping of image pixels into regions corresponding to the different objects in the scene. Although performed effortlessly by humans, computationally it is a hard problem. Segmentation techniques can be either contour-based, which work by linking image edges into smooth closed contours, or region-based, which seek an optimal partitioning of the image into regions of homogeneous texture or color. Segmentation is too vast a subject to be even summarized here; the interested reader is referred to Shi and Malik (2000), and Malik *et al*. (2001).

Following detection and segmentation, the problem is reduced to recognizing an isolated, non-occluded object presented under arbitrary viewpoint and illumination.

The computational and psychophysical studies of object recognition have mainly focused on the problem of recognizing rigid objects under variable viewpoint. Although humans effortlessly recognize objects from different orientations, the underlying computational problem is quite difficult. The image

change resulting from rotation in 3-D followed by projection onto the image plane can be very substantial, rendering direct approaches based on storing 'enough' views impractical.

The following sections review the most important computational methods for recognizing rigid objects under variable viewpoint.

Object Recognition by Part Decomposition

Many objects appear to be arrangements of simple shapes such as cylinders, cones, or blocks. These volumetric primitives have been modeled traditionally in computer vision and graphics by *generalized cylinders*. A generalized cylinder (Binford, 1987) is a 3-D volume generated by a planar shape (the cross-section) swept along a curve (the axis) according to a sweeping rule specifying how the cross-section changes during the sweep. By changing the shape of the cross-section, the curve, and the sweeping rule, a wide variety of shapes can be generated. Influential early 3-D shape representation schemes based on generalized cylinders are Binford (1971), Marr and Nishihara (1978), and Brooks (1981).

An important class of parametrized generalized cylinders are the deformable superquadric ellipsoids (Pentland, 1986). By adjusting some 20 shape control parameters of a superquadric, a large repertoire of volumetric primitives can be generated. The use of deformable superquadrics in object part modeling has been limited to fitting depth images (Dickinson *et al*., 1997b); attempts to fit superquadrics to intensity images have not been very successful.

Biederman (Biederman, 1985, 1987) developed the generalized cylinder shape representation idea into a theory of human visual object recognition called Recognition by Components (RBC). A basic assumption of RBC is that objects are arrangements of simplified generalized cylinders called geons. The shape differences between geons are not metrical, but qualitative. Geon axes can be straight or curved (it does not matter how curved), cross-sections can be either polygonal or smooth, and the cross-section sweep function can be either constant or increasing/decreasing. The resulting geon repertoire is small (a few tens), and includes shapes such as cylinders, cones, wedges, and blocks. The level of shape detail in the RBC scheme is such that most everyday objects are decomposed into less than ten geons.

The RBC scheme provides qualitative descriptors of the spatial relations among object geons (such as on-top-of, perpendicular-to, etc.) thus providing a complete structural object description. The resulting encoding of shape is qualitative: under the RBC scheme a dog is indistinguishable from, say, a horse.

To be used in recognition RBC must provide a method for segmenting an object into component geons and for recognizing the segmented geons in an input image. The RBC scheme assumes that an idealized edge detection stage provides a line drawing of the object. The object is segmented starting at the deep concavities of its outline, and using the constraint that there exists one pair of such concavities per geon, the silhouettes of the component geons are extracted. The qualitative shape of a geon can be inferred from its silhouette almost independently of viewpoint by using silhouette properties that directly reflect 3-D shape and are quasi-viewpoint invariant. For example, a straight image contour indicates a straight line in space (and thus a straight geon), two parallel image curves indicate parallel space lines (and thus a constant-section geon), (skew) symmetry in the image indicates a symmetric cross-section, etc. Such image properties are termed *nonaccidental* (Witkin and Tenenbaum, 1983), and are reliable indicators of 'true' 3-D shape. While a straight image segment can in principle be the projection of a curved line – say, an arc of circle – it is very unlikely, requiring a viewing direction perfectly aligned with the plane of the curve. Any perturbation of this special viewpoint will replace the straight line segment with an arc of ellipse.

The RBC scheme has two basic advantages over image-based recognition methods. First, it can be used for analyzing unfamiliar objects by decomposing them into familiar parts. Second, it can handle certain deformable objects – those composed of articulated rigid geons.

RBC also has serious limitations (see Dickinson *et al*. (1997a) for an in-depth discussion). First, it is very difficult to recover geons from real-world intensity images – mainly because available edge detectors cannot produce good quality line drawings. Implementations of RBC have sidestepped this difficulty by assuming the line drawings to be given; an example is the neural network model described in Hummel and Biederman (1992). A second problem is that many objects (a shoe for example) are not composed of geons. Third, RBC provides only a qualitative description of shape and thus is not suitable for object identification; consequently, RBC can be considered a theory of basic level shape classification.

However, RBC was intended to be not so much a computer vision recognition system as a model of human object recognition. In this connection, one of the most important – and disputed – predictions of RBC is that object recognition performance should be nearly viewpoint invariant when diagnostic component geons are not occluded or severely foreshortened. Biederman and his collaborators have published several psychophysical studies supporting this prediction; a representative study is Biederman and Gerhardstein (1993). In contrast, view-based models of object representation hold that recognition should be strongly viewpoint dependent. Many psychophysical studies indicate that object recognition is viewpoint dependent; two relevant papers are Tarr and Bülthoff (1995), and Tarr *et al*. (1997).

Object Recognition Using the Alignment Method

The alignment method, like RBC, uses 3-D models to represent objects, but, unlike RBC, it represents shapes quantitatively and holistically rather than qualitatively and by parts.

Under the alignment scheme an object is recognized if its image(s) can be reproduced by rotating some internal, pre-stored, 3-D object model. Let $\mathcal{M} = \{M_1, \ldots, M_n\}$ be the set of internal 3-D object models. The models are subjected to certain transformations, typically 3-D rotation, scaling, translation, and imaging transformations (perspective or orthographic projection). The recognition of an input image amounts to finding the element of $\mathcal{M}$ that under an allowable transformation best fits the input image. Given an input image I, the recognized 3-D model $M_{\hat{k}}$ best reproduces the input image when subjected to the optimal transformation $T(M_{\hat{k}})$:

$$\hat{k} = \arg\min_{k} \mathcal{D}[I - T(M_k)M_k] \qquad (1)$$

where $\mathcal{D}$ is some image distortion (distance) measure. The minimization in equation 1 is performed over the discrete set of stored models and for each model over the set of allowable transforms T. In general, T consists of a rotation R, a translation t, scaling s, and the 3D-2D imaging projection P. When homogeneous coordinates are employed, the compound transform is expressed as a product of matrices $T = PtRs$. The optimal aligning transformation depends both on the input image I and on the optimal model $M(\hat{k})$, leading to a nontrivial minimization problem.

The alignment scheme provides a method for performing this optimization. A key assumption of alignment is that several localized features (called anchor points) can be identified both in the input image and the models under consideration, and that it is known which point in the image corresponds to which point in the model. The image and the models are said to be *in correspondence*. Establishing correspondence is in itself a difficult problem, typically requiring an extensive search even when geometrical constraints are used to eliminate candidate feature pairings.

Good feature points must be reliably identifiable over a large range of viewpoints, that is, to be quasi-viewpoint invariant. Examples of such features are maxima of object surface curvature (corners), inflection points along contours, surface markings, etc.

In the alignment scheme the object models are, essentially, object views enhanced with depth values. Due to self-occlusion, a single 3-D object requires several such view-specific models. Model information includes the 3-D coordinates of the anchor points and other object features, such as internal contours and silhouette points, visible at the orientation the object is modeled from. The anchor points are used for aligning the model to the image, and the other features are used in evaluating the degree of agreement between the model and the input image.

Once correspondence between the image and model anchor points is established, the optimal alignment transformation is easily determined for *all* internal models, both correct and incorrect.

The transformation $T(M_k)$ necessary for aligning 3-D model M_k to the input image can be determined from the coordinates of the corresponding features in the image and model. Under orthographic projection, three pairs of corresponding feature points are sufficient, the only constraint being that the points not be co-linear. $T(M_k)$ can be determined given the image-plane coordinates (u_i, v_i) of the three feature-points and the 3-D coordinates (x_i, y_i, z_i), $i = 1, 2, 3$ of the same feature-points in a coordinate system attached to the internal model. Determining the transform T amounts to determining the rotation matrix R (three degrees of freedom), the translation t (two degrees of freedom) and the scaling factor s (one degree of freedom).

Following alignment, the minimization in equation 1 is reduced to searching over the discrete set of object models only, and selecting the model that best matches the input image under the measure $\mathcal{D}$.

Typically, matching is performed by comparing the locations of contour corners and inflection points in the image and the model (Huttenlocher and Ullman, 1990).

Determining feature correspondence

The preceding discussion assumes that correspondence has been established between the image and object features; in practice, computing correspondence is the most difficult stage of alignment. A simple approach to correspondence computation is to try all possible pairings of image and model features, selecting the one resulting in the best post-alignment match. This strategy can be improved by restricting the pairings to like features, for example corners to corners, blob centers to blob centers, etc. For polyhedral objects, Huttenlocher and Ullman also used connectivity information to narrow down matches: a pair of point features (polyhedron vertices) joined by an image contour (polyhedron edge) is matched to a pair of point features in the model only if they are joined by a straight model contour.

Dealing with self-occlusion

Not all surface points of a solid 3-D object are visible from all viewpoints, because the object is not transparent – it self-occludes. This poses a problem for alignment, as there exist object views in which the anchor points are not visible. Therefore, for such a view the alignment transform cannot be computed. The solution is to store, for a given 3-D object, *several* models and feature triplets. A single object model handles the range of viewing directions from which its anchor points are visible. Several such models are necessary to cover the entire viewing sphere. Each model represents the object from a certain range of viewpoints, and from any viewpoint a model and a feature triplet are available for alignment. It must be noted that establishing correspondence and tackling self-occlusion are difficult, basic problems that any 3-D object recognition technique must address.

View-based Recognition Schemes

Recognition by linear combination of views

In contrast to alignment, which uses 3-D object models, the linear combination of views approach uses only 2-D (image-plane) information.

Consider a rigid cloud of N 3-D points, rotating in space, and projected (imaged) orthographically onto the XY plane. A view v of the point cloud is specified by the XY coordinates of the image points: (x_{vi}, y_{vi}), $i = 1,\ldots,N$. It can easily be shown that any view v of the cloud can written as a linear combination of three, arbitrarily selected, basis object views α, β, γ:

$$x_{vi} = a_{v1}x_{\alpha i} + a_{v2}x_{\beta i} + a_{v3}x_{\gamma i}$$

$$y_{vi} = b_{v1}y_{\alpha i} + b_{v2}y_{\beta i} + b_{v3}y_{\gamma i}$$

where the coefficients $a_{v1,2,3}$, $b_{v1,2,3}$, can be interpreted as the 'coordinates' of the view v in the space spanned by the three basis views. The only constraint is that three 'basis' views must not have been generated by a rotation around the same axis. The fact that the views are generated by rotation of a *rigid* point cloud followed by *orthographic* projection imposes certain constraints on the values of the coefficients a, b, c. Note that correspondence is given and that there is no self-occlusion, the object being a cloud of discrete points.

This scheme can be directly applied to rotating polyhedral objects, for which the features are image contours corresponding to the edges and corners of the polyhedron. The linear combination of views technique assumes that the same feature points are visible in all the views. However, this is generally not possible due to self-occlusion. The solution is to store a number of view triplets, linear combinations thereof representing the object from all possible viewing directions.

Smooth objects are harder to handle by the alignment or the linear combination of views schemes than polyhedral objects: for smooth objects the linear combination method requires five rather than three basis views.

In conclusion, the set of all possible views of any object (whether smooth or not) can be expressed as the combination of a small number of its views.

The linear combination principle can be used for deciding whether a new view is a possible view of a stored model. Consider an input view for which a small number of features can be put in correspondence to those of the basis views. First, these corresponding features are used for recovering the coefficients of the input view. Next, these coefficients are used to generate a correct object view by combining the basis views. The recognition decision is based on comparing the generated view to the input image.

Recognition using nonlinear image combinations

An object view is a feature vector, that is, a point in a multidimensional feature space. According to the linear combination of views principle, the views of

an object (assuming no feature occlusion) occupy a low-dimensional linear subspace of the feature space.

The radial basis function (RBF) interpolation/approximation methods (Poggio, 1990; Poggio and Girosi, 1990; Poggio and Edelman, 1990) use nonlinear (rather than linear) interpolation between feature vectors of the basis views. The RBF method also requires that feature correspondence between views be established.

The idea of view recognition by RBF-based interpolation is simple. Views are N-dimensional vectors $\mathbf{x}$. The views of the target object are to be recognized by performing a certain computation on their feature vectors resulting in a characteristic constant value, c; when a view of a different object is subjected to the same computation the result c' should substantially differ from c. An (approximately) constant function $f(\mathbf{x}) = c$ must thus be defined on the set of views of the target object. M training object views $\mathbf{x}_1, \ldots, \mathbf{x}_M$ are available, and therefore for these views it is known that $f(\mathbf{x}_k) = c$. The value of the function f for an arbitrary view $\mathbf{x}$ is calculated by taking a weighted sum of M radial basis functions (typically N-dimensional Gaussians) centered on the training views $\mathbf{x}_k$. The resulting function f, being a superposition of Gaussians, is smooth. If $\mathbf{x}$ is a view of the target object, the resulting value for $f(\mathbf{x})$ will not be very different from c, essentially because $\mathbf{x}$ cannot be far from the training views $\mathbf{x}_1,\ldots,\mathbf{x}_M$. On the contrary, if $\mathbf{x}$ is not a target view, $f(\mathbf{x})$ will differ from c substantially.

The disadvantage of this method is that it ignores the linearity of the viewspace of rigid objects under orthographic projection; the advantage is that it can handle nonrigidity, image distortions and perspective projection.

Object Recognition Using Geometric Invariants

A geometric invariant is a function defined on images that (1) does not change with changes in the imaged object's orientation, or, more generally, with changes in viewing conditions (2) changes only if object shape changes. Finding such an invariant would solve the problem of recognizing objects under variable viewing conditions. However, it is easy to see that geometric invariants do not exist in the general case. Consider two objects that look identical from a certain viewpoint and are otherwise different: condition (1) is satisfied but (2) is not.

In addition, a genuine geometrical invariant ought to be calculable from a single object image. However, in Burns *et al*. (1992) it is shown that it is not possible to define an invariant based on a single view of a cloud of 3-D points; two such views are necessary.

The definition above can be relaxed to allow for functions that are approximately invariant to viewpoint change and differentiate only among objects from a certain, restricted, category. In practice, a number of different invariants are used together to form a vector that can be used to index a database of object models, or can be further analyzed by statistical pattern classification techniques (Duda *et al*., 2001).

The geometric invariant approach has been most successful when applied to the recognition of planar or nearly planar objects such as airplanes. For planar objects it is straightforward to derive geometrical invariants from a single object view. Consider a planar object of polygonal shape imaged by *orthographic projection* onto the image plane. Orthographic projection is an adequate image formation model only when object size is small relative to its distance from the camera. When the object polygon rotates in 3-D, the image polygon undergoes a so-called *affine transformation*. Under an affine transformation parallel lines remain parallel, length ratios of parallel segments and ratios of areas of triangles are preserved. The values of these ratios are shared by all the views of the planar object and by the object itself. These simple properties provide the basis for more sophisticated invariants used for viewpoint invariant recognition of planar shapes under orthographic projection.

If the polygon object is imaged by a pin-hole camera, that is, by *perspective projection*, the transformation in the image plane is no longer affine, but projective. Projective transformations are more general than affinities and correctly model camera image formation. Projective transformations do not preserve parallelism or the other affine invariants described above. Projective transformations preserve only the *cross-ratio*, which is defined as a ratio of ratios of lengths or areas. Affine transformations are a special case of projective transformations, so cross-ratio is also an affine invariant.

The invariants discussed above are appropriate for polygonal lines and require the establishment of point correspondence across the different images. Affine invariants based on image moments are global quantities based on the entire image and thus correspondence is not required; in addition, image moments are defined for gray-level images, not just for contours. The disadvantage of moment invariants is that being global image properties, they are affected by image occlusion.

In conclusion, planar objects can be reliably recognized by geometric invariants. An in-depth treatment of recognition of flat shapes by invariants is given in Reiss (1993).

The problem of finding invariants of gray-level images of 3-D objects is much harder. In the last few years a number of single view invariants for 3-D smooth surfaces have been developed; these advances are beyond the scope of this review and are presented in Rothwell (1995); Mundy *et al*. (1994).

VISUAL CATEGORIZATION

Categorization is arguably a more difficult task than identification, because in addition to changing viewing conditions it has to handle certain shape variations. Note that recognition does not imply categorization: an unusual object can be recognized without being classifiable.

Much of the current understanding of human (visual) categorization is due to the theoretical and experimental work of Eleanor Rosch (Rosch *et al*., 1976; Rosch, 1978).

Natural object categories have a hierarchical structure (for example: Siamese $\subset$ cats $\subset$ felines $\subset$ quadrupeds $\subset$ mammals $\subset$ animals).

Class members have different degrees of typicality. Each category has a prototype, which is its most typical (average) member. Visual categorization is faster for more typical objects.

An object is recognized (named) spontaneously by observes at an intermediate level of its class hierarchy, called by Rosch the *basic level*. For example, a Siamese cat will be spontaneously recognized as *cat*, not as *feline* or *Siamese*. Categories above the basic level are called superordinate and categories below the basic level are called subordinate.

Further research (Jolicoeur *et al*., 1984) has shown that atypical objects are first classified at a subordinate level, and the term *entry level* has been proposed for designating the class to which an object is spontaneously assigned.

Interestingly, just like the different members of a class, the different views of a 3-D object are consistently judged by observers as being more or less typical; the most typical view is called the canonical view (Palmer *et al*., 1981). Categorization is fastest when the object is presented in the canonical orientation.

Categorization is based on visual similarity at the basic level and below; above the basic level categorization is not based on appearance but on abstract criteria. Understanding visual categories thus requires understanding *visual similarity*. Biederman's RBC scheme can be viewed as a theory of basic-level object categorization, as objects from the same basic level class share the same geons and geon spatial relations. RBC does not, however, offer a computational account of shape similarity. Not all objects in a basic level class are equally similar to each other; there are metric differences that RBC fails to capture. On the other hand, RBC does not define the similarity of objects that have different geon structural descriptions.

A model of visual similarity must take metrical properties of shape into account. One possibility (Shepard, 1980) is to represent a shape as a point in a multidimensional metric feature space and shape dissimilarity as distance in this space. Perceived similarity as well as similarity of long-term memory traces for a class of complex 3-D objects has been found to be highly correlated to feature-space distance (Cutzu and Edelman, 1998).

An in-depth discussion of visual similarity and its role in object representation is given in Edelman (1999).

USING VISION FOR OBJECT MANIPULATION AND NAVIGATION

Besides recognition, vision is used for guiding the navigation of an organism in the environment and for guiding object-grasping and manipulation.

Visual Control of Object Manipulation

An active research area, with practical applications in robotics, is the visual control of grasping. One problem is the determination of the best, most stable, grasp points for an object that must be picked up and handled. The simple variant of this problem uses an opposing, two-fingered grasp model, while the more complex variants use multi-fingered grasps. A related problem is the visual guidance of the robot gripper to the grasp points. This represents a computationally difficult visual task, requiring the tracking of the fingers and the object, and detection of object contacts and collisions in three dimensions.

Generally, vision alone is insufficient for hand–eye coordination and object manipulation control; feedback from proprioceptors, haptic and force sensors is essential. Purely vision-based solutions must be considered given that most robotic manipulators generally lack non-visual senses.

Visual Control of Navigation

Vision-based navigation (Borenstein *et al*., 1996) involves *goal specification, localization*, and *path*

planning and *following*. Localization is the process whereby the navigator's position is identified on a map, or more generally, in a stored model of the navigation environment. Path planning is the determination of the sequence of movements leading to the final destination. Path following is the actual execution of the planned movements, and involves issues such as dealing with moving obstacles, and the correction of errors.

Location determination requires extracting (point or contour) features from both model and input image, establishing correspondence between them, and the computation of the position of the observer with respect to environment on this basis. Necessary 3-D information is usually supplied by stereoscopic vision. The problem is difficult in unstructured outdoor environments, mainly due to the unreliability of edge-based feature extraction and ambiguities in feature correspondence; the problem is simplified in structured indoor environments by the presence of linear structures and unambiguous landmarks.

Path following requires the determination of both ego-motion and motion of mobile objects in the scene. Consider a pair of video cameras (a stereo head) mounted on a mobile robot moving in a rigid environment. From an image pair taken at an initial location, a stereo algorithm yields the depth (relative to the camera coordinate system) of the relevant image features (for example, rectilinear image contours can be corners for office scenes). After a robot move, another image pair is captured and feature depth values are computed at the new vantage point. The ego-motion of the robot is calculated as the rigid transformation (rotation and translation) aligning the corresponding features in the two consecutive depth images. In the case where some objects in the scene are also moving, their features will not be matched across views by the algorithm calculating ego-motion, which calculates the dominant rigid motion field in the scene. To determine the movement of the mobile objects in the scene, the features matched by the ego-motion algorithm are eliminated, and the ego-motion algorithm is re-applied to the remaining, previously unmatched features. The resulting rigid transformation is subtracted from the rigid transformation corresponding to ego-motion, obtaining the displacement of the mobile object (Faugeras, 1993).

Research in this area has the goal of developing robots capable of autonomous navigation. While most research has focused on navigation in indoor (structured) environments, the problem of navigation in outdoor, unstructured environments is of greater interest, given its multiple applications, ranging from cruise missile control to robotic rover planetary exploration.

CONTENTS

Comparison of localist, distributed, and rule-based models of working memory gives insight into the essential processes underlying short-term retention of information.

VARIETIES OF MEMORY

Memory researchers often distinguish between two manifestations of memory, one dedicated to the retention of information for very short periods, known as short-term memory (STM) or working memory, and one dedicated to long-term storage, known as long-term memory (LTM). Working memory is involved when information is needed briefly but immediately; for example, when dialling a telephone number after looking it up in the directory. Long-term memory, by contrast, is involved when information needs to be available for repeated access across larger timescales, for example one's own telephone number.

Many theorists view working memory as a distinct functional and structural entity that requires examination and explanation in its own right. In support of this view, many empirical dissociations between working memory and LTM have been reported. For example, whereas working memory is adversely affected by phonological similarity (e.g., memory for the list 'B D T V G' is poorer than for the list 'T K X S M'), this has little effect on LTM. Conversely, semantic similarity has little effect on working memory whereas its effects on LTM can be pronounced.

This article focuses on models of working memory, in particular those that are formulated at a computational rather than a verbal level. Computational models provide a quantitative account of the data (e.g., through computer simulation), and thus offer more theoretical precision than verbal models. Although contemporary computational models encompass a diverse range of theoretical approaches and assumptions, they all focus on performance in the immediate serial recall task, in which individuals must repeat back short sequences of verbal items in the correct order.

Much of the research involving this task was stimulated by Baddeley's (1986) pioneering verbal theory of working memory, in particular his conception of the so-called phonological loop. Many contemporary models retain at least an empirical connection with Baddeley's proposal.

Baddeley's Phonological Loop

In Baddeley's (1986) model of working memory, verbal information such as lists of digits, letters, or words is maintained in a system known as the 'phonological loop'. The phonological loop involves two components: a phonological store, which is a receptacle, of limited capacity, of information that is subject to constant decay, and an articulatory control process, which is a rehearsal mechanism that counteracts decay by periodically refreshing the items in the phonological store. Because the representational code is phonological, similar-sounding items interfere with each other, thus producing the observed disadvantage for lists of phonologically similar items.

At a verbal level of explanation, these simple assumptions account for numerous results, for example the fact that memory span (the number of items for which immediate serial recall is possible) is a linear function of pronunciation rate of the material. Memory span is smaller for items that take longer to pronounce, presumably because this increases their exposure to decay in between rehearsals. The phonological loop also

accommodates the observed elimination of this effect when subjects recite irrelevant material during list presentation. Under these 'articulatory suppression' conditions, memory span for visually presented lists is poor, but equal for items with short and long pronunciation durations, presumably because the rehearsal that could prevent trace decay is suppressed.

WORKING MEMORY AS ACTIVE LOCALIST UNITS

Several computational models have been proposed that formalize some of the concepts arising from verbal theorizing within the phonological loop framework. Although these models handle a largely overlapping set of phenomena, they differ in the processes thought to underlie maintenance and retrieval of information. We first consider 'localist' models, in which each item is represented by a distinct unit whose activation represents memorial strength.

A Localist Connectionist Network Model of the Phonological Loop

Burgess and Hitch (1999) presented a network model of the phonological loop that combines localist representations with a time-driven 'competitive queuing' mechanism for ordered retrieval. Thus, when an item is presented for study, phoneme units that correspond to its pronunciation pattern are activated, and that activation is fed forward to a layer of representational units. The representational unit whose activation is greatest, because it is excited by all presented phonemes, is associated with a temporal 'sliding window' representation of context. Context is represented by numerous units that are organized in temporal sequence, so that a contiguous cluster is activated at any given time. Across time, the set of activated units slides along the temporal dimension, thus producing some overlap between the sets of units that are active at adjacent timesteps. At each timestep, the weights between the activated representational unit and the context units are strengthened through Hebbian learning. Connection weights are also assumed to decay with time, thus capturing the transient nature of the phonological loop.

At recall, the context signal is reset, and its subsequent advance along the original temporal sequence is used to cue retrieval. The context signal activates a given representational unit to the extent that it overlaps with the time signal present at study. Because temporally adjacent context representations overlap, several units will be partially activated. The resultant competition among representational units is resolved through a 'winner takes all' process based on mutual inhibition. Once an item has been selected for report, its associated output phoneme pattern is activated, which simulates spoken recall. Immediately upon recall, the representational unit is suppressed and thus removed from subsequent competitions. This item selection process is known as 'competitive queuing'.

Several components of the model can be linked to Baddeley's verbal theory. Competitive queuing implements (part of) the articulatory control process within the phonological loop; and the phoneme units that activate representational units instantiate the phonological store.

The model handles the effects of pronunciation time and articulatory suppression mentioned above in connection with Baddeley's model. Moreover, in important contrast to other computational models, Burgess and Hitch can accommodate a large body of neuropsychological literature by simulating various different types of brain damage through selective lesioning of connections. Finally, the model handles many basic aspects of serial recall, such as the bowed shape of the serial position curve, error patterns, and so on. An earlier version of the model, using the same basic architecture and representation of context, also accommodated the effect of temporal grouping of items on the serial position curve.

Two drawbacks of the model can be identified. Firstly, the model mixes representational approaches: representational units are localist (each item is represented by a single unit) whereas context is represented in a distributed manner. It is unclear on what grounds this mixed representation could be justified. Secondly, the model is complex: it includes four sets of weights, connecting context to items, input phonemes to items, items to output phonemes, and input phonemes to output phonemes. All but the last set of connections are adjustable through Hebbian learning, and each adjustable set in turn involves a variable short-term weight that decays over time as well as a static long-term weight. A large number of parameters is required to govern and coordinate these multiple sets of weights, which renders it difficult to assess the overall parsimony of the approach and the power of its core assumptions. The latter issue can be examined by considering a much simpler model that also uses localist representations and competitive queuing.

The Primacy Model: Parsimonious Competitive Queuing

The primacy model (Page and Norris, 1998) implements competitive queuing without a context or timing signal. At study, localist item nodes are activated to an extent determined by the positions of the corresponding items in the list. The first list item is maximally activated, and the activation of all other nodes decreases for successive serial positions, thus setting up a 'primacy gradient'. Mimicking the presumed properties of the phonological loop, the activation of a node begins to decay immediately after the item has been presented. If rehearsal occurs, decay is reversed and activations are restored to their original levels as dictated by the primacy gradient.

At recall, the strongest item is reported and then immediately suppressed. Thus, because the first list item is maximally active, it will also be recalled first. Because recall is followed by suppression, that item is unlikely to be recalled again, and the second most active item is recalled next. This process of recall followed by suppression continues until all list items have been recalled. To allow the model to generate errors, noise is introduced into activations before selecting an item for report.

The model, though relying on very few parameters, can account for many results. It predicts the standard serial position curve, with an advantage for items at the start of the list (the primacy effect) and a similar, though smaller, advantage for the last few items in a list (the recency effect). The model also predicts the associated patterns of transposition errors, in particular the 'locality constraint', which refers to the fact that items tend to be reported in proximity to their correct positions. The model also handles modality effects (recall is enhanced for words presented auditorily), the effects of pronunciation time discussed earlier, and list length effects (recall is worse for longer lists).

One shortcoming of the primacy model concerns 'fill-in'. This is the observed phenomenon whereby if an item is recalled too early (e.g. item 2 is recalled first), the displaced item is more likely to be recalled next than the item following the transposed item (i.e. item 1 is more likely to be recalled next than item 3). The primacy model handles the phenomenon of fill-in, but greatly over-predicts its extent, as an earlier item not recalled will be a formidable competitor at the next output position.

Another limitation of the primacy model is that it cannot account for grouping effects. Temporal separation of a list into distinct small groups is known to change the serial position curve and patterns of transpositions (see below); this is often taken as evidence of a hierarchical or multi-level representation. As the primacy model can order items only along the single dimension of node activations, grouping effects are beyond its purview. A model that overcomes these limitations is the 'start–end model'.

The Start–End Model

The start–end model (SEM) (Henson, 1998) assumes that, at presentation, a new token is created in short-term memory that contains a representation of the list item and information about its list position. That positional context information is provided by a start marker and an end marker whose strengths decrease and increase, respectively, across list positions. When considered together, the strengths of the start and end markers define a unique list position, and those strengths are stored together with the list item. At retrieval, the positional context for each position is reinstated, and the token whose encoded context is most similar to the cue is recalled. Thus the success of recall depends on the overlap between the positional context provided by the start and end markers for that position and all other possible positions. As in the primacy model, the assessment of overlap is noisy, and report of an item is followed by its suppression.

SEM matches the explanatory power of the primacy model. It also reproduces retention interval effects and the finding that protrusion errors (i.e. incorrectly recalling an item from list $n-1$ on list n) tend to maintain their position from list $n-1$. Notably, SEM gives a thorough account of grouping effects. Grouping increases overall list recall and yields a scalloped serial position curve, with small primacy and recency effects within each group. SEM accounts for these grouping effects by incorporating two sets of markers, item markers and group markers. SEM also handles the intricate pattern of transposition errors in grouped lists, for example the fact that terminal group items are likely to transpose with each other even if group sizes are unequal. For example, in a list presented as a group of three followed by a group of four, the third item in the first group, when erroneously recalled in the second group, is more likely to be reported in group position 4 than position 3. This supports SEM's assumption of relative coding involving end markers; and it casts doubt on absolute coding, such as that used in the Burgess and Hitch model, which would predict that transpositions between groups should maintain their positions within the groups.

Most problematic in SEM is the end marker, whose strength increases exponentially across serial positions, with a predetermined maximum value for the last input position. This requires that the list length be known ahead of presentation, which is an unreasonable assumption: the experimental data remain largely unchanged even if people cannot anticipate list lengths. Henson and Burgess (1997) suggest a solution to this problem that involves competition among multiple autonomous oscillators of different frequencies. When list presentation is complete, only those oscillators retain a role in item coding whose distinctiveness has reached a peak at the end of the list.

WORKING MEMORY AS A DISTRIBUTED NETWORK

Distributed models differ from the localist models described above by assuming that items are represented not by identifiable single units but as patterns of activation across a collection of units. Typically, each unit is involved in the representation of several items, and information storage is accomplished by adjusting the weights between layers of such units.

Unlike some of the localist models, distributed models typically reject any explicit theoretical link with the phonological loop and its notions of decay and rehearsal. Instead, they typically ascribe forgetting to interference. These models also postulate that memory is inherently associative and thus requires some form of cue to elicit recall.

The Oscillator-based Model of Associative Recall

In the 'oscillator-based model of associative recall' (OSCAR) of Brown *et al*. (2000), study items are represented by vectors that consist of many elements. Each element takes on an activation value that is randomly sampled from a Gaussian distribution. Upon presentation, each item is associated with a contextual cue, and, through Hebbian learning, is superimposed upon all earlier memories in a matrix of weights. The contextual cue is provided by a collection of temporal oscillators with differing frequencies whose overall activation pattern uniquely specifies a given point in time.

At recall, the temporal signal is reproduced by first resetting the oscillators and then letting them oscillate. Items are retrieved by cueing the memory matrix with the temporal context at each timestep. Owing to the distributed representations and the use of Hebbian learning, the retrieved item is 'noisy' and needs to be 'redintegrated' into an overt response. (Redintegration is the process by which partial memorial information is disambiguated and hence rendered available for output.) In OSCAR, redintegration is performed by comparing the retrieved item with a pool of possible responses and choosing the one that is most similar. Once a response has been chosen, it is typically suppressed and thus unavailable for further report.

The explicit representation of temporal context is related to the approach chosen by Burgess and Hitch (1999), and it allows OSCAR to handle time effects like recency judgments and various retention intervals. However, the strict adherence to temporal oscillators brings the model into conflict with the observation that transpositions between groups tend to maintain their relative positions within groups. Another limitation, typical of distributed models, is the fact that redintegration and response suppression affect a different form of representation (i.e. discrete responses among the pool of competitors) from that used to encode serial order (i.e. the weight matrix). A recent solution to this problem is presented below.

The Theory of Distributed Associative Memory

Brief consideration must be given to the 'theory of distributed associative memory (TODAM) (Lewandowsky and Murdock, 1989). Although this theory has been superseded by contemporary approaches, the reasons for its obsolescence are informative.

In contrast to all models discussed so far, TODAM rejects the idea of positional encoding; instead, successive items are associated with each other in a chain. Recall involves probing memory with each successive list item. In its simplest version, this 'chaining' model is immediately ruled out because it postulates that recall ceases with the first error, and thus cannot accommodate recency. TODAM circumvents this problem because its distributed representations, as in OSCAR, lead to 'noisy' retrievals that require subsequent redintegration. This can generate recency because the retrieved approximation can correctly cue the next item even though redintegration yields an incorrect response. However, like OSCAR, TODAM implements redintegration by comparing the retrieved response candidate with discrete representations of all possible responses. As with OSCAR, this solution is unsatisfactory because the representational assumptions of an important retrieval component are at odds with the essential properties of a distributed memory system.

TODAM handles many of the serial order effects reviewed in the context of the earlier models. Notwithstanding that apparent success, several recent studies cast doubt on the plausibility of chaining as a mechanism for ordering items (e.g., Henson *et al*., 1996). Chaining of items predicts catastrophic errors in lists of mixed confusable and non-confusable items, as the large overlap between similar items should cause much interference among cues, and recall of the following items should be impaired. The data very clearly do not exhibit this pattern, and the failure of TODAM thus strongly suggests that associations between items do not play a crucial role in the representation of serial order information.

Redintegration With Distributed Representations

The redintegration difficulties mentioned in connection with OSCAR and TODAM have been, at least in principle, resolved by a recent dynamic attractor model (Lewandowsky, 1999). This model was not intended as a complete description of serial recall, but instead provides a mechanism for the redintegration of the noisy outputs of distributed models, such as TODAM and OSCAR, into overt responses. The model redintegrates a partial response by iteratively feeding it back into a weight matrix composed of the self-associations of all study items. After enough iterations, the partial response is mathematically guaranteed to be disambiguated into some overt response, though the probability of the correct response being chosen depends (roughly) on the similarity between the partial response and the correct item.

Lewandowsky's (1999) redintegration model, with minimal assumptions about how partial information is retrieved from memory, can account for many aspects of serial recall. It produces the recency portion of the serial position curve, the correct shape of the transposition gradient, and the relative incidence of other errors across lists and output positions.

RULE-BASED MODELS OF WORKING MEMORY

In contrast to all the models described above, rule-based models represent a list as a collection of propositions, and as such are only tenuously related to Baddeley's (1986) notion of the phonological loop. The principal model of this type is the ACT-R theory of Anderson (Anderson and Matessa, 1997), according to which a list is encoded in a hierarchical structure composed of propositions that encode the identities of items and their positions in groups and lists.

Retrieval is coordinated by 'production rules', which are condition–action pairs: that is, they execute particular functions when their conditions are true. Errors occur through partial matching of the condition of a production; hence items sharing similar codes may both be activated, leading to potential confusion when noise is incorporated.

ACT-R handles the standard serial position curve, list length effects, the effects of pronunciation duration, the pattern of transpositions, phonological similarity effects, and the role of articulatory suppression. Some of these effects (e.g., list length) occur because there is a limited 'pool' of activation, so that the activation available per item decreases as list length increases. Importantly, the model also accommodates the scarce available latency data from serial recall tasks.

The strength of ACT-R is that it integrates explanations for serial recall performance into a wider theory of cognition. There are, however, also noticeable shortcomings. Although the model qualitatively explains many phenomena, an associated quantitative fit is lacking (Anderson and Matessa, 1997, Figure 8). In particular, ACT-R fails to capture the extent of primacy and recency in the standard serial position curve.

CONCLUSION

Several general comments can be made about the state of computational modeling in working memory. Firstly, there is little connection between the introspectively appealing notion of rehearsal that was central to Baddeley's (1986) phonological loop and the mechanisms embodied in current models. Even the theory that is most closely allied to the phonological loop, that of Burgess and Hitch (1999), does not contain a process that retains the intuitive character of subvocal rehearsal. A reasonable interpretation of this state of affairs is that introspection and intuition can be poor guides to theorizing.

Secondly, there are some interesting similarities between theories. For example, virtually all models assume some form of response suppression to prevent the same unit of information being repeatedly accessed. Another unifying assumption in many of the models is the superiority of encoding of early list items, which results in the primacy effect. In OSCAR, TODAM, SEM, the primacy model, and Lewandowsky's (1999) redintegration model, this is explained using some parameter which causes the

quality of storage to decay across serial positions. Similarly, most models explain the phonological similarity effect by relying on several stages to allow independent item and order confusions. This strategy is followed in the primacy model, SEM, the Burgess and Hitch (1999) model, and ACT-R.

The differences between the models are also enlightening. For example, it appears highly unlikely that a model without any kind of associations (e.g., the primacy model) will be able to account for grouping effects. Similarly, a comparison of TODAM with the other models suggests that pure chaining cannot underlie serial recall and that positional coding is a more likely alternative. A comparison of the Burgess and Hitch model and SEM suggests further that that positional encoding is relative, not absolute.

Some of the present models characterize working memory, STM, as a separate system, differing from LTM in processes and representation of items (e.g., the primacy model and SEM). These models probably cannot accommodate the ample evidence that LTM can affect performance on working memory tasks (e.g. Hulme *et al*., 1997). The issue of an LTM contribution is important because it relates to the purpose of working memory. There is now much empirical evidence that a separate verbal short-term system plays an integral role in vocabulary acquisition, or that vocabulary acquisition and immediate serial recall have a common substrate (Baddeley *et al*., 1998). Although the models discussed here have not been applied to vocabulary acquisition, improved knowledge of how temporal order is represented in the serial recall paradigm may be critical to our understanding of language development.

Asset Market Experiments

Intermediate article

Daniel Friedman, University of California, Santa Cruz, California, USA
Hugh M Kelley, Indiana University, Bloomington, Indiana, USA

CONTENTS

Laboratory evidence indicates that prices of financial assets such as stocks and bonds respond to changes in the assets' fundamental value but are also sometimes distorted by investors' cognitive and other biases.

INTRODUCTION

Any society allocates some resources to current consumption and some to investment, to building a better future. Asset markets determine the extent and form of investment in modern economies. Non-market allocation procedures such as those once used in Communist countries clearly worked less well and became less prevalent in the late twentieth century. Asset markets now have global scope and significance.

By definition, asset markets are efficient when asset prices reflect all relevant information about investment opportunities. Theory shows that efficient asset markets lead society to choose only the most productive investment prospects, and to choose the best overall level of investment.

The efficient asset price is called *fundamental value*. Actual asset prices are set by fallible human investors in imperfect markets, and thus may contain other components, called *bubbles*, that can lead to inefficient resource allocation and impair future wellbeing.

Laboratory and field evidence sheds light on asset market efficiency. Asset markets sometimes compensate for investors' cognitive biases, but at other times they amplify them and produce large bubbles. Laboratory experiments help to test policies intended to improve asset market efficiency.

FUNDAMENTAL ASSET VALUE

An asset is anything that provides its owner with a stream of benefits over time. Its economic value is the monetary equivalent of the net benefits it provides. Valuation of a real asset (such as a house, a pizza delivery car or a microprocessor production facility) involves estimating prices for the services the asset generates and for the resources required to maintain its productivity. This article will focus on financial assets, such as stocks and bonds, which are easier to value since they directly promise a monetary income stream. A stock, for example, promises annual per share dividends chosen by the company's board of directors.

Valuing a known income stream is straightforward. One computes the discounted present value: the amount of cash that, if put on deposit now and withdrawn over time, could replicate the income stream. For example, if the asset is an annuity (a simple bond) that promises \$1000 every year for 30 years, and the annual interest rate is 7%, then the asset value is $(\$1000)((1.07)^{-1} + (1.07)^{-2} + \ldots + (1.07)^{-30})$ or, summing the geometric series and simplifying, $(\$1000)(1 - (1.07)^{-30})/(0.07) = \$12{,}409$.

Valuation is more interesting when the income stream is uncertain, either because the promise is vague (as for a stock) or because the promise might not be kept (as in the case of a 'junk' bond). The economic value is defined to be the mathematical expectation of the income stream, discounted at the interest rate appropriate for the associated risk. For example, if the \$1000 annual payment in the previous example had a 50% independent probability of being canceled every year, and this requires a 2% risk premium or 9% interest rate, then the expected annual income is \$500 and the asset value is $(\$500)(1 - (1.09)^{-30})/(0.09) = \$5137$.

Two questions arise. Firstly, what is the appropriate interest rate (or risk premium)? This question stimulated the development of modern finance theory in the 1950s and 1960s, but we will not pursue it here. Secondly, how can people with diverse information arrive at a common expectation

of the income stream (or its discounted present value)? Some people may know a lot about the technical performance of a company's new product, others about customer demand, or competing products, or production costs, or the company's management and financing capacity. Usually nobody has all the relevant knowledge.

'Fundamental asset value' is the present value expectation incorporating all existing information regarding future income. The definition seems to assume that people immediately share all knowledge and combine it without bias or distortion. But people may not share information; they often are cognitively biased. Cognitive biases might cause the market price to deviate from fundamental value.

COGNITIVE BIASES

Which cognitive biases might distort people's estimates of asset value? Some of the main biases are summarized below (Camerer, 1993; Rabin, 1998; Thaler, 1992).

Firstly, judgment biases may distort the aggregation of diverse information (Massaro and Friedman, 1990) and income stream estimates. In particular, investors may:

- neglect some pieces of information and over-weight others, as in cue competition;
- overestimate the resemblance of the future to the immediate past, as in the well-known availability and representativeness heuristics or the anchoring and inertia biases;
- over-weight new information and neglect old information, as in overreaction to news and base rate neglect;
- regard ambiguous news as reinforcing current beliefs, as in the confirmatory bias;
- overrate the precision of their own information, relative to other traders' information, as in overconfidence;
- indulge in the gambler's fallacy or magical thinking, perceiving patterns in random data;
- react incorrectly to increasing information precision, or switch biases depending on state, for example, by overreacting to news when asset prices are volatile but underreacting otherwise.

Secondly, when moving from income estimates to asset value estimates, investors may apply hyperbolic discounting, using too high interest rates when comparing current income with near future income, and too low interest rates when comparing income received at two distant dates (Ainslie, 1992).

Thirdly, investors may make decision errors when they buy and sell assets, such as overvaluing assets they currently hold, as in the endowment effect, or making inconsistent risky choices, as in prospect theory, regret theory, or (more generally) decision field theory (Busemeyer and Townsend, 1993).

Fourthly, investors may learn by trial and error, some faster than others, creating additional asset price deviations from fundamental value (Kitzis *et al*., 1998; Busemeyer *et al*., 1993).

Note, however, that individual investors' biases do not translate directly into asset price biases. Market prices are set by subtle interactions between investors that may either attenuate (e.g., Friedman, 2001) or amplify (e.g., Akerlof and Yellin, 1985; DeLong *et al*., 1990) the individual biases and learning heterogeneities. Thus, whether (or when) asset price follows fundamental value is an empirical question in its own right.

FIELD EVIDENCE

Evidence from existing asset markets is interesting but inconclusive. Historians point to dramatic episodes of asset price increase and collapse, from the South Sea bubble and 'tulipmania' in the sixteenth century to Japan's 'bubble' economy of the late 1980s, various 1990s financial crises (in Western Europe, Latin America, East Asia, and Russia), and the 'dot com' bubble of 2000.

Some economists argue that these episodes are merely unusual movements in fundamental value (Garber, 2000). Economists cannot observe the private information held by traders in the field, and therefore have no direct measure of fundamental value or bubbles. Some indirect field evidence, however, favors the bubbles interpretation.

Shiller (1981) and later writers surveyed in LeRoy (1989) show that stock market indices are much more volatile than would be justified by subsequent changes in dividends. Roll (1984) argues that changes in the fundamental value of US orange juice futures come predominantly from two observables (Florida weather hazard and Brazil supply) but account for only a small portion of the actual price variability. Additionally, nonfundamental effects consistently observed, such as the day of the week or month and January effects, also suggest that stock prices are more volatile than fundamental values. Finally, in a natural field experiment, the stock prices (but arguably not the fundamental values) are far less volatile on weekends and days when the exchange is closed for upgrades. On the other hand there is also field evidence suggesting efficient information aggregation. The Iowa Electronic Market has consistently outperformed major polls in predicting election outcomes (Forsythe *et al*., 1999) and

similarly with the Hollywood Stock Exchange for box office revenues and Oscar winners (Pennock *et al*., 2001).

Field evidence is indirect and can seem either to support or to undermine claims of market efficiency.

LABORATORY EVIDENCE

Laboratory asset markets provide direct evidence, because the experimenter can control the information available to traders and can always compute the fundamental value. The first generation of asset market experiments in the early 1980s used oral double auction trading procedures similar to the traditional Chicago trading pits. To sharpen inferences, the laboratory markets are much simpler than field markets: for example, they often allow only 8 to 16 subjects to trade a single asset. Most of the results described below involve experienced traders who are fully adapted to the laboratory market. See Sunder (1993) for an excellent early survey, and Holt (1999) for an online bibliography.

Market Attenuation of Traders' Biases

There are several distinct forces that tend to attenuate biases. Firstly, people can learn to overcome their biases when the market outcomes make them aware of their mistakes. Secondly, to the extent that biased traders earn lower profits (or make losses), they will lose market share and will have less influence on asset price. Thirdly, institutions evolve to help people overcome cognitive limitations: for example, telephone books mitigate the brain's limited digital storage capacity. Trading procedures such as the oral double auction evolved over many centuries and seem to enhance market efficiency.

Oral double auctions allow all traders to observe other traders' attempts to buy and sell, and might enable them to infer other traders' information. Moreover, the closing price is not set by the most biased trader or even a random trader. The most optimistic traders buy (or already hold), and the most pessimistic traders sell (or never held), the asset, so the closing price reflects the moderate expectations of 'marginal' traders, the most reluctant sellers and buyers.

These attenuating forces may explain the surprisingly rapid convergence of asset price to fundamental value in the first generation of laboratory experiments. Forsythe *et al*. (1982) obtained such convergence for assets that paid different dividends to different traders over two periods. Likewise, Plott and Sunder (1982) obtained convergence to an efficient asset price for a single-period asset even when some traders had inside information. Friedman *et al*. (1984) found that simultaneous operation of spot and futures markets improved convergence to an efficient asset price and allocation when assets paid different dividends to different traders over three periods and traders knew only their own dividend schedule. Generally, convergence was first observed in the last dividend period, then in the middle period as traders correctly anticipated last-period prices, and finally in the first trading period as traders learned the asset's present value.

Market Amplification of Traders' Biases

Later experiments detected systematic discrepancies between price and fundamental value in more complex environments. Copeland and Friedman (1991) found that in a computerized double auction with three information events and eight states, a model of partial aggregation predicted price better than full aggregation or fundamental value.

Several experimental teams found that insider information was incorporated into asset price less reliably and less quickly when the asset paid the same dividend stream to each trader and the number (or presence) of insiders was not publicly known. Some data suggest the following scenario. An uninformed trader A observes trader B attempting to buy (due to some slight cognitive bias, say) and mistakenly concludes that B has favorable inside information. Then A tries to buy. Now trader C concludes that A (or B) is an insider and tries to mimic their trades. Other traders follow, creating a price bubble.

Such 'information mirages', or 'herding' bubbles, amplify the biases of individual traders, but they cannot be produced consistently, since incurred losses teach traders to be cautious when they suspect the presence of better-informed traders. (This lesson does not necessarily improve market efficiency, however, since excessive caution impedes the aggregation of information.)

Smith *et al*. (1988) found large positive bubbles and crashes for long-lived assets and inexperienced traders. Their interpretation invokes the 'greater fool' theory, another bias amplification process. Traders who themselves have no cognitive bias might be willing to buy at a price above fundamental value because they expect to sell later at even higher prices to other traders dazzled by rising prices. Subsequent studies confirmed that such dazzled traders do exist, and that bubbles are

more prevalent when traders are less experienced (individually and as a group), have larger cash endowments, and have less conclusive information.

Other mechanisms that amplify biases in laboratory asset markets include firm managers' discretionary release of information and fund managers' rank-based incentives (James and Isaac, 2000).

Policy Studies

We have only a tentative and fragmentary understanding of when asset markets amplify or attenuate investors' cognitive biases. The impact of proposed policy changes often cannot be predicted reliably, and must be assessed empirically by regulators, asset market makers contemplating reform, and entrepreneurs creating new asset markets. Laboratory markets offer helpful guidance at low cost. Recent relevant research includes performance assessment of:

- alternative market formats, including oral (or face-to-face) double auctions, anonymous electronic double auctions, call or uniform price periodic auctions, and fragmented opaque (or bilateral search) markets;
- trader privileges, such as price posting and access to order flow information;
- transaction taxes, price change limits, and trading suspensions intended (usually ineffectively) to mitigate price bubbles and panics;
- new derivative securities such as call and put options and state-contingent claims.

Current Research

Research continues at a rapid rate along all the lines mentioned. One promising new line of research investigates learning, and judgment and decision biases, in environments similar to asset markets. These environments clearly do attenuate some sorts of biases (Kelley and Friedman, forthcoming) and amplify others (Ganguly *et al*., 2000); eventually such work should clarify the patterns.

Other promising new lines of research integrate agent-based simulation models (e.g. Epstein and Axtell, 1996) into asset markets that may include human traders. The simulated agents, or 'bots', incorporate specified cognitive limitations and the simulations examine the market-level influence of these (e.g. Arthur *et al*., 1997). Gode and Sunder (1993) showed that simple (non-asset) double auction markets are efficient even when populated by 'zero intelligence' agents, bots that are constrained not to take losses but are otherwise quite random. Research is beginning to show how these and more intelligent bots affect efficiency in various sorts of asset markets and how they interact with humans.

The laboratory asset market evidence is more direct than the field evidence, but is still mixed. The laboratory evidence clearly demonstrates that asset price bubbles exist and persist under some circumstances, but that under other circumstances asset prices closely track fundamental values. Future work promises to identify more clearly the circumstances that promote or impair market efficiency. This should lead to improved policy and a better-functioning economy.

Bayesian Learning in Games

Intermediate article

JS Jordan, Pennsylvania State University, University Park, Pennsylvania, USA

CONTENTS

Bayesian learning is a method by which players in a game attempt to infer each other's future strategies from the observation of past actions. Under certain assumptions, learning is successful in the sense that players' expectations converge to Nash equilibria of the game.

INTRODUCTION

A Nash equilibrium of a game consists of a strategy for each player that maximizes the player's expected pay-off against the strategies of the other players. It is natural to assume that players seek to maximize their expected pay-offs, but the assumption that each player correctly anticipates the strategies of the others is more problematic. If the players' pay-off functions are public knowledge, then presumably each player could compute the equilibrium strategies, provided that some selection criterion is adopted in the case of multiple equilibria. In most applications of game theory to economics, however, individual characteristics are private information not directly observable by others. This raises the question of whether players might learn from experience.

Suppose that the game is repeated over time while pay-off functions remain fixed. If the actions taken by each player at each repetition are publicly observable, then players might, through some form of inductive inference, learn to form the correct expectations. In game theory, the canonical model of expectation formation is Bayes' theorem, so Bayesian learning provides a natural model of inductive inference. In a Bayesian learning model, each player has probabilistic beliefs about the sequence of actions that the repeated game will generate, and updates those beliefs at each iteration in response to the actions observed up to that point. The question is whether, over time, each player's beliefs about the future actions of the others converge to the correct Nash equilibrium expectations.

If all of the players except one were machines that take the same, possibly randomized, action each time, the inference problem for the single real player would be a straightforward problem of consistent statistical inference. Instead, the fact that all players are learning from each other's actions means that Bayesian learning produces complex interactive dynamics. Despite this complication, the Bayesian learning model provides some encouraging results on the possibility of learning Nash equilibrium expectations.

It is useful to distinguish between two different versions of the Bayesian learning model, which in this article will be termed 'sophisticated' and 'naive'. In the sophisticated Bayesian learning model, players are assumed to be knowledgeable game theorists who derive their expectations of the other players' actions from prior beliefs about the other players' pay-off functions. After each repetition, the observed actions cause them to revise their beliefs and update their expectations. In the naive Bayesian learning model, the players' prior beliefs are arbitrary probability distributions over sequences of actions. Expectations of future actions are updated directly from observed actions via Bayes' theorem, with no knowledge of game theory required.

SOPHISTICATED BAYESIAN LEARNING

Myopic Behavior

Since the game is repeated, players receive a stream of pay-offs over time. If the players ignore future pay-offs in each period, and seek to maximize their one-period pay-off against the expected actions of the other players, then it is natural to ask whether expectations approach correct Nash equilibrium expectations for the one-shot game that is being played each period. In contrast, if players anticipate future repetitions and seek to maximize the

expected discounted sum of future pay-offs, then it is more natural to ask whether expectations approach correct Nash equilibrium expectations for the full repeated game. The case of myopic behavior will be discussed first.

The actions available to player i at each iteration lie in a finite set S_i. There are n players, and, following interation t, each player observes the entire n-tuple $s_t = (s_1, \ldots, s_{nt})$ of chosen actions. A learning process for player i is a sequence of expectation functions e_{it} which associate with any observed finite history of play $h_t = (s_{1t}, \ldots, s_t)$ an expectation $e_{it}(h_t) \in \Delta(S_{-i})$, where $\Delta(S_{-i})$ is the set of probability distributions over $(n-1)$-tuples $s_{-i} = (s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_n)$ of actions to be chosen by the other players in period $t+1$. After each iteration t, each player i receives the pay-off $u_i(s_t)$. Player i knows the pay-off function u_i, which remains fixed through time, but does not know the pay-off function of any other player. Player i chooses s_{it} in period t to maximize the one-period expected value of u_i against the expectation $e_{i(t-1)}(h_{t-1})$ of the other players' actions. The question is whether the expectations sequence $(e_{it}(h_t))_{t=1}^{\infty}$ approaches the set of Nash equilibrium expectations.

A Nash equilibrium consists of a strategy $\sigma_i^* \in \Delta(S_i)$ for each player i that is expected-pay-off-maximizing against the strategies of the other players, that is,

$$\sum_{s_i \in S_i} \sigma_i^*(s_i) \sum_{s_{-i} \in S_{-i}} u_i(s_i, s_{-i}) \sigma_{-i}^*(s_{-i}) \geq \sum_{s_i \in S_i} \sigma_i(s_i) \sum_{s-i \in S-i} u_i(s_i, s_{-i}) \sigma_{-i}^*(s_{-i})$$

for every other strategy $\sigma_i \in \Delta(S_i)$. (We write $u_i(s_i, s_{-i})$ for the pay-off resulting from player i using strategy s_i and the other players using strategies s_{-i}.) Given a Nash equilibrium $(\sigma_1^*, \ldots, \sigma_n^*)$, player i's Nash equilibrium expectation is the probability distribution $\sigma_{-i}^* = \sigma_1^* \times \cdots \times \sigma_{i-1}^* \times \sigma_{i+1}^* \times \cdots \times \sigma_n^* \in \Delta(S_{-i})$. Learning has the desired convergence property if, as $t \to \infty$, the distance between $e_{it}(h_t)$ and the nearest Nash equilibrium expectation σ_{-i}^* goes to zero for every player i. Since many games have multiple Nash equilibria, the sequence of expectations may have multiple limit points because it has subsequences converging to different Nash equilibrium expectations. The desired convergence property is that each limit point be a Nash equilibrium.

The expectation functions that constitute Bayesian learning can be derived as follows. The fact that player i knows u_i but not u_j for all $j \neq i$ means that the players face a game of incomplete information, in which each player's private type is the player's pay-off function. The incomplete information is modeled by supposing that player i believes that, prior to the first iteration, Nature chooses each pay-off function u_j according to a probability distribution μ_j over pay-off functions. Since the domain of pay-off functions S is finite, pay-off functions lie in the finite-dimensional vector space $\mathbb{R}^S$. Since best-response strategies are invariant with respect to positive linear transformations, we can reduce the space of possible pay-off functions to the unit sphere $B \subset \mathbb{R}^S$, which is an innocuous but convenient normalization. The pay-off functions determine the game that is being learned, so let $G = B^n$ denote the space of all possible games. All players believe that a game $(u_1, \ldots, u_n) \in G$ is initially chosen by nature according to the prior distribution $\mu = \mu_1 \times \cdots \times \mu_n$ over G. In particular, it is assumed that players share the common belief μ, under which the pay-off functions of different players are independently distributed. These assumptions can be relaxed, as will be discussed below.

The initial expectations e_{i0} are derived as a Bayesian Nash equilibrium of the incomplete information game in which each player i knows u_i and believes that each u_j is distributed according to μ_j. Given an initial expectation $e_{i1} \in \Delta(S_{-i})$, there is a best response $b_i(u_i) \in \Delta(S_i)$ associated with each possible pay-off function u_i. Together with the initial distribution of pay-off functions μ_i, a best-response function $b_i(\cdot)$ determines a distribution of player-i actions $\sigma_i \in \Delta(S_i)$, as $\sigma_i(s_i) = \int_B b_i(u_i)(s_i)\, \mu_i(\mathrm{d}u_i)$. The Bayesian Nash equilibrium condition is that, for each i, $e_{i0} = \sigma_{-i}$, that is, each player's expectation is simply the derived distribution of the best responses of the other players to their expectations.

The actions $(s_{11}, \ldots, s_{n1})$ are chosen at the first iteration as best responses to the expectations e_{i0} for the true pay-off functions $(u_1, \ldots, u_n)$. Each player i then observes each s_{j1} and revises the prior distribution μ_j according to Bayes' theorem. The revised distribution $(\mu_1 = \mu_{11} \times \cdots \times \mu_{n1})$ over G results in new Bayesian Nash equilibrium expectations $e_{i1}(h_1)$, where h_1 is the one-period history $h_1 = (s_{11}, \ldots, s_{n1})$, and so on. At each iteration t, the expectations $e_{it}(h_t)$ are derived as a Bayesian Nash equilibrium for the revised beliefs μ_t. Bayesian Nash equilibria need not be unique, so the expectation functions are not generally determined uniquely. The Bayesian learning model encompasses all expectation functions derived in this way from all initial beliefs $\mu = \mu_1 \times \cdots \times \mu_n$, although many of the convergence results mentioned below place restrictions on the initial beliefs.

Although the expectation functions are not unique, the players' best-response strategies have a useful deterministic property. A mixed strategy can only be a best response if there are two or more actions that each maximize the player's expected pay-off. In particular, there must be actions s_i and s_i' that yield the same expected pay-off, $\sum_{s_{-i}} u_i(s_i, s_{-i}) e_{it}(s_{-i}|h_t) = \sum_{s_{-i}} u_i(s_i', s_{-i}) e_{it}(s_{-i}|h_t)$. Given the expectations $e_{it}(h_t)$, this equation is satisfied only for a proper linear subspace of the space of pay-off functions $\mathbb{R}^S$, and therefore only for a set of pay-off functions having Lebesgue measure zero, i.e., probabilistically negligible. For each t, the set of possible t-period histories is finite; so the set of all histories is countable. Therefore, given any sequence of expectation functions, all pay-off functions except for a set of Lebesgue measure zero have unique best-response actions in every period for every history. If the prior distributions μ_i are absolutely continuous with respect to Lebesgue measure on the sphere $B \subset \mathbb{R}^S$, then the set of pay-off functions having unique best responses throughout the learning process has probability one. Given the expectation functions $e_{it}(\cdot)$, Bayesian-learning players never play mixed strategies, except for a set of games having Lebesgue measure zero.

2×2 games

In general, the derivation of expectations as Bayesian Nash equilibria makes their explicit computation problematic. However, in the case of 2×2 games with uniform prior beliefs, the derivation of expectations is straightforward and provides a useful illustration.

Let player 1 be the row player, player 2 the column player, $S_1 = \{U, D\}$, and $S_2 = \{L, R\}$. Then player i's pay-off function is a 2×2 matrix with the entries $u_i(U, L)$, $u_i(U, R)$, $u_i(D, L)$, and $u_i(D, R)$. However, it will be convenient to employ a normalization, which reduces each player's space of possible pay-off functions to the unit circle $C \subset \mathbb{R}^2$. To motivate this normalization, suppose that player 1 anticipates that player 2 will play L with probability $\sigma_2(L)$. Then player 1's optimal strategy is U, D, or both, according as the quantity

$$\sigma_2(L)[u_1(U, L) - u_1(D, L)] + (1 - \sigma_2(L))[u_1(U, R) - u_1(D, R)]$$

is positive, negative, or zero. Therefore we can subtract the second row of player 1's pay-off matrix from each row, so that the top row is $(u_1(U, L) - u_1(D, L), u_1(U, R) - u_1(D, R))$ and the bottom row is $(0, 0)$. Applying the same normalization to the columns of player 2's pay-off matrix produces the pay-off bimatrix in Table 1. If we ignore the measure-zero possibility that $a = b = 0$, that is, $u_1(U, L) = u_1(D, L)$ and $u_1(U, R) = u_1(D, R)$, then we can further normalize (a, b) to the unit circle without affecting player 1's best response to any mixed strategy played by player 2. Thus we can assume that $a^2 + b^2 = 1$, and (for player 2) that $\alpha^2 + \beta^2 = 1$. Under this normalization, each player's pay-off function is a point on the unit circle, and each 2×2 game is a point on the torus $C \times C$ (we will continue to exclude the degenerate cases $a = b = 0$ and $\alpha = \beta = 0$).

An obvious choice for the priors is the uniform distribution on the unit circle C. For this prior distribution, we will derive the expectations along the two-period history $((U, R), (D, L))$. More precisely, we will compute the first-period expectations $e_0(\cdot)$ and second-period expectations $e_1(\cdot|U, L)$, which are uniquely determined, and show that there are three possible choices for the third-period expectations $e_2(\cdot|(U, L), (D, R))$. First, let σ_2 denote the initial probability distribution on $S_2 = \{L, R\}$ facing player 1. That is, $\sigma_2(L)$ is the probability that player 2 will play L in the first period. Then player 1 will play U in period 1 if player 1's pay-off function, represented by (a, b), satisfies $a\sigma_2(L) + b(1 - \sigma_2(L)) > 0$. That is, the set of player-1 'types' that play U in period 1 is a semicircle $\{(a, b) : a\sigma_2(L) + b(1 - \sigma_2(L)) > 0\}$. The set $\{(a, b) : a\sigma_2(L) + b(1 - \sigma_2(L)) = 0\}$ has prior probability zero and thus can be ignored. Hence, for any expectation $\sigma_2(L)$, the measure of the set of player-1 types that play U, which is simply the prior probability of a semicircle, equals $\frac{1}{2}$. Since this reasoning applies to both players symmetrically, the unique first-period Bayesian Nash equilibrium expectations are $e_{20}(U) = e_{20}(D) = \frac{1}{2}$ and $e_{10}(L) = e_{10}(R) = \frac{1}{2}$.

Now suppose that the actions (U, R) are played in period 1. This reveals that player 1's pay-off function lies in the semicircle $\mathcal{T}_1 = \{(a, b) : \frac{1}{2}a + \frac{1}{2}b > 0\}$, and that player 2's pay-off function lies in the semicircle $\mathcal{T}_2 = \{(\alpha, \beta) : \frac{1}{2}\alpha + \frac{1}{2}\beta < 0\}$. To solve for the Bayesian Nash equilibrium conditional expectations $e_1(\cdot|(U, R))$, let $x = e_{21}(U|(U, R))$, the conditional measure of the set of

Table 1. Normalized pay-off bimatrix for a 2×2 game

	L	*R*
U	*a*, α	*b*, 0
D	0, β	0, 0

player-1 types that play U in period 2, and let $y = e_{11}(L|(U,R))$. Given y, x is simply $\mu_1(\{(a,b) \in \tau_1 : ay + b(1-y) > 0\})/\mu_1(\mathcal{T}_1)$, where μ_1 denotes the uniform distribution on the unit circle. Thus x is simply the relative arc length given by the formula

$$x = (\pi - |\theta(y)|)/\pi$$

where $\theta(y)$ is the angle between the expectations vectors $(\frac{1}{2}, \frac{1}{2})$ and $(y, 1-y)$ (in radians). The analogous formula for y as a function of x is

$$1 - y = (\pi - |\theta(x)|)/\pi$$

These two equations have a unique solution, $x^* \approx 0.82$ and $y^* \approx 0.18$, so the unique Bayesian Nash equilibrium expectations are $e_{21}(U|(U,R)) = x^*$ and $e_{11}(L|(U,R)) = y^*$.

Now suppose that the strategies (D, L) are played in period 2. This reveals that (a, b) and (α, β) satisfy the following conditions:

$$\frac{1}{2}a + \frac{1}{2}b > 0$$

$$y^*a + (1-y^*)b < 0$$

$$\frac{1}{2}\alpha + \frac{1}{2}\beta < 0$$

$$x^*\alpha + (1-x^*)\beta > 0$$

Since $y^* > \frac{1}{2}$ and $x^* > \frac{1}{2}$, equations 5 to 8 imply that $a > 0$, $b < 0$, and $\alpha > 0$, $\beta < 0$. It follows that (U, L) and (D, R) are pure-strategy Nash equilibria for every game $((a,b), (\alpha,\beta))$ that generates the two-period history $((U, R), (D, L))$. It also follows that there is a mixed-strategy Nash equilibrium, but the equilibrium mixed strategies are not yet revealed.

Thus there are three possible Bayesian Nash equilibrium expectations:

- $e_{22}(U|(U,R),(D,L)) = e_{12}(L|(U,R),(D,L)) = 1$
- $e_{22}(U|(U,R),(D,L)) = e_{12}(L|(U,R),(U,L)) = 0$
- $e_{22}(U|(U,R),(D,L)) \approx 0.61$, $e_{12}(L|(U,R),(U,L)) \approx 0.39$

The first two are 'pure strategy' Bayesian Nash equilibria. They correspond to the pure-strategy Nash equilibria and reveal no further information about each player's pay-off function. The third is a 'quasi-mixed' Bayesian Nash equilibrium. It further partitions the pay-off types revealed by the history $((U, R), (D, L))$.

This multiplicity of Bayesian Nash equilibria continues for all future periods. If the 'quasi-mixed' equilibrium is selected infinitely often, the expectations in those periods will converge to the mixed-strategy Nash equilibrium determined by the true pay-off types (a, b) and (α, β).

Far-sighted Behavior

The learning model described above addresses the question of whether players can learn from repeated experience to form correct Nash equilibrium expectations for the true game determined by the pay-off functions $(u_1, \ldots, u_n)$. However, the repetitions introduce the possibility that players may anticipate future pay-offs and take account of the effect that their current actions may have on the future actions of the other players. This can be modeled by supposing that player i has an additional pay-off characteristic consisting of a discount factor $1 > \delta_i \geq 0$, and chooses an action s_{it} in period t to maximize the expected discounted sum of current and future pay-offs $(1-\delta_i)\sum_{\tau=t}^{\infty} \delta_i^{\tau-t} u_i(s_\tau)$. Myopic behavior corresponds to the special case $\delta_i = 0$ (under the convention $0^0 = 1$). The prior beliefs μ_i can be extended to cover the discount factors δ_i as well as the stage-game pay-off functions u_i. The game that the players are learning about is now the full repeated game determined by the discount factors together with the stage-game pay-off functions. Like the stage game, the true repeated game is stationary over time, so the true repeated game is itself being repeated over time in the sense that each period is the first period of the game to be played from that period on.

A strategy for player i in a repeated game is a sequence of functions $f_{it} : S_1 \times \cdots \times S_t \to \Delta(S_i)$ that determine player i's (possibly randomized) action in period $t+1$ as a function of the previous history of play. The sequence of functions $(f_{it})_{t=0}^{\infty}$ is called a 'behavior strategy'. A Nash equilibrium for a repeated game consists of a behavior strategy for each player that maximizes the expected discounted sum of pay-offs against the behavior strategies of the other players. Any Nash equilibrium of the stage game, if repeated every period, is also a Nash equilibrium of the repeated game. More precisely, if $(\sigma_1^*, \ldots, \sigma_n^*) \in \Delta(S_1) \times \cdots \times \Delta(S_n)$ is a Nash equilibrium of the stage game, then the constant-behavior strategies in which player i plays σ_i^* in every period after every history is also a Nash equilibrium of the repeated game. However, repeated games typically have many more Nash equilibria, in which players can influence one another's actions over time, especially if the discount factors are near unity.

The derivation of expectations as Bayesian Nash equilibria extends directly to repeated games

(Jordan, 1995). In this setting, player i's initial expectation e_{i0} is a probability distribution over the behavior strategies of the other players. A theorem due to Kuhn simplifies the analysis by establishing that any probability distribution over behavior strategies generates the same distribution over action sequences as a single appropriately chosen behavior strategy. Hence the expectation e_{i0} can be represented as an $(n-1)$-tuple of behavior strategies $((f^i_{jt})^\infty_{t=1})_{j\neq i}$, and the subsequent expectations $e_{it}(h_t)$ reduce to the behavior strategies $((f^i_{j\tau}(h_t,\cdot))^\infty_{\tau=t})_{j\neq i}$. The question is whether these expected behavior strategies approach Nash equilibrium behavior strategies for the true pay-off characteristics $((u_1,\delta_1),\ldots,(u_n,\delta_n))$.

NAIVE BAYESIAN LEARNING

The naive Bayesian learning model drops the assumption that expectations are derived as Bayesian Nash equilibria from underlying prior beliefs about private pay-off characteristics. Instead, players are assumed to have arbitrarily given prior beliefs about the strategies of the other players, and to form expectations by conditioning their prior beliefs on the histories of observed actions. This model of expectation formation accommodates both far-sighted and myopic behavior. As in the sophisticated Bayesian learning model, the players choose actions in each period as best responses to their expectations, which generate the histories that the players observe over time.

In the case of myopic behavior, naive Bayesian learning accommodates all possible expectation functions. Given an arbitrary sequence of expectation functions $e_{it}(\cdot)$, one can construct a prior distribution μ_i over S^∞ using the expectations $e_{it}(h_t)$ as successive conditional distributions over $s_{-i(t+1)}$. The only restriction on the expectation functions is that player i expects players j and k to choose their next-period actions independently, that is, $s_{j(t+1)}$ and $s_{k(t+1)}$ are independently distributed under $e_{it}(h_t)$. Subject to this restriction, naive Bayesian learning formally includes all learning models in which players choose actions in each period as one-period best responses to expectations. The naive Bayesian learning model that is perhaps most in the spirit of Bayesian inference is fictitious play (e.g. Krishna and Sjöström, 1998). In fictitious play, player i expects player j's next-period action to be drawn randomly, and uses the observed frequency distribution of player j's past actions as the expected distribution.

A general model of naive Bayesian learning with far-sighted players is formulated by Kalai and Lehrer (1993a). Player i has an arbitrarily given prior belief μ_i over the behavior strategies of the other players. Given player i's pay-off characteristics (u_i,δ_i) and the expected behavior strategies $((f^i_{jt})^\infty_{t=1})_{j\neq i}$, player i chooses a best-response behavior strategy $(f^i_{it})^\infty_{t=1}$. Kalai and Lehrer do not assume that prior beliefs are common across players, so players i and j may have different expectations about the behavior strategies of player k. A behavior strategy specifies what a player would do in response to every possible history, and Nash equilibrium requires that each player have the correct expectations about the behavior strategies of all other players. In particular, this requires players i and j to have the same expectations about what player k would do in response to every possible history. Kalai and Lehrer (1993b) broaden the concept of Nash equilibrium to 'subjective equilibrium' by allowing players to have different expectations about the behavior strategies of third players for histories that occur with probability zero in equilibrium. Asymptotic expectations are more appropriately compared to subjective equilibria than Nash equilibria, since the observed history may not be sufficient to resolve disparities in expectations about behavior for all histories.

CONVERGENCE TO NASH EQUILIBRIUM

In each of the Bayesian learning models described above, players form expectations about the actions of the other players and choose their own actions in each period as best responses to their expectations. The best responses, which may be mixed, constitute the probability distribution of action sequences that the players will observe over time. In the case of sophisticated Bayesian learning, the expectations are derived as Bayesian Nash equilibria from a prior belief over the pay-off characteristics that constitute the true game. Each game generates a best-response sequence, so the prior distribution over games, together with the best-response process for each game, generates a joint distribution over games and action sequences. In this context, one can ask whether a random draw of a game and action sequence from this joint distribution will produce expectations that approach Nash equilibria of the drawn game.

In the case of naive Bayesian learning, the true game is taken as given and players' expectations are given initially rather than derived as Bayesian Nash equilibria. In this case, one can ask whether a random draw from the best-response distribution over action sequences will produce expectations

that approach Nash equilibria of the true game. One can also ask this question in the case of sophisticated Bayesian learning. That is, one can take the view, common in Bayesian statistics, that the derivation of expectations from a prior distribution is merely a heuristic device for obtaining expectations, and regard the expectations and the true game as given in the same sense as in myopic Bayesian learning.

The answers that have been obtained thus far to these and other questions are described below. For games with multiple Nash equilibria, convergence to Nash equilibrium will be understood to mean that the sequence of expectations has one or more limit points, all of which are Nash equilibria.

Sophisticated Bayesian Learning

In the model of sophisticated Bayesian learning with far-sighted behavior, with probability one, a randomly drawn game and best-response path has expectations that converge to Nash equilibrium. This was proved by Jordan (1995) under the assumptions that all players have the same prior beliefs about other players' pay-off characteristics, and that the pay-off characteristics of different players are independently distributed under the common prior. The common-prior assumption implies that any two players have the same expectations about the behavior strategies of third players, ensuring that limit points are Nash equilibria as opposed to subjective equilibria. This result is inherited under myopic behavior as a special case of far-sighted behavior with zero discount factors, but in the case of myopic behavior, Nyarko has substantially generalized the assumptions on prior beliefs. Nyarko (1998) retains the independence assumption but generalizes the common prior assumption to a condition ensuring that each player's prior belief is absolutely continuous with respect to a common distribution. The concept of prior belief is also extended to a hierarchy of beliefs, beliefs about beliefs and so on. Nyarko (1994) drops the independence assumption. In this case, a player's knowledge of his or her own pay-off characteristics may provide information about the pay-off characteristics of other players. Nyarko shows that with probability one, expectations converge to correlated equilibria.

These results imply that the set of games for which expectations do not converge to equilibria has probability zero according to the prior beliefs from which the expectations are derived. For the case of myopic behavior, a stronger assumption on prior beliefs makes it possible to derive expectations that converge for every game. Suppose that the prior beliefs, in addition to being the same for all players and satisfying the independence of pay-off characteristics across players, are 'smooth', in the sense that the prior distribution has a density function with respect to Lebesgue measure that is bounded from above and bounded from below away from zero. The uniform prior, as in the 2×2 example discussed above, is the natural example. Jordan (1991) establishes that in this case, for every game, the distribution of best-response paths generates expectations that converge to Nash equilibria of the game with probability one. Except for a set of games having Lebesgue measure zero, best-response actions are unique in every period (even when there are multiple Nash equilibria), and convergence is guaranteed along the unique best-response path. Moreover, under the same assumptions, except for a set of games having Lebesgue measure zero, expectations converge to Nash equilibria at an exponential rate (Jordan, 1992).

These results can be illustrated in the 2×2 game represented by the pay-off bimatrix in Table 2. The unique Nash equilibrium of this game is the mixed equilibrium in which the row player chooses T with probability 0.4 and the column player chooses L with probability 0.6.

Under the expectations derived from the uniform prior distribution (with pay-offs normalized as above), Table 3 shows the expectations, rounded to four decimal places, and the best-response actions for the first 12 iterations.

The table illustrates the rapid convergence of expectations to the unique Nash equilibrium. However, it also illustrates a typical disparity between expectations and actions in the case of convergence to mixed equilibrium. Player 1 is rapidly learning to predict that player 2 will choose L with probability 0.4, but in every period, player 2 actually chooses L with either probability one or probability zero. Since $e_{2(t-1)}(U \mid h_{t-1})$ is never exactly 0.6, player 2 always has a unique best-response action. This raises the question whether player 1 could eventually recognize that s_{2t} is not a random draw from the expected distribution $e_{1(t-1)}(h_{t-1})$. There is a precise sense in which the answer to this question is 'no'.

Table 2. A pay-off bimatrix representing a 2×2 game

	L	*R*
U	−2, 3	3, 0
D	0, −2	0, 0

Table 3. Expectations and best-response actions for the first 12 iterations of the game in Table 2

t	s_t	$e_{1(t-1)}(L \mid h_{t-1})$	$e_{2(t-1)}(U \mid h_{t-1})$
1	*U*, *L*	0.5000	0.5000
2	*D*, *L*	0.8192	0.8192
3	*D*, *R*	0.7624	0.1494
4	*D*, *R*	0.6514	0.3917
5	*U*, *L*	0.5808	0.4552
6	*D*, *L*	0.6203	0.4314
7	*D*, *L*	0.6037	0.4158
8	*U*, *L*	0.5944	0.4061
9	*U*, *L*	0.6000	0.4004
10	*D*, *R*	0.6022	0.3970
11	*D*, *R*	0.6013	0.3990
12	*D*, *R*	0.6007	0.3998

The actual performance of any probabilistic forecasting procedure can be evaluated by means of 'calibration tests'. For example, one can ask whether it actually rained on more than half the days for which the forecast probability of rain was greater than 50%. In the case of myopic behavior, any given calibration test comparing sophisticated Bayesian expectations with the actual sequence of best-response actions will be passed for every game with the exception of a set of games having Lebesgue measure zero. This result, due to Turdaliev (2002), assumes that the prior distribution is common, independent, and smooth.

Naive Bayesian Learning

In the naive Bayesian learning model, the true game and players' expectations of each other's actions are both arbitrary, so no convergence results are possible without further assumptions. In the case of myopic behavior, fictitious play is known to converge in zero-sum games and 2×2 games, but otherwise can fail to converge (e.g. Krishna and Sjöström, 1998).

For the more general case of far-sighted behavior, Kalai and Lehrer (1993a) prove convergence under the assumption that the distribution of best-response paths determined by the true game is absolutely continuous with respect to each player's expectations. Under this assumption, they prove that each player's expectations approach the true best-response distribution, and therefore that the players' best responses are approximately Nash. In the case of myopic behavior, this is enough to ensure that each player's expectations converge to Nash equilibria. In the more general case of far-sighted behavior, two players may continue to differ in their expectations of a third player's future response to actions off the best-response path, so that expectations are only guaranteed to converge to subjective equilibria.

The absolute-continuity assumption ensures that players' best-response strategies converge to Nash equilibrium, unlike the situation demonstrated in Table 3. If, as in Table 3, expectations converge to a mixed equilibrium while the best-response actions in each period are unique, the absolute-continuity assumption is clearly violated. If the true game is the game in Table 2, then the absolute-continuity assumption requires that, after some finite number of periods, each player's expectations are equal to the unique Nash equilibrium. Otherwise the players' best-response strategies would fail to be approximately Nash infinitely often.

The convergence of best-response strategies as well as expectations means that any calibration test comparing expectations with a randomly drawn sequence of best-response actions will be passed with probability one (Kalai *et al.*, 1999). This result applies to the general case of far-sighted behavior, for every game, provided the expectations and best-response distributions satisfy the absolute-continuity assumption.

WHAT IS BEING LEARNED?

Bayesian learning enables players to learn Nash equilibrium expectations over time without knowing the pay-off functions of the other players. It is natural to ask what players must already know in order to be capable of Bayesian learning. In all Bayesian learning models, players choose their actions as best responses to their expectations, so players must know their own pay-off functions. Naive Bayesian learning takes the players' expectations about future play paths as given, although each player is aware of the separate identities of the other players, in the sense that different players are expected to choose their actions independently conditional on past play. No additional knowledge is explicitly assumed, but the absolute-continuity assumption imposes a strong implicit relation between the players' expectations and the paths of best-response actions determined by the true pay-off functions.

Sophisticated Bayesian learning can be viewed as assuming that the players are knowledgeable game theorists who derive their expectations as Bayesian Nash equilibria from a common prior distribution over the unknown pay-off functions. In addition to having a common (or at least mutually consistent)

prior distribution, players share a common selection process for choosing among multiple Bayesian Nash equilibria. The resulting structure of expectations avoids the need for the absolute-continuity assumption, albeit at the expense of losing the convergence of best-response strategies in the case of mixed equilibria.

Alternatively, the sophisticated Bayesian expectations could be viewed as having been derived by a game theorist who does not know the players' payoff functions. If the players rely on the theorist's predictions, their faith will be vindicated by the convergence of the expectations to Nash equilibria of the true game, at least in the case of myopic behavior and the theorists' use of a prior distribution satisfying the smoothness and independence conditions. Thus the sophisticated Bayesian learning model can be viewed simply as providing a class of expectation functions that can be used by myopic players in any game to learn Nash equilibrium expectations.

Bidding Strategies in Single-unit Auctions

Intermediate article

Bart Wilson, George Mason University, Fairfax, Virginia, USA

CONTENTS

Economists have developed models of auctions to enhance our understanding of one of the most commonly observed exchange institutions. Auction models are used to examine the allocation of products from an auctioneer to a number of bidders. The optimal bidding strategies and efficiency of four different auction institutions (first-price sealed bid, second-price sealed bid, English, and Dutch) can be analysed.

INTRODUCTION

Economists have developed models of auctions to enhance our understanding of one of the most commonly observed exchange institutions. Auction models are used to examine the allocation of products from an auctioneer to a number of bidders. For example, a manufacturer may procure inputs by soliciting sealed bids that name each supplier's contract price. In addition to their use in industrial procurement, auctions have been used to allocate products as varied as art, cattle, produce, government securities, and offshore mineral rights. As the internet reduces the costs of conducting auctions, this type of exchange will become still more pervasive.

AUCTION INSTITUTIONS

In this introduction to auctions and bidding, the discussion is limited to a few simplifying, yet often realistic, assumptions that will facilitate our analysis. The first is that an auctioneer is selling a single unit of a good to only one of several potential buyers, who are the bidders in the auction. The second assumption is that each bidder i knows the value v_i from consuming the item. This assumption allows each bidder to ignore any information from rivals in establishing a value estimate. The buyer's value indicates the maximum amount that the bidder is willing to pay for the item. The third assumption is that the bids b_i are statistically independent and derived from a known distribution, presumably estimated from history. Lastly, we will assume that the bidders are risk-neutral; i.e., the bidders are indifferent between playing a lottery and receiving the expected pay-off from the lottery with certainty.

The winning bidder w wins the auction, pays the price p, and receives a pay-off of $v_w - p$. All other buyers receive no pay-off. The seller's profit is $p - c$, where c is the (opportunity) cost to the seller of supplying the item. Hence, the total surplus from the exchange is $v_w - c$. The 'efficiency' of the auction – the metric by which we evaluate auction mechanisms – is defined as $(v_w - c)/(v_h - c)$, where v_h is the highest realized v_i. If the bidder with the highest value wins the auction, then the auction is perfectly efficient, or equivalently, the auction maximizes the gains from exchange.

The auctioneer chooses the institutional rules by which the bids determine who is the winning bidder and what price the winning bidder pays. As an indication of the extent to which the details of the institution matter in an auction, consider the following four different auction institutions: first-price sealed bid, second-price sealed bid, English, and Dutch auctions.

In a first-price sealed bid auction, the buyers independently submit a private sealed bid to the seller. The seller then awards the item to the highest bidder at a price equal to the highest bid. Ties are broken randomly. Note how this institution forces the buyers to simultaneously condition their bids on the other buyers' expected bids. The bidders do not use any information from the actual auction process in forming their bids.

The 'outcry' version of an English auction differs significantly from the first-price sealed bid auction in that the bidders call out increasing bids until only the highest bidder remains. Again, the highest bidder wins the auction and pays a price equal to his or her bid, but in this case the bids are conditioned on buyers' actual bids.

The second-price sealed bid auction, as its name suggests, is similar to the first-price auction in that the seller awards the item to the bidder with the highest (simultaneously submitted) bid. However, the price that the highest bidder pays is equal to the second-highest submitted bid. (In the case of a tie, one of the bidders is randomly chosen and pays the price of the other tied bidder's identical bid.)

In a Dutch auction, the auctioneer begins with a very high price which none of the bidders is willing to pay, and then in real time lowers the bid until one bidder claims the good, paying a price exactly equal to the bid called by the auctioneer.

OPTIMAL BIDDING STRATEGIES

Let us first analyze the optimal bidding strategy for the first-price sealed bid auction. For ease of exposition suppose that there are two bidders ($i = 1, 2$) whose values are independently and uniformly distributed on the interval [0, 1]. We constrain the bids to be nonnegative. Bidder i's pay-off is

$$u_i = \begin{cases} v_i - b_i & \text{if } b_i > b_j \\ \frac{(v_i - b_i)}{2} & \text{if } b_i = b_j \\ 0 & \text{if } b_i < b_j \end{cases} \quad (1)$$

A player's strategy is a function that maps values (v_i) to actions (b_i). To find the optimal bidding strategy we will assume that player 1's strategy $b_1(v_1)$ is a best response to player 2's strategy $b_2(v_2)$, and vice versa. Player 1 thus chooses the strategy b_1 to maximize the expected pay-off from the auction, or $(v_1 - b_1)\ P(b_1 > b_2(v_2))$. (Technically, we should include the pay-off $\frac{1}{2}(v_1 - b_1)\ P(b_1 = b_2(v_2))$, but since the values are continuously distributed, the probability of identical values is zero.) That is, in choosing a bid b_1, player 1 weighs the probability that b_1 will be greater than player 2's bid, which is a function of player 2's value. (*See* **Games: Coordination**)

Rasmusen (2001) provides an accessible derivation of the optimal bidding function in equilibrium, namely that a player's best-response strategy is $b_i(v_i) = \frac{v_i}{2}$. That is, each bidder submits a bid equal to one-half of the value. Notice how this optimal bidding function weighs the bidder's fundamental trade-off in the auction. The lower the bid, the more likely that the bidder will win the gain from an increased pay-off from winning the auction; but the higher the bid, the more likely that the bidder will actually win the auction. Note that the bidder with the highest value will always win the auction, so that the auction is perfectly efficient.

In contrast to a risk-neutral bidder, a risk-averse bidder will prefer to increase the probability of winning the auction at the cost of a lower pay-off by submitting a bid greater than $\frac{v_i}{2}$. In particular, it is possible that a more risk-averse bidder with a lower value will submit a bid greater than that of the bidder with the highest value who is less risk-averse. This results in an inefficient allocation if the highest bidder does not win the auction.

Now consider the English auction. If the auctioneer starts the bidding at the price of zero, every bidder is willing to purchase the item and is willing to submit a bid of some minimum increment, say 0.01. Each bidder continues to raise the bid until the standing bid exceeds his or her value. This process continues until the bidder with the second-highest value drops out of the auction at price equal to v_i (± 0.01). Hence, the bidder with the highest value wins the auction and pays a price equal to the second-highest value (± 0.01). This auction is also perfectly efficient. Furthermore, risk aversion does not change this result. Because the bidding occurs in real time, a bidder always knows whether or not he or she holds the highest bid and what is necessary to become the current highest bidder. Trying to determine the optimal bid as a function of this value is unnecessary: a bidder can always respond with a highest bid until the current highest bid exceeds his or her value. Hence, the cognitive costs of participating in this auction are much lower. (*See* **Markets, Institutions and Experiments**)

Even though it is a one-shot game, bidding incentives in a second-price auction lead to outcomes identical to those in an English auction. The optimal bidding strategy in a second-price sealed bid auction is a simple one: $b_i = v_i$. To understand why, first note that it is never profitable for a bidder i to submit a bid b_i greater than v_i, because if the second-highest bid happens to be less than b_i but greater than v_i then bidder i wins the auction but incurs a negative pay-off since the price (the second-highest bid) is greater than the value v_i. To eliminate such a possibility, the bidder should reduce his or her bid to v_i. A bidder should also never submit a bid less than the value, because the bidder gains nothing in terms of pay-off should he or she win: the price is determined by the second-highest bid, submitted by another bidder. Moreover, lowering a bid only reduces the likelihood that the bidder actually submits the highest bid and is declared winner. Hence, the optimal bid in a second-price sealed bid auction is $b_i = v_i$.

An interesting feature of this result is that bidding one's value is optimal, independently of the

other bidders' actions. A strategy that is always a best response to any strategy employed by the other players is known as a dominant strategy (see Rasmusen (2001) for a discussion). Notice that when every bidder plays the dominant strategy, the bidder with the highest value wins the auction and pays the price equal to the second-highest bid, which is equivalently the second-highest value. This outcome is identical to that of the English auction. Notice also that because setting $b_i = v_i$ is optimal regardless of what the other players do, the outcomes in this auction institution are robust to risk aversion: a bidder can never lose and only gain by playing the dominant strategy. Hence, the second-price sealed bid auction is perfectly efficient with risk-averse or risk-neutral bidders.

While seemingly quite different from the first-price sealed bid auction, the Dutch auction is strategically equivalent to it. We will call the successively lower prices offered by the auctioneer the 'bid' in a Dutch auction. When the auction begins at a very high bid, a bidder will first consider claiming the item when the bid falls to v_i. If another bidder has not already claimed the item by the time the bid reaches v_i, then the bidder must consider allowing the auctioneer to continue lowering the bid to increase the pay-off to the bidder from winning the auction, but the further the bid drops, the more likely it becomes that another bidder will actually win the auction at a price less than the bidder's own value. A bidder evaluates precisely the same trade-off in the first-price auction. Because the winner in a Dutch auction pays a price equal to his or her bid, the optimal bidding strategy, and concomitant results for efficiency and prices, in a Dutch auction are isomorphic to those in a first-price sealed bid auction.

EXPERIMENTAL RESULTS

There have been many experimental studies of bidding behavior in auctions (for a more comprehensive discussion, see Kagel and Roth (1995)). Two early studies test the strategic equivalence of first-price and Dutch auctions. Coppinger *et al*. (1980) and Cox *et al*. (1982) both find that prices are higher in first-price auctions than in Dutch auctions, and that bidding is consistent with risk-averse behavior. Cox *et al*. (1982) suggest two alternative models for the lower bidding in Dutch auctions. The first conjecture is that the bidders derive utility from the 'suspense' associated with the anticipation of purchasing at a lower and lower price, which is added to the pay-off from buying at a price less than the value for it. The second conjecture is that the real-time nature of the Dutch auction leads bidders to mistakenly update the estimates of their rivals' values to be lower when no one has taken the item at successively lower prices. Cox *et al*. (1983) test these alternative explanations and find that the probability miscalculation hypothesis cannot be rejected in favor of the suspense hypothesis. (*See* **Asset Market Experiments**; **Choice under Uncertainty**)

The predicted isomorphism between English and second-price auctions also fails to be observed. Coppinger *et al*. (1980) and Kagel *et al*. (1987) find that bidding in the English outcry auction conforms to the theoretical predictions, while in the one-shot second-price auction bidders consistently bid higher than the dominant-strategy prediction, even with experience in the auction mechanism (Kagel and Levin, 1993). One explanation for the deviation in behavior is that the real-time nature of the English auctions produces strong, immediate, and overt feedback as to what a bidder should and should not bid. The English auction makes immediately transparent the potential of a negative pay-off from bidding above one's value. The one-shot nature of the second-price auction obscures this realization. If the highest-value buyer submits a bid slightly greater than his or her value and still wins the auction, but the price (equal to the second-highest bid) is still less than that value, then the winning bidder is no worse off for having bid above the value. Since the price equals the second-highest bid, Kagel *et al*. speculate that bidders are deceived by the illusion that bidding higher is a low-cost means of increasing the probability of winning. This raises an interesting question for further research. Is this illusion based on familiarity with the standard first-price sealed bid and English auctions, where the buyer's own bid simultaneously determines the price and improves his or her chances of winning? Or does bidding one's own value present a cognitive impediment?

Choice under Uncertainty

Advanced article

Mark J Machina, University of California, San Diego, California, USA

CONTENTS

The standard theory of individual choice under uncertainty consists of the joint hypothesis of expected utility risk preferences and probabilistic beliefs. Experimental work by both psychologists and economists has uncovered systematic departures from both hypotheses, and has led to the development of alternative, usually more general, models.

INTRODUCTION

Decisions under uncertainty take place in two types of settings. In settings of 'objective uncertainty', the probabilities attached to the various outcomes are specified in advance, and the objects of choice consist of 'lotteries' of the form $P = (x_1, p_1; \ldots; x_n, p_n)$, which yield outcomes or monetary pay-offs x_i with probability p_i, where $p_1 + \ldots + p_n = 1$. Examples include games of chance involving dice and roulette wheels, as well as ordinary lotteries.

In settings of 'subjective uncertainty', probabilities are not given, and the objects of choice consist of 'bets' or 'acts' $f(\cdot) = [x_1 \text{ on } E_1; \ldots; x_n \text{ on } E_n]$, which yield outcomes or pay-offs x_i in event E_i, for some mutually exclusive and exhaustive collection of events $\{E_1, \ldots, E_n\}$ which can be thought of as a partition of the set S of all possible 'states of nature'. Examples include bets on horse races or the weather, as well as standard insurance contracts.

Under objective uncertainty, choices are determined by an individual's attitudes towards risk. Under subjective uncertainty, they are additionally determined by the individual's subjective beliefs about the likelihoods of the various states and events.

EXPECTED UTILITY THEORY AND EXPERIMENTAL EVIDENCE

Axiomatic and Normative Foundations of Expected Utility Theory

The earliest formal hypothesis of individual attitudes towards risk, proposed by Pascal, Fermat and others in the seventeenth century, was that individuals evaluate monetary lotteries $P = (x_1, p_1; \ldots; x_n, p_n)$ simply on the basis of their mathematical expectation $E[P] = \sum_{i=1}^{n} x_i \cdot p_i$. This hypothesis was dramatically refuted by Daniel Bernoulli's 'St Petersburg paradox'. In this game, a fair coin is repeatedly flipped until it lands heads. If it lands heads on the first flip, the player wins \$1; if it does not land heads until the second flip, the player wins \$2; and in general, if it does not land heads until the i^{th} flip, the player wins $\$2^{i-1}$. Most people would prefer to receive a sure payment of, say, \$50 than a single play of the St Petersburg game, even though the expected pay-off of the game is $\frac{1}{2}\cdot\$1 + \frac{1}{4}\cdot\$2 + \frac{1}{8}\cdot\$4 + \ldots = \$\frac{1}{2} + \$\frac{1}{2} + \$\frac{1}{2} + \ldots = \$\infty$. In the first of what has turned out to be a long series of such developments, Bernoulli weakened the prevailing expected-value hypothesis by positing that individuals instead evaluate lotteries on the basis of their 'expected utility' $\sum_{i=1}^{n} U(x_i) \cdot p_i$, where the utility $U(x)$ of receiving a monetary amount x is probably subproportional to x. Bernoulli himself proposed the form $U(x) = \ln(x)$, which leads to an evaluation of the St Petersburg game consistent with typical actual play.

The expected utility hypothesis came to dominate decision theory on the twin bases of its elegant and highly normative axiomatic development (von Neumann and Morgenstern, 1944; Marschak, 1950)

and its analytical power (Arrow, 1965; Pratt, 1964). In the modern approach, risk preferences are denoted by the individual's 'weak preference' relation $\succeq$ over lotteries, where $P^* \succeq P$ reads 'P^* is weakly preferred to P', and its implied 'strict preference' relation $\succ$ (where $P^* \succ P$ iff $P^* \succeq P$ but not $P \succeq P^*$) and 'indifference' relation $\sim$ (where $P^* \sim P$ iff $P^* \succeq P$ and $P \succeq P^*$). The preference relation $\succeq$ is said to be 'represented' by an expected utility preference function $V_{\mathrm{EU}}(P) = \sum_{i=1}^{n} U(x_i) \cdot p_i$ if $P^* \succeq P \Leftrightarrow V_{\mathrm{EU}}(P^*) \geq V_{\mathrm{EU}}(P)$. $U(\cdot)$ is called the 'von Neumann–Morgenstern utility function'.

The axiomatic and normative underpinnings of expected utility theory are based on the notion of a 'probability mixture' $\alpha \cdot P + (1-\alpha) \cdot P^*$ of two lotteries $P = (x_1, p_1; \ldots; x_n, p_n)$ and $P^* = (x_1^*, p_1^*; \ldots; x_{n^*}^*, p_{n^*}^*)$, which is the lottery that would be generated by a coin flip yielding the lotteries P and P^* as prizes with respective probabilities α and $1-\alpha$, and where both stages of uncertainty (the coin flip and the resulting lottery) are realized simultaneously, so that we can write $\alpha \cdot P + (1-\alpha) \cdot P^* = (x_1, \alpha \cdot p_1; \ldots; x_n, \alpha \cdot p_n; x_1^*, (1-\alpha) \cdot p_1^*; \ldots; x_{n^*}^*, (1-\alpha) \cdot p_{n^*}^*)$. A preference relation $\succeq$ will then be represented by an expected utility preference function $V_{\mathrm{EU}}(\cdot)$ for some utility function $U(\cdot)$ if and only it satisfies the following axioms:

- *Completeness*. For all lotteries P and P^*, either $P \succeq P^*$ or $P^* \succeq P$, or both.
- *Transitivity*. For all lotteries P, P^* and P^{**}, if $P \succeq P^*$ and $P^* \succeq P^{**}$ then $P \succeq P^{**}$.
- *Mixture Continuity*. For all lotteries P, P^* and P^{**}, if $P \succ P^*$ and $P^* \succ P^{**}$ then $P^* \sim \alpha \cdot P + (1-\alpha) \cdot P^{**}$ for some $\alpha \in (0,1)$.
- *Independence Axiom*. For all lotteries P, P^* and P^{**} and all $\alpha \in (0,1)$, if $P \succeq P^*$ then $\alpha \cdot P + (1-\alpha) \cdot P^{**} \succeq \alpha \cdot P^* + (1-\alpha) \cdot P^{**}$.

Completeness and Transitivity are standard axioms in preference theory, and Mixture Continuity serves as the standard Archimedean property in the context of choice over lotteries. The key normative and behavioral axiom of the theory is the Independence axiom. Behaviorally, it corresponds to the property of separability across mutually exclusive events. Normatively, it corresponds to the following argument: 'Say you weakly prefer P to P^*, and have to choose between an α:$(1-\alpha)$ coin flip yielding P if heads and P^{**} if tails, or an α:$(1-\alpha)$ coin flip yielding P^* if heads and P^{**} if tails. Now, either the coin will land tails, in which case your choice won't have mattered, or it will land heads, in which case you are back to a choice between P and P^*, so you should weakly prefer the first coin flip to the second.'

The tension between the compelling nature of the Independence axiom and its systematic violations by experimental subjects has led to a sustained debate over the validity of the expected utility model, with some researchers continuing to posit expected utility maximization, and others developing and testing alternative models of risk preferences.

Analytics of Expected Utility Theory

Analytically, the expected utility hypothesis is characterized by the simplicity of its representation (involving the standard concepts of utility and mathematical expectation) as well as by the elegance of the correspondence between standard features of risk preferences and mathematical properties of $U(\cdot)$. The most basic of these properties is 'first-order stochastic dominance preference', which states that raising the level of some pay-off x_i in a lottery $P = (x_1, p_1; \ldots; x_n, p_n)$ – or alternatively, increasing its probability p_i at the expense of a reduction in the probability p_j of some smaller pay-off x_j – will lead to a preferred lottery. An expected utility maximizer's preferences will exhibit first-order stochastic dominance preference if and only if $U(\cdot)$ is an increasing function of x.

A second property is 'risk aversion'. Originally, this was defined as the property whereby the individual would always prefer receiving the expected value of a given lottery with certainty, rather than bearing the risk of the lottery itself. This is equivalent to the condition that the individual's 'certainty equivalent' $\mathrm{CE}(P)$ of a nondegenerate lottery $P = (x_1, p_1; \ldots; x_n, p_n)$ – that is, the value that satisfies $U(\mathrm{CE}(P)) = \sum_{i=1}^{n} U(x_i) \cdot p_i$ – is always less than the expected value of P. In modern treatments, risk aversion is defined as an aversion to all 'mean-preserving spreads' from any (degenerate or nondegenerate) lottery, where a mean-preserving spread consists of a decrease in the probability of a pay-off x_i by some amount Δp, and increases in the probabilities of some higher and lower pay-offs $x_i + \alpha$ and $x_i - \beta$ by the respective amounts $\Delta p \cdot \beta/(\alpha+\beta)$ and $\Delta p \cdot \alpha/(\alpha+\beta)$. This 'spreads' the probability mass of the lottery in a manner that does not change its expected value, so it can be thought of as a 'pure increase in risk'. An expected utility maximizer will be risk-averse in both the original and the modern senses if and only if $U(\cdot)$ is a strictly concave function of x. If $U(\cdot)$ is twice continuously differentiable, strict concavity is equivalent to a negative second derivative $U''(\cdot)$. Although the widespread purchase of actuarially unfair state lottery tickets is evidence of the opposite property of 'risk preference', the even

more widespread purchase of insurance and the prevalence of other risk-reducing instruments has led researchers to hypothesize that individuals are for the most part risk-averse.

After these basic characterizations, the most important analytical result in expected utility theory is the Arrow–Pratt characterization of 'comparative risk aversion', which states that the following four conditions on a pair of risk-averse von Neumann–Morgenstern utility functions $U_A(\cdot)$ and $U_B(\cdot)$ are equivalent:

- *Comparative Concavity*. $U_A(\cdot)$ is an increasing concave transformation of $U_B(\cdot)$, that is, $U_A(x) \equiv \rho(U_B(x))$ for some increasing concave function $\rho(\cdot)$.
- *Comparative Arrow–Pratt Measures*. $-U_A''(x)/U_A'(x) \geq -U_B''(x)/U_B'(x)$ for all x.
- *Comparative Certainty Equivalents*. For any lottery $P = (x_1, p_1; \ldots; x_n, p_n)$, if $\mathrm{CE}_A(P)$ and $\mathrm{CE}_B(P)$ satisfy $U_A(\mathrm{CE}_A(P)) = \sum_{i=1}^n U_A(x_i)\cdot p_i$ and $U_B(\mathrm{CE}_B(P)) = \sum_{i=1}^n U_B(x_i)\cdot p_i$, then $\mathrm{CE}_A(P) \leq \mathrm{CE}_B(P)$.
- *Comparative Demand for Risky Assets*. For any initial wealth W, constant $r > 0$, and random variable $\tilde{x}$ such that $E[\tilde{x}] > r$ but $P(\tilde{x} < r) > 0$, if γ_A^* and γ_B^* respectively maximize $E[U_A(\gamma\cdot\tilde{x} + (W-\gamma)\cdot r)]$ and $E[U_B(\gamma\cdot\tilde{x} + (W-\gamma)\cdot r)]$, then $\gamma_A^* \leq \gamma_B^*$.

(Note: here and elsewhere we write $P(\cdot)$ for the probability of an event. This should not be confused with the use of P to stand for a lottery.)

Each of these conditions can be interpreted as saying that $U_A(\cdot)$ is at least as risk-averse as $U_B(\cdot)$. The first condition extends the above characterization of risk aversion by the concavity of $U(\cdot)$ to its comparative version across individuals, and the second shows that this can be expressed in terms of a numerical index $-U''(x)/U'(x)$, known as the 'Arrow–Pratt index of absolute risk aversion'. The third condition extends the original notion of risk aversion as low certainty equivalents (lower than the mean) to its comparative form.

The fourth condition involves comparative optimization behavior. Consider an individual with initial wealth W to be divided between a riskless asset yielding gross return r, and a risky asset whose gross return $\tilde{x}$ has a higher expected value, but offers some risk of doing worse than the riskless asset. This condition states that the less risk-averse utility function $U_B(\cdot)$ will always choose to invest at least as much in the risky asset as will the more risk-averse $U_A(\cdot)$.

The equivalence of the above four conditions, the first two mathematical and the second two behavioral, and their numerous additional behavioral equivalencies and implications, has made the Arrow–Pratt characterization one of the central theorems in the analytics of expected utility theory, with applications in insurance, financial markets, auctions, the demand for information, bargaining, and game theory.

Experimental Evidence on the Independence Axiom

Experimental testing of the expected utility hypothesis has centered on the Independence axiom, either directly or via its implication that the expected utility preference function $V_{\mathrm{EU}}(P) = \sum_{i=1}^n U(x_i)\cdot p_i$ is linear in the probabilities p_i. One of the best-known tests is the 'Allais paradox' (Allais, 1953). An individual is asked to rank each of the following two pairs of lotteries (where \$1M = \$1,000,000):

- $a_1 = \{1.00$ chance of \$1M versus
  $a_2 = \begin{cases} .10 \text{ chance of } \$5\text{M} \\ .89 \text{ chance of } \$1\text{M} \\ .01 \text{ chance of } \$0 \end{cases}$
- $a_3 = \begin{cases} .10 \text{ chance of } \$5\text{M} \\ .90 \text{ chance of } \$0 \end{cases}$ versus
  $a_4 = \begin{cases} .11 \text{ chance of } \$1\text{M} \\ .89 \text{ chance of } \$0 \end{cases}$

The expected utility hypothesis implies that the individual's choices from these two pairs must either be a_1 and a_4 (whenever $.11\cdot U(\$1\text{M}) > .10\cdot U(\$5\text{M}) + .01\cdot U(\$0)$), or else a_2 and a_3 (whenever $.11\cdot U(\$1\text{M}) < .10\cdot U(\$5\text{M}) + .01\cdot U(\$0)$). However, when presented with these choices, most subjects choose a_1 from the first pair and a_3 from the second, which violates the hypothesis. Only a small number violate the hypothesis in the opposite direction, by choosing a_2 and a_4.

Although the Allais paradox was originally dismissed as an 'isolated example', subsequent experimental work by psychologists, economists and others has uncovered a similar pattern of violation over a range of probability and pay-off values, and the Allais paradox is now seen to be just one example of a type of systematic violation of the Independence axiom known as the 'common-consequence effect'. It is observed that for lotteries P, P^* and P^{**}, pay-off c, and mixture probability $\alpha \in (0,1)$, such that P^{**} first-order-stochastically dominates P^* and c lies between the highest and lowest pay-offs in P, preferences depart from the Independence axiom in the direction of exhibiting $\alpha\cdot P + (1-\alpha)\cdot P^* \succ \alpha\cdot c + (1-\alpha)\cdot P^*$ yet $\alpha\cdot P + (1-\alpha)\cdot P^{**} \prec \alpha\cdot c + (1-\alpha)\cdot P^{**}$. (In the Allais paradox, these constructs are $P = (\$5\text{M}, 10/11; \$0, 1/11)$, $P^* = (\$0, 1), P^{**} = (\$1\text{M}, 1), c = \$1\text{M}$ and $\alpha = .11$.)

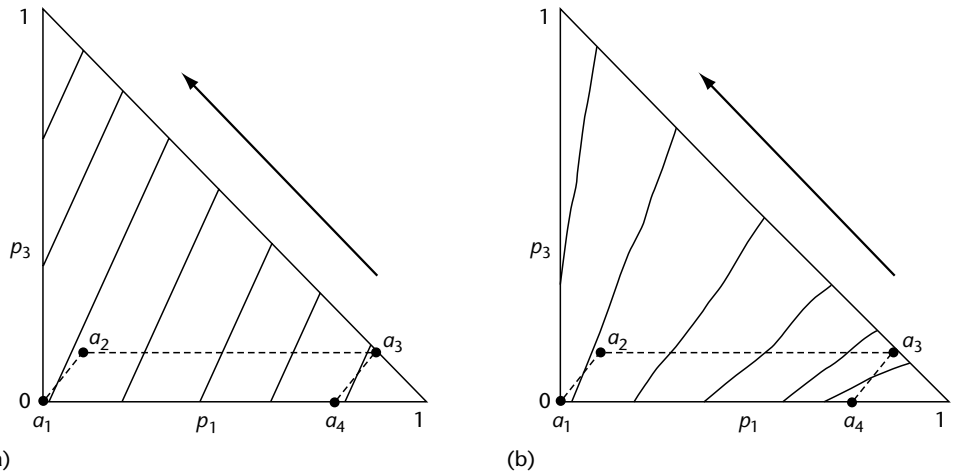

Figure 1. Indifference curves in the probability triangle. (a) Expected utility indifference curves, which are parallel straight lines. (b) Non-expected utility indifference curves, which 'fan out', illustrating the common-consequence effect.

Both the implications of the Independence axiom and the nature of this violation can be illustrated in the special case of all lotteries $P = (\bar{x}_1, p_1; \bar{x}_2, p_2; \bar{x}_3, p_3)$ over a triple of fixed pay-off values $\bar{x}_1 < \bar{x}_2 < \bar{x}_3$. Since we can write $P = (\bar{x}_1, p_1; \bar{x}_2, 1 - p_1 - p_3; \bar{x}_3, p_3)$, each such lottery is uniquely associated with a point in the (p_1, p_3) triangles of Figures 1(a) and 1(b). Since we can write $V_{\mathrm{EU}}(P) = U(\bar{x}_1)\cdot p_1 + U(\bar{x}_2)\cdot(1 - p_1 - p_3) + U(\bar{x}_3)\cdot p_3$, the loci of constant expected utility ('expected utility indifference curves') consist of parallel straight lines as in Figure 1(a). Since upward shifts in the triangle represent increases in p_3 at the expense of p_2, and leftward shifts represent reductions in p_1 to the benefit of p_2, first-order stochastic dominance preference implies that these indifference curves will be upward-sloping, with increasing levels of preference in the direction indicated by the arrows.

Fixing the pay-offs at $\bar{x}_1 = \$0$, $\bar{x}_2 = \$1\mathrm{M}$ and $\bar{x}_3 = \$5\mathrm{M}$, the Allais paradox lotteries a_1, a_2, a_3 and a_4 are seen to form a parallelogram when plotted in the probability triangle, which explains why parallel straight-line expected utility indifference curves must either prefer a_1 and a_4 (as illustrated for the relatively steep indifference curves of Figure 1(a)) or else prefer a_2 and a_3 (for relatively flat expected utility indifference curves). Figure 1(b) illustrates 'non-expected utility indifference curves' that 'fan out', and are seen to exhibit the typical Allais paradox rankings of $a_1 \succ a_2$ and $a_3 \succ a_4$.

Another type of systematic experimental violation of the Independence axiom that has been uncovered is known as the 'common-ratio effect'. For pay-offs $x^* > x > 0$, probabilities $p^* < p$ and $r \in (0, 1)$, preferences depart from the Independence axiom in the direction of exhibiting $(x^*, p^*; 0, 1 - p^*) \prec (x, p; 0, 1 - p)$ yet $(x^*, r\cdot p^*; 0, 1 - r\cdot p^*) \succ (x, r\cdot p; 0, 1 - r\cdot p)$. For losses $0 > -x > -x^*$, with $p^* < p$ and $r \in (0, 1)$, preferences depart in the reflected direction of $(-x^*, p^*; 0, 1 - p^*) \succ (-x, p; 0, 1 - p)$ yet $(-x^*, r\cdot p^*; 0, 1 - r\cdot p^*) \prec (-x, r\cdot p; 0, 1 - r\cdot p)$.

With the pay-offs $\bar{x}_1 = 0$, $\bar{x}_2 = x$ and $\bar{x}_3 = x^*$, the line segment between the lotteries $b_1 = (x^*, p^*; 0, 1 - p^*)$ and $b_2 = (x, p; 0, 1 - p)$ in the probability triangle of Figure 2(a) is seen to be parallel to that between $b_3 = (x^*, r\cdot p^*; 0, 1 - r\cdot p^*)$ and $b_4 = (x, r\cdot p; 0, 1 - r\cdot p)$, and the common-ratio-effect rankings of $b_1 \prec b_2$ and $b_3 \succ b_4$ again suggests that indifference curves depart from expected utility by fanning out. For losses, with $\bar{x}_1 = -x^*$, $\bar{x}_2 = -x$ and $\bar{x}_3 = 0$ (to maintain the ordering $\bar{x}_1 < \bar{x}_2 < \bar{x}_3$), the reflected rankings of $-b_1 \succ -b_2$ and $-b_3 \prec -b_4$ again suggest fanning out, as in Figure 2(b). Fanning out is consistent with other observed forms of departure from the Independence axiom, although it is not universal across subjects, and seems to be more pronounced near the edges of the triangle than in its central region.

GENERALIZATIONS OF EXPECTED UTILITY THEORY

Non-Expected Utility Functional Forms

The above phenomena, as well as other systematic departures from linearity in the probabilities, have prompted researchers to develop more general models of preferences over lotteries, primarily by generalizing the functional form of the lottery preference function $V(P) = V(x_1, p_1; \ldots; x_n, p_n)$. The earliest of these attempts, which used the form $V(P) = \sum_{i=1}^{n} U(x_i)\cdot\pi(p_i)$, was largely abandoned

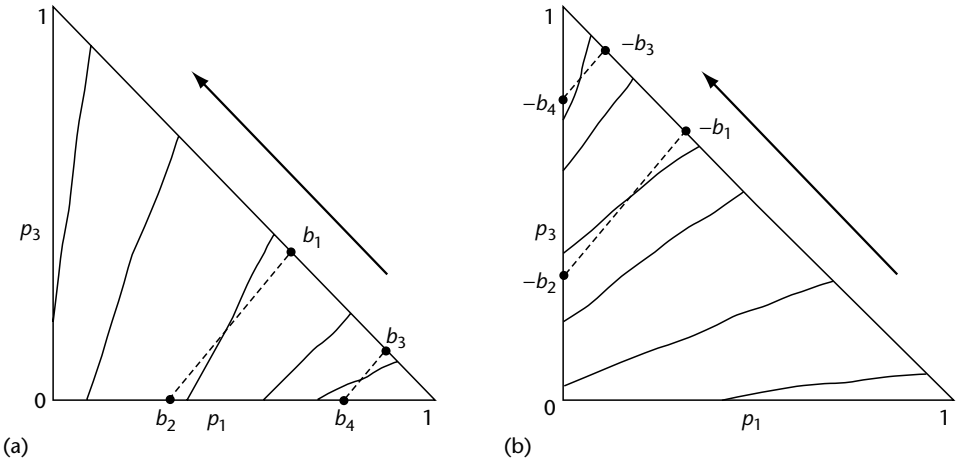

Figure 2. Probability triangles illustrating the common-ratio effect. (a) Positive pay-offs. (b) Negative pay-offs (losses).

when it was realized that, except for the case $\pi(p) \equiv p$ when it reduced to expected utility, it was inconsistent with the property of first-order stochastic dominance preference. Current models include the following:

- *Weighted Utility*. $V(P) = \sum_{i=1}^{n} U(x_i)\cdot\pi(p_i)/\sum_{i=1}^{n} S(x_i)\cdot\pi(p_i)$
- *Moments of Utility*. $V(P) = F(\sum_{i=1}^{n} U(x_i)\cdot p_i, \sum_{i=1}^{n} U(x_i)^2\cdot p_i, \sum_{i=1}^{n} U(x_i)^3\cdot p_i)$
- *Rank-Dependent Expected Utility*. $V(P) = \sum_{i=1}^{n} U(x_i)\cdot(G(\sum_{j=1}^{i} p_j) - G(\sum_{j=1}^{i-1} p_j))$for $x_1 \preceq \ldots \preceq x_n$
- *Quadratic in the Probabilities*. $V(P) = \sum_{i=1}^{n}\sum_{j=1}^{n} T(x_i, x_j)\cdot p_i\cdot p_j$

Under the appropriate monotonicity or curvature assumptions on their constituent functions $U(\cdot)$, $\pi(\cdot)$, $G(\cdot)$, etc., each of these forms is capable of exhibiting first-order stochastic dominance preference, risk aversion and comparative risk aversion, as well as many of the types of observed systematic violations of the Independence axiom. Researchers have also used these forms to revisit many of the applications previously modeled by expected utility theory (e.g. insurance, financial markets, auctions), to determine which of the earlier expected utility-based results are crucially dependent on preferences exhibiting the expected utility functional form, and which are robust to departures from expected utility.

Generalized Expected Utility Analysis

An alternative branch of research on non-expected utility preferences does not rely on any specific functional form, but links properties of attitudes towards risk directly with the probability derivatives of a general (i.e. not necessarily expected utility) preference function $V(P) = V(x_1, p_1; \ldots; x_n, p_n)$ over lotteries. Such analysis reveals that the basic analytics of the expected utility model as outlined above are in fact quite robust to general smooth departures from linearity in the probabilities. It proceeds from the correspondence between the properties of a linear function as determined by its coefficients and the properties of a nonlinear function as determined by its partial derivatives – in this case, between the 'probability coefficients' $U(x_1), \ldots, U(x_n)$ of the expected utility form $\sum_{i=1}^{n} U(x_i)\cdot p_i$ and the 'probability derivatives' $\partial V(x_1, p_1; \ldots; x_n, p_n)/\partial p_1, \ldots, \partial V(x_1, p_1; \ldots; x_n, p_n)/\partial p_n$ of a general smooth preference function $V(x_1, p_1; \ldots; x_n, p_n)$. Under such a correspondence, most of the fundamental analytical results of expected utility theory pass through directly (Machina, 1982). For example:

- *First-Order Stochastic Dominance Preference*. Under expected utility, this is equivalent to $U(x)$ (the coefficient of $P(x)$) being an increasing function of x. For a general smooth $V(\cdot)$, if $\partial V(P)/\partial P(x)$ is an increasing function of x at every lottery P, then for any pay-offs $x_i > x_j$ we will have $\partial V(P)/\partial p_i > \partial V(P)/\partial p_j$ at each P, so any (small or large) rise in p_i and matching fall in p_j will lead to an increase in $V(P)$ and hence will be preferred.
- *Risk Aversion*. Under expected utility, this is equivalent to $U(x)$ being a strictly concave function of x. For a general smooth $V(\cdot)$, if $\partial V(P)/\partial P(x)$ is a strictly concave function of x at each P, then for any pay-offs $x_i - \beta < x_i < x_i + \alpha$ we will have $[\partial V(P)/\partial P(x_i) - \partial V(P)/\partial P(x_i - \beta)]/\beta > [\partial V(P)/\partial P(x_i + \alpha) - \partial V(P)/\partial P(x_i)]/\alpha$ at each P, which implies that each mean-preserving spread over the pay-offs $x_i - \beta < x_i < x_i + \alpha$ will lead to a reduction in $V(P)$ and hence will be dispreferred.
- *Comparative Risk Aversion*. Under expected utility, this is equivalent to $U_A(\cdot)$ being an increasing concave transformation of $U_B(\cdot)$. For general smooth $V_A(\cdot)$ and

$V_B(\cdot)$, if at each P the function $\partial V_A(P)/\partial P(x)$ is some increasing concave transformation of $\partial V_B(P)/\partial P(x)$, then $V_A(\cdot)$ and $V_B(\cdot)$ will exhibit the above conditions for comparative certainty equivalence and comparative demand for risky assets.

In addition to the above theoretical results, this approach also allows for a direct characterization of the fanning-out property in terms of how the probability derivative $\partial V(P)/\partial P(x)$, treated as a function of x, varies with the lottery P. Namely, the indifference curves of a preference function $V(\cdot)$ will fan out for all pay-offs $\bar{x}_1 < \bar{x}_2 < \bar{x}_3$ if and only if $\partial V(P^*)/\partial P(x)$ is a concave transformation of $\partial V(P)/\partial P(x)$ whenever P^* first-order-stochastically dominates P.

Regret Theory

Another type of non-expected utility model dispenses with the assumption of an underlying preference order $\succeq$ over lotteries, and instead derives choice behavior from the underlying psychological notion of 'regret' – that is, the reaction to receiving an outcome x when an alternative decision would have led to a preferred outcome x^* (Loomes and Sugden, 1982). The opposite experience, namely of receiving an outcome that is preferred to what the alternative decision would have yielded, is termed 'rejoice'. The primitive for this model is a 'rejoice function' $R(x, x^*)$ which is positive if x is preferred to x^*, negative if x^* is preferred to x, and zero if they are indifferent, and satisfies the skew-symmetry condition $R(x, x^*) \equiv -R(x^*, x)$.

In the simplest case of pairwise choice over two lotteries $P = (x_1, p_1; \ldots; x_n, p_n)$ and $P^* = (x_1^*, p_1^*; \ldots; x_{n^*}^*, p_{n^*}^*)$ that are realized independently, the individual's expected rejoice from choosing the lottery P over the alternative lottery P^* is given by the formula $\sum_{i=1}^{n}\sum_{j=1}^{n^*} R(x_i, x_j^*)\cdot p_i \cdot p_j^*$, and the individual is predicted to choose P if this value is positive, to choose P^* if it is negative, and to be indifferent if it is zero. Various proposals for extending this approach beyond pairwise choice have been made, including a formal result that shows that for any finite collection of lotteries, one of these lotteries or some randomization over them will exhibit nonnegative expected rejoice with respect to every other lottery or randomization.

As with the non-expected utility functional forms listed above, various monotonicity and curvature assumptions on the rejoice function $R(\cdot,\cdot)$ can be shown to correspond to various properties of risk preferences, such as risk aversion and comparative risk aversion, as well as to the general fanning-out property. Since this model derives from the pairwise comparison of lotteries rather than from their individual evaluation by some preference function, it allows pairwise choice to be intransitive, so that an individual could choose P over P^*, P^* over P^{**}, and P^{**} over P. Although some have argued that such cyclic choice allows for the phenomenon of 'money pumps', it also allows the model to solve the problem of 'preference reversal' described below.

SUBJECTIVE EXPECTED UTILITY AND AMBIGUITY

Axiomatic and Normative Foundations of Subjective Expected Utility

The expected utility model of choice under subjective uncertainty – sometimes called the 'subjective expected utility' model – hypothesizes that the individual's preference relation $\succeq$ over subjective acts $f(\cdot) = [x_1 \text{ on } E_1; \ldots; x_n \text{ on } \mathrm{E_n}]$ can be represented by a preference function of the form $W_{\mathrm{SEU}}(f(\cdot)) = \sum_{i=1}^{n} U(x_i)\cdot\mu(E_i)$ for some von Neumann–Morgenstern utility function $U(\cdot)$ and 'subjective probability measure' $\mu(\cdot)$ over events. Thus, both attitudes towards risk and subjective beliefs are specific to the individual, and the values $\mu(E_1), \ldots, \mu(E_n)$ are sometimes called 'personal probabilities'. By virtue of its independent representation of risk attitudes by the utility function $U(\cdot)$, and beliefs by the subjective probability measure $\mu(\cdot)$, the subjective expected utility model is sometimes described as achieving a 'separation of preferences and beliefs'.

By analogy with the probability mixture of two objective lotteries, the axiomatic and normative underpinnings of the subjective expected utility model are based on the notion of a 'subjective mixture' $[f(\cdot) \text{ on } E; f^*(\cdot) \text{ on } \sim E]$ of two acts $f(\cdot) = [x_i \text{ on } E_1; \ldots; x_n \text{ on } E_n]$ and $f^*(\cdot) = [x_1^* \text{ on } E_1^*; \ldots; x_{n^*}^* \text{ on } E_{n^*}^*]$, which is the act that would yield the same outcome as $f(\cdot)$ should the event E occur, and the same outcome as $f^*(\cdot)$ should the event $\sim E$ occur, so that we can write $[f(\cdot) \text{ on } E; f^*(\cdot) \text{ on } \sim E] = [x_1 \text{ on } E \cap E_1; \ldots; x_n \text{ on } E \cap E_n; x_1^* \text{ on } \sim E \cap E_1^*; \ldots; x_{n^*}^* \text{ on } \sim E \cap E_{n^*}^*]$. An event E is said to be 'null' for the individual if $[x^* \text{ on } E; f(\cdot) \text{ on } \sim E] \sim [x \text{ on } E; f(\cdot) \text{ on } \sim E]$ for all outcomes x and x^* and all acts $f(\cdot)$, so that the individual effectively treats E as if it had zero likelihood. Since we can identify each outcome x with the 'constant act' $[x \text{ on S}]$, we can write $x^* \succeq x$ if and only if $[x^* \text{ on S}] \succeq [x \text{ on S}]$. The individual's preferences over subjective acts can then be represented by a subjective expected utility preference function

$W_{\text{SEU}}(f(\cdot)) = \sum_{i=1}^{n} U(x_i) \cdot \mu(E_i)$ for some $U(\cdot)$ and $\mu(\cdot)$ if and only they satisfy the following axioms (Savage, 1954):

- *Completeness*. For all acts $f(\cdot)$ and $f^*(\cdot)$, either $f(\cdot) \succeq f^*(\cdot)$ or $f^*(\cdot) \succeq f(\cdot)$, or both.
- *Transitivity*. For all acts $f(\cdot)$, $f^*(\cdot)$ and $f^{**}(\cdot)$, if $f(\cdot) \succeq f^*(\cdot)$ and $f^*(\cdot) \succeq f^{**}(\cdot)$ then $f(\cdot) \succeq f^{**}(\cdot)$.
- *Eventwise Monotonicity*. For all outcomes x^* and x, non-null events E and acts $f(\cdot)$, $[x^* \text{ on } E; f(\cdot) \text{ on } \sim E] \succeq [x \text{ on } E; f(\cdot) \text{ on } \sim E]$ if and only if $x^* \succeq x$.
- *Weak Comparative Probability*. For all events A and B and outcomes $x^* \succ x$ and $y^* \succ y$, $[x^* \text{ on } A; x \text{ on } \sim A] \succeq [x^* \text{ on } B; x \text{ on } \sim B]$ implies $[y^* \text{ on } A; y \text{ on } \sim A] \succeq [y^* \text{ on } B; y \text{ on } \sim B]$.
- *Small-Event Continuity*. For all acts $f(\cdot) \succ g(\cdot)$ and outcomes x, there exists a partition $\{E_1,\ldots,E_n\}$ such that $f(\cdot) \succ [x \text{ on } E_i; g(\cdot) \text{ on } \sim E_i]$ and $[x \text{ on } E_i; f(\cdot) \text{ on } \sim E_i] \succ g(\cdot)$ for each $i = 1,\ldots,n$.
- *Sure-Thing Principle*. For all events E and acts $f(\cdot)$, $f^*(\cdot)$, $g(\cdot)$ and $h(\cdot)$, $[f^*(\cdot) \text{ on } E; g(\cdot) \text{ on } \sim E] \succeq [f(\cdot) \text{ on } E; g(\cdot) \text{ on } \sim E]$ implies $[f^*(\cdot) \text{ on } E; h(\cdot) \text{ on } \sim E] \succeq [f(\cdot) \text{ on } E; h(\cdot) \text{ on } \sim E]$.

Completeness and Transitivity are as before, and Eventwise Monotonicity is the subjective analogue of first-order stochastic dominance preference. Weak Comparative Probability essentially ensures that the individual's 'revealed likelihood ranking' of a pair of events A and B, as given by their preference for staking the more preferred of a pair of prizes on A versus staking it on B, is stable in the sense that it does not depend on the particular prizes involved. Small-Event Continuity serves as the standard Archimedean property in the context of choice over subjective acts. The key normative and behavioral axiom of subjective expected utility theory is the Sure-Thing Principle. Behaviorally, it once again corresponds to the property of separability across mutually exclusive events. Normatively, it corresponds to the same argument as for the Independence axiom, with the objective randomization by the α:$(1-\alpha)$ coin replaced by the 'subjective randomization' via the events E and $\sim E$.

State-dependent Utility

In some subjective settings, the individual's valuation of outcomes may depend on the source of uncertainty itself. Thus, for the mutually exclusive and exhaustive events ('rain','shine') and prizes ('umbrella', 'sun lotion'), each of which is preferred to \$0, the individual may well exhibit the preferences [umbrella on rain; \$0 on shine] $\succ$ [umbrella on shine; \$0 on rain] and [sun lotion on rain; \$0 on shine] $\prec$ [sun lotion on shine; \$0 on rain], which violates the Weak Comparative Probability axiom for $x^* = \text{umbrella}$, $y^* = \text{lotion}$, $x = y = \$0$, $A = \text{rain}$ and $B = \text{shine}$, and hence is inconsistent with the subjective expected utility preference function $W_{\text{SEU}}(\cdot)$. This phenomenon, known as 'state dependence', can occur even when the outcomes are monetary pay-offs: if the state of nature is the individual's health, the utility of a \$50,000 prize may be very high in states where the individual requires a \$50,000 operation to survive, much lower in states where the individual requires much more than that for the operation, and somewhere in between in states of good health.

The subjective expected utility model can be easily adapted to accommodate the phenomenon of state dependence, by allowing the utility function $U(\cdot|E)$ to depend upon the event or state of nature, so that the preference function over acts takes the 'state-dependent expected utility' form $W_{\text{SDEU}}(x_1 \text{ on } E_1; \ldots x_n \text{ on } E_n) = \sum_{i=1}^{n} U(x_i|E_i) \cdot \mu(E_i)$. Most of the analytics of the standard (i.e. 'state-independent') form $W_{\text{SEU}}(\cdot)$ extend to the state-dependent case (Karni, 1985). However, under state dependence, subjective probabilities cannot be uniquely inferred from preferences over acts: for any state-dependent preference function $W_{\text{SDEU}}(f(\cdot)) = \sum_{i=1}^{n} U(x_i|E_i) \cdot \mu(E_i)$, and any distinct subjective probability measure $\mu^*(\cdot)$ that satisfies $\mu^*(E) > 0 \Leftrightarrow \mu(E) > 0$, $W_{\text{SDEU}}(\cdot)$ is indistinguishable from the preference function $W^*_{\text{SDEU}}(f(\cdot)) = \sum_{i=1}^{n} U^*(x_i|E_i) \cdot \mu^*(E_i)$ with $U^*(\cdot|\cdot)$ defined by $U^*(x|E) = U(x|E) \cdot [\mu(E)/\mu^*(E)]$.

Ambiguity and Nonprobabilistic Beliefs

A more serious departure from the notion of well-defined probabilistic beliefs arises from the phenomenon of 'ambiguity', which is distinct from the phenomenon of state dependence and much more difficult to model. The best-known example is the 'Ellsberg paradox' (Ellsberg, 1961). An individual must draw a ball from an opaque urn that contains 30 red balls and 60 black or yellow balls in an unknown proportion, and is offered four possible bets on the color of the drawn ball, as shown in Figure 3.

Most individuals exhibit the preference rankings $f_1(\cdot) \succ f_2(\cdot)$ and $f_4(\cdot) \succ f_3(\cdot)$. When asked why, they explain that the probability of winning under $f_2(\cdot)$ could be anywhere from 0 to $\frac{2}{3}$ whereas the probability of winning under $f_1(\cdot)$ is known to be exactly $\frac{1}{3}$, and they prefer the act that offers the known probability. Similarly, the probability of winning under $f_3(\cdot)$ could be anywhere from $\frac{1}{3}$ to 1 whereas the probability of winning under $f_4(\cdot)$ is known to be exactly $\frac{2}{3}$, so it is preferred. However, these preferences are inconsistent with any assignment of

	30 balls	60 balls	
	Red	Black	Yellow
$f_1(\cdot)$	\$100	\$0	\$0
$f_2(\cdot)$	\$0	\$100	\$0
$f_3(\cdot)$	\$100	\$0	\$100
$f_4(\cdot)$	\$0	\$100	\$100

Figure 3. Four possible bets on the color of the drawn ball in the 'Ellsberg paradox'. The proportion of black to yellow balls is unknown. Most individuals prefer $f_1(\cdot)$ to $f_2(\cdot)$ and $f_4(\cdot)$ to $f_3(\cdot)$.

numerical subjective probabilities μ(red), μ(black), μ(yellow) to the three events: if the individual were choosing on the basis of such probabilistic beliefs, the ranking $f_1(\cdot) \succ f_2(\cdot)$ would reveal that $\mu(\text{red}) > \mu(\text{black})$, but the ranking $f_4(\cdot) \succ f_3(\cdot)$ would reveal that $\mu(\text{red}) < \mu(\text{black})$.

This phenomenon be cannot be accommodated by simply allowing the event to enter the utility function and working with the state-dependent form $\sum_{i=1}^{n} U(x_i|E_i)\cdot\mu(E_i)$, since this form still satisfies the Sure-Thing Principle, whereas the preferences $f_1(\cdot) \succ f_2(\cdot)$ and $f_4(\cdot) \succ f_3(\cdot)$ violate this axiom (for $E = \text{red} \cup \text{black}$ and $\sim E = \text{yellow}$). The Ellsberg paradox and related examples are attributed to the phenomenon of 'ambiguity aversion', whereby individuals exhibit a general preference for bets based on probabilistic partitions such as {red, black ∪ yellow} rather than on ambiguous partitions such as {black, red ∪ yellow}.

Just as the Allais paradox and related violations of the Independence axiom led to the development of non-expected utility models of risk preferences, the Ellsberg paradox and related examples have led to the development of nonprobabilistic models of beliefs. The most notable of these involves replacing the additive subjective probability measure $\mu(\cdot)$ over events by a 'capacity' $C(\cdot)$, which is similar to $\mu(\cdot)$ in that it satisfies the properties $C(\emptyset) = 0$, $C(S) = 1$, and $E \subseteq E^* \Rightarrow C(E) \leq C(E^*)$, but differs from $\mu(\cdot)$ in that it is not necessarily additive. By labeling the outcomes in any act so that $x_1 \preceq \ldots \preceq x_n$ and writing the subjective expected utility formula as $W_{\text{SEU}}(f(\cdot)) = \sum_{i=1}^{n} U(x_i)\cdot\mu(E_i) = \sum_{i=1}^{n} U(x_i)\cdot(\mu(\cup_{j=1}^{i} E_j) - \mu(\cup_{j=1}^{i-1} E_j))$, we can generalize from an additive $\mu(\cdot)$ to a non-additive $C(\cdot)$ to obtain the 'Choquet expected utility' preference function $W_{\text{Choquet}}(f(\cdot)) = \sum_{i=1}^{n} U(x_i)\cdot(C(\cup_{j=1}^{i} E_j) - C(\cup_{j=1}^{i-1} E_j))$ over subjective acts (Schmeidler, 1989). Selecting $U(\$100) = 1$, $U(\$0) = 0$, $C(\text{red}) = \frac{1}{3}$, $C(\text{black} \cup \text{yellow}) = \frac{2}{3}$, $C(\text{black}) = \frac{1}{2}$, $C(\text{red} \cup \text{yellow}) = \frac{3}{4}$ yields the values $W_{\text{Choquet}}(f_1(\cdot)) = \frac{1}{3}$, $W_{\text{Choquet}}(f_2(\cdot)) = \frac{1}{4}$, $W_{\text{Choquet}}(f_3(\cdot)) = \frac{1}{2}$, $W_{\text{Choquet}}(f_4(\cdot)) = \frac{2}{3}$, which correspond to the typical Ellsberg rankings.

Another alternative to the subjective expected utility model of act preferences, also capable of exhibiting ambiguity aversion, is the 'maxmin expected utility' form, which involves a family $\{\mu_\tau(\cdot)\,|\tau \in T\}$ of additive probability measures over the events, and the preference function $W_{\max\min}(f(\cdot)) = \min_{\tau\in T} \sum_{i=1}^{n} U(x_i)\cdot\mu_\tau(E_i)$.

DESCRIPTION AND PROCEDURE INVARIANCE

Although the alternative models described above drop or weaken many of the axioms of standard objective and subjective expected utility theory, they typically retain the primary implicit assumptions of the standard theory, namely that: the objects of choice (objective lotteries or subjective acts) can be unambiguously described; net changes in wealth are combined with any initial endowment and evaluated in terms of the final wealth levels they imply; and situations that imply the same set of final opportunities (the same set of objective lotteries or same set of subjective acts over final wealth levels) will lead to the same choice. They also assume that the individual is able to perform the mathematical operations necessary to determine this opportunity set, e.g. to calculate the probabilities of compound or conditional events and add net changes to initial endowments. However, psychologists have uncovered several systematic violations of these assumptions.

Framing Effects

Effects whereby alternative descriptions of the same decision problem lead to systematically different responses are called 'framing' effects. Some framing effects in choice under uncertainty involve alternative representations of the same likelihood. For example, contingency of a gain or loss on the joint occurrence of four independent events, each with probability p, is found to elicit a different response from contingency on the occurrence of a single event with probability p^4. In comparison with the single-event case, making a gain contingent on the joint occurrence of events seems to make it more attractive, and making a loss

contingent on the joint occurrence of events seems to make it more unattractive (Slovic, 1969).

Other framing effects in choice under uncertainty involve alternative representations of the same final wealth levels. Consider the following two proposals.

- 'In addition to whatever you own, you have been given 1,000 (Israeli pounds). You are now asked to choose between a ½:½ chance of a gain of 1,000 or 0 or a sure chance of a gain of 500.'
- 'In addition to whatever you own, you have been given 2,000. You are now asked to choose between a ½:½ chance of a loss of 1,000 or 0 or a sure loss of 500.'

These two problems involve identical distributions over final wealth. However, when put to two different groups of subjects, 84% chose the sure gain in the first problem but 69% chose the ½:½ gamble in the second (Kahneman and Tversky, 1979).

Response-Mode Effects and Preference Reversal

Effects whereby alternative response formats lead to systematically different inferences about underlying preferences are called 'response-mode' effects. For example, under the expected utility hypothesis, an individual's von Neumann–Morgenstern utility function can be assessed or elicited in a number of different ways, which typically involve a sequence of prespecified lotteries P_1, P_2, P_3,…, and ask for the individual's certainty equivalent $\mathrm{CE}(P_i)$ for each lottery P_i, or else the 'gain equivalent' G_i that would make the lottery $(G_i, \frac{1}{2};\ \$0, \frac{1}{2})$ of equal preference to P_i, or else the 'probability equivalent' $\wp_i$ that would make the lottery $(\$1000, \wp_i;\ \$0, 1-\wp_i)$ of equal preference to P_i. Although such procedures should be expected to generate equivalent assessed utility functions, they have been found to yield systematically different ones (Hershey and Schoemaker, 1985).

In an experiment that demonstrates what is now known as the 'preference reversal phenomenon', subjects were first presented with a number of pairs of bets and asked to choose one bet out of each pair. Each pair of bets took the form of a 'p-bet', which offered a p chance of $\$X^*$ and a $1-p$ chance of \$X, versus a '\$-bet', which offered a q chance of $\$Y^*$ and a $1-q$ chance of \$Y, where $X^* > X, Y^* > Y, p > q$ and $X^* < Y^*$. The names 'p-bet' and '\$-bet' derive from the greater probability of winning in the first bet, and greater possible gain in the second bet (in some cases, X and Y took on small negative values). Subjects were next asked for their certainty equivalents of each of these bets, via a number of standard elicitation techniques.

The expected utility model, and most of the aforementioned alternative models, predict that for each such pair, the bet that was selected in the direct-choice problem would also be the one assigned the higher certainty equivalent. However, subjects exhibit a systematic departure from this prediction in the direction of choosing the p-bet in a direct choice but assigning a higher certainty equivalent to the \$-bet (Lichtenstein and Slovic, 1971). Although this finding initially generated widespread scepticism, especially among economists, it has been widely replicated by both psychologists and economists in a variety of different settings involving real-money gambles, patrons of a Las Vegas casino, group decisions, and experimental market trading. By viewing it as an instance of intransitivity ($\$\text{-bet} \sim \mathrm{CE}(\$\text{-bet}) \succ \mathrm{CE}(p\text{-bet}) \sim p\text{-bet} \succ \$\text{-bet}$), some economists have explained the phenomenon in terms of the regret theory model. However, most psychologists and a growing number of economists regard it as a response-mode effect, specifically, that the psychological processes of valuation (which generates certainty equivalents) and choice are differentially influenced by the probabilities and pay-offs involved in a lottery, and that under certain conditions this can lead to choice and valuation that reveal opposite 'underlying' preference rankings over a pair of gambles.

SUMMARY

Since the work of Bernoulli, the theory of choice under uncertainty has seen both a tension and a scientific interplay between theoretical models of decision making and experimentally observed violations of these models. Current research in the field continues to reflect this tension, while the degree of interplay has increased, with theorists now more willing to model experimentally generated phenomena, and experimenters more willing to provide constructive feedback on these attempts.

Decision-making, Intertemporal

Intermediate article

David Laibson, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

Intertemporal decisions imply trade-offs between current and future rewards. Intertemporal discounting models formalize these trade-offs by quantifying the values of delayed pay-offs.

INTRODUCTION

Decision-makers confront a wide range of critical choices that involve trade-offs between current and future rewards. For example, young workers save part of their paycheck to raise their quality of life in retirement. Habitual heroin users also make decisions with intertemporal consequences when they choose a short-term drug-induced pleasure that jeopardizes their long-term well-being.

To evaluate such trade-offs, decision-makers must compare the costs and benefits of activities that occur at different dates in time. The theory of discounted utility provides one framework for evaluating such delayed pay-offs. This theory has normative and positive content. It has been proposed as both a description of what people should do to maximize their well-being, and to describe what people actually do when faced with intertemporal decisions. Both applications of the model are controversial.

Discounted utility models typically assume that delayed rewards are not as desirable as current rewards or, similarly, that delayed costs are not as undesirable as current costs. This delay effect may reflect many possible factors. For example, delayed rewards are risky because the decision-maker may die before the rewards are experienced. Alternatively delayed rewards are more abstract than current rewards, and hence a decision-maker may not be able to appreciate or evaluate their full impact in advance. Some contributors have argued that delayed rewards should be valued no less than current rewards, with the sole exception of discounting effects that arise from mortality.

DISCOUNTED UTILITY

Formal discounting models assume that a consumer's welfare can be represented as a discounted sum of current and future utility. Specifically, the model assumes that at each point in time, t, the decision-maker consumes goods $c(t)$. These goods might be summarized by a single consumption index (say a consumption budget for period t), or these goods might be represented by a vector (say apples and oranges). The subjective value to the consumer is given by a utility function $u(c(t))$, which translates the consumption measure, $c(t)$, into a single summary measure of utility at period t.

To evaluate future consumption, the consumer discounts utility with a discount function $F(\tau)$, where τ is the delay between the current period and the future consumption. For example, if the current period is date t and a consumer evaluates consumption half a year from now, the consumer calculates the discounted utility value $F\left(\frac{1}{2}\right)u\left(c\left(t+\frac{1}{2}\right)\right)$.

Since future consumption is usually assumed to be worth less than current consumption, the discounted utility model posits that $F(\tau)$ is decreasing in τ. The more utility is delayed, the less it is worth. Since utility is not undesirable, $F(\tau) \geq 0$ for all values of τ. The model is normalized by assuming $F(0) = 1$. Combining these properties we have

$$1 = F(0) \geq F(\tau) \geq F(\tau') \geq 0, \qquad (1)$$

for $0 < \tau < \tau'$. For example if flows of utility a year from now are worth only $\frac{2}{3}$ of what they would be worth if they occurred immediately, then $F(1) = \frac{2}{3}F(0)$.

Continuous-time Discount Functions

Intertemporal choice models have been developed in both continuous-time and discrete-time settings.

Both approaches are summarized here. Readers without a calculus background may wish to skip directly to the discrete-time analysis.

In continuous-time, the welfare of the consumer at time t – sometimes called the objective function or utility function – is given by

$$\int_{\tau=0}^{\infty} F(\tau)u(c(t+\tau))d\tau, \tag{2}$$

where $F(\tau)$ is the discount function, $u(\cdot)$ is the utility function, and $c(\cdot)$ is consumption.

In both continuous-time and discrete-time models, discount functions are described by two characteristics: discount rates and discount factors. Discount rates and discount factors are normalized with respect to the unit of time, which is usually assumed to be a year.

A discount rate at horizon τ is the rate of decline in the discount function at horizon τ:

$$r(\tau) \equiv \frac{-F'(\tau)}{F(\tau)}. \tag{3}$$

Note that $F'(\tau)$ is the derivative of F with respect to time. Hence, $F'(\tau)$ is the change in F per unit time, so $r(\tau)$ is the rate of decline in F. The higher the discount rate, the more quickly value declines with the delay horizon.

A discount factor at horizon τ is the value of a util discounted with the continuously compounded discount rate at horizon τ:

$$f(\tau) \equiv \lim_{\Delta\to 0}\left(\frac{1}{1+r(\tau)\Delta}\right)^{1/\Delta} = \exp(-r(\tau)). \tag{4}$$

The lower the discount factor, the more quickly value declines with the delay horizon.

Discrete-time Discount Functions

Analogous definitions apply to discrete-time models. For this class of models the discount function, $F(\tau)$, need only be defined on a discrete grid of delay values: $\tau \in \{0, \Delta, 2\Delta, 3\Delta, \ldots\}$. For example, if the model were designed to reflect weekly observations, then $\Delta = \frac{1}{52}$ years.

Once the discrete-time grid is fixed, the discount function can then be written

$$\{F(0), F(\Delta), F(2\Delta), F(3\Delta), \ldots\}. \tag{5}$$

The welfare of the consumer at time t is given by

$$\sum_{\tau=0}^{\infty} F(\tau\Delta)u(c(t+\tau\Delta)). \tag{6}$$

At horizon τ, the discount function declines at rate

$$r(\tau) = -\frac{(F(\tau) - F(\tau-\Delta))/\Delta}{F(\tau)}. \tag{7}$$

The numerator of this expression represents the change per unit time.

The discount factor at horizon τ is the value of a util discounted with the discount rate at horizon τ compounded at frequency Δ.

$$f(\tau) = \left(\frac{1}{1+r(\tau)\Delta}\right)^{1/\Delta} = \left(\frac{F(\tau)}{F(\tau-\Delta)}\right)^{1/\Delta}. \tag{8}$$

As the time intervals in the discrete-time formulation become arbitrarily short (i.e. $\Delta \to 0$), the discrete-time discount rate and discount factor definitions converge to the continuous-time definitions.

Exponential Discounting

Almost all discounting applications use the exponential discount function: $F(\tau) = \exp(-\rho\tau)$. This discount function is often written $F(\tau) = \delta^{\tau}$, where $\delta \equiv \exp(-\rho)$. For the exponential discount function the discount rate is constant and does not depend on the horizon:

$$r(\tau) = \frac{-F'(\tau)}{F(\tau)} = \rho = -\ln\delta. \tag{9}$$

Likewise, the discount factor is also constant:

$$f(\tau) = \exp(-r(\tau)) = \exp(-\rho) = \delta. \tag{10}$$

Figure 1 plots three discount functions, including an exponential discount function. Note that the exponential discount function displays a constant rate of decline regardless of the length of the delay. Typical calibrations adopt an annual exponential discount rate of 5 percent.

Non-exponential Discounting

A growing body of experimental evidence suggests that decision-makers' valuations of delayed rewards are inconsistent with the constant discount rate implied by the exponential discount function. Instead, measured discount rates tend to be higher when the delay horizon is short than when the delay horizon is long. One class of functions that satisfies this property is generalized hyperbolas (Chung and Herrnstein, 1961; Ainslie, 1992; Loewenstein and Prelec, 1992). For example,

$$F(\tau) = (1+\alpha\tau)^{-\gamma/\alpha}. \tag{11}$$

For these functions, the rate of decline in the discount function decreases as τ increases:

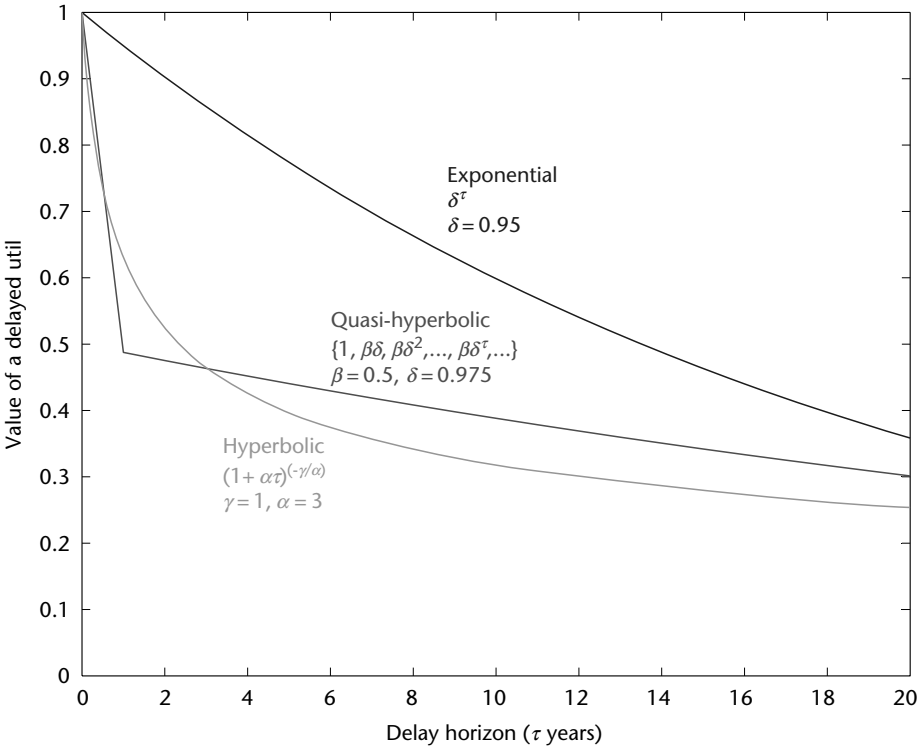

Figure 1. Three discount functions.

$$r(\tau) = \frac{-F'(\tau)}{F(\tau)} = \frac{\gamma}{1+\alpha\tau}. \tag{12}$$

When $\tau = 0$ the discount rate is γ. As τ increases, the discount rate converges to zero. Figure 1 also plots this generalized hyperbolic discount function. Note that the generalized hyperbolic discount function declines at a faster rate in the short run than in the long run, matching a key feature of the experimental data.

To capture this qualitative property, Laibson (1997) adopts a discrete-time discount function, $\{1, \beta\delta, \beta\delta^2, \beta\delta^3, \ldots.\}$, which Phelps and Pollak (1968) had previously used to model intergenerational time preferences. This 'quasi-hyperbolic function' reflects the sharp short-run drop in valuation measured in the experimental time preference data and has been adopted as a research tool because of its analytical tractability. The quasi-hyperbolic discount function is only hyperbolic in the sense that it captures the key qualitative property of the hyperbolic functions: a faster rate of decline in the short run than in the long run. This discrete-time discount function has also been called 'present-biased' and 'quasi-geometric'.

The quasi-hyperbolic discount function is typically calibrated with $\beta \simeq \frac{1}{2}$ and $\delta \simeq 1$. Under this calibration the short-run discount rate exceeds the long-run discount rate:

$$r(1) = 1 > 0 = r(\tau > 1). \tag{13}$$

More generally, any calibration with $0 < \beta < 1$, implies that the short-run discount rate exceeds the long-run discount rate.

Measuring Discount Functions

Measuring discount rates has proved to be controversial. Most discount rate studies give subjects choices among a wide range of delayed rewards. The researchers then impute the time preferences of the subjects based on the subjects' laboratory choices.

In a typical discount rate study, the researchers make three very strong assumptions. First, the researchers assume that rewards are consumed when they are received by the subjects. Second, the researchers assume that the utility function is linear in consumption. Third, the researchers assume that the subjects fully trust the researchers' promises to pay delayed rewards.

If these assumptions are satisfied, it is then possible to impute the discount function by offering subjects reward alternatives and asking the subjects

to pick their preferred option. For example, if a subject prefers \$x today to \$y in one year, then the experimenter concludes that

$$F(0) \cdot x > F(1) \cdot y. \tag{14}$$

Once the subject answers a wide range of questions of this general form, the researcher attempts to estimate the discount function that most closely matches the subject responses.

Such experiments usually reject the exponential discount function in favor of alternative discount functions characterized by discount rates that decline as the horizon is lengthened (Thaler, 1981). Related experiments also reject the implicit assumption that the utility function at date t is not affected by consumption at other dates. This 'separability' assumption is contradicted by the finding that subjects care both about the level *and* the slope of their consumption profiles (see Loewenstein and Thaler (1989) for findings that violate the discounted utility model).

DYNAMIC CONSISTENCY AND SELF-CONTROL

Exponential discount functions have the convenient property that preferences held at date t do not change with the passage of time. Consider the following illustration of this 'dynamic consistency' property. Suppose that at date 0 a consumer with an exponential discount function with discount factor δ, is asked to evaluate a project that requires investments that cost c utils at time 10 with resulting benefits of b utils at time 11. From the perspective of date zero, this project has utility value $\delta^{10}(-c) + \delta^{11}b$. Assume that this utility value is positive and that at date zero the consumer plans to execute the project.

Now imagine that 10 periods pass, and the consumer is asked whether she wishes to reconsider her decision to make the planned investment. From the perspective of period 10, the value of the project to the consumer is $-c + \delta b$. The costs are no longer discounted, since they need to be made in the current period. Likewise, the benefits are only discounted with factor $F(1) = \delta^1$ since they will now be available at only one period in the future.

Note that the consumer's original preference to pursue the project is unchanged by the passage of time, since $\delta^{10}(-c) + \delta^{11}b > 0$ implies that $-c + \delta b > 0$ (divide both sides of the original inequality by δ^{10}). This property of intertemporally consistent preferences is called 'dynamic consistency' and the property will always arise when the discount function is exponential. The passage of time will *never* cause the consumer to switch her preference regarding the investment project (unless new information arrives).

However, dynamic consistency is not a general property of intertemporal choice models. In fact, the only stationary discount function that generates this property is the exponential discount function. All other discount functions imply that preferences are dynamically inconsistent: preferences will sometimes switch with the passage of time. To see this, reconsider the investment project described above and evaluate it with the quasi-hyperbolic discount function (assume $\beta = \frac{1}{2}$ and $\delta = 1$). Suppose that the project requires an investment that costs 2 utils at time 10 and generates a pay-off of 3 utils at time 11. From the time 0 perspective,

$$\beta\delta^{10}(-c) + \beta\delta^{11}b = \frac{1}{2}(-2) + \frac{1}{2}3 = \frac{1}{2}, \tag{15}$$

so the project is worth pursuing. However, from the perspective of period 10, the project generates negative discounted utility

$$-c + \beta\delta b = -2 + \frac{1}{2}3 = -\frac{1}{2}. \tag{16}$$

Hence, the project that the consumer wished to pursue from the perspective of time 0 ceases to be appealing once the moment for investment actually arises in period 10.

This example captures a tension that many decision-makers experience. From a distance a project seems worth doing, but as the moment for sacrifice approaches the project becomes increasingly unappealing. For this reason, quasi-hyperbolic discount functions have been used to model a wide range of self-regulation problems, including procrastination, credit card spending, and drug addiction.

Sophistication, Commitment, and Naivité

The analysis above does not take a stand on whether consumers foresee these preference reversals. Strotz (1956) identifies two paradigms that can be used to analyze the question of consumer foresight: sophistication and naivité.

Sophisticated consumers will anticipate their own propensity to experience preference reversals. Such consumers will recognize the conflict between their early preference – i.e. the preference to undertake the investment project – and their later contradictory preferences. Such sophisticated consumers may look for ways to lock themselves into the investment activity. For example, consider a person

who forces himself to exercise by making an appointment with an expensive trainer.

At the other extreme, Strotz also considered consumers who exhibit naivité about their future preference reversals. Such consumers fail to foresee these reservals and expect to engage in investments that they will not actually carry out (e.g. quitting smoking or completing a project with no deadline). Akerlof (1991) discusses such procrastination problems and O'Donoghue and Rabin (2001) propose a framework that continuously indexes the degree of naivité.

SUMMARY

The discounted utility model provides a way of formally evaluating intertemporal trade-offs. The principal component of the model is a discount function that is used to calculate the discounted value of future utility flows. The key characteristics of the discount function are the discount rate and the discount factor. The discount rate measures the rate of decline of the discount function. The discount factor measures the value of a discounted util. Exponential discount functions are commonly used in most applications of the discounted utility model. Exponential discount functions have a constant discount rate. Exponential discount functions also have the convenient property that they do not generate preference reversals. However, the experimental evidence contradicts the constant discount rate property. Most experimental evidence suggests that the discount rate declines with the length of the delay horizon. Such discounting patterns may play a role in generating self-control problems.

Dynamic Decision Makers, Classification of Types of

Intermediate article

Daniel Houser, University of Arizona, Tucson, Arizona, USA

CONTENTS

A dynamic decision problem is one that requires a sequence of decisions in a setting where pay-offs and alternatives available for later decisions depend on earlier choices. Analysis of data from dynamic behavioral experiments can shed light on the nature of the different types of dynamic decision makers in the population.

INTRODUCTION

Types

Suppose a general orders his troops into battle against an approaching enemy and valiantly leads the charge himself. One of his soldiers takes advantage of the momentary confusion surrounding the order by slipping away from the battlefield to an area of relative safety. One reasonable explanation for the different decisions made by the general and soldier is straightforward: they are different 'types' just in that they face different incentives. Victory in battle means lasting glory and honor for the general, while the soldier might receive little but the chance to fight again another day. It is less straightforward, however, to explain why one soldier flees while his comrades, who are in the same situation, rush forward with the general into combat. As a casual description, we might also say that 'observationally' identical soldiers who make different decisions are different 'types'.

In order to decide whether to flee or fight, soldiers must solve a dynamic decision problem. It is dynamic because their decision affects in a nontrivial way the alternatives available to them at later times. For example, the soldier who fights might be in a position to save the life of a wounded comrade on the battlefield. The soldier who flees might save his own life, but at the risk of being punished for desertion. Their eventual decision rests on idiosyncratic characteristics such as preferences and subjective assessments of battlefield risks.

Game theory defines people who have different preferences as different 'types'. Unfortunately, preferences are not observable. In practice, it is more useful to define people as different types of dynamic decision makers if, like the soldiers, they make different decisions in observationally identical dynamic situations.

Interest in classifying and characterizing dynamic decision makers has grown as the importance of accounting for type heterogeneity in dynamic economic models has become apparent. This importance stems from the fact that most of dynamic economics has as its final goal policy analysis. That is, the goal is to predict how different sorts of incentive structures (e.g. the tax system) affect dynamic decisions (e.g. work and educational choices). As the example of the soldiers makes clear, not everybody responds to the same incentives in the same way. Economists increasingly recognize that analyses, which assume that firms and societies can be described as collectives and modeled as though they were single agents, can often lead to very misleading conclusions and policy recommendations (Furubotn and Richter, 2000). Models that take account of type heterogeneity have the potential to improve policy analysis substantially.

Decision Rules

Economists use so-called 'decision rules' to describe the way a person's actions depend on personal information. 'Information' here should be thought of broadly as everything a person knows (including demographic variables) that could be relevant to a decision. The soldiers above, for example, can be thought of as having the choice either to fight or flee. When presented with the information that the enemy is approaching, the decision rules of some soldiers generate the

decision to flee, while those of others generated the decision to fight. In general, people in observationally identical situations who make different decisions are viewed as using different decision rules, and a person's 'type' is defined by the decision rule they use. Increasingly, research is directed towards identifying, at least within narrow contexts, the number and nature of different decision rules, or types, that exist in the population.

Differences in decision rules can arise from differences in preferences. This is a good explanation in many situations, particularly when trying to explain idiosyncratic differences in tastes for, say, coffee and tea. On the other hand, differences along dimensions such as propensities to cooperate, which are well documented and involve higher-order cognitive processing, seem less naturally attributable to preferences. There is some evidence that differences in decision rules associated with higher-order functions are due to different cognitive algorithms employed to determine actions (e.g. McCabe *et al*., 2001). Such differences are analogous to the difference between human and computer decision making. When a human plays chess against a computer, both parties have the same objective and information, yet their decision rules differ because they use different algorithms to determine their moves.

Expectations

A higher-order task of particular importance to dynamic decisions is expectation formation, because all dynamic decision problems require some sort of forward-looking behavior. Economists have been using the 'rational expectations' assumption to model forward-looking behavior for decades. However, numerous studies in economics and psychology suggest that expectations are not formed rationally. Moreover, it is straightforward to show that different expectation formation mechanisms lead to different dynamic decision rules.

An important, and often-replicated, finding in the literature on static decision making is that, except in very simple cases, people do not assess objective probabilities correctly (e.g. Camerer, 1995). Since probability assessment is cognitively difficult, it is presumably accomplished with idiosyncratic heuristics. Moreover, because probability assessment is fundamental to expectation formation, it seems likely that expectations are formed with idiosyncratic and imperfect heuristics. Although research in this area is still in its early stages, it seems plausible that heterogeneity in expectation formation underlies much of the idiosyncratic variation in dynamic decision rules.

TYPE ELICITATION

Stopping Experiments

Dynamic decision problems (DDPs) faced by individuals provide perhaps the simplest interesting environment in which to study dynamic decision rule heterogeneity. In these environments an individual makes several decisions sequentially, and the decisions made early in the problem affect the nature of the decision task later in the problem. For example, a person might first decide whether to bicycle or walk to work, and then decide on the route to follow. This is a DDP, because the set of candidate routes depends on the outcome of the first decision. (Economists contrast DDPs with sequential 'static' decision problems, where one makes a series of unrelated decisions.) It is important to understand how people actually solve DDPs, particularly when the dynamic nature of the problem involves deciding between different pay-offs at different times (so-called 'intertemporal' decision problems), because many actual consumption, savings, and labor supply decisions must be made within this context.

'Stopping problems', a widely studied class of DDPs, have proved useful tools in classifying and characterizing dynamic decision rules. In a simple stopping experiment, subjects receive payment offers sequentially from the experimenter until they accept one, at which time the experiment ends. Many variants of this basic design have been studied. For example, subjects might have to pay for offers; they might not know the distribution from which offers are generated; they might be able to accept previously rejected offers; and they might not know the exact amount of the offer, but only whether it is higher or lower than other offers. An advantage of this framework is that theoretical predictions about behavior under various decision rules are straightforward to derive. Different decision rules often imply different stopping points. Hence, observing stopping times allows one to draw simple and compelling inferences about the sorts of decision rules that are used in the population.

Analysis of stopping experiment data, using techniques such as that of El-Gamal and Grether (1995) discussed below, show that there is great heterogeneity in the ways subjects solve experimental stopping problems. There is little evidence to suggest that people decide in ways that are

consistent with rational expectations. Instead, subjects seem to use sophisticated, nonstationary reservation pay-off heuristics. This means that subjects stop as soon as their pay-off is sufficiently high, where 'sufficiently' depends, for example, on the number of times they have had to search and on whether they are paying search costs.

There is a small set of reservation pay-off decision rules into which most subjects' behavior seems to fall. Moreover, there are two features that most of these rules share. Firstly, subjects who use them tend to stop searching somewhat earlier than a rational expectations searcher would. Secondly, these heuristics work well in the sense that subjects who use them earn only slightly less on average (often about one percent) than they would have if they had followed the rational expectations rule. Since the rational expectations rule is cognitively very complex to implement, there may be a sense in which using reservation pay-off heuristics is in fact optimal. For a survey of results from the experimental stopping experiment literature, see Cox and Oaxaca (1996).

The Voluntary Contribution Mechanism

Types can also be discerned in game environments where multiple subjects interact and make strategic decisions that affect each other's pay-off. The voluntary contribution mechanism (VCM) is an important example of such a game. There are N players, and player n has endowment w_n. Player n contributes g_n to the public good and leaves the remainder in a private account. The total contribution to the public good is $G = \sum_n g_n$. The interesting feature of the VCM is that the return on investment in the public account differs from that on investment in the private account. Without loss of generality we can suppose that the return to each player on the total investment in the public account is given by r while the return on the private account is set to unity. This means that the pay-off function for player n is

$$\Pi(g_n, \hat{g}_n) = (w_n - g_n) + rG \tag{1}$$

where $\hat{g}_n$ represents the vector of contributions of everyone except player n. Provided that $r < 1$ it is easy to see that, given any arrangement of contributions by the other subjects, each player maximizes his or her individual pay-off by 'free-riding', or contributing zero to the public good. Hence, free-riding is a dominant Nash equilibrium strategy. But if $rN > 1$ then it is Pareto optimal for each player to contribute everything to the public good, and this strategy Pareto-dominates free-riding. The parameter r is the marginal per-capital return (MPCR). When designing VCM experiments, the MPCR and the number of subjects are usually chosen to exploit the tension between free-riding and Pareto optimality.

Experimental research with the VCM, has generated many widely-replicated results, including clear evidence of decision rule heterogeneity (for a survey see Ledyard, 1995). In particular, there is usually a subset of subjects, 'free-riders', whose decision is to contribute very little to the public good in every round, and another subset, 'cooperators', who systematically contribute a large fraction of their endowment to the public good. A third subset uses 'reciprocal' rules, trying to match others' contributions.

The presence of reciprocal decision rules suggests that group dynamics might be influenced by the type composition of groups. For example, the presence of players who contribute little or nothing to the public good could lead to decreasing aggregate contributions over time if reciprocators attempt to match free-riders' small contributions. Hence, a feedback system that is sensitive to the proportion of each type within the group could be created, and could affect the extent to which a group is able to sustain cooperation.

Recent research has found that type composition seems to have important effects on group dynamics (e.g. Gunthorsdottir *et al.*, 2001). In particular, the number of free-riders in a group influences that group's path over the course of a game. Without free-riders, groups are capable of sustaining high levels of contribution to the public good; while the presence of free-riders often pushes groups towards successively lower levels of contributions.

TYPES AND PERSONALITY SURVEYS

The ability to learn about a person's behavioral type from a personality survey would be useful, since the dependence of group outcomes on type composition implies that knowledge of types could be used to design groups (such as school classes) efficiently. However, whether behavioral types broadly and systematically correlate with personality surveys is an open question, and experiments have generated widely conflicting results. Nevertheless, some personality variables seem to correlate with propensities to cooperate in experiments. Personality dimensions displaying this correlation include Machiavellianism, self-monitoring, and three of the 'big five' personality traits.

Machiavellianism

Inspired by the writings of Niccolo Machiavelli (1469–1527), and first developed by Christie and Geis (1970), the Machiavellianism (or Mach) scale measures the extent to which a person agrees that the end sanctifies the means. People who score highly on the Mach scale tend to be manipulative, opportunistic, and rational. Low Machs tend to be more emotional and less likely to depart from social norms in order to pursue their own self-interest. While high Machs tend to be competitive and exploitative, low Machs are usually more willing to cooperate (Gunnthorsdottir, McCabe and Smith, 2002).

Self-monitoring

The 'self-monitoring' scale is an measure of the dependence of an individual's behavior on the social context. High self-monitors work to create the impression needed to obtain their social goals, while low self-monitors are less concerned about the impression they make. High self-monitors have been found to be more likely to cooperate, particularly in experiments where repeated interactions with the same counterpart are possible.

The Big Five

The 'big five' personality traits are extraversion, agreeableness, conscientiousness, neuroticism, and openness. Among these, extraversion and agreeableness seem to be positively correlated with cooperativeness, while neuroticism seems to be negatively correlated. The relation of the other two traits with cooperativeness is not clear.

Many other personality variables, including self-esteem and locus of control, have been studied in relation to cooperation, but without clear results. For further discussion on the connection between types and personality surveys, see Kurzban and Houser (2002).

STATISTICAL METHODS FOR TYPE CLASSIFICATION

Sophisticated statistical procedures are not usually required to determine whether subjects in an experiment behave according to a particular decision rule. Intuitively, all that is required is to compare actual decisions with those that would arise under a hypothesized behavior. Although the details depend on the experimental design, formal procedures to accomplish this sort of comparison are typically straightforward. A more difficult task, and one that typically requires sophisticated statistics, is to determine how people actually make decisions in a given dynamic environment.

Attempting to characterize actual decision making requires, at least, allowing for multiple decision rules to be used in the population. The task is then to determine the number of decision rules, and to assign each subject to a decision rule. Broadly, there are two ways in which this can be done. We will briefly summarize the two approaches, and then discuss in greater detail an instance of each of them.

One approach, exemplified by a procedure suggested by El-Gamal and Grether (1995), requires one to specify in advance a set of candidate decision rules. A statistical procedure is then used to choose a 'best' subset of these rules. Finally, each subject is assigned to one of the rules in the subset. An advantage of this sort of procedure is that it is relatively straightforward to implement. However, unless it is feasible to include all of the rules that subjects might possibly use in the prespecified superset, a potential drawback is that the right rules might not be included. Misspecification could mask underlying commonalities in subjects' play.

An alternative approach, exemplified by a method suggested by Houser *et al*. (2001), requires no assumptions about the number of decision rules used in the population, the nature of each decision rule, or the assignment of subjects to decision rules. This approach requires cluster analysis: subjects are clustered according to commonalities in their behavior.

The goal of both these approaches is to put each subject into a behavioral category. El-Gamal and Grether require one to specify the categories in advance, while Houser *et al*. allow the categories to be determined by the data. Of course, it may not be easy to assign behavioral labels to groups that follow statistically similar decision rules.

The Classification Procedure of El-Gamal and Grether

Suppose one has data from a behavioral laboratory experiment where each of N subjects makes T decisions. Let C^K denote the prespecified set of K heuristics (i.e., decision rules) that subjects might use to make these decisions, and let $c \in C^K$ denote a particular heuristic. The idea is to determine, for each subject, the number of decisions consistent with each possible heuristic, and then assign that subject to the heuristic that best fits his or her behavior.

To implement the procedure one assumes that each subject follows exactly one of the heuristics in C^K. In practise, of course, a subject's behavior may not be perfectly consistent with any of the heuristics in C^K. El-Gamal and Grether (1995) circumvent this problem by assuming that subjects follow their heuristics with error.

Heuristics are chosen that specify a subject's decision uniquely from his or her state. A subject's 'state', which generally changes after each decision, is a vector that summarizes all of the person's decision-relevant information. Let x_t^c be an indicator variable that takes the value one if the subject's tth decision agrees with heuristic c and takes the value zero otherwise. Assume that the decisions are made independently with common error rate ε.

Let $(x_{n1}, \ldots, x_{nT})$ be a vector denoting subject n's actions, and let $(x_{n1}^c, \ldots, x_{nT}^c)$ be a vector of zeros and ones that summarizes the consistency of the subject's choices with c. That is, assume that $x_{nj}^c = 1$ if decision rule c predicts decision x_{nj}, and $x_{nj}^c = 0$ otherwise. Then set $X_n^c = \sum_t x_{nt}^c$. The likelihood function for the subjects' actions is then:

$$f^c(x_{n1}, \ldots, x_{nT}) = (1 - \varepsilon/2)^{X_n^c} (\varepsilon/2)^{T - X_n^c} \tag{2}$$

It is natural to assign each subject to the heuristic from the candidate set that maximizes his or her likelihood function.

This model can be 'overfit': including a large number of heuristics in C^K would allow the statistical model to fit a sample arbitrarily well. Overfitting usually leads to results with little external validity. To avoid overfitting, El-Gamal and Grether suggest penalizing the likelihood for each additional heuristic that is included in the set of candidate heuristics. Let C^k denote a subset of $k \leq K$ decision rules. El-Gamal and Grether argue that a reasonable penalized log-likelihood is obtained by forming the Bayesian posterior that arises under the following priors: (1) the probability that the population includes exactly k heuristics is $1/2^k$; (2) all possible k-tuples of heuristics in any C^k are equally likely (each with probability $1/K^k$); (3) all allocations of heuristics to subjects are equally likely (each with probability $1/k^N$); (4) all error rates (between zero and one) are equally likely; and do not depend on the number of rules used in the population or on the way those rules are assigned. This generates the following penalized log-likelihood function:

$$\log\left(\prod_n \max_{c_n \in C^k} f^{c_n}(x_{n1}, \ldots, x_{nT})\right) - k \log 2 - N \log k - k \log K \tag{3}$$

Determination of the population of heuristics as well as the assignment of subjects to heuristics is accomplished by simply maximizing the above expression over the set of all possible k-tuples that can be formed from the set of K decision rules.

The Classification Procedure of Houser, Keane, and McCabe

Suppose that subjects solve a 15-period DDP. At each period, subjects choose either A or B, each of which results in a nonnegative monetary reward. Pay-offs are stochastic. The realizations of the random variables for period t occur before the decision at t is made, and the realizations of the random variables for period $t+1$ occur after the decision at t. Each subject's total pay-off is the sum of the rewards earned over the 15 periods. Subjects have complete information regarding the stochastic link between their current choices and future pay-offs, but the link is complicated and it is difficult to determine the decision rule that maximizes expected total pay-offs.

The goal is to learn about the dynamic decision rules that subjects actually use when solving this difficult problem. Houser *et al*. (2001) begin by assuming that subjects are rational in a weak sense. In particular, a subject will choose alternative A in period t if and only if, in period t, the value the person places on choosing A is greater than the value he or she places on choosing B. Because the problem is dynamic, the values that subjects place on A and B depend both on the immediate reward to each choice and on the way subjects believe that choice would influence their future pay-offs. Houser *et al*. assume that alternative valuations are additively separable into a 'present' component, which captures immediate rewards (in this case the immediate monetary pay-off), and a 'future' component, which captures any benefits expected to accrue in subsequent periods as a result of that choice (in this case future monetary pay-offs).

Since the present pay-off structure is known for each agent, differences in behavior result only from differences in the future component. Hence, all differences in decision rules between subjects can be captured by differences in the future component. Houser *et al*. propose clustering subjects into groups that seem to have similar future components, while simultaneously drawing inferences about the future components' forms. In this way, they avoid the need to prespecify the nature of the decision rules used by the subjects.

Drawing on Geweke and Keane (1999), Houser *et al*. model the unobserved future component of each alternative's value as a parametric function of the subject's information set I_{nt}. The information set can include anything the researcher believes is relevant to the subject when making his or her decision, such as choice and pay-off histories. Then, the value that subject n assigns to alternative $j \in \{A, B\}$ in period t, V_{njt} (I_{nt}), assuming that the person uses decision rule k, can be written

$$V_{njt}(I_{nt}|k) = w_{njt} + F(I_{n,t+1}|I_{nt}, j, \pi_k, \varsigma_{njtk}) \quad (4)$$

$$I_{n,t+1} = H(I_{nt}, j) \quad (5)$$

Here, w_{njt} is the known immediate pay-off associated with alternative j. $F(\cdot)$ represents the future component. It depends on the alternative j and information set I_{nt} and is characterized by a finite vector of parameters π_k, whose values determine the nature of decision rule k, and a random variable ς_{njtk} that accounts for idiosyncratic errors subjects make when attempting to implement decision rule k. (The researcher must specify the distribution of the idiosyncratic errors.) The function $H(\cdot)$ is the information set's (possibly stochastic) law of motion. It provides the dynamic link between current information, actions and future information. Note that it does not vary with the decision rule.

We denote the choice in period t of subject n following decision rule k with information I_{nt} by

$$d_k(I_{nt}) = \begin{cases} A & \text{if } Z_{nt}(I_{nt}|k) > 0 \\ B & \text{otherwise} \end{cases} \text{ for all } k \in K, \quad (6)$$

where $Z_{nt}(I_{nt}|k) = V_{nAt}(I_{nt}|k) - V_{nBt}\ (I_{nt}|k)$.

The goal is to draw inferences about the parameters $\pi_k (k \in K)$, and about the probability with which each subject uses each decision rule. To this end, Houser *et al*. construct the likelihood function associated with this framework. This requires knowing the probability, conditional on a subject's information set, that he or she will choose A or B.

The probability that subject n using decision rule k chooses alternative A at period t, given that the person has information I_{nt}, is given by

$$\begin{aligned} P(d_k(I_{nt}) = A) &= P(V_{nAt}(I_{nt}) > V_{nBt}(I_{nt})) \\ &= P(w_{nAt} - w_{nBt} + f(I_{nt}|\pi_k) > 0) \end{aligned} \quad (7)$$

where $f(\cdot)$ is a stochastic function that represents the differenced future components $F(I_{n,t+1}|I_{nt}, A, \pi_k, \varsigma_{nAtk}) - F(I_{n,t+1}|I_{nt}, B, \pi_k, \varsigma_{nBtk})$. The conditional probability that B is chosen is one minus the conditional probability that A is chosen.

Knowing the conditional choice probabilities, it is straightforward to construct the likelihood function needed to draw inferences about the different decision rules used in the population, and the probability with which each subject uses each rule. Under the distributional assumptions made by Houser *et al*. the likelihood function corresponds to a mixture of normals probit model. Unfortunately, this likelihood can be computationally difficult to maximize. Further discussion of this point (and estimation strategies) can be found in Houser *et al*. (2001) and Geweke and Keane (1999).

CONCLUSION

Economists say that people who make different decisions in observationally identical situations are different 'types'. Decision rules form the link between a person's situation and decisions, and it is natural to define a person's type by the decision rule he or she uses. Investigating the nature of the various decision rules at use in the population is important, because the effects of incentives on behavior depend on the decision rules that incentives act upon.

Many economists are particularly interested in the decision rules people use in dynamic environments. Experimental studies have found that a small number of decision rules seem to explain most observed behavior in very narrow contexts, and that these rules do not usually include the rational expectations rule. Further research is needed to determine the nature and number of decision rules in the population, the relationship between decision rules used in different contexts, and consequent implications for individual and group outcomes and incentive structures. Such research may employ sophisticated statistical procedures that group people according to common behavioral patterns. These patterns may be either specified in advance or discerned directly from experimental data.

CONTENTS

Models of learning in economics are used to explain how people use information about past prices and other signals to make good decisions. These models can be tested with economics experiments in which decisions are made in a sequence of rounds or trading periods.

INTRODUCTION

The main focus of economic analysis is on equilibrium steady states, e.g. on prices determined by the intersection of supply and demand. The preoccupation with equilibrium is perhaps due to the fact that many markets operate for protracted periods of time under fairly stationary conditions. The awareness that there may be multiple equilibria, some of which are bad for all concerned, has raised interest in why behavior might converge to one equilibrium and not to another. As a result, there is renewed interest among economists in mathematical models of learning that were studied extensively by psychologists in the 1960s. This article will describe two of those models, 'reinforcement learning' and Bayesian 'belief learning'. These models and their generalizations will be discussed in the context of a binary prediction task, which may generate the kind of behavior that is known in the psychology literature as 'probability matching'.

We will then use these learning models to analyze behavior in an economic market where firms choose prices. Markets and games are more complex than individual decision tasks, in that people's choices affect others' beliefs. One role of learning models in such situations is to provide an explanation of the dynamic paths of prices, which can shed light on the nature of adjustment towards equilibrium. The equilibrium is characterized by an unchanging (steady-state) distribution of beliefs across individuals, which we call a 'stochastic learning equilibrium'.

TYPES OF LEARNING MODELS

We will introduce the basic learning models in the context of a binary prediction task that has been familiar to psychologists since the 1950s. This task is of special interest because humans are thought to be slow learners in this context. The typical setup involves two lights, each with a corresponding lever (or computer key). A signal light indicates that a decision can be made, and then one of the levers is pressed. Finally, one of the lights is illuminated. Animal subjects like rats and chicks are reinforced with food pellets when the prediction is correct. Human subjects are sometimes told to 'do your best' to predict accurately or to 'maximize the number of correct choices'. In other studies, humans are paid small amounts, typically pennies, for correct choices, and penalties may be deducted for incorrect choices.

The general result seems to be that humans are subject to 'probability matching', predicting each event with a frequency that approximately matches the frequency with which it actually occurs. For example, if the left light is illuminated three-fourths of the time, then subjects would come to learn this by experience and would tend to predict 'left' three-fourths of the time.

This behavior is not rational. A consistent prediction of the more likely event will be correct three-fourths of the time. Matching behavior will only generate a correct prediction with a probability of $\frac{3}{4} \times \frac{3}{4} + \frac{1}{4} \times \frac{1}{4}$ (the first term corresponds to predicting the more likely event with probability $\frac{3}{4}$ and being correct with this prediction three-fourths of

the time, and similarly for the second term). Thus, the probability of being correct under probability matching is $\frac{5}{8} < \frac{3}{4}$.

In a recent summary of the probability-matching literature, the psychologist Fantino (1998, pp. 360–361) concludes: 'Human subjects do not behave optimally. Instead they match the proportion of their choices to the probability of reinforcement.… This behavior is perplexing given that non-humans are quite adept at optimal behavior in this situation.' For example, Mackintosh (1996) conducted probability-matching experiments with chicks and rats, and the choice frequencies were well above the probability-matching predictions in most treatments.

The resolution of this paradox may be found in the work of Sidney Siegel, who is perhaps the psychologist who has had the largest impact on experiments in economics. His early work from the 1960s exhibits a high standard of careful reporting and procedures, appropriate statistical techniques, and the use of financial incentives where appropriate. His work on probability matching is a good example. In one experiment, 36 male Penn State students were allowed to make predictions for 100 trials, and then 12 of these students were brought back on a later day to make predictions in 200 more trials (Siegel *et al*., 1964). The proportions of predictions for the more likely event are shown in Figure 1, in which each point is an average over 20 trials.

The 12 subjects in the 'no pay' treatment were simply told to 'do your best' to predict which light bulb would be illuminated. These prediction rates begin at about 0.5, as would be expected in early trials with no information about which event is more likely. Notice that the proportion of predictions for the more likely event converges to 0.75, as predicted by probability matching, with very close matching from about trial 100.

In the 'pay/loss' treatment, 12 participants received 5¢ for each correct prediction, and they lost 5¢ for each incorrect prediction. The rate seems to converge to about 0.9.

A third 'pay' treatment offered a 5¢ reward for a correct prediction but no loss for an incorrect prediction. The results (not shown) are in between those of the other two treatments, and clearly above 0.75.

Clearly, then, incentives matter. Probability matching is not observed with incentives in this context.

Siegel's findings suggest a resolution to the paradox that rats are smarter than humans in binary prediction tasks. You cannot tell a rat to 'do your best': incentives such as food pellets must be used. Consequently, the choice proportions are closer to those observed with financially motivated human subjects. In a recent survey of over 50 years of probability-matching experiments, Vulkan (2000) separates those studies that used real incentives from those that did not, and he concluded that probability matching is generally not observed with real pay-offs. However, humans can still be surprisingly slow learners in this simple setting. For this reason, probability-matching data are particularly interesting for valuating alternative learning theories.

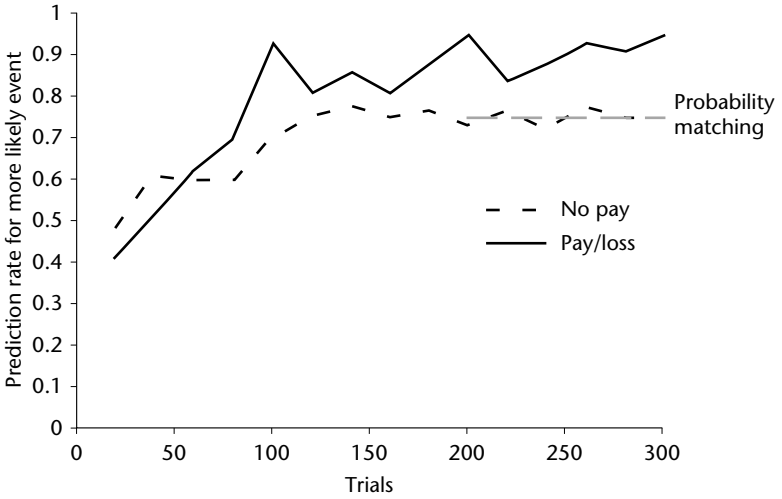

Figure 1. Prediction frequencies for an event that occurs with probability $\frac{3}{4}$ (Siegel *et al*., 1964). Each point plotted represents an average over 20 trials. The 'no pay' group were simply told to 'do your best'. The 'pay/loss' group received 5¢ for each correct prediction and forfeited 5¢ for each incorrect prediction.

Reinforcement Learning

One prominent theory of learning associates changes in behavior to the reinforcements actually received. Initially, when no reinforcements have been received, it is natural to assume that the choice probabilities for each decision are equal to one-half. Suppose that in the experiment there is a reinforcement of x for each correct prediction, and nothing otherwise. So if one predicts event L and is correct, then the probability of choosing L should increase. The extent of the behavioral change is assumed to depend on the size of the reinforcement. As the total earnings received for a particular decision increase, the probability of making that decision is assumed to increase. Suppose that event L has been predicted N_L times and that the predictions have sometimes been correct and sometimes not. Then the total earnings for predicting L, denoted by e_L, would be less than xN_L. Similarly, let e_R be the total earnings from the correct R predictions. One way to model the effect of total earnings for each decision on choice probabilities is to choose L or R with the following probabilities:

$$P(\text{choose L}) = \frac{\alpha + e_L}{2\alpha + e_L + e_R} \quad (1)$$

$$P(\text{choose R}) = \frac{\alpha + e_R}{2\alpha + e_L + e_R} \quad (2)$$

The parameter α determines how quickly learning responds to the reinforcements. Note that, as additional reinforcements are received, they are added into the relevant numerator, and to both denominators, to ensure that the probabilities sum to 1.

This kind of model might explain some aspects of behavior in probability-matching experiments with financial incentives. The choice probabilities would be equal initially, but a prediction of the more likely event will be correct 75% of the time, and the resulting asymmetries in reinforcement would tend to raise the prediction probability for that event, and the total earnings for this event would tend to be much larger than for the other event. If L is the more likely event, then e_L would be growing faster, so that e_R/e_L would tend to get smaller. Thus the probability of choosing L would tend to converge to 1.

This learning model can be simulated by using past accumulated earnings to compute choice probabilities. Then a random-number generator determines the actual choices. To make our data comparable with Siegel's data, we simulate decisions of a cohort of 1000 individuals for 300 periods, and calculate the 20-period choice averages for the more likely event.

The simulations were done for $\alpha = 5$ and $x = 1$. The value of α was chosen to create some initial inertia in behavior, which will tend to disappear after 40 or 50 periods. Setting α equal to 5 is analogous to having had each decision reinforced five times initially. Figure 2 shows simulated choice averages together with Siegel's original data. The simulated data are smoother, and start somewhat higher to start with, but the general pattern and final tendencies are similar. Erev and Roth (1998)

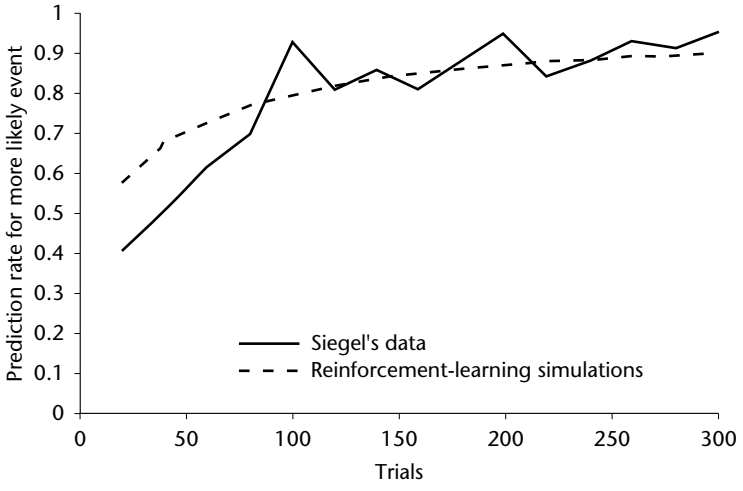

Figure 2. Data for Siegel's probability-matching experiment ('pay/loss' condition), with reinforcement-learning simulation data superimposed ($\alpha = 5$).

have used reinforcement learning to explain behavior in simple matrix games.

A Simple Model of Belief Learning

With reinforcement learning, beliefs are not explicitly modeled. An alternative approach that is more natural to economists is to model learning in terms of (Bayesian) updating of beliefs. Given the symmetry of Siegel's experimental setup, a person's initial beliefs ought to be that each event is equally likely, but the first observation should raise the probability associated with the event that was just observed. Moreover, the probability of event L should be an increasing function of the number N_L of times that this event has been observed, and a decreasing function of the number N_R of times that event R has been observed. Let N be the total number of observations to date. Then a standard belief-learning model is:

$$P(\mathrm{L}) = \frac{\beta + N_L}{2\beta + N} \tag{3}$$

$$P(\mathrm{R}) = \frac{\beta + N_R}{2\beta + N} \tag{4}$$

where $N = N_L + N_R$. Note that β determines how quickly the probabilities respond to the new information; a large value of β will keep these probabilities close to $\frac{1}{2}$. These formulae for calculating probabilities can be derived from Bayesian statistical principles (DeGroot, 1970, p. 160). In the early periods, the totals N_L and N_R might sometimes switch in terms of which one is higher, but the more likely event will soon dominate, and therefore $P(\mathrm{L})$ will be greater than $\frac{1}{2}$.

The beliefs determine the expected pay-offs (or utilities) for each decision, which in turn determine the decisions made. In theory, the decision with the highest expected pay-off should be selected with certainty. The prediction of the belief-learning model is, therefore, that all people will eventually predict the more likely event every time.

In an experiment, however, some randomness in decision-making might be observed if the expected pay-offs for the two decisions are similar. This randomness may be due to changes in emotions, calculation errors, selective forgetting of past experience, etc. Following Luce (1959), we introduce some 'noise' via a probabilistic choice model, where decision probabilities are positively but not perfectly related to expected pay-offs. Let π_L and π_R denote the expected pay-offs from choosing 'left' and 'right' respectively. Luce provided a set of axioms under which the choice probability is calculated as

$$P(\text{choose L}) = \frac{(\pi_L)^{1/\mu}}{(\pi_L)^{1/\mu} + (\pi_R)^{1/\mu}} \tag{5}$$

$$P(\text{choose R}) = \frac{(\pi_R)^{1/\mu}}{(\pi_L)^{1/\mu} + (\pi_R)^{1/\mu}} \tag{6}$$

The parameter μ is an 'error' parameter. It determines the sensitivity of choice probabilities to differences in expected pay-offs. In the limit when μ tends to zero, the decision with the higher expected pay-off is selected with probability 1. In the other extreme as μ gets large, behavior is random and independent of pay-offs.

In the probability-matching experiment, the expected pay-off of choosing 'left' is the reward (of 1, say) times the probability of 'left' that represents the person's beliefs. Thus the expected pay-off of 'left' is $P(\mathrm{L})$, and similarly the expected pay-off of 'right' is $P(\mathrm{R})$. $P(\mathrm{L})$ is greater than one-half if 'left' is more likely, and the error parameter μ determines how close the choice probability for the more likely event is to 1.

Figure 3 shows a simulation of the belief-learning model for $\beta = 20$. The thin solid line represents the average of the belief probabilities for the 12 simulated subjects. Notice that beliefs start close to one-half and converge to the true probability of the more likely event $\left(\frac{3}{4}\right)$. These beliefs determine expected pay-offs, and hence choice probabilities, via equations 5 and 6.

The dashed lines show the simulated average choice frequencies for three different levels of the error parameter. With high error ($\mu = 1$), the choice frequencies are close to the belief line, which would correspond to probability matching. This result is to be expected, since expected pay-offs are equal to belief probabilities. The denominator on the right-hand side of equations 5 and 6 is 1 when $\mu = 1$, and hence the probability of choosing 'left' equals π_L, which is equal to the belief probability.

As the error is reduced, the simulated choice frequencies move upwards towards the optimal level of 1. The top line, with $\mu = \frac{1}{3}$, converges to the level of about 0.9, which is close to the choice frequency observed by Siegel.

The simulations in Figure 3 were done for a cohort of size 12, to be comparable with Siegel's experiment. This allows us to see the degree of variation in the simulated data with a small group. In order to predict the average over a large number of individuals, we ran the simulation 1000 times, and the average proportions of choices for

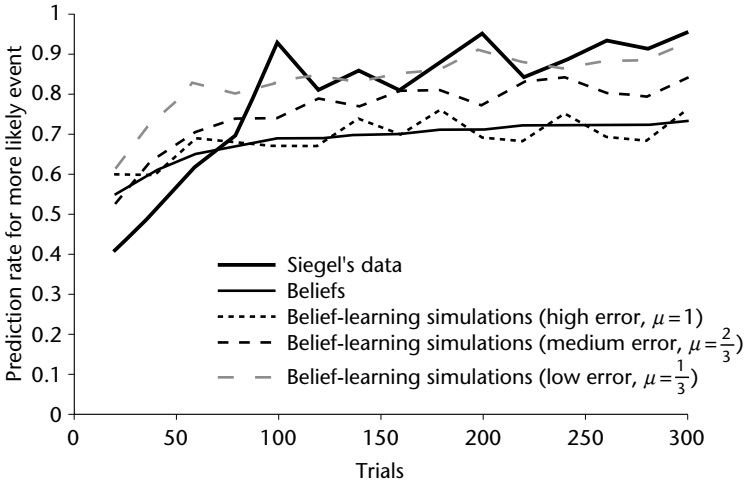

Figure 3. Data for Siegel's probability-matching experiment ('pay/loss' condition), with belief-learning simulation data superimposed ($\beta = 20$). The error parameter μ ranges from 1 (high error) to $\frac{1}{3}$ (low error).

the more likely event were: 0.76 for $\mu = 1$, 0.80 for $\mu = 0.67$, and 0.87 for $\mu = 0.33$.

Generalizations

Both of the learning models discussed above are somewhat simple, and this is part of their appeal. The reinforcement model builds in some randomness in behavior, and has the appealing feature that incentives matter. But it has less of a cognitive element. There is no reinforcement for decisions not made. For example, suppose that a person chooses L three times in a row (by chance) and is wrong each time. Since no reinforcement is received, the choice probabilities stay at 0.5 even after three incorrect predictions. This seems unreasonable. People do learn something in the absence of previous reinforcement, since they realize that making a good decision may result in higher earnings in the next round. Camerer and Ho (1999) have developed a generalization of reinforcement learning that contains some elements of belief learning. Roughly speaking, outcomes that are observed receive partial reinforcement even if nothing is earned.

These learning models can be enriched in other ways to obtain better predictions of behavior. For example, the sums of event observations in the belief-learning model weigh each observation equally. It may be reasonable to allow for 'forgetting' in some contexts, so that the observation of an event in the most recent trial may carry more weight than something observed a long time ago. This can be done by replacing sums with weighted sums. For example, if event L was observed three times, N_L in equation 3 would be 3, which can be thought of as $1 + 1 + 1$. If the most recent observation (listed on the right in this sum) is twice as prominent as the one before it, then the prior event would get a weight of one-half, and the one before that would get a weight of one-fourth, and so on. This type of 'recency' effect will be discussed below in the context of an interactive market game.

Finally, 'Luce's probabilistic-choice rule' (equations 5 and 6) is often replaced with the 'logit rule':

$$P(\text{choose L}) = \frac{\exp(\pi_L/\mu)}{\exp(\pi_L/\mu) + \exp(\pi_R/\mu)} \tag{7}$$

$$P(\text{choose R}) = \frac{\exp(\pi_R/\mu)}{\exp(\pi_L/\mu) + \exp(\pi_R/\mu)} \tag{8}$$

where μ is an error parameter as before. The Luce and logit rules are often similar in effect, and both are commonly used. The logit probabilities are unchanged when all pay-offs are increased by a constant, and the Luce probabilities are unchanged when all pay-offs are multiplied by a positive constant.

LEARNING AND PRICE DYNAMICS IN A MARKET GAME

We use a simple price competition example from Capra *et al*. (2002) to illustrate the effects of learning in an interactive setting. Consider a market game in which firms 1 and 2 simultaneously choose prices p_1 and p_2 in the range [60, 160] (units are cents). Demand is assumed to be a fixed total quantity ('perfectly inelastic'). The sales quantity of the firm with the lower price $p_{\min}$ is normalized to be

one, so the low-price firm earns an amount equal to its price. The high-price firm sells a 'residual' amount R, which is less than 1. The amount by which this residual is less than 1 indicates the degree of buyer responsiveness to price. The high-price firm has to match the lower price in order to make any sales, but some sales are lost because of the initially higher price. We assume that the high-price firm only earns $Rp_{\min}$, where $R<1$. In the event of a tie, the $1+R$ sales units are shared equally, so that each seller earns $(1+R)\,p_{\min}$.

As long as the high-price firm obtains less than half the market ($R<1$), the Nash equilibrium prediction is for both firms to set the lowest possible price of 60. To see this, note that at any common price, each firm has an incentive to undercut the other by a small amount to increase its market share. Therefore, the unique Nash equilibrium involves both firms charging the lowest possible price. The harsh competitive nature of the Nash prediction seems to go against the simple economic intuition that the degree of buyer inertia will affect the behavior of firms. When $R=0.8$, say, the loss from having the higher price is relatively small, and firms should be more likely to set prices above 60 when there is a small chance that rivals will do the same. Indeed, in the extreme case when $R=1$ it becomes a dominant strategy for both firms to choose the highest possible price of 160. While a standard Nash analysis predicts no change as long as $R<1$ (and then an abrupt change when $R=1$), it seems plausible that prices will gradually rise with R.

We ran an experiment based on this market game, using six cohorts of 10 subjects each. Each group of 10 subjects was randomly paired, with new partners in each of 10 periods. A period began with all subjects selecting a price in the interval [60, 160]. After these prices were recorded, subjects were matched, and each person was informed about the other's price choice. Pay-offs were calculated as described above: the low-price firm earned an amount equal to its price, and the high-price firm earned R times the lowest price. Three sessions were conducted with $R=0.2$ and three with $R=0.8$. Figure 4 shows the period-by-period average price choices. The upper solid line shows the average prices when buyers were relatively unresponsive ($R=0.8$), and the lower solid line shows average prices when buyers were relatively responsive ($R=0.2$). Recall that the Nash equilibrium was 60 for both treatments, as shown by the horizontal dashed line at 60. As intuition suggests, changes in the buyers' responsiveness has a large effect on price, even though the Nash equilibrium remains unchanged.

Notice that prices start high and stay high in the $R=0.8$ treatment, while prices decline before leveling off in the $R=0.2$ treatment. Standard economic models cannot explain either the levels or

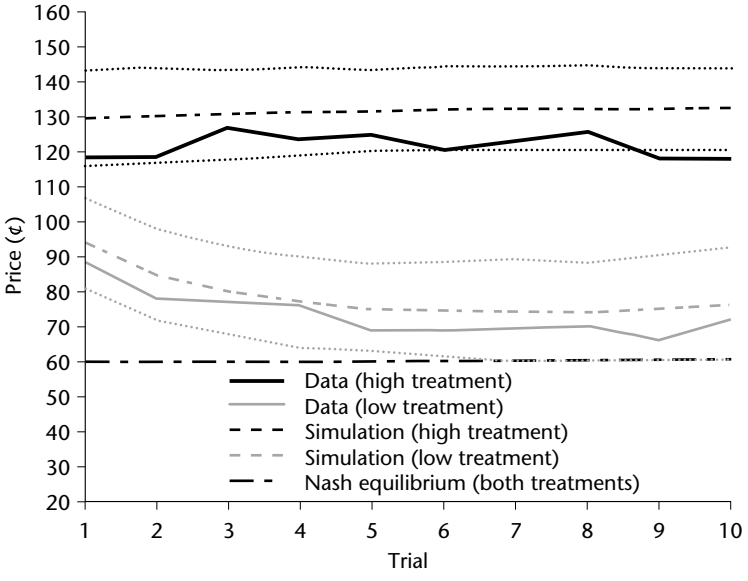

Figure 4. Data and simulations (plus or minus two standard deviations indicated by dotted lines) for a market game. In the 'high' treatment, buyers were relatively unresponsive to differences in price; in the 'low' treatment, buyers were relatively responsive. The simulations are based on a simple belief-learning model using a logit rule to determine probabilities.

the patterns of adjustment. Our approach is to consider a naive learning model in which players use observations of rivals' past prices to update their beliefs about others' future actions. In turn, the expected pay-offs based on these beliefs determine players' choice probabilities via a logit rule. This model was used to simulate behavior in the experiment.

To obtain a tractable model, the price range [60, 160] is divided into 101 one-cent categories. Players assign weights to each category and use observations of their rivals' choices to update these weights as follows: each period, all weights are 'discounted' by a factor ρ and the discounted weight of the observed category is increased by 1. In other words, the weight w of an observed category is updated as $w \to \rho\, w + 1$, whereas the other weights are updated as $w \to \rho w$. The belief probabilities in each period are obtained by dividing the weight of each category by the sum of all the weights. Hence, the learning parameter ρ determines the importance of new observations relative to previous information. Since the most recent observation gets a weight of 1, a lower value of ρ reduces the importance of prior history and increases recency effects.

Generally ρ will be between 0 and 1. When $\rho = 0$, the observations prior to the most recent one are ignored, and the model is one of best response to the previously observed price (Cournot dynamics). At the other extreme, when $\rho = 1$, the model reduces to 'fictitious play', in which each observation is given equal weight, regardless of the number of periods that have elapsed since. For intermediate values of ρ, the weight given to past observations declines geometrically over time.

The expected pay-off for player i choosing a price in category j is denoted by $\pi_i^{\mathrm{e}}(j|\rho)$. This determines player i's decision probabilities via the logit rule

$$P_i(j|p) = \frac{\exp\left(\pi_i^{\mathrm{e}}(j\,|\,\rho)/\mu\right)}{\sum_{k=1}^{101} \exp\left(\pi_i^{\mathrm{e}}(k\,|\,\rho)/\mu\right)},\ j = 1, \ldots, 101 \qquad (9)$$

Choice probabilities and expected pay-offs depend on the learning parameter. In this dynamic model, beliefs, and hence choices, depend on the history of what has been observed up to that point. Since individual histories are realizations of a stochastic process, the predictions of this model will be stochastic and can be analyzed with simulation techniques.

The structure of the computer simulation program matches that of the experiment reported below: for each session, or 'run', there are 10 simulated subjects who are randomly matched in a sequence of 10 periods. We specify initial prior beliefs for each subject to be uniform on the integers in the set [60, 160]. These priors determine expected pay-offs for each price, which in turn determine the choice probabilities via the logit rule in equation 9. The simulation begins by determining each simulated player's actual price choice for period 1 as a draw from the logit probabilistic response to the pay-offs for priors that are uniform on [60, 160]. The simulated players are randomly divided into five pairs, and each player 'sees' the other's actual price choice. These price observations are used to update players' beliefs using the naive learning rule explained above, with a learning parameter $\rho = 0.72$ (which was estimated from the data). The updated beliefs, which become the priors for period 2, will not all be the same if the simulated subjects encountered different price choices in period 1. The process is repeated, with the period-2 priors determining expected pay-offs, which in turn determine the logit choice probabilities, and hence the observed price realizations for that period. The whole process is repeated for 10 periods.

Figure 4 shows the sequences of average prices obtained from 1000 simulations, together with dotted lines indicating two standard deviations of the average. These simulation results predict that average prices decline in the $R = 0.2$ treatment and stay the same in the $R = 0.8$ treatment, as observed in the data. Thus, the learning model explains the salient features of the experimental data: both the directions of adjustment and the steady-state levels.

STOCHASTIC LEARNING EQUILIBRIUM

Next we consider what the learning model implies about the long-run steady-state distribution of price decisions. In particular, will learning generate a price distribution that corresponds to some equilibrium?

At any point in time, different people will have different experiences or histories. These differences may be due to the randomness in individuals' decisions or to randomness in the random matching. For each person, the history of what they have seen will determine a probability distribution over their decisions. This mapping of histories to decision probabilities may be direct, as in reinforcement learning. Alternatively, histories may generate beliefs, which in turn produce decisions via a probabilistic choice rule. The decisions made are then appended to the existing histories, forming new histories. Because of the randomness in

decision-making, there will be a probability distribution over all possible histories.

In a steady state of the learning model, the probability distribution over histories remains unchanged over time. The 'stochastic learning equilibrium' is defined as the steady-state probability distribution over histories. This formulation is general and includes many learning models as special cases. Goeree and Holt (2002) show that this equilibrium always exists when there is a finite number of decisions and players have finite (but possibly long) memories.

For example, consider the extreme case where a person can only remember the two most recent observations in the probability-matching experiment. There are four possible remembered histories: LL, LR, RL, and RR, with exogenously determined probabilities of $\frac{3}{4}\times\frac{3}{4}$, $\frac{3}{4}\times\frac{1}{4}$, $\frac{1}{4}\times\frac{3}{4}$, and $\frac{1}{4}\times\frac{1}{4}$, respectively. A stochastic learning equilibrium in this context would be a vector of transition probabilities between these states. The formulation of this model in terms of histories (instead of single-period choice distributions) allows the possibility of dynamic effects such as cycles and endogenous learning rules. The focus on histories (sequences of vectors of players' decisions) also facilitates the proof that a stochastic learning exists under fairly general conditions.

Given a specific learning rule, it is possible to determine the stochastic learning equilibrium. To illustrate, consider the market price game under two extreme conditions, fictitious play ($\rho = 1$) and Cournot best response ($\rho = 0$). Since there is no 'forgetfulness' in fictitious play, any steady-state distribution of decisions will eventually be fully learned by all players, i.e. the empirical frequencies of price draws from the distribution will converge to that distribution. In this case, each player is making a logit probabilistic best response to the empirical distribution, and these best responses match the empirical distribution. Notice that all players must have identical beliefs in this equilibrium. This is known as a 'quantal response equilibrium' as defined by McKelvey and Palfrey (1995.)

When $\rho = 0$, a player's history is simply the most recent observation, and beliefs are necessarily different across players. These differences in individuals' beliefs add extra randomness into the steady state. Figure 5 illustrates these observations for the high-R treatment of the price-choice game. The solid line represents the stochastic learning equilibrium with an infinite memory ($\rho = 1$), and the dashed line represents the price distribution for the case of one-period memory ($\rho = 0$). Both of these distributions are hump-shaped, with means near the price average observed in the experiment. The implied distribution of price choices is flatter and more dispersed for the case of one-period memory, since beliefs are being moved around by recent observations, which introduces extra randomness. Both cases, however, capture the salient feature of the prices observed in the high-R treatment of the market experiment. In particular, price averages are more than twice as high as the unique Nash equilibrium prediction.

When maximum-likelihood techniques are used to estimate the learning parameter from the choices made by the human subjects, the resulting estimate ($\rho = 0.72$) is intermediate between the extreme cases shown in Figure 5, and the resulting steady-state price distribution will also be intermediate. In fact, the weights determined by powers of 0.72 decline very quickly, and the equilibrium price distribution is rather close to the flatter ($\rho = 0$) case, as can be confirmed with computer simulations. Simulations of individual cohorts of 10 subjects (not shown) show the same up-and-down patterns exhibited by comparably sized cohorts of humans. The simulation averages shown in Figure 4 track the main features of the human data: prices start high and stay high in one treatment, and they start high and decline towards the Nash prediction in the other. Thus, computer simulations of learning models can explain data patterns that are not predicted with standard equilibrium techniques. In fact, we ran the computer simulations before we ran the experiments with human subjects, using the learning and error parameter estimates from a previous experiment (Capra *et al*., 1999). The simulations helped us select two values of the treatment parameter R that would ensure that there would be a strong treatment effect that is not predicted by the Nash equilibrium.

SUMMARY

The learning models presented here were pioneered by Bush and Mosteller (1955), and the stochastic choice models were introduced by the mathematical psychologist Luce (1959) and others. These techniques no longer receive much attention in the psychology literature, where the main interest is in theories of learning, biases, and heuristics that have a richer cognitive content. Yet they have yielded important insights in explaining economics experiments where the anonymity and repetitiveness of market interactions dominate. The incorporation of insights from the literature on heuristics and biases may also prove to be valuable in the future.

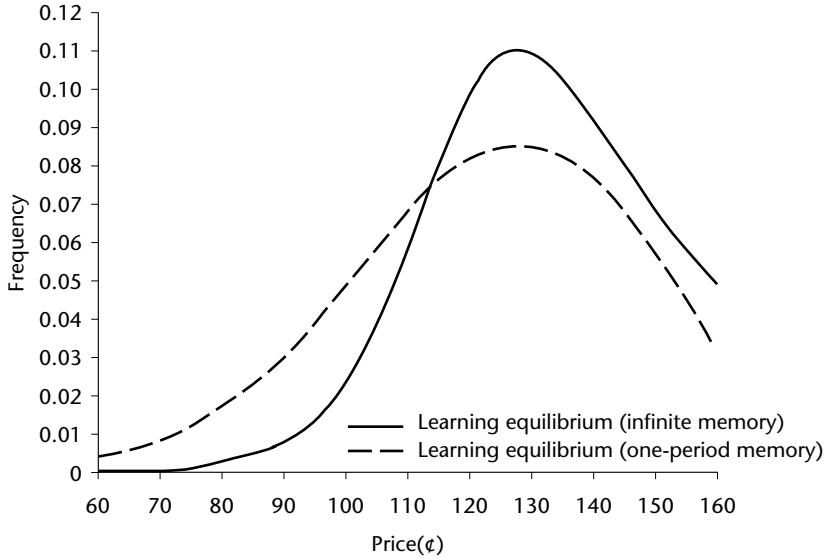

Figure 5. Stochastic learning equilibrium distribution of prices in the price-choice game for $R = 0.8$.

The belief- and reinforcement-based learning models depend on past history in a somewhat mechanical manner. In contrast, some laboratory experiments provide situations in which learning seems to proceed in response to cognitive insights. For example, if one subject observes that another has earned more money, the first person may decide to try to imitate the other. Consider a market in which subjects choose 'production quantities' simultaneously, with the advance knowledge that the price at which all production is sold will be a decreasing function of the total quantity produced. Since all output is sold at the same price, the person with the highest quantity will have the highest sales revenue. To the extent that high revenues translate into high profits, the sellers with low quantities may be tempted to imitate the high-output strategies of those who have higher earnings. In this context, the process of imitating high-production sellers can cause the total production to be high. The implications of imitation learning have been studied in a series of recent economics experiments. Offerman and Sonnemans (1998), for example, find evidence that learning is induced to some extent both by imitation of others and by one's own experience.

When some people are following predictable learning patterns, it may be advantageous to try to manipulate others' beliefs via 'strategic teaching'. For example, a dominant seller may punish new entrants by expanding production quantity and thereby driving prices down. This behavior may be intended to 'teach' potential rivals not to enter. This is an important area for future research, and it is complicated by the fact that the person doing the teaching should have a mental model of the others' learning processes.

In some economic situations, learning may occur as a sudden realization that some different decision will provide higher earnings or will avoid losses. A first step in the study of this type of learning may be to measure biological indicators of mental activity for economic tasks that may involve sharp changes in behavior or attempts to anticipate others' decisions (McCabe *et al*., 2000).

CONTENTS

Experimental economics uses laboratory methodology to examine motivated human behavior and its interpretation in small group interactive games, and in bidding, auctioning, and market institutions. Subjects earn cash payments depending upon their joint interactive decisions, and the rules governing their interactions.

INTRODUCTION

It is useful to distinguish three complex self-ordering systems: the internal order of the mind (Hayek, 1952); the external order of social exchange between minds (McCabe and Smith, 2001); and the extended order of cooperation through markets and other cultural institutions (Hayek, 1988). Our concern here is with the first two.

We focus on social exchange because it was the cooperative behaviors registered in two-person anonymous interaction that first alerted experimental economists to a significant class of phenomena that violate certain static equilibrium concepts in game theory. Game theory is about strategic interdependent choice when the pay-off benefit to each of two or more people depends jointly on their decisions. These refutations generated alternative interpretations of that theory, and motivated questions directly concerned with the internal order of the mind. They are now leading to the study of the neural correlates of human decision-making in two-person strategic interactions.

Why do we study anonymous interactions? First, our theoretical model of single-play games assumes strangers without a history or a future, and anonymity provides the required control for testing this theory. Also, it is well documented that the effects of face-to-face interaction hide more subtle procedural effects in yielding cooperative outcomes (Hoffman and Spitzer, 1985). As will be illustrated in the experiments reported below, the anonymity condition provides great scope for exploring the natural human instinct for social exchange, and how it is affected by context, reward, and procedure.

Why Should Context Matter?

Context matters because all memory involves relationships and is associative. For example, priming experiments use cues to improve retrieval from memory because of associations between the cue and the stimulus. People perform better at completing word fragments (filling in missing letters) on words they have observed beforehand in lists, even if they are not told that the words appeared in the earlier list. Some priming effects are almost equally strong whether the interval between the original list and the test is a matter of hours or days. Furthermore, being able to state that a word was seen before does not correlate with improved completion performance. How one perceives a current task depends upon unconscious cues to past experience that are triggered by the context of the task. Two decision tasks with the same underlying logical structure may lead to different responses because they are embedded in different contexts and invoke different memory experiences (Gazzaniga *et al.*, 1998, pp. 258–261). This is because of the fundamental, though nonintuitive, nature of perception.

In the early 1950s Hayek articulated certain principles of perception, which are consistent with current neuroscientific understanding:

1. It is incorrect to suppose that experience is formed from the receipt of sensory impulses reflecting unchanging attributes of external objects in the physical environment. Rather, the process by which we learn about the external environment involves a relationship between current conditions and our past experience of similar conditions (Hayek, 1952, p. 165).
2. Categories are formed by the mind according to the relative frequency with which current perception and memory (past perceptions) concur (p. 64). What are

stored in memory are external stimuli modified by processing systems whose organization is conditioned by past experience of stimuli. All perception is produced by memory.

3. This leads to a 'constant dynamic interaction between perception and memory, which explains the … identity of processing and representational networks of the cortex that modern evidence indicates' (Fuster, 1999, p. 89). 'Although devoid of mathematical elaboration, Hayek's model clearly contains most of the elements of those later network models of associative memory … [and] comes closer, in some respects, to being neurophysiologically verifiable than those models developed 50 to 60 years after his.' (Fuster, 1999, pp. 88–89).

Hayek's model is incomplete, and did not influence the research it anticipated, but it captures the idea that perception is self-organized, created from abstract function combined with experience. This is relevant to the question of why context is important in the experiments reported below.

MENTAL MODULES AND EVOLUTIONARY PSYCHOLOGY

Evolutionary psychologists argue that the mind consists of circuitry, or interactive modules, that are specialized for vision, for language learning, for socialization, and for a host of other functions (Cosmides and Tooby, 1992). Language and socialization, which are of recent evolutionary origin, are hypothesized to have evolved in the two to three million years during which humans subsisted as hunter–gatherers. It is in this evolutionary environment of our ancestors (EEA) that humans developed mechanisms of social exchange in which assistance, meat, favors, information and other services and valuables were traded across time. This is evident in extant hunter–gatherer societies (e.g. the Ache of Paraguay) in which the product of the hunt is widely shared within the tribe as well as within the nuclear and extended family. In a world without refrigeration and only rare success in hunting, this made sense: if I am lucky in the hunt today, I share the meat with others; and tomorrow, when I fail to make a kill, you share your kill with me and with others. In contrast, the products of gathering – fruit, nuts, roots – depend more on effort than on luck, are much more predictable from day to day, and are shared only in the nuclear family where effort can be closely monitored. Traditions of sharing across time provide gains from exchange that support limited forms of specialization: women and children do the gathering; adult men do the hunting; older men make tools, advise in the hunt, and assist in gathering. Such patterns (subject to numerous variations) are common in tribal communities.

But delayed exchange across time based on reciprocity is hazardous. Favors cannot be retracted, and you might systematically fail to return mine. Without money – a recent invention not available in the EEA – it is adaptive to develop some skill in making judgments about who can or cannot be trusted. This puts a premium on 'mindreading', the ability to infer mental states from the words and actions of others. The minimal mental equipment required is a 'cheater-detector module' for social exchange. The results of experiments designed by Cosmides (1985) are consistent with the hypothesis that the human mind is attuned to detecting cheaters on perceived social contracts. With the development of language, our instincts for cheater detection were enhanced by gossip: comparing notes to determine those with good reputations for returning favors. Gossip, like language and reciprocity, is a human universal, an activity pursued in all human communities. None of this mental equipment was the product of our reason: rather, it was the unconscious product of the biological and cultural evolution that distinguished us from other primates.

Evolutionary psychologists see an inevitable tension between who we are (based on what we have inherited from the EEA) and the demands made on us by the world since the agricultural revolution 10,000 years ago. One account of this tension was articulated by Hayek: 'Part of our present difficulty is that we must constantly adjust our lives, our thoughts and our emotions, in order to live simultaneously within different kinds of orders according to different rules. If we were to apply the unmodified, uncurbed rules (a caring intervention to do visible good) … of the small band or troop, or of, say, our families, to … our wider civilization (the extended order of the market), as our instincts … often make us wish to do, *we would destroy it*. Yet if we were always to apply the rules of the extended order (action in the self-interest within competitive markets) to our more intimate groupings, *we would crush them*. So we must learn to live in two sorts of world at once.' (Hayek, 1988, p. 18).

This observation raises questions about game theory, which postulates that the players are strictly self-interested and that this condition is common knowledge to all the players. How is action in the self-interest affected by whether the anonymous players are in an *n*-person market or a two-person interactive game? How do the players come to have 'common knowledge'? Does the

procedural and instructional context of a two-person game affect cooperation by influencing how the players perceive the game? It is most natural to investigate such questions in experimental environments where monetary pay-offs, context, and interaction procedures can be controlled.

EXPERIMENTAL PROCEDURES

The experiments reported below show that context is important in the decision behavior we observe. This is to be expected, given what is known about the autobiographical character of memory and the interaction between current and past experience in creating memory. Below are reported behavioral results in two-person sequential-move game trees in which each pair plays once and only once through the move sequence defined by the tree, and the game is completely known to the subjects. However, the instructions for the experiments do not (except in systematic treatments) use words like 'game', 'play', 'player', 'opponent', or 'partner'; rather, reference is made to the 'decision tree', 'decision maker' 1 (DM1) or 2 (DM2), 'your counterpart', and other terms designed to provide a baseline context.

Your experience as a subject in a typical experiment might be as follows. You have been recruited to participate in an economics experiment for which you will be paid \$5 (or more, in some cases) for arriving on schedule, plus the amount in cash that you earn from your decisions, to be paid to you at the end. You arrive, sign in, receive \$5, and are assigned to a computer terminal in a large room with 40 stations. There are 11 other people, well spaced throughout the room. Each station is a partially enclosed booth, making it very easy to maintain your privacy. After everyone has arrived you log in to the experiment as directed on your screen. You read through the instructions for the experiment at your own pace, respond to the questions, and learn that in this experiment you are matched anonymously with another person in the room, whose identity you will never know, and vice versa. This does not mean that you know nothing about that person: it may seem evident that he or she is another 'like' person – for example, an undergraduate – with whom you may feel more or less of an in-group identity. Obviously, you bring with you a host of past experiences and impressions that you are likely to apply to the experiment.

Ultimatum Game Experiments

Consider the following simple two-stage two-person game. A fixed sum of money m is provided by the experimenter (e.g. m might be 10 one-dollar bills, or 10 ten-dollar bills). Player 1 moves first, proposing that a portion $x \leq m$ of the money be offered to player 2, player 1 retaining $m - x$. The offer is a 'take it or leave it' ultimatum. Player 2 then responds by either accepting the offer, in which case the experimenter pays $m - x$ to player 1 and x to player 2, or rejecting the offer, in which case each player receives 0.

Now consider four different instructional–procedural contexts in which an ultimatum game with this underlying abstract structure is played. In each case, imagine that you are the first mover (player 1 in the above abstract form). (See Hoffman *et al.* (2000) for instructional details, and for references to the literature and origins of the ultimatum game.)

Context 1: 'divide \$10'

In the first context, the instructions state that you and your anonymous counterpart have been 'provisionally allocated \$10'. Your task is to 'divide' the \$10 using the following procedure. You have been randomly assigned to the role of first mover. You (as person A) are asked to complete boxes (4) and (5) of the proposal form shown in Figure 1. The form then goes to your counterpart (person B) who checks 'Accept' or 'Reject'.

In this version, the \$10 consists of 10 one-dollar bills. In another version, there is \$100 (10 ten-dollar bills) to be divided.

Context 2: 'contest entitlement'

In the second context, each of the 12 people in the room takes the same general-knowledge quiz (10 questions). The results are used to determine the positions of persons A and B in each pairing. Your score is the number of questions answered

(1) Identification number..... #A

(2) Paired with..... #B

(3) Amount to divide..... \$10

(4) Person B receives .....

(5) Person A receives (3)–(4) .....

(6) Accept ☐ Reject ☐

Figure 1. Proposal form for an ultimatum game experiment using the 'divide \$10' context. You (as person A) are asked to complete boxes (4) and (5); the form then goes to your counterpart (person B) who checks 'Accept' or 'Reject'.

correctly, with ties broken in favor of the person who finished the quiz fastest. The scores are ranked from 1 (highest) to 12 (lowest). Those ranked from 1 to 6 will have 'earned' the right to be person A; the other six will be person B.

Context 3: 'exchange'

In the third context, person A is a 'seller' and B is a 'buyer'. A table lists the profit of the seller and of the buyer for each possible price ($0, $1, $2, …, $10) charged by the seller if the buyer chooses to buy. The profit of the seller is equal to the price chosen; the profit of the buyer is $10 minus the price. The profit of each is zero if the buyer refuses to buy at the price chosen by the seller.

Context 4: 'contest–exchange'

The fourth context combines the second and third: 'sellers' are selected by a general-knowledge quiz. In one version the total amount is 10 one-dollar bills; in another, it is 10 ten-dollar bills.

Results of Ultimatum Game Experiments

The game-theoretic concept of sub-game perfect equilibrium (SPE) yields the same prediction in all of these versions of the ultimatum game (Selten, 1975): player 1 offers the minimum positive unit of account ($1 if $m = \$10$, $10 if $m = \$100$), and player 2 accepts the offer. The analysis assumes that each player is self-interested in the sense of always choosing the largest of two pay-offs for himself or herself; that this condition is common knowledge for the two players; and that player 1 applies backward induction to the decision problem faced by player 2, conditional on player 1's offer. Thus player 1 should reason that any positive pay-off is better than zero for player 2, and therefore, player 1 need only offer the minimum positive amount.

But there are other models of decision for games like the ultimatum. A problem with the above analysis is that, perhaps depending on context, the ultimatum interaction may be interpreted as a social exchange between any two anonymously matched players who normally read intentions into the actions of others (Baron-Cohen, 1995). Suppose that the ultimatum game is perceived as a social contract in which player 2 has a ('fair claim') entitlement to more than the minimum unit of account; then an offer of less than the perceived entitlement (say, only $1, or perhaps even $2 or $3) may be rejected by some players 2. Player 1, reading this potential mental state of player 2 (e.g. by imagining what he or she would do in the same circumstance), might then offer substantially more than $1 to ensure acceptance.

Observe that in context 1, the original $10 is allocated imprecisely to both players, and does not clearly belong to either person A or B. Further, a common interpretation of the word 'divide' involves the separation of some divisible quantity into equal parts. Moreover, in western culture the use of a lottery or other random device is recognized as a standard mechanism for 'fair' or equal treatment. Hence, the instructions can be interpreted as suggesting that the experimenter is engaged in a 'fair' treatment of the subjects. This can serve as a strong, albeit unconscious, cue that the subjects ought to be 'fair' in their treatment of each other.

By contrast, context 2 deliberately introduces a contest procedure, before the game itself, in which those who score the highest earn the right to be person A, and those who score the lowest will be person B. In this treatment, nothing is said about who has been initially allocated the money, and the word 'divide' is not used. Rather, person A must choose how much person B is to receive, and person B must choose to accept or reject the proposal. Consequently, the instructions may cue some norm of 'just desert' based on test performance.

In context 3, the abstract ultimatum game is embedded in a transaction between a buyer and a seller. In such exchanges, buyers (in western culture) do not normally question the right of the seller to move first by quoting a price, nor that of the buyer to respond with a decision to buy or not to buy.

Context 4 combines the implicit 'property right' norm of a seller with an explicit mechanism whereby subjects 'earn' the privilege of being the seller in a contest whose outcome provides the same opportunity for all participants, depending on their general knowledge. This treatment introduces the 'equal opportunity' norm, as opposed to 'equality of outcome'.

Table 1 summarizes the results from two different studies of ultimatum game bargaining with stakes of either 10 one-dollar or 10 ten-dollar bills, where the number of pairs of players varies from 23 to 27. Note that 'divide' with random entitlement corresponds to context 1; 'divide' with earned entitlement to context 2; 'exchange' with random entitlement to context 3; and 'exchange' with earned entitlement to context 4.

Comparing 'divide $10' with 'divide $100' under random entitlement, we observe a trivial difference

Table 1. Mean percentage offered in ultimatum games, by context treatment. Data from Hoffman *et al*. (1996) and (1994)

		$10 stakes 'Divide'	*$100 stakes 'Exchange'*	*'Divide'*	*'Exchange'*
Random entitlement	Mean offer	43.7%	37.1%	44.4%	(n/a)
	N	24	24	27	(n/a)
	Rejection rate[a]	8.3%	8.3%	3.7%	(n/a)
Earned entitlement	Mean offer	36.2%	30.8%	(n/a)	27.8%
	N	24	24	(n/a)	23
	Rejection rate[a]	0	12.5%	(n/a)	21.7%

[a]Percentage of the *N* pairs in which the second player rejects the offer of the first.

in the amount offered between the low stakes (43.7%) and the high stakes (44.4%). There is no significant difference in the rate at which offers are rejected (8.3% and 3.7% respectively).

When 'exchange' is combined with an earned entitlement, the increase in stakes seems to lower the offer percentage from 30.8% for $10 stakes to 27.8% for $100 stakes, but this difference is within the normal range of sampling error using different groups of subjects and is not significant. Surprisingly, this minuscule decline in the mean offer correlates with an increase in the rejection rate from 12.5% to 21.7%. In the high-stake game, three out of four subject players 1 offering $10 are rejected, and one offer of $30 is rejected. As we shall see below in other games, this behavior is associated with a strong human propensity to incur personal cost to punish those who are perceived as cheaters, even under strict anonymity (as in Cosmides, 1985).

Comparing the 'divide' and 'exchange' conditions with random entitlement and $10 stakes, the offer percentage declines from 43.7% to 37.1%, and comparing the 'divide' conditions with random and earned entitlement and $10 stakes the offer percentage declines from 43.7% to 36.2%. Both reductions are statistically significant. Even more significant is the reduction from 43.7% to 30.8% with the 'exchange' condition and earned entitlement. Moreover, in all four of these contexts the rejection rate is null or modest (0 to 12.5%).

The small proportion of offers rejected (except when the stakes are $100 in the 'contest–exchange' context, where the mean offers decline to 27.8%) indicates that players 1 generally read their counterparts well and offer a sufficient amount to avoid being rejected. The one exception shows that trying to push back the boundary, even if it seems justified by the higher stakes, may provoke rejections.

One obvious conclusion from these data is that the effect of context on behavior cannot be ignored in the ultimatum game: the percentage offered varies by over a third between the highest (44%) to the lowest (28%) measured values. Studies of cross-cultural variation in ultimatum offers show a comparable variation. Thus, a comparison of two hunter–gatherer and five modern cultures reveals a variation from a maximum of 48% (Los Angeles subjects) to a minimum of 26% (Machiguenga subjects from Peru) (Heinrich, 2000). These comparisons attempted to control for instructional differences across different languages, but of course this is inherently problematic in that one cannot be sure that the translations, or the procedures for handling the subjects, completely control for context across cultures. Nor can it be assumed that the pay-offs are subjectively comparable across currencies.

The instructional comparisons also call into question the extent to which one can define what is meant by 'unbiased' instructions. Some results may be robust with respect to instructional changes, but this can only be established empirically, since we know little about the sources of behavioral variation due to context. Indeed, unless such robustness is established no claims can be made concerning the relative 'neutrality' of instructions, and the extent to which differences in behavior can be attributed to differences between cultures.

Because of the nature of perception and memory, we should expect context to be an important factor. In the ultimatum game, the variation of observed results with systematic instructional changes designed to alter context shows clearly that context can and does matter.

Trust Games

Ultimatum games have been studied extensively, but because of their simplicity they leave unanswered many questions about what underlies the behavior manifest in them. For example, one

cannot vary independently the cost of player 2's rejection of player 1's offer. The game is constant-sum, and is inherently confrontational: neither player can take action that increases the total gains from the transaction, and therefore the interpretation of the game as an exchange is limited.

We turn therefore to a somewhat richer class of two-person extensive-form trust games in which the return to equilibrium play, cooperation, defection, and the prospect of costly punishment of defection can be studied in a richer parameter space than that of the ultimatum game.

Figure 2(a) shows a trust game tree. Play starts at the top, node x_1, with player 1. Player 1 can move right; this stops the game, yielding \$7 to player 1 and \$14 to player 2. Alternatively, player 1 can move down, in which case player 2 has to choose a move at node x_2. If player 2 moves right, each player gets \$8. If player 2 moves down, player 1 can then move right at node x_3, yielding \$10 for each, or down, yielding \$12 for player 1 and \$6 for player 2.

The SPE is \$8 for each player. This is because at node x_1 player 1 can look ahead (use 'backward induction') to see that if play reaches node x_3 player 1 will want to move down. But player 2, also using backward induction, will see that at node x_2 player 2 should move right. Since this yields a higher pay-off to player 1, at node x_1 player 1 should move down.

The SPE outcome would prevail by the logic of self-interested players who always choose dominant strategies. There are other behavioral possibilities, however, depending on whether other preferences or perceptions of the interaction are applied.

If player 1 has other-regarding preferences (altruism, or utility from the other's pay-off), and is willing to incur some cost to greatly increase the pay-off to player 2, player 1 may move right at x_1. That way, at a cost of \$1, player 1 can increase player 2's pay-off by \$6, compared with the SPE. Thus, player 1 need have only a modest preference for an increase in player 2's welfare in order to move right.

At x_2, player 2 may move down, signaling to player 1 that such a move enables both to profit, provided that at x_3 player 1 cooperates by reciprocating player 2's favor. Alternatively, at x_3 player 1 can defect, by choosing the dominant strategy and moving down.

Figure 2(b) shows the tree for a punishment version of the trust game shown in Figure 2(a). The trees are identical except that at node x_3, player 1 chooses between the cooperation pay-off and passing back to player 2 at node x_4. Now player 2 decides whether to accept the defection or, at a cost, punish player 1 for the defection. By backward induction, the SPE is the same in the punishment version. The cooperation outcome can be justified (as a Nash equilibrium) only if the threat of punishment by player 2 at node x_4 is credible. But under the anonymity conditions, with no capacity to communicate, such a threat is not credible.

The outcome frequencies for the trust game ($N = 26$ pairs), and for the trust–punishment game ($N = 29$ pairs) are summarized in Figure 3.

In neither game is there a single case of a player 1 choosing the altruism outcome: all choose to pass to player 2, seeking a higher pay-off for themselves, and being content to give player 2 a much smaller pay-off than would be achieved by altruism.

The sub-game perfect equilibrium is chosen by 54% of the pairs in the trust game, and 55% in the trust–punishment game. Thus, there is no significant difference in behavior between the two games in terms of the frequency with which players 2 offer to cooperate by passing to players 1 at x_2.

There is, however, a considerable difference in the response of players 1 to the offer to cooperate: only 50% cooperate in the trust game, while 85% cooperate when facing the prospect of punishment for defection.

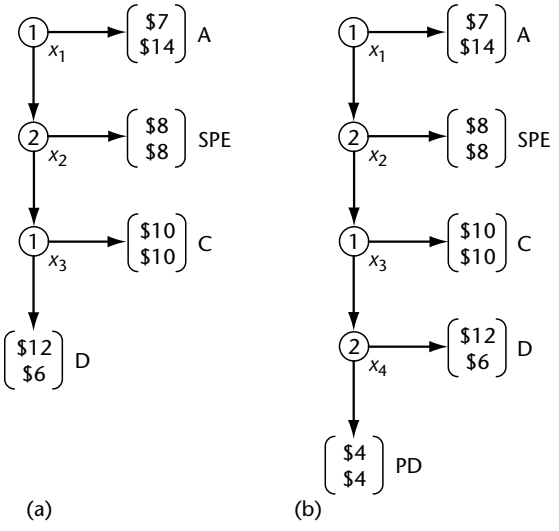

Figure 2. Trust game trees, (a) without punishment and (b) with punishment. At each terminal node the pay-off to player 1 is shown above the pay-off to player 2.

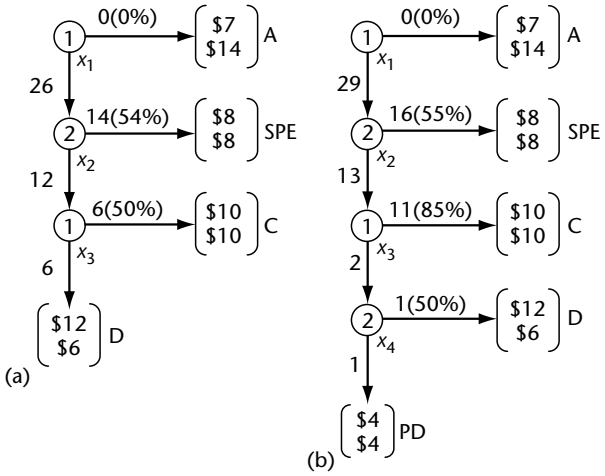

A: Altruism
SPE: Sub-game perfect equilibrium
D: Defection
C: Cooperation
PD: Punish defection

Figure 3. Experimental outcomes for the (a) trust and (b) trust–punishment games shown in Figure 2. A total of 26 subject pairs took part in the trust game and 29 in the trust–punishment game. The figures beside the arrows indicate the number of pairs following each route through the game tree and the percentage moving right at each decision node. The data are from McCabe *et al*. (2000). Source data for larger trees have been trimmed to eliminate rare outcomes, with commensurate reduction in sample size (from 30 to 29 in the punishment version).

Across the two games, why do nearly half of the players 1 forgo the sure SPE payoff in favor of the risky prospect of cooperation? McCabe and Smith (2001) argue that humans are eminently adapted for social exchange, or reciprocity among the individuals that constitute the small groups that form our primary networks of relationships. We constantly trade favors, services and assistance, with little conscious awareness of these trading relationships that are so much a part of our humanity. McCabe and Smith postulate an implicit mental accounting system for keeping track of trustworthy trading partners. This accounting system is part of the framework of our friendships and social connections.

Reciprocity is a human universal, characteristic of all cultures, as is the use of a spoken language. Like language, the form of reciprocity varies across cultures, but its common functionality is to produce gains from exchange. Smith (1998) argues that reciprocity in the family, extended family, and tribe is what ultimately led to the extended order of cooperation through market trade. He postulates that this proclivity for reciprocal social exchange is so natural and instinctive that it survives even in interactions between anonymously paired subjects in the two-person extensive-form games described above.

This interpretation has been reinforced by many other extensive-form game-tree experiments. Thus, in the game shown in Figure 4, player 1 chooses between the SPE, \$10 for each, and passing to player 2 who chooses between pay-offs of \$15 and \$25 (for players 1 and 2 respectively) and pay-offs of \$0 and \$40. The move frequencies for 24 pairs of undergraduates are shown on the tree. Very similar outcomes prevail with a group of graduate students trained in economics and game theory (McCabe and Smith, 1999).

Effects of Context, Repetition, and Opportunity Costs in Trust Games

The sensitivity of cooperative behavior in trust games to the procedural, instructional, and opportunity cost context of the experiment has been demonstrated by several treatment manipulations.

'Partners' versus 'opponents'

Consider two treatment variations on the trust game of Figure 2(a): wherever the word 'counterpart' is used in the instructions to refer to the other decision maker, substitute the word 'partner' in one treatment and 'opponent' in the other (Burnham *et al.*, 2000). Subjects (156 pairs in total) were recruited in either 'small' groups of 12 in a session or 'large' groups of 24 in a session. In all sessions, half of the subjects (6 or 12) were randomly assigned to each of the two instructional conditions;

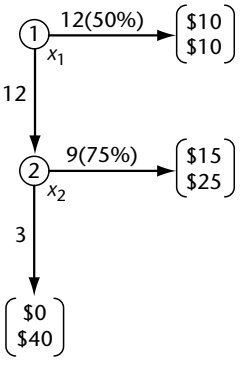

Figure 4. Experimental outcomes for a simple trust game (McCabe and Smith, 1999). A total of 24 subject pairs took part in the game. The figures beside the arrows indicate the number of pairs following each route though the game tree and the percentage moving right at each decision node.

each person was randomly paired with another and assigned to the player 1 or player 2 role; and the two experiments were run simultaneously in the same room. Neither group was informed that the other was reading slightly different instructions. Thus, the experimental design consisted of two group sizes, 12 or 24, and two instructional conditions, 'partner' and 'opponent'.

Each session began with a single play of the trust game. The subjects were then paid and informed that they would also participate in a second experiment. This second experiment used the same instructions except that the game was repeated for 10 periods of play. On each period of play, each person was matched with a new person, then randomly assigned the role of player 1 or 2. Each repetition was therefore between paired strangers. This is called 'repeat single' play. Repeat single play is like single play except that the subjects acquire experience under procedures that control for reputation formation across successive interactions.

It was found that 'partners' are more trusting (players 2 move down at node x_2) and more trustworthy (players 1 move right at x_3) than 'opponents'. (In the first single-play game, however, no difference was observed in the frequency of trust between the two treatments, but 68% of the 'partner' players 1 cooperated following an offer of cooperation, while only 33% of the 'opponent' players did.)

Over time (single play followed by 10 repeat single plays), with 'partners' trust increases through the first five plays then declines, while with 'opponents' trust steadily declines. Trustworthiness declines over time for 'partners', and remains low for 'opponents'. Hence, 'partners' learn to defect, but 'opponents' defect from the beginning.

Pairs who interact in groups of size 24 are less trusting than those in groups of size 12.

These results provide further support for the hypothesis, based on cortical memory theory, that context should matter. In this case, a simple two-level variation on the language used to describe the other person in each trial is sufficient to yield statistically significant differences in trust and trustworthiness.

Repeat single with and without punishment

The tendency for cooperation eventually to decline as play is repeated with distinct 'partners' is already suggested by Figure 3(a): of the 12 players 1 arriving at node x_3, half reciprocate and half defect. Hence, it is not profitable to offer cooperation in the trust game, and repetition with strangers is likely to cause a decline in cooperation, both offered and reciprocated, across time.

In the trust–punishment game in Figure 3(b), however, 85% reciprocate at node x_3, and only 15% defect, of which half are punished. Hence, it is profitable to offer cooperation, and it is not profitable to defect. This suggests that in repetition, using the repeat-single protocol, cooperation might not diminish. In fact, this is the case: when defection can be punished, the conditional probability of reciprocal cooperation by players 1 actually increases modestly across 15 periods of play (McCabe *et al.*, 2000).

Opportunity cost

An important implication of reciprocity theory (the value of option 'y' given up by choosing 'x') is that when person A chooses to forgo the SPE outcome and offer the cooperative option to person B, the pay-off alternatives should be such that person B sees clearly that person A is incurring an 'opportunity cost' – forgoing a smaller pay-off in an attempt to allow both persons to achieve larger pay-offs. There should be a cost incurred in order to gain from exchange. Failing this condition, the basis for an exchange, or reciprocation, is compromised: person B would be less likely to read clearly the intentions of person A, and person A will anticipate that an unclear message would be being conveyed.

Thus, in Figure 2, if instead of \$8 the SPE is \$10 for each player – identical to the 'cooperative' outcome – the outcome frequency results should change dramatically. This has been tested for the trust–punishment game tree in Figure 2(b) (McCabe *et al.*, 2002). The effect is to increase the frequency of the SPE outcome to about 95%. Thus, players have no difficulty concluding that the attempt to cooperate by player 2 at node x_2 is risky, and will not be chosen unless there is a compensating potential gain.

Another test of reciprocity is to contrast two versions of a game with the structure of Figure 4. Version 1 is like that in Figure 4, with different pay-offs but qualitatively the same outcomes. In version 2, player 1 has no option to move right. The prediction is that version 1 will yield more cooperative outcomes then version 2. In fact, defection is twice as frequent in version 2 as it is in version 1. The interpretation is that if nothing was given up by player 1 – the move did not deliberately forgo the pay-offs achievable at the SPE – then player 1's move does not constitute an 'offer'; so nothing need be reciprocated.

THEORY OF MIND AND ITS NEURAL CORRELATES

Experimental tests of non-cooperative equilibrium theory using anonymously paired subjects in two-person games consistently show that people do cooperate. Almost all subjects in the ultimatum game offer amounts in excess of the equilibrium predictions, and when they do offer equilibrium amounts their counterparts almost always reject the offer. Similarly, in trust games, up to half of subjects offer to cooperate at the risk of defection; and in varying degrees, depending on context, their counterparts cooperate at a cost to themselves. These data cannot be explained simply in terms of preferences – a utility for the other's payoff – nor can they be dismissed by the argument that the subjects are too unsophisticated or inadequately motivated.

A more satisfactory model is based on reciprocity and the human ability to communicate intentions through actions. This ability to invoke shared-attention, intention-detector, and 'mindreading' mechanisms in the brain is relevant to other observations of behavior in people impaired by frontal lobe damage and by autism.

Autism (whose genetic basis is indicated by its greater incidence in siblings and in identical twins) is characterized by 'mind blindness', a severe deficit in one's innate awareness of mental phenomena in other people. Children with autism fail developmentally to use pointing gestures to request objects or otherwise call the attention of others to items of joint interest. In contrast, blind children at age 3 are aware of what 'seeing' is in others, and will say 'see what I have'. At about age 3 or 4, normal children become aware of beliefs in others, and understand that others can hold false beliefs. Thus, shown a candy box, and asked what it contains, normal children will say that it contains candy. Upon opening the box, the child sees that pencils have replaced the candy. The child is then asked what the next child who comes in the room will think is in the box. Normal children will reply 'candy', whereas the majority of autistic children will say 'pencils' (Baron-Cohen, 1995).

Studies of autism, and of certain forms of brain damage from accidents or surgery, support hypotheses that particular regions of the brain have circuitry devoted to 'mindreading', an innate capacity for unconscious awareness of what others think or believe. Brain imaging studies of third-party false beliefs in story comprehension tasks have found activation in Broadman's area 8 (medial prefrontal cortex), and in other supporting regions such as the orbital frontal cortex (Fletcher *et al*., 1995). This role of Broadman's area 8 has been specifically corroborated by functional magnetic resonance imaging of subjects playing trust and trust–punishment games like those presented above (McCabe *et al*., 2001). These studies compare subjects' decision making when playing a human counterpart and when playing computer strategies with fixed known probabilities of moving 'left' or 'right'. Activation is significantly greater in the mindreading areas when playing a human than when playing a computer.

Thus, independent strands of research into the internal order of the mind and the external order of social exchange appear to be converging in support of the hypothesis that humans are so well adapted to personal exchange that reciprocity survives even in anonymous interactions.

Game Theory in Economics

Advanced article

Kevin A McCabe, George Mason University, Fairfax, Virginia, USA

CONTENTS

Game theory is an increasingly important tool to help economists understand the strategic interaction between groups of individual decision makers.

INTRODUCTION

One of the most frequent observations in experimental economics is that there is a great deal of variation in how subjects play. It seems reasonable to hypothesize that this variation exists because individuals differ in how they think about other players' rationality. While game theory provides us with a wealth of models that help provide retrospective explanations of why this variation is observed, these models have far less predictive capability. What seems to be missing is a unified treatment of cognition in strategic settings.

GAME THEORY AND DECISION THEORY

Game theory can be seen as the natural extension of rational-choice models of individual decision making as modeled by decision trees (Luce and Raiffa, 1957). Figure 1 gives a simple example of a decision tree. The first and second nodes of the decision tree are decision nodes, the first belonging to player 1, and the second to Nature. Player 1 must decide, before knowing Nature's move, whether or not to stop and make \$10 for sure, or go on and face a probability p of getting \$15 and $1-p$ of getting \$0. If player 1 desires to maximize the expected pay-off, then the decision whether or not to go on depends on whether p is sufficiently large that $p \times 15 + (1-p) \times 0 \geq 10$. If $p \geq \frac{2}{3}$ then player 1 should go on.

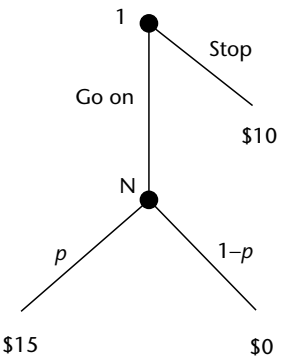

Figure 1. An individual decision problem for player 1 with perfect information.

We have assumed that the individual is interested in the monetary pay-offs associated with the outcome (or terminal) nodes. The usual economic assumption is that, everything else being equal, our player will prefer more money to less. However, in Figure 1 our player must choose between \$10 for sure, or a gamble g that pays \$15 with probability p and \$0 with probability $1-p$. We have assumed that our player will compute the expected value of g, that is, $15p$, in order to compare the value of the gamble to \$10. More generally, we could use expected-utility theory to model how our individual will choose between \$10 and the gamble. Let $U(x)$ be the subjective value that our player places on $\$x$. We assume U is an increasing, but not necessarily linear, function. In expected-utility theory, the value of g is calculated as $EU(g) = pU(15) + (1-p)U(0)$, and to make a choice our player would compare $U(10)$ to $EU(g)$. If the subject is trying to maximize expected utility, then the utility values should replace the pay-offs shown in Figure 1.

If the utility function for a player is nonlinear, an experimenter who wants to control individual values in an experiment faces a difficulty, since ultimately the experimenter pays off in dollars, not utilities. One approach is to risk-neutralize a subject by inducing a linear utility function. To do this, give the subject only two possible pay-offs, say \$5 and \$25. Now replace each dollar of pay-off with

a red lottery ticket. For example, \$0 is replaced by 0 red tickets, \$10 is replaced by 10 red tickets, and \$15 is replaced by 15 red tickets. When an outcome node is reached, the subject earns some number of red lottery tickets. Blue lottery tickets are then added until the total number of tickets is equal to 15, and all the tickets are then placed in an urn. One ticket (red or blue) is then randomly drawn from the urn. If the ticket is red, the subject earns \$25, valued at $U(25)$, and if it is blue, the subject earns \$5, valued at $U(5)$. Now, a subject who stops earns 10 tickets, valued at $\frac{1}{3}U(5)+\frac{2}{3}U(25)$. A subject who goes on earns either 15 tickets, valued at $U(25)$, with probability p, or 0 tickets, valued at $U(5)$, with probability $1-p$. We then know that the subject should go on just when $p \geq \frac{2}{3}$ since this is exactly the condition for $pU(25)+(1-p)U(5) \geq \frac{1}{3}U(5)+\frac{2}{3}U(25)$.

From here on we will simply use pay-off numbers, which can be thought of as utility values, but in experiments these numbers are either dollars or lottery tickets.

Consider the decision problem in Figure 2. Nature moves twice, but our player does not know which branch Nature chooses initially. If Nature has chosen the left branch, then Nature will be more likely ($p=\frac{3}{4}$) to choose 15 for the player, but if Nature has chosen the right branch, then Nature will be less likely ($p=\frac{1}{4}$) to choose 15 for the player. In the figure the decision nodes for the player are connected by a dashed line, indicating that they are in the same information set for the player. Nodes in the same information set must have the same number of branches, and they must all be played in the same way by the player, since the player does not know which of the decision nodes he or she is at. Suppose the player believes that Nature will choose the left branch 90% of the time, i.e., $q=0.9$. If the player decides to stop, the player gets 10, but if the player decides to go on, the expected pay-off is $0.9\times\frac{3}{4}\times 15+0.1\times\frac{1}{4}\times 15=10.5$. Since $10.5>10$, player 1 should go on.

EXTENSIVE-FORM GAMES

In Figure 1, Nature does not get a pay-off, or make choices, but instead is regarded as a probability distribution over possible actions outside the control of the individual. The use of types is suggested by Harsanyi (1995). If we replace Nature with another individual, we get the game tree shown in Figure 3. The pay-offs to player 2 are written below those to player 1. Thus, if player 1 stops, then player 2 also gets 10, but if player 1 goes on, then player 2 can either move left, in which case player 2 gets 25, or right, in which case player 2 gets 40. Given that player 2's actions are still outside the control of player 1, how should player 1 decide? To answer this question we can analyze the new decision problem as a two-person extensive-form game.

An extensive-form game with complete and perfect information can be defined as follows. Define a 'branch' as an arc that connects two nodes. A branch represents a move in the game. A node is an 'initial' node if it has no branches going into it, but has at least one branch leaving it. A node is a 'terminal' node if it has at least one branch going into it but no branches leaving it. A 'path' is a sequence of nodes that are connected by branches, starting at an initial node and ending at a terminal node. Nodes and branches must satisfy the following properties:

- All decision nodes are played by only one player.
- Each terminal node has a pay-off for every player in the game.

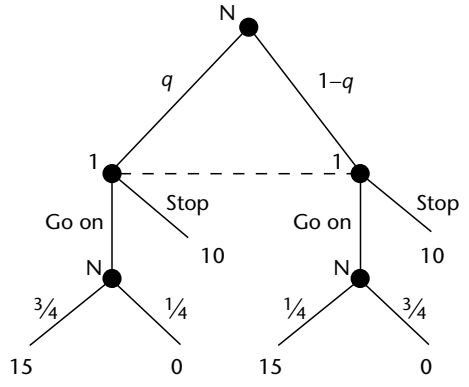

Figure 2. An individual decision problem for player 1 with imperfect information.

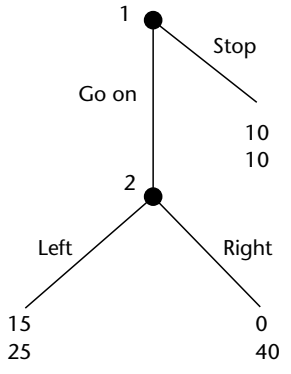

Figure 3. A two-person decision problem with perfect information.

- There is only one initial node.
- Every node, except the initial node, is connected to some earlier node (called its 'predecessor') by a single branch.
- Every terminal node is connected to the initial node by a unique path.

Kuhn (1953) showed that the principle of backwards induction can be used to guide player decisions. In backwards induction, each player reasons backwards through the tree, starting with the terminal nodes, and making the rational choice for each player at each decision node, assuming that decisions made after that node will also be rational.

The decision problem shown in Figure 3 is an extensive-form game with complete and perfect information. Using backwards induction, player 1 should reason as follows. If player 2 gets to move, player 2 will move right, since $40 > 25$. Therefore player 1 should stop.

However, in experiments with cash-motivated subjects, about half of the player 1s choose to go on, and of those player 2s who get to move, over two-thirds reciprocate the favor by moving left.

How can we explain this divergence from the theory? The value of game theory as a modeling tool becomes apparent as the experimenter attempts to reconcile the differences between theory and observation. One approach to explaining this divergence is to assume that Nature produces different types of player 2s.

Consider a simple model in which Nature creates two types of individuals who may end up being player 2. A 'trustworthy' type of player feels strongly compelled to reciprocate when believing she has received a favor. Moving left as player 2 may result in a pay-off of 40, but player 2 may 'feel' far worse off, like getting a pay-off of only 20. Trustworthy players will therefore move left, because $25 > 20$. The second type for player 2, the 'me' type of player, feels no such compunction, and plays right, since $40 > 25$.

This game can be described as in Figure 4, with Nature moving first. Notice the addition of an information set as a dashed line connecting player 1's two decision nodes. Player 1 does not know which node he is at, that is, which type player 2 is, when it is player 1's turn to move. On the other hand, player 2 knows his or her own type when player 2 gets to move.

Now suppose player 1 believes that more than two-thirds of player 2s provided by Nature are of the trustworthy type. (This frequency is shown as q in Figure 4.) Then player 1's expected pay-off is higher by going on, since $q \times 15 + (1 - q) \times 0 > 10$.

STRATEGIC-FORM GAMES

The extensive-form game shown in Figure 3 can be rewritten as the 'normal-form' or 'strategic-form' game shown in Figure 5. While in extensive-form games the order of moves is important, in a strategic-form game players choose their strategies simultaneously. All normal-form games can be written as n-dimensional arrays, with n being the number of players, making the game simpler to analyze. Kohlberg and Mertens (1986) show that the essential strategic features of all extensive-form games are retained when the games are converted to strategic form. When players move simultaneously it is less clear how they should think about the other player. Consequently, from a cognitive viewpoint it is likely that subjects think differently about how to play an extensive-form game and a strategically equivalent strategic-form game.

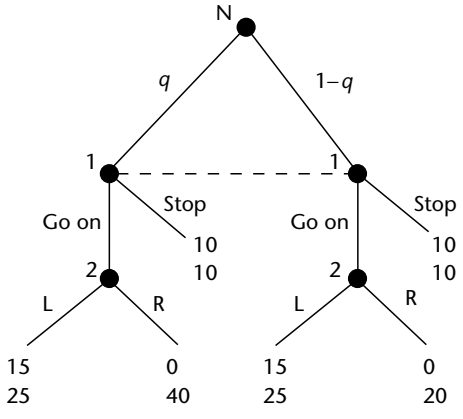

Figure 4. A two-person decision problem with incomplete information.

Player 1 \ Player 2	Left	Right
Stop	10 10	10 10
Go on	15 25	0 40

Figure 5. A two-person decision problem as a normal-form game.

In analyzing a strategic game, players must put themselves in each other's shoes and try to reason about how the other player will reason. For example, in Figure 5, player 1 can notice that player 2 is always no worse off by moving right. Such a choice is called a 'weakly dominant' strategy for player 2. Alternatively, we can say that moving right is a best response for player 2 independently of player 1's choice. For player 1, stopping is a best response to player 2's decision to move right. The pair of pure (deterministic) strategies (Stop, Right) is thus a 'Nash equilibrium', defined as a strategy for each player that is a best response to all the others.

Not every strategic-form game has a pure-strategy Nash equilibrium: consider, for example, the popular children's game of rock–scissors–paper, shown in Figure 6. If we extend our concept of a strategy to include 'mixed strategies' – choices of probability distributions over pure strategies – then, as Nash proved, every strategic game has a Nash equilibrium. In the case of rock–scissors–paper, each player should play each strategy with equal probability; i.e., the Nash equilibrium strategy is (⅓, ⅓, ⅓).

However, if player 2 knows that player 1 will play (⅓, ⅓, ⅓), then player 2 is just as well off playing (1, 0, 0), or rock for sure. Of course, player 2 does not want player 1 to know this, but how will player 1 find out? One approach to solving the 'incentive problem' associated with mixed strategies is to view a mixed strategy as the frequency distribution of pure strategies played in a frequently-replayed perturbed version of the original game (Harsanyi, 1977). Imagine that a game is frequently occurring and that a large population of potential players keeps experiencing minor fluctuations in their pay-offs. On average, they expect to play against someone playing (⅓, ⅓, ⅓). But suppose that if rock wins player 2's payoff is now $1+\varepsilon$, where $\varepsilon > 0$ is the small perturbation. Clearly player 2 now prefers (1, 0, 0), and will play it.

Figure 7 illustrates a game with two Nash equilibria, (Up, Left) and (Down, Right). What makes this game interesting is that even though (Up, Left) is preferred by both players, coordinating strategies on this equilibrium in simultaneous play is made difficult by the degree of risk associated with being wrong about guessing what the other player will do. Player 1 may reason as follows. 'If I play Up, and player 2 plays Right, then I get my worst pay-off, 0, and player 2 gets 9. Since getting 9 is not much worse than getting 10, player 2 has not given up much by playing Right, and if I play Down, then player 2 still gets 5. So player 2 has a lot of reasons to play Right. What is worse is that player 2 has probably reasoned the same way about me and is now convinced I will play Down, which I better now do.' Harsanyi and Selten (1988) appeal to the 'principle of insufficient reason' to define an equilibrium as 'risk-dominant' if each equilibrium strategy is a best response to the $n-1$ other-players mixed strategies that put equal weight on each of their possible pure strategies.

RATIONALIZING OTHER PLAYERS' DECISIONS

An important question in game theory is: what do people need to know about each other in order to make rational strategic choices? We have mentioned the 'default' reasoning, the principle of insufficient reason, which gives equal weight to other players' strategies. However, before falling back on this principle, subjects may do better to apply other methods such as backwards induction. Backwards induction can be generalized to strategic-form games as follows.

Player 1 \ Player 2	Rock	Scissors	Paper
Rock	0 0	1 0	0 1
Scissors	0 1	0 0	1 0
Paper	1 0	0 1	0 0

Figure 6. The game of rock–scissors–paper.

Player 1 \ Player 2	Left	Right
Up	10 10	0 9
Down	9 0	5 5

Figure 7. A risky coordination problem.

We say that a player's strategy s_i, is 'strictly dominated' by another strategy s_j if playing the strategy s_j will always return a higher pay-off than playing the strategy s_i. In this case, there is no set of beliefs for this player about the other players that would rationalize the use of the strategy s_i, and therefore we can eliminate this strategy from the player's choices. We can then repeat this procedure, eliminating any strictly-dominated strategies that remain, until all such strategies are gone. This process of iterative elimination of strictly-dominated strategies leaves only those strategies that are 'rationalizable'.

This principle can be generalized (Bicchieri, 1993; Osborne and Rubenstein, 1994). For example, we can extend this procedure to also eliminate weakly-dominated strategies. In Figure 5, Right weakly dominates Left for player 2 since it makes player 2 no worse off, no matter what player 1 does. Therefore we should eliminate Left. But then, for player 1 Stop strictly dominates Go-on, so we should eliminate Go-on. What remains is the dominance-solvable pair (Stop, Right).

Another principle that players may use is the principle of forward induction, as illustrated in Figure 8 – an extension of the game shown in Figure 4. In this game, after Nature moves by choosing player 2's type, player 2 gets to move. Player 2 can opt out and get 30, or player 2 can continue. The principle of forward induction asks: what should player 1 assume about player 2's strategy if player 2 chooses to continue? Obviously, player 2 is trying to win more than 30, which can occur only if Nature has chosen a 'me' type of player on the left branch. So, if player 2 chooses to continue, player 1 should realize that player 2 plans to move right, and therefore player 1 should stop. But this means that player 2 should always opt out, leaving player 1 with 5.

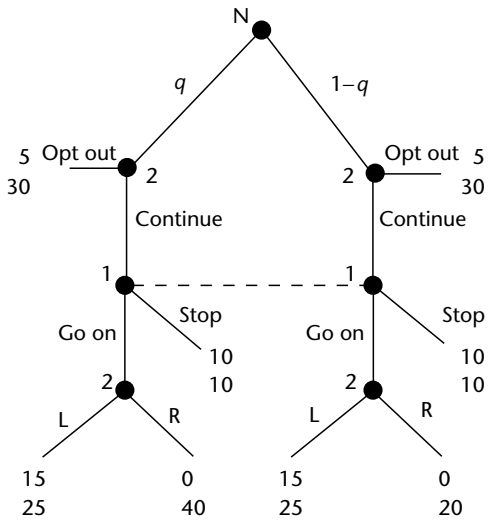

Figure 8. A two-person decision problem with incomplete information.

Going back to the risky coordination game in Figure 7, suppose we add the proviso that player 1 gets to choose whether or not to opt out and get 6 or continue and play the game. Again using the principle of forward induction, player 2 should assume that by choosing to continue player 1 plans to play Up. Furthermore, player 1 should assume that player 2, having made this analysis, will play Left. Thus player 1 should choose Continue, and then play Up with greater confidence that he or she will end up with 10.

REPEATED GAMES

Repeating a game allows for strategy spaces in which the play in future games depends on the play in past games. For example, in Figure 5, repeat game strategies (such as 'tit-for-tat' in the prisoner's-dilemma game) may be useful in achieving the more efficient (15, 25) or (0, 40) outcomes rather than the (10, 10) outcomes. Suppose, for example, player 1 adopts the following 'trigger' strategy: start by playing Go-on, and continue to play Go-on as long as player 2 continues to play Left; if player 2 chooses to play Right, then play Stop from then on. By playing Right, player 2 can get 40 (instead of 25), but from then on player 2 will get only 10.

If there is a fixed number of periods, this strategy is not an equilibrium strategy, for the following reason. In the last period, player 2 should play Right. Player 1 should realize this and play Stop. But then, player 2 should play Right in the second-to-last period. Again, player 1 should realize this and play Stop. By backwards induction, cooperation is unraveled all the way to the first period, with player 1 playing Stop. Kreps *et al.* (1982) show how adding a little bit of uncertainty about the other player's type is sufficient to achieve cooperation in the finitely-repeated prisoner's-dilemma game. Axelrod (1984) has shown that in practice people don't unravel the game using backwards induction, but rather play relatively myopically, while still incorporating elements of the repeat-game strategy. Given this, the trigger strategy can be replaced by the more forgiving strategy tit-for-tat, resulting in even larger efficiency gains.

McCabe and Smith (2002) report on a series of experiments with properties similar to the game shown in Figure 3, but where they vary the

likelihood that people will play each other again. They find that the likelihood of meeting again influences subjects' levels of cooperation. Both theoretical and empirical results point to the need for the experimenter to control for this likelihood. Different protocols are possible for an experiment with four people in which no pair will play each other twice. In the 'everyone meets once' condition, a total of six games will take place. However, there is still room for an indirect effect. In the first period, subjects 1 and 2 play and subjects 3 and 4 play. In the second period, subjects 1 and 3 play and subjects 2 and 4 play. In the third period, subjects 1 and 4 play and subjects 2 and 3 play. But subject 1 has already played subject 2 who has already played subject 4, so it is possible that subject 1 has already influenced subject 4's behavior before they play. To eliminate this contagion effect, the 'turnpike matching' condition is employed. This control reduces the number of observation pairs to four. In the first period, subjects 1 and 4 play. In the second period, subjects 1 and 3 play and subjects 2 and 4 play. In the third period, subjects 2 and 3 play. So subject 1 meets subject 4 and then subject 3, and subject 2 meets subject 4 and then subject 3.

CONTENTS

The centipede game is a finite N*-person extensive form game with perfect information for which the backward induction solution yields paradoxical results. It raises important questions concerning beliefs, knowledge, and rationality in interactive decision-making, which can be examined both theoretically and experimentally.*

INTRODUCTION

The discipline of game theory studies mathematical models of conflict and cooperation between rational decision-makers (called 'players') whose decisions affect each other. The centipede game is a game-theoretical model of a class of interactive decision situations that have challenged a basic solution concept of game theory called 'backward induction'. The centipede game has stimulated much theoretical research into the nature of beliefs, knowledge, and rationality in interactive decision situations, and experimental research on conflict, cooperation, and trust.

Formally, the centipede game is a finite N-person extensive form game with complete and perfect information and no chance moves. It consists of the following elements:

- A game tree, which is a graph with m nodes and $m-1$ links in which every two adjacent nodes are connected by exactly one link. The game tree includes a distinguished node, called the *origin* of the tree, which designates the first mover. Node k in the tree is said to *follow* node j if there is a path from the origin to node k through node j. A *terminal* node is one with no followers.
- A partition of the non-terminal (decision) nodes into player sets labeled $1, \ldots, n$. A node in the player set only i corresponds to a choice of move (a decision) by player i ($i = 1, \ldots, n$).
- Associated with every terminal (outcome) node is a vector of n real numbers. The ith component of this vector gives player i's utility ('pay-off') for the outcome represented by the terminal node.

For this class of games, perfect information means that when it is her turn to choose an immediate follower from any of her non-terminal nodes, a player knows perfectly all the choices made at the previous decision nodes. There is no possibility of secret moves. The assumption of complete information means that everything about the extensive form is known to all the players.

DESCRIPTION OF THE CENTIPEDE GAME

A two-person centipede game was introduced by Rosenthal (1981) and later studied theoretically by Aumann (1992, 1995, 1998), Ben-Porath (1997), Feinberg (2001), Ponti (2000), Stalnaker (1998), and many others. In a variant of this game discussed by Aumann (1992), there are two players, Alice and Bob, and a sum of \$10.50 lying on the table in front of them. Moving first, Alice has the option of taking \$10 and leaving \$0.50 to Bob. If she does so ('exit'), the game is over. If not ('continue'), the amount on the table is increased tenfold, to \$105, and it is Bob's turn to play next. Now Bob has the option of taking \$100, leaving \$5 to Alice. If he does so ('exit'), the game is over. If not ('continue'), the amount is increased tenfold, to \$1050. Continuing in this way, with players' roles being interchanged and payoff increasing tenfold on each move (stage), the game terminates after three full rounds of play (i.e. six stages). In the sixth and final stage, Bob has the opportunity of taking \$1 000 000, leaving \$50 000 to Alice. Otherwise, the game terminates with each player receiving zero pay-off.

Figure 1 displays this interactive situation as a finite extensive form game. There are six decision nodes, labeled alternately as 'Alice' and 'Bob' with Alice the first player to move. There are seven terminal nodes. Associated with each terminal node are two numbers. The top number is Alice's pay-off on this outcome, and the bottom number is Bob's pay-off on this outcome.

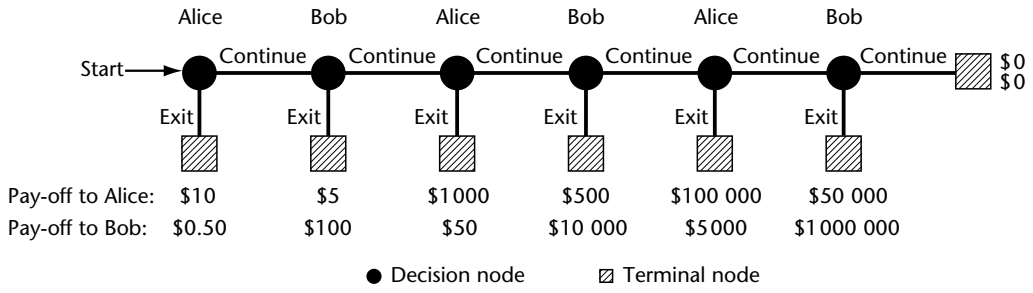

Figure 1. Two-person six-move centipede game (Aumann, 1992).

There are two major features that lend this game special interest. Firstly, the pay-offs are structured in such a way that both players are better off if play continues for at least two stages (one complete round). Secondly, if one of the players continues and the other exits on the immediately following stage, then the player who continues is worse off and the one who exits is considerably better off. Thus, there is an incentive to defect (exit) rather than cooperate (continue) and thereby risk a lower pay-off.

BACKWARD INDUCTION

How should rational players behave in this game if it is played only once? The standard way of answering this question for finite extensive form games with perfect information is by a process known as *backward induction*. Backward induction (also known as 'dynamic programming') is used to obtain the optimal decision in multistage individual decision-making problems described by decision trees. It is also used to derive the solution for the well-known finitely iterated two-person 'prisoner's dilemma' game. For the game in Figure 1, the recursive process of backward induction is straightforward. Begin with the sixth and final stage. At this node, Bob's option to exit (and receive $1 000 000) dominates his option to continue (and receive $0). Therefore, Bob will definitely exit if the game reaches stage 6. Move back to stage 5, where it is Alice's turn to play. Assuming that Bob will act rationally and exit at stage 6, Alice's option to exit at stage 5 (and receive $100 000) dominates her option to continue (and receive $50 000 at stage 6). Hence, Alice should exit if the game reaches stage 5. With the same reasoning applying to all decision nodes, an exit decision at each stage is prescribed. Therefore, by the logic of backward induction, Alice will exit at stage 1, with pay-offs of $10 and $0.50 to Alice and Bob respectively. Hence the paradox. Note that, provided the game is finite, the process of backward induction does not depend on the number of stages. The game in Figure 1 could be extended to any finite number of stages, with the pay-offs becoming enormous, without changing the solution.

Reactions of people to this solution vary. Some may feel that the solution for the centipede game is not really counterintuitive. Although Alice may feel frustrated, a careful analysis of the game may convince her in the end to exit immediately and collect the $10. As noted by Aumann, there is a difference between frustration and paradox. Thus, players in the one-shot 'prisoner's dilemma' game may feel frustrated by the prescription to always defect, but the logic of the game is compelling. However, most reasonable people are not willing to accept this solution, or at best believe that it represents an approach of little practical value. Aumann considers the centipede game to be one of the 'disturbing counterintuitive examples of rational interactive decision-making' (1992, p. 219). McKelvey and Palfrey, who have studied the game experimentally, claim that the solution is 'widely acknowledged to be intuitively unsatisfactory' (1992, p. 803). The experimental evidence is reviewed below.

THEORETICAL EXPLANATIONS

To get a better feel for the issues raised by the centipede game, consider a shorter, simpler, and slightly different version of the game with only three stages and considerably smaller pay-offs. In contrast to the game in Figure 1, if Alice 'continues' on her second (and last) decision node in the game in Figure 2, both players receive positive pay-offs ($2 and $3 for Alice and Bob respectively). By the same backward induction reasoning as before, Alice should exit at her first decision node. She should do so if she expects that she will behave rationally at her second decision node, and if she expects that Bob expects that she

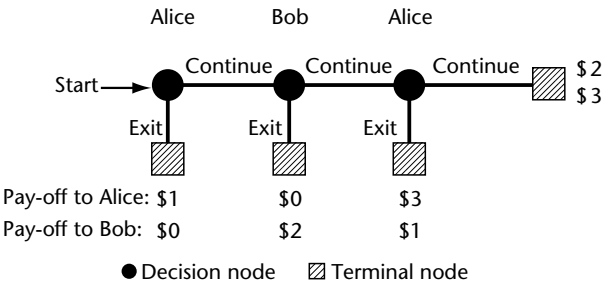

Figure 2. Two-person three-move centipede game.

will do so and that he will then act rationally (Feinberg, 2001).

The crucial question is what to make of her decision if she decides to continue on her first decision node. Bob may interpret this move in several possible ways. He may ascribe it to an error on Alice's part. He may believe that this move is intended to signal Alice's intention to continue on her second decision node, in which case he would receive his largest possible pay-off ($3). Or he may believe that Alice is attempting to trick him to continue so that she can exit on her second move and receive her largest possible pay-off ($3). In any case, Bob must realize that under the backward induction reasoning, continuing is not optimal for Alice, and that consequently this reasoning may be invalid. Bob's decision will clearly depend on his interpretation of Alice's decision to continue. If he believes that she intends to continue on her second move, the rational decision for him is to continue too. This, then, would imply that the rational decision for Alice on her first move is, indeed, to continue, since she would have been wrong in assuming that if she continues then Bob will exit.

The examples in Figures 1 and 2 raise two theoretical questions. The first is how to account for the paradox of backward induction; and the second is how to justify the process of backward induction in the centipede game. There has been considerable theoretical work on these questions, which has resulted in explications and clarifications of the elusive concepts of rationality, knowledge, and beliefs in extensive form games. This body of literature is too technical to be described in detail here. The basic ideas underlying some of the theoretical studies are briefly described below.

Common Knowledge of Rationality

Consider first the concept of knowledge in interactive decision-making. An event is called *common* knowledge if all players know it, all know that all know it, and so on *ad infinitum*. An event is called *mutual* knowledge if all players know it. It is called second-order mutual knowledge if it is mutual knowledge that it is mutual knowledge; and so on for any finite order. As illustrated above, the analysis of Alice's decision to exit on her first move in Figure 2 was based on iterated knowledge ('Alice knows that Bob knows that Alice knows…') of rationality up to a specified level, which depends on the number of decision nodes in the game tree, but no further.

Aumann noted that common knowledge of rationality and even the considerably weaker mutual knowledge of rationality are very strong assumptions and not likely to be true in practice. To resolve the paradox of backward induction in the centipede game, he proposed to relax this assumption by allowing a very small measure of doubt to enter at a high order of mutual knowledge of rationality. He showed that a small breakdown in the commonality of the knowledge of rationality is enough to justify the kind of behavior in the centipede game that most people would consider 'reasonable.' His approach is of particular relevance to cognitive scientists who are aware of the limitations of the human cognitive system and consider human rationality to be bounded. It reflects the fact that in real interactive situations there is typically uncertainty about what others will do, the extent of their rationality, and what others think about what you think and about your own rationality.

Aumann (1995, 1998) drew a distinction between *substantive* and *material* rationality. Substantive rationality refers to the condition where it is assumed common knowledge that each player i would act rationally at each of his decision nodes v, even when i knows that v will not be reached. The alternative condition of material rationality stipulates that player i acts rationally only at those of his decision nodes that are actually reached. The counterfactual component of the latter condition is smaller than in substantive rationality, as nothing is assumed about what actions players may take at unreached decision nodes. Aumann (1995) proved that if common knowledge of substantive rationality obtains in perfect information games, then backward induction is sustained. In a subsequent paper (1998) he proved that, in the particular case of the centipede game, the weaker condition of common knowledge of material rationality is sufficient to ensure backward induction.

Other Explanations

Additional theoretical work invoking other concepts has followed. Using evolutionary arguments

rather than assumptions about common knowledge and rationality, Ponti (2000) has shown that backward induction can still accurately predict players' behavior in the centipede game provided they are given enough time to study and appreciate the strategic environment in which they operate.

Stalnaker (1998) extended the notion of rationality by arguing that the rationality of choices in a game depends not only on what the players believe, but also on the way they revise their beliefs in response to some new or contradictory piece of information. In this framework for reasoning about hypothetical situations, he showed that the common knowledge of substantive rationality need not imply backward induction.

Ben-Porath (1997) has shown that common belief with probability one (instead of common knowledge) of rationality need not imply backward induction.

Feinberg (2001) argued that whereas a particular action can be called 'rational' in a well-specified context, ascribing rationality to a decision-maker is more problematic. This is because of the conflicting nature of objectivity and freedom of choice. If the player is 'objectively' rational, then his decisions are deterministic. But if the player is 'subjectively' rational, in the sense that his actions are perceived and evaluated as rational by an outside observer, this rationality becomes a descriptive and predictive tool for the observer. This interpretation implies that, from the subjective point of view of the observer, the player's rationality may be refuted. Rather than modeling the players' reasoning in the centipede game as an added structure separate from the game itself, Feinberg proposes a representation of dynamic games in which the game is described by the subjective knowledge of players at hypothetical situations. He further shows that common subjective knowledge ('confidence') of rationality contradicts the assumptions of the centipede game. However, rationality and common confidence of future rationality are shown to imply backward induction for perfect information games.

EXPERIMENTAL FINDINGS

Beliefs about the rationality and intentions of the other player, which may be revised during the course of the game, largely determine a player's decisions. Powerful and profound as they are, the theoretical analyses of the centipede game shed little light on how reasonable people, whose rationality is bounded, actually solve the conflict embedded in the centipede game. Only controlled experiments may provide some answers. The results of two experiments are described below.

McKelvey and Palfrey (1992)

Figures 3 and 4 show two examples of a variant of the two-person centipede game investigated experimentally by McKelvey and Palfrey (1992). These two games are similar to the game in Figure 2 in that if the final stage is reached, player 2 can reward player 1 for the trust placed in him by deciding to continue. If he does so, player 2 forgoes half of his pay-off in order to increase player 1's pay-off eightfold. The game in Figure 3 consists of two rounds of play, while the game in Figure 4 consists of three rounds.

McKelvey and Palfrey reported the results of multiple sessions of two carefully conducted centipede game experiments. The participants were undergraduate students who were paid in accordance with their performance. Each game started with a total pot ('pie') of 50 cents, divided into a 'large' pile of 40 cents and a 'small' pile of 10 cents. Each time a player 'continued', both piles were doubled in value and the roles of the two players were interchanged. Each experimental session included 20 or 18 participants who were divided into two groups (player 1 and player 2) at the beginning of the session. Player roles (types) remained fixed during the session. Each participant played one game with each of the participants assuming the opposite role. Thus, no participant was ever matched with another participant more than once. All this was common knowledge.

These two games were designed to study the descriptive power of the backward induction solution. Under this solution, all the games end at the first terminal node. On the other hand, if the two players fully cooperate by always continuing, all the games end in the final terminal node. The results support neither of these predictions (see Table 1). Out of a total of 281 plays of the four-

move game in Figure 3, the proportions of plays ending in the 1st, 2nd, 3rd, 4th, and 5th terminal nodes were 0.071, 0.356, 0.370, 0.153, and 0.049, respectively. Out of a total of 281 plays of the six-move game in Figure 4, the proportions of plays ending at the 1st, 2nd, 3rd, 4th, 5th, 6th, and 7th terminal nodes were 0.007, 0.064, 0.199, 0.384, 0.253, 0.078, and 0.014, respectively. With 7% of the four-move plays and less than 1% of the six-move plays ending in the first terminal node, there is clearly no support for backward induction. Moreover, the evidence suggests that whatever support this solution receives decreases with the number of rounds of play.

McKelvey and Palfrey also estimated the conditional probability of exit at each decision node j, denoted by $P(E|j)$; that is, the probability of exiting at node j if node j is actually reached. Table 2 shows that for each of the two games the values of $P(E|j)$ almost always increase with j ($j = 1, \ldots, 4$ in Figure 3 and $j = 1, \ldots, 6$ in Figure 4). Thus, as play progresses the tendency to cooperate decreases.

Rapoport, Stein, Parco, and Nicholas (2000)

Rapoport *et al*. (2000) have argued that the two-person centipede game constitutes a special case – albeit an important one – where reciprocity may assume a critical role. As the number of interacting players increases, the effects of reciprocity may diminish. Rapoport *et al*. proposed an extension of the centipede game from two to three players in an attempt to study the generality of the results reported by McKelvey and Palfrey. Figure 5 shows their game, which includes three players

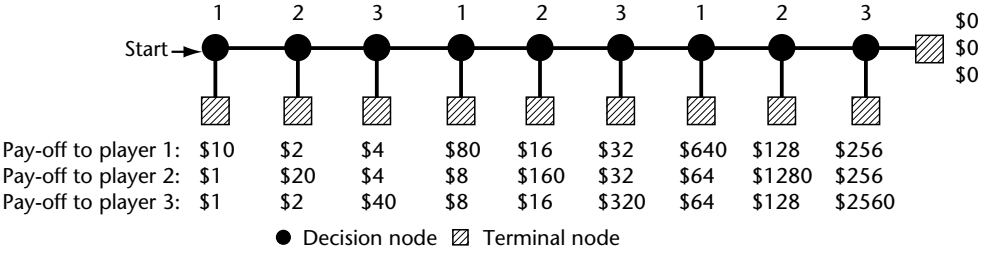

Figure 5. Three-person nine-move centipede game (Rapoport *et al.*, 2000).

and three full rounds of play (nine decision nodes). This game is similar to the one in Figure 1, in that the decision to continue on the last decision node results in zero pay-off to all players. If play continues for at least three stages (a single round), all three pay-offs increase eightfold. But if a player continues and either of the other two players exits at the next opportunity, the player who continues is worse off.

Although the six-move centipede game of McKelvey and Palfrey and the nine-move game of Rapoport *et al*. each includes three rounds of play, and the 'pie' doubles in size on each stage, the two studies are not directly comparable. Firstly, they differ in the number of players. Secondly, they differ in the assignment of pay-offs to the outcome resulting if all players always continue. Thirdly, they differ in the number of iterations of the game: 10 and 60 respectively. Fourthly, they differ in the method of assigning roles to players. Rapoport *et al*. conducted four sessions, each including a population of 15 participants who were divided on each iteration into five groups of three players each. Group membership was changed randomly from one iteration to another, as was the assignment of the group members to the three player roles. Although players received information only about their own pay-offs, their decisions could slowly and indirectly affect the behavior of the other members of the player population. Thus, population learning was possible. The fifth and possibly most important difference was in the size of the stakes. If player 3 exits on the last decision node in the study of Rapoport *et al*., his

pay-off is \$2560. Actual payment was half of the nominal earnings, so the maximum pay-off was a factor of 200 higher than in Figure 3 and 50 times higher than in Figure 4.

The bottom panel of Table 1 presents the proportions of games ending at each of the nine terminal nodes. The results are presented separately for each of the four sessions (five groups, with 60 iterations per group, for a total of 300 plays per session) and then combined across all sessions. There are three major findings. Firstly, except for the 9th decision node in session 1, all the nine decision nodes were reached in each session. Secondly, in contrast the results reported by McKelvey and Palfrey, the proportions of exit decisions tended to decrease across the nine decision nodes. Thirdly, and most importantly, backward induction was supported 46.3%, 39.3%, 30.3%, and 40.7% of the time across the four sessions. These results differ markedly from those reported by McKelvey and Palfrey. The bottom panel of Table 2 presents the values of $P(E|j)$ at each decision node j. If we exclude the inferred conditional probabilities $P(E|j)$ that are based on fewer than 10 observations (these were mostly contributed by a small subset of participants), the values of $P(E|j)$ are seen to be remarkably stable across the decision nodes 2 through 8. This finding, too, differs from the findings of McKelvey and Palfrey shown in the upper two panels of Table 2.

The most important result in the study of Rapoport *et al*. concerns the dynamics of play. Figure 6 shows (in three parts) the arithmetic moving average (in steps of 10) of the $P(E|j)$ values. The results are presented separately for the first three decision nodes in round 1 ($j=1, 2, 3$). For $j=1$ (top panel), the initial propensity in the first 10 or so iterations is to continue; the mean values of $P(E|j)$ in the first 10 iterations are about 0.10. However, all four functions in the top panel of Figure 6 tend to increase with further iterations. The values of $P(E|j=1)$ are seen to increase steadily in sessions 1 and 4. In session 2 they reach a plateau after 20 or so iterations but start increasing again after the 40th iteration. In session 3, the values of $P(E|j=1)$ are rather flat for the first 45 or so iterations and then start increasing. Although the trends in $P(E|j=2)$ (middle panel) and $P(E|j=3)$ (bottom panel) are also generally increasing, they are more difficult to characterize.

What we observe in each of the four sessions is a slow breakdown in mutual trust resulting in a trend towards the backward induction solution. No such trends were reported by McKelvey and Palfrey. Any of the differences in the design of the two experiments (particularly the difference in size of stakes), or a combination of them, may account for the differences in the results.

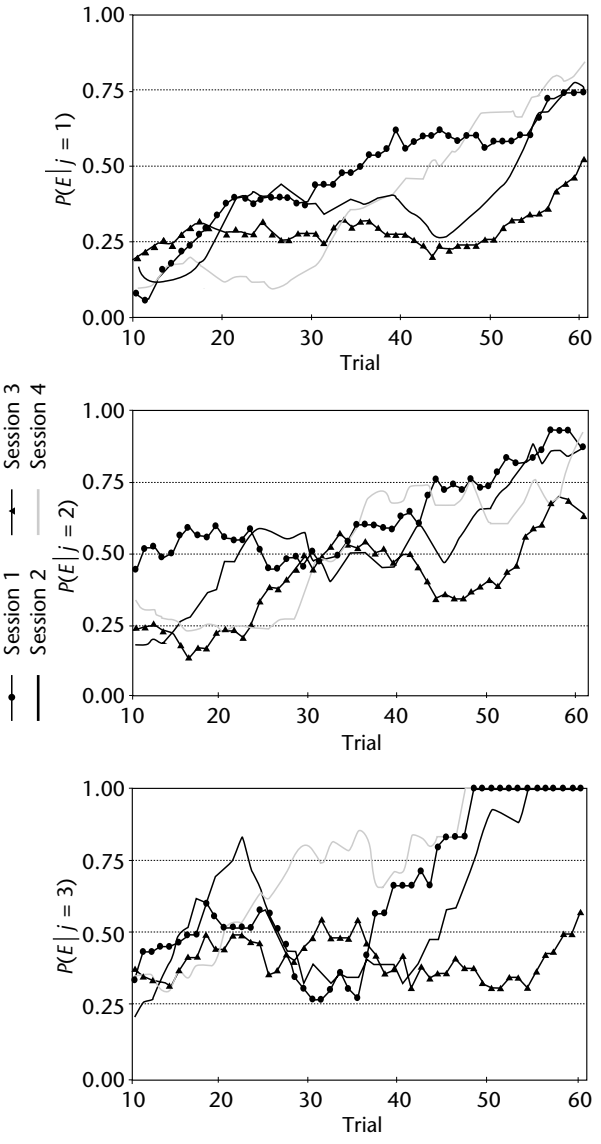

Figure 6. Arithmetic moving averages of the inferred conditional probabilities of exit on decision node j ($j = 1, 2, 3$) across players by session (Rapoport *et al*., 2000). The results for the first, second, and third decision nodes are displayed in the top, middle, and bottom panels, respectively. For $j=3$ (bottom panel) there were insufficient data in session 4 beyond trial 48.

CONCLUSION

The centipede game has extended and intensified the discussion of fundamental concepts of the evolving discipline of game theory. There is a need for further theoretical work on the concepts

of rationality, common knowledge, backward induction, and beliefs in interactive decision-making, as well as related experimental work on the effects of size of stakes, number of players, type of interaction, and rationality of the players on conflict, cooperation, and trust.

Games: Coordination

Intermediate article

Jacob K Goeree, University of Virginia, Charlottesville, Virginia, USA

CONTENTS

Coordination games typically possess multiple Nash equilibria, some of which are preferred by one or more players. Coordination on desired equilibria can be facilitated by communication, repetition, and introspection.

INTRODUCTION

Despite the well-known efficiency properties of competitive markets, economists have long been concerned that there may be multiple equilibria in complex social systems. The possibility of becoming mired in a bad equilibrium dates back at least to Thomas Malthus's notion of a 'general glut'. The problem is one of coordination: e.g. it may not make sense for me to go to the market to trade if you are going to stay home on the farm. This situation is one of common interest in that everyone prefers the equilibrium with high market activity to the one without any trade. Coordination problems can also arise when there is a conflicting interest, i.e. when each person prefers a different equilibrium outcome. The classic example is the 'battle-of-the-sexes' game, where the man prefers to attend a baseball game and the women prefers to attend an opera, but both would rather do something together than go to separate events. In all of these examples there are multiple outcomes that are equilibria in the sense that no single individual has an incentive to deviate if others are conforming to that outcome. For instance, in the battle-of-the-sexes, the man would attend the opera if he thinks the woman will be there even though he prefers the other equilibrium outcome in which both attend the baseball game.

Society has developed a number of ways to solve such coordination problems. The most obvious cases involve social norms and rules, e.g. driving on the left side of the road in the UK and Japan. In the absence of explicit rules, individuals may rely on focalness, e.g. Schelling (1980) points out that two people who are supposed to meet each other somewhere in New York city are likely to go to Times Square. Historical accidents and precedents can also be used as coordination devices, since past experience often affects beliefs about others' future behavior. For example, prior discrimination against workers of a particular racial background may produce a situation in which the workers do not invest in skills because they anticipate unfavorable job assignments. These beliefs can be self-fulfilling since the workers' choices make it rational for the employer to expect low performance from those workers. In this case, a period of 'reversed' discrimination, e.g. affirmative action, may be needed to change expectations and allow coordination on the preferable merit-based equilibrium. Coordination can also be achieved through explicit communication and reciprocity, e.g. in the battle-of-the-sexes game the man and the woman agree to attend the baseball game this weekend and opera next.

Economists and psychologists are also interested in strategic settings where opportunities for communication and reciprocity are limited, perhaps due to the large number of people involved. Rapoport *et al*. (1998), for example, consider a large group of sellers who must decide whether or not to enter a particular market that is profitable only in the absence of excessive entry. Even without communication, low profits will drive some sellers away while high profits will attract more sellers, and observed behavior in laboratory experiments shows that the costs of uncoordinated outcomes can be negligible. Laboratory experiments such as these have uncovered interesting patterns of behavior that have led to theoretical models of equilibrium selection. These models of learning and introspection provide natural extensions of classical equilibrium concepts, which are unable to predict which outcome has the strongest drawing power.

TYPES OF COORDINATION GAMES

A typical coordination game with conflicting interests is the battle-of-the-sexes game where the preferred equilibrium provides a player with a high payoff of 600, while the less preferred equilibrium only yields 200. This game, shown in Table 1, was used by Cooper *et al*. (1989) in a laboratory experiment that was presented in neutral terms. There are two obvious Nash equilibria of this game: (baseball, baseball) and (opera, opera). In addition, there is an equilibrium involving randomization, where both the man and woman choose their preferred activity with probability 0.75. In this manner, each person is indifferent between the two options since each yield a payoff of 150 on average ($0.75 \times 200 = 0.25 \times 600 = 150$).

Another coordination game with opposing interests is the market entry game shown in Table 2. Two firms have to decide whether or not to incur a cost of 50 to enter a market. The entrant's profits will be 150 if it is alone, but will be zero if both firms enter. The profits from staying out are zero independent of the rival's choice. Again there are two obvious Nash equilibria and each firm prefers the outcome in which it is the sole entrant. Notice that the case of excess entry produces losses for each firm, which makes this a 'game of chicken'. This terminology is inspired by the movie *Rebel Without a Cause*, where James Dean and his competitor drive toward a cliff and the first to stop is considered to be 'chicken'. Each prefers the outcome where the other one stops first, but if neither stops both incur a severe cost (possibly worse than -50).

Table 1. A battle-of-the-sexes game (woman's payoff, man's payoff)

		Man	
		Opera	Baseball
Woman	Baseball	0, 0	200, 600
	Opera	600, 200	0, 0

Table 2. A market entry game (Firm 1's payoff, Firm 2's payoff)

		Firm 2	
		Stay Out	Enter
Firm 1	Stay Out	0, 0	0, 100
	Enter	100, 0	-50, -50

Rousseau's classic 'stag hunt' game describes a situation in which two hunters decide to hunt for stag or hare. Each hunter alone could be sure of bagging a hare, but both hunters are needed to corner the stag, which is the preferred outcome. If only one hunts stag, that person is left empty handed, so there is a low payoff equilibrium in which both hunt hare and a high payoff equilibrium in which both hunt stag. Unlike the two previous examples, this game is one of common interests since both prefer the 'better' outcome. Rousseau's game has a 'weakest link' property since the stag will escape through any sector left unguarded by a hunter. This is analogous to a situation where workers provide different parts to be assembled, and the final product requires all parts. In this case, the total amount produced is determined by the slowest worker, i.e. the weakest link in the production chain.

One way to model a weakest-link, or minimum-effort coordination game is to let players choose effort levels, 1 or 2, where each unit of effort results in a cost of $c < 1$. The output per person is determined by the minimum of the effort levels chosen. For example, if both choose an effort level of 1, then each player receives a payoff of $1 - c$, as shown in the upper-left box of Table 3. Similarly, when both choose a high effort level of 2, they each obtain $2 - 2c$. But if they fail to coordinate with effort choices of 1 and 2, then the minimum is 1 and payoffs are $1 - c$ for the low effort individual and $1 - 2c$ for the high effort individual. Notice that the low effort outcome is an equilibrium since a costly increase in effort by only one person will not raise the amount produced. The high effort outcome is also an equilibrium, since a reduction in effort by only one person will lower the minimum by more than the cost savings c.

The game in Table 3 can be generalized to allow for more than two players and multiple effort levels, with payoffs determined by the minimum effort level chosen. If a player's effort is denoted by e_i, $i = 1, \ldots, n$, payoffs are:

$$\pi_i(e_1, \ldots, e_n) = \min\{e_1, \ldots, e_n\} - ce_i, \quad i = 1, \ldots, n, \tag{1}$$

Table 3. A 2×2 coordination game (Player 1's payoff, Player 2's payoff)

		Player 2's effort	
		1	2
Player 1's effort	1	$1 - c$, $1 - c$	$1 - c$, $1 - 2c$
	2	$1 - 2c$, $1 - c$	$2 - 2c$, $2 - 2c$

where c is the per-unit effort cost. As long as c is less than 1, payoffs are maximized when all players choose the highest possible effort. Note, however, that *any* common effort level constitutes a Nash equilibrium, since a costly unilateral increase in effort will not raise the minimum, and a unilateral decrease will reduce the minimum by more than the cost when $c < 1$. This argument does not depend on the number of players, so noncritical changes in c and n will not alter the set of Nash equilibria, despite the reasonable expectation that efforts should be high for sufficiently low effort costs and low numbers of participants.

EXPERIMENTAL EVIDENCE

Van Huyck *et al*. (1990) used a minimum-effort structure in one of the most widely cited and influential game theory experiments. In their experiment subjects could choose seven possible effort levels, 1 through 7, and payoffs were a linear function of the difference between the minimum effort and one's own divided by two ($c = ½$). Thus there are seven equilibria in which all players choose the same effort level, but the equilibrium with the highest payoff is the one where all players choose an effort of 7. The experiment involved 14–16 players who made independent effort choices. After choices were collected and the minimum was announced, payoffs were calculated. This whole process was repeated for 10 rounds. Van Huyck *et al*. report that efforts declined dramatically, with the final-period efforts clustered at the equilibrium that is worst for all. This result surprised many game theorists, who were comfortable assuming that rational individuals would be able to coordinate on an outcome that is best for all. Van Huyck *et al*. also find that an extreme reduction in the cost of effort ($c = 0$) results in an overwhelming number of high effort decisions, which is not surprising since raising effort is costless.

Goeree and Holt (2000) explored the effects of changes in effort cost and the number of players more systematically. They reported two- and three-player minimum-effort coordination game experiments with varying effort costs. Individuals could choose continuous effort levels in the range from 110 to 170 with payoffs determined as in (1). With two players, average effort levels are initially around the midpoint 140 in both the low-cost ($c = ¼$) and high-cost ($c = ¾$) treatments. By the third period, however, there is a strong separation, with higher efforts for the low cost treatment. In the final rounds, the average effort was 159 in the low cost treatment and 126 in the high cost treatment. Even though *any* common effort in the range from 110 to 170 is a Nash equilibrium independent of the effort cost, the observed behavior is affected by the magnitude of the effort cost in an intuitive manner. Similarly, Goeree and Holt (2000) found that an increase in the number of players tends to decrease the final-period effort levels.

A different line of experimentation involved factors that facilitate coordination. Cooper *et al*. (1989) investigated the effects of 'cheap talk' forms of communication in a battle-of-the-sexes game as shown in Table 1. Subjects first submitted a message about which choice they intended to make. These messages were nonbinding in the sense that a player could deviate from his or her reported intent after seeing the other's message. When both messages matched one of the equilibria, i.e. (baseball, baseball) or (opera, opera), then actual decisions corresponded to stated intentions more than 80 percent of the time. When messages differed, however, individuals tended to deviate from their original message and chose their preferred activity about 71 percent of the time. Communication can therefore facilitate coordination, but when communication fails the behavior corresponds more closely to the equilibrium in randomized strategies (choosing the preferred activity with probability 0.75).

The Cooper *et al*. (1989) experiments involved random pairings of subjects in each period. In contrast, fixed pairings permit coordination that is based on the history of past decisions. Prisbrey (1991) finds a common pattern of alternating choices, with outcomes (baseball, baseball) and (opera, opera) in successive rounds. (As in the other papers mentioned above, Prisbrey used neutral terminology in presenting the payoffs to subjects.) This alternation can be interpreted as a form of reciprocity, where 'nice' behavior in one round is rewarded by a nice response in the next. A number of other coordination experiments are surveyed in Ochs (1995).

THEORETICAL EXPLANATIONS

One of the most commonly suggested criteria for the analysis of games with multiple equilibria is to select the one with the highest payoffs for all, if such a 'Pareto-dominant' outcome exists. The Van Huyck *et al*. (1990) experiment showed that this method is incorrect, and the Goeree and Holt (2000) experiment showed that any explanation must take into account the effort cost and the number of players.

Harsanyi and Selten's (1988) notion of risk dominance is sensitive to the effort cost that determines

the losses associated with deviations from best responses to others' decisions. To illustrate the concept of risk dominance, consider the two-person minimum-effort game shown in Table 3. When both players are choosing efforts of 1, the cost of a unilateral deviation to 2 is only the cost of the extra effort, c, which will be referred to as the 'deviation loss'. Similarly, the deviation loss at the (2, 2) equilibrium is $1-c$, since a unilateral reduction in effort reduces the minimum by 1 but saves the marginal effort cost c. The deviation loss from the low effort equilibrium is greater than that for the high effort equilibrium if $c>1-c$, or equivalently, if $c>½$, in which case we say that the low effort equilibrium is risk dominant. Risk dominance, therefore, has the desirable property that it selects the low effort outcome if the cost of effort is sufficiently high.

There is, however, no consensus on how to generalize risk dominance for games with more players, a continuum of decisions, etc. A related concept that does generalize is the notion of maximization of a 'potential' of a game. Loosely speaking, the idea behind a potential is to find a function for a game that is maximized by a Nash equilibrium for that game. Stated differently, a potential function is a mathematical formula that is positively related to individual players' payoffs: when a change in a player's own decision raises that player's payoff, then this change necessarily raises the value of the potential function by the same amount, and vice versa for decreases. If such a potential function exists for the game, then each person trying to increase their own payoff may produce a group result that maximizes the potential function for the game as a whole. Think of two people holding adjacent sides of a treasure box, with one pulling uphill along the East–West direction and the other pulling uphill along the North–South axis. Even though each person is only pulling in one direction, the net effect will be to take the box to the top of the hill, where there is no tendency to change (a Nash equilibrium that maximizes potential).

For instance, for the n-player minimum effort game given in (1), the potential function is simply the common production function that determines a *single* player's payoff, minus the sum of *all* players' effort costs:

$$V(e_1,\ldots,e_n)=\min\{e_1,\ldots,e_n\}-c\sum_{i=1}^{n}e_i. \quad (2)$$

The maximization of potential will obviously require equal effort levels. At any common effort, e, the potential in (2) becomes: $V=e-nce$, which is maximized at the lowest effort when $nc>1$, and is maximized at the highest effort when $nc<1$. In two-person games, this condition reduces to the risk dominance comparison of c with ½.

The notion of potential can be used to evaluate results from previous laboratory experiments. Van Huyck *et al*. (1990) conducted games with 14–16 players and an effort cost of either 0 or ½, so nc was either zero or about seven. Compared to the critical nc value of 1, these parameter choices appear rather extreme which may explain why their data exhibit a huge shift in effort decisions. By the last round in the experiments in which $nc=0$, almost all (96 percent) participants chose the highest possible effort, while over three-quarters chose the lowest possible effort when nc was around seven. One purpose of Van Huyck *et al*. (1990) was to show that a Pareto-inferior outcome may arise in coordination games, presumably because it is harder for large numbers of participants to coordinate on good outcomes. Other experiments were conducted with two players, but the payoff parameters were such that nc exactly equaled the critical value 1, and, with a random matching protocol, the data showed a lot of variability. The Goeree and Holt (2000) experiment also implements two-person random pairings in order to avoid the serious possibility of tacit collusion in repeated games which may drive efforts to maximal levels in sufficiently long series of repeated two-person coordination games. Given the knife-edge properties of $c=½$ for two-person coordination games, we conducted one treatment with $nc=½$ and another with $nc=⅔$. As noted above, this change has a large effect on observed final-period effort choices even though the set of Nash equilibria is unaffected.

Risk dominance (or some generalization) predicts well in the long run, but the patterns of adjustment suggest that theories of learning and adaptation play an important role in the analysis of coordination. Each round of an experiment provides some information about others' decisions and the resulting payoffs, and individuals may adapt their behavior in the direction of a best response to past decisions. This is the approach taken by Crawford (1995), who specifies and estimates a model in which a person's decision is a weighted average of the person's past decision and the decision that would have been a best response to others' decisions in the past. This model incorporates some type of inertia, as well as an adaptive response. Another low cognitive model is that players respond to payoffs received. These reinforcement

learning models have been successfully applied by Erev and Roth (1997). In contrast, belief learning models assume that players use the history of past decisions to predict their opponents' next choice. Camerer and Ho (1999) have developed a hybrid model that combines elements of both reinforcement and belief learning models. Learning models such as these are especially useful in predicting how final-period behavior may be explained by the history of past decisions.

Finally, many games in real life are played only once: e.g. elections, military contests, and legal disputes. In such cases, there is no relevant past history and players must rely on introspection about what others might do. This problem is particularly interesting for coordination games with multiple equilibria:

> It should be emphasized that coordination is not a matter of guessing what the 'average man' will do. One is not, in tacit coordination, trying what another will do in an objective situation; one is trying to guess what the other will guess one's self to guess the other to guess, and so on ad infinitum. (Schelling, 1980, pp. 92–93)

Formal models of introspection often have such an iterative structure, incorporating responses to others' conjectured responses to others' conjectures, etc. Although these models are less well developed, they have shown some promise for explaining behavior in games played only once (Goeree and Holt, 2001).

Games: Dictator

Introductory article

Mary Rigdon, George Mason University, Fairfax, Virginia, USA

CONTENTS

A dictator game is a game between two players, a 'dictator' and a 'serf'. The task is for the dictator to split some amount M *of money between the two of them.*

GAME-THEORETIC DESCRIPTION

A *dictator game* is a game between two players: a *dictator* (D), and a *serf* (S). The task is for the dictator to split some amount M of money (or whatever it is that the players have well-behaved utility functions for) between the two players. The serf cannot respond: the split decided upon by the dictator is the final allocation. Non-cooperative game theory makes a simple prediction about how dictators will behave in these games: a self-interested, non-satiated dictator will take M, leaving nothing for the serf. (*See* **Games: Ultimatum**)

Assume that M is a finite sum of money, and that it is discrete; i.e. there is a smallest unit of account c. We can think of the choice facing D as the choice among the different amounts of M that D can keep (since whatever D does not keep S gets). The dictator then has the pure strategy space $\mathfrak{S}_D = \{M - 0, M - c, \ldots, M - M\}$. S has only the empty strategy space, since S has no actions at all: $\mathfrak{S}_S = \emptyset$. The outcome of the game is solely determined by the action of D, and so the outcome is a reflection of D's preferences. A rational D prefers more money (or other utility) to less. Therefore, a rational D will take all of M and leave the serf with nothing. That is, $M - 0$ strictly dominates all other choices open to D, since, no matter what S does, D is better off doing $M - 0$ than anything else. The strategy profile in which D chooses $M - 0$ is a Nash equilibrium: no player in the game could achieve a better outcome by making a different choice (holding the actions of the other player constant).

BASIC EXPERIMENTAL RESULTS

Imagine you have been invited to participate in an experiment. You enter the laboratory and are paid $3 (or sometimes more) for arriving on time. There are 12 people in the room, spaced well apart. You begin by reading a set of instructions at your own pace, which are then read aloud by the experimenter. You are randomly assigned the role of person A (the dictator) or person B (the serf). Each experimental session involves only one pairing and only one decision by the randomly selected dictator. You will not be told who your counterpart is, either during or after the experiment, and they will not be told who you are, either during or after the experiment. The instructions state that 'a sum of $10 has been provisionally allocated to each pair, and person A in each pair can propose how much of this each person is to receive … The amount that person A is to receive is simply the amount to be divided, $10, minus the amount that person B is to receive'. If you are randomly chosen as a dictator, you indicate on a form how much of M you wish to keep for yourself and how much the serf will therefore receive. Once all of the dictators have made their decisions, the experiment is complete and you are paid your dollar earnings privately by the experimenter. (*See* **Economics, Experimental Methods in**)

Contrary to the game-theoretic prediction, many dictators offer more than $0 to their serf: 20% do give nothing, but 20% give away an equal share of the pie, $5. A large proportion of dictators transfer between 1 and 5 dollars: approximately 17% pass $1, 13% pass $2, 30% pass $3, and 0% pass $4. There are virtually no offers greater than half of the pie.

TREATMENT EFFECTS

Given the experimental results in the dictator game, which do not conform to the theoretical prediction, we need to investigate whether the results are robust to changes in the design of the experiment. Results of interpersonal experiments like the dictator game may be sensitive to the instructional and procedural settings of the experiment.

The instructions quoted above do not define a clear property right to the sum of $10. In fact, they suggest that it provisionally belongs to both of the participants. Will the dictator's offer be more self-regarding if players have to earn the right to move first, rather than being randomly given the role? One way to implement a contest treatment is to use subjects' scores on quizzes about current events to determine who will be the dictator in the pairings. Suppose subjects are ranked from highest to lowest using the number of correct answers given on the quiz, the top half earning the right of dictatorship and the bottom half becoming their serfs. Suppose this pairing rule is common knowledge to the subjects. Such a treatment lowers the offer distribution relative to the base-line. In fact, the fraction who offer $0 more than doubles, and there are now virtually no offers of equal division.

When role entitlement is combined with framing of the exchange as that between a seller and a buyer, where the seller sets the price for a precommitted buyer, the results are even more skewed towards self-regarding outcomes: 40% of the dictators now offer $0, and another 40% offer $1 or $2. Only 4% offer $4, and there are virtually no offers of equal division. This difference is significant at the 99% level of confidence.

In the above experiments, subjects are anonymous with respect to each other, but the experimenter still knows who made what decisions. The experimental protocol is 'single-blind'. Under such a protocol, subjects do not know the identities of their counterparts, and so fear of social reprisal by their peers cannot be an explanation of the results. However, there is another variable which affects social distance: the experimenter knows the identities of the subjects and actions each takes in the experiment. A natural question is whether a 'double-blind' protocol, in which neither other subjects, the experimenter, nor anyone else can map subjects to their actions, would yield different results.

A standard version of a double-blind dictator experiment runs as follows. Each (randomly selected) dictator is given an envelope which contains 10 one-dollar bills and 10 blank slips of paper. Each proceeds in turn to the back of the room, opens the envelope, and makes his or her decision privately. The task is to keep 0 to 10 of the one-dollar bills and 10 to 0 of the slips of paper, so that the number of bills plus the number of slips of paper in the serf's envelope equals the total size of the allocation ($10). The dictators leave the experiment and the envelopes are transferred to the room with the serfs. A paid monitor calls each person one at a time. The serf selects and opens an envelope, keeping the contents. The monitor records the amount on a sheet of paper without any names on it. The double-blind treatment has a very significant effect on dictator giving: more than two-thirds of the dictators offer $0, with 84% offering $0 or $1. A very small number (about 8%) offer $5. The results in this treatment more closely approach the game-theoretic prediction. These results from double-blind dictator games have been replicated by several researchers, suggesting they are indeed robust.

The results of experimental work on dictator games suggests three lessons: (1) the concept of Nash equilibrium neither adequately predicts nor explains all of the observed behavior in these games; (2) there is a significant 'property right' effect on dictator giving; and (3) the results are sensitive to procedural variation in the experiments themselves – varying the 'social distance' between dictator and serf, and between subject and experimenter – shifts the outcomes in systematic and interesting ways.

Games: Principal–Agent

Intermediate article

Corinne Alexander, University of California, Davis, California, USA

CONTENTS

Principal–agent games address the situation where one party (the agent) can take an action unobserved by the other party (the principal), who bears the full consequences for that action. Anticipating that the agent may not act in the principal's best interest, the principal offers the agent incentives to influence the agent's actions.

INTRODUCTION

Consider the relationship between the shareholders or owners of a firm (the principal) who delegate the task of running the firm to the managers (the agent). The shareholders may be concerned that the managers are more interested in perks such as private jets than in working hard to benefit the shareholders. This problem of moral hazard (also called 'hidden action') arises when there is a conflict of interest between the agent who is taking an action for which the principal bears the consequences and the principal is unable to observe the agent's choice. The 2002 Enron scandal provides a dramatic example of moral hazard: the company executives created off-the-book partnerships to hide losses incurred from some poor decisions, and once these accounting practices were discovered, the shareholders lost their investment. Fundamentally, moral hazard also lowers the welfare of the agent, especially if the principal chooses not to hire the agent due to anticipated losses from moral hazard. Subsequent to the Enron scandal, investors have been reluctant to enter the market and companies face the challenge of convincing investors that they will act in their best interests.

Since both the principal and the agent profit from their relationship, both have the incentive to ensure that the agent delivers what the principal wants. The principal can alleviate the problem of moral hazard by giving the agent incentives to perform in the best interests of the principal. For example, since the shareholders of a firm want the managers to work hard to increase profits, they may make the managers' wages contingent on the firm's profit by offering stock options. Alternatively, the agent actively seeks the principal's trust by building a reputation or hiring monitoring services such as those offered by auditors.

Principal–agent theory predicts how rational individuals will behave in a complex decision-making environment, where one individual may rationally cheat another. Laboratory experiments have tested the predictions of principal–agent theory and tested other behavioral predictions based on reciprocity.

PRINCIPAL–AGENT MODEL

There are three key features to the principal–agent model: first, the principal delegates tasks to the agent, requiring the agent to exert effort; second, the agent's choice of effort is unobservable to the principal; and third, there is a conflict of interest since that effort is costly to the agent. The principal's solution to the moral hazard problem is to offer the agent an incentive compatible contract that aligns the agent's objectives with the principal's. A contract is incentive compatible when, given the contract specifications, the agent prefers the principal's desired action to all other possible actions. The principal uses a combination of punishments and rewards contingent on the outcome of the task which induce the agent to work hard.

The principal–agent relationship can be modeled as a two-stage game. In the first stage, the principal moves first and offers the agent a take-it-or-leave-it contract from the set of incentive compatible contracts. In the second stage, the agent accepts or rejects the contract. If the agent accepts the contract, then the agent chooses the optimal action or effort level in response to the contract specifications. The outcome or profit is a function of the agent's chosen effort. Ideally, the principal would like to appropriate all the gains from trade. However, the principal must offer the agent some of the profits in order

to incentivize the agent. (*See* **Game Theory in Economics**)

Full Information Benchmark

If effort is verifiable (either effort is directly observable or output is a perfect predictor of effort), then it is straightforward and costless for the principal to delegate a task with correct incentives. The principal can offer the agent a contract where payment is contingent on the desired action. One example of an optimal contract when output is a perfect predictor of effort is the piece-rate contract offered to strawberry pickers. The pickers are paid for the number of flats of strawberries picked which provides clear incentives. In contrast, according to principal–agent theory, an hourly wage would give the workers no incentive to work hard since they would receive the same pay even if they sat in the shade drinking lemonade.

Asymmetric Information

The principal's problem of designing a contract to reduce the problem of moral hazard becomes more complex when there is asymmetric information about the agent's effort. If the agent's action is hidden, the relationship between the unobservable action and the observable outcome must be probabilistic – where there is a higher probability of a good outcome if the agent exerts high effort. However, even if the agent takes the desired action, a bad outcome could occur. In the case of a bad outcome, the principal will be unable to distinguish whether it was caused by the agent's choice of action or events outside the agent's control.

In designing the incentive compatible contract, the principal has to take account of the following: the agent's risk preferences, any limits on the agent's liability, and additional sources of information on the agent's behavior.

Risk Preferences

Most individuals are 'risk averse', meaning that they dislike being faced with uncertain situations. For example, if the risk averse individual is offered a choice between two gambles with the same expected payoff, the individual will prefer the less risky gamble. Suppose the individual is offered the choice between a gamble with a 50 percent chance of earning \$40 and a 50 percent chance of earning \$0 and a second gamble where there is a 50 percent chance of earning \$30 and a 50 percent chance of earning \$10, both yielding expected winnings of \$20. The second gamble is less 'risky' because the bad outcome of \$10 is better than \$0. The risk averse individual prefers gambles where the bad outcome is less bad, even if it means forgoing the chance of a better outcome, in this case accepting a good outcome of \$30 over the good outcome of \$40. In order for the risk averse individual to be indifferent between the two gambles, the first gamble with a 50 percent chance of \$0 will have to be associated with a good outcome large enough so that the individual can expect to win more than the \$20 offered by the second, less risky gamble. In contrast, a risk neutral individual would be indifferent between the two gambles. (*See* **Choice under Uncertainty**)

In the context of the principal–agent model, when the principal conditions the agent's wage on the outcome, the agent shares the risk of the bad outcome faced by the principal. Risk sharing means dividing up the proceeds from a risky gamble among individuals.

Insurance provides the best example of risk sharing. Consider fire insurance for a community of a hundred homes. Suppose the probability of any one house getting burned down in any year is 0.01, so that on average one house is destroyed by fire each year. If the average cost of a home is \$50,000, then the community expects to lose \$50,000 each year in fire damage. While the risk of losing his or her home is large for each individual homeowner, the probability of fire is low. Suppose each homeowner pays a \$500 premium to an insurance company, so the community pays a total of \$50,000, and then each is fully reimbursed if an individual member's home is destroyed. In *ex ante* terms, everyone is better off and the community has shared the risk of a fire (Kanodia, 1991).

When a risk neutral individual and a risk averse individual maximize their joint expected utility over a risky gamble, it is optimal for the risk neutral individual to bear all the risk, fully insuring the risk averse individual (the risk averse individual receives the same payoff regardless of the outcome). In the principal–agent model, since the principal is risk neutral, when the agent is risk averse, optimal risk sharing calls for the principal to offer the agent a fixed wage contract. However, the agent's best response to a fixed wage contract is to shirk.

If the agent is risk neutral, then there is no cost associated with asymmetric information. The principal can achieve the same expected profit whether or not the agent's actions are observable by offering a contract that is contingent on the outcome. The optimal contract rewards the agent for the good

outcome and penalizes the agent in the bad outcome. Since agents bear the full consequences of their actions, they have the incentive to choose high effort. However, an incentive contract contingent on the outcome requires that the agents have sufficient wealth to forfeit in the case of the bad outcome. Furthermore, individuals are risk averse.

When the agent is risk averse, the optimal contract does not provide full insurance because the risk of a low payoff in the bad outcome provides a strong incentive for the risk averse agent to exert high effort. However, the use of performance incentives is costly to the principal because agents will demand a larger expected wage to compensate for the risk of a bad outcome outside their control. The principal faces a trade-off between inducing effort and providing insurance to agents.

Limited Liability

In the optimal contract, the principal uses punishment in the event of a bad outcome as an incentive for the agent to exert high effort. However, the agent's liability for the bad outcome may be limited by the agent's assets, or by legal institutions like bankruptcy. When the principal's optimal contract is constrained by the agent's limited liability, incentives that induce high effort are both more costly and less effective. In contrast, as the agent's liability increases, the agent is more likely to exert high effort.

Monitoring and Signals

The principal can hire supervisors to monitor the agent's behavior in order to generate additional information on the agent's behavior. Alternatively, the principal may be able to use publicly available information to aid in evaluating the agent's performance. The principal can use the informative signal to design a contract with more efficient risk sharing (more insurance for the agent). Consider the steel industry, where firms' profits are sensitive to the prices of raw materials such as iron and coal. If the owners or shareholders pay the executives based on the firm's absolute profits, they would be penalized for events beyond their control such as a spike in the price of coal. Instead, the owners could insure their executives against negative pay shocks due to unfavorable industry conditions by making executive compensation contingent on their firm's performance relative to the rest of the industry (information on the steel industry performance is publicly available).

Reputation

The agent's incentives change dramatically in a multiperiod game, where the principal can form expectations about the agent's future performance based on the agent's past actions. The agent will want to 'make a good impression', in order to receive favorable contracts in the future. In the quality-assuring price model, the principal is willing to pay reputable agents a price that includes a premium above their costs of delivering high quality. In addition, agents have an incentive to forgo the higher profits that can be attained by shirking in the current period in order to maintain their reputation and receive higher profits in the future. (*See* **Games: Signaling**; **Bayesian Learning in Games**; **Decision-making, Intertemporal**)

FAIR WAGE–EFFORT HYPOTHESIS

Akerlof and Yellen (1990) present an alternate model of the relationship between the firm and workers where their behavior is based on social norms rather than risk sharing, or reputation as in the quality-assuring price model. The fair wage–effort hypothesis asserts that workers have a perception of whether the wage they are offered is fair. Further, workers respond to wages that they perceive to be unfair by reducing their level of effort. Conversely, if wages are above the fair wage (also called an efficiency wage), workers will reciprocate by supplying more effort (also called voluntary cooperation). The fair wage–effort hypothesis and the model of quality assuring price predict observationally equivalent behavior; the only functional distinction is that a quality assuring price depends on the worker's reputation, while the fair wage–effort hypothesis holds in absence of reputation.

EXPERIMENTAL RESULTS

The experimental studies on principal–agent games have focused on three questions. First, is moral hazard a problem? The basic assumption of the principal–agent model is that in the absence of incentives the agent will always shirk. With the exception of Fehr and Gächter (2002), all the studies reported here find that a substantial portion of agents choose to shirk when incentive mechanisms are either weak or absent.

Second, can the moral hazard problem be eliminated by the incentive mechanisms described in the principal–agent literature? There is a large theoretical literature on the design of incentive

contracts and the trade-off between risk sharing and incentives. Only three experiments examine risk sharing in the context of a moral hazard problem; the rest of the experimental studies offer the agent a fixed wage contract. The other studies, which examine the role of accounting and auditing in mitigating moral hazard, focus on the effectiveness of incentives provided by reputation, monitoring, and liability.

Third, are there other incentive mechanisms beyond the scope of the principal–agent literature which can solve the moral hazard problem? Several studies examine a larger set of incentive mechanisms that include motivators such as trust, fairness, and reciprocity. These studies prevent the formation of reputations in order to test cleanly the fair wage–effort hypothesis. One study compares incentive compatible contracts, which are the traditional solution to moral hazard, with contracts enforced by reciprocity.

Risk Sharing

Berg *et al*. (1992) compare the principal's choice of contract, and the agent's subsequent choice of action in a no moral hazard environment, to a moral hazard environment. In each environment, the principal can offer one of three contracts: a flat wage contract which is the optimal risk sharing contract, or one of two incentive compatible contracts where the agent's wage is contingent on the outcome. In the no moral hazard environment, the principal offers the flat wage contract, and the agent chooses the optimal effort. In the moral hazard environment, the principal offers an incentive contract, and the agent chooses the optimal effort. They find that for the majority of the time principals and agents choose the predicted contract–action pair for the environment, demonstrating that the principals recognize the moral hazard problem, and that the agents respond to the incentives as expected.

Risk Sharing and Signals

Berg *et al*. (1990) examine whether the option for the agent to communicate additional information allows the principal to offer a contract with improved risk sharing (where the risk averse agent bears less risk) because the principal has the option to condition the contract both on the outcome and on the agent's report. In the experiment, the agent chooses an unobservable action (high or low) and subsequently also receives private, unverifiable information about the outcome (high or low). The principal chooses one of three contracts: a communication-independent contract where the agent's compensation depends only on the outcome, a truth-communication contract where the agent's compensation depends on both the outcome and the report and includes incentives for high action and truthful reporting, or a disincentives contract that encourages low action and misrepresentation of the signal. They compare the principal's choices in two different environments; first the principal chooses between the communication-independent contract and the truthful reporting contract and, second, the principal chooses between the communication-independent contract and the disincentives contract. They find that subjects respond to incentives for truthful reporting or for misrepresentation when the parameters provide large rewards for optimal decisions. In contrast, when the parameters offered smaller rewards, the principal's choice of contracts was statistically indistinguishable from random.

Reputation

DeJong *et al*. (1985a) examine whether moral hazard is a problem when the principal and the agent can develop individual reputations. They design a laboratory environment where the principal faces an uncertain payoff, and the principal can reduce the probability of a loss by purchasing services from an agent. The agents submit sealed offers to each principal, stating a price and level of service. The principals then choose among the offers. If an agent's offer is accepted, then the agent chooses the level of service to deliver, and both parties are informed about the outcome. Hence, the principal cannot directly observe the quality of the service provided by the agent and so cannot distinguish whether the loss was caused by bad luck or shirking. This design does not match all of the characteristics of the principal–agent model, because there are multiple principals and multiple agents, the agent moves first, and the agent offers a contract. But, once the principal chooses a contract, the agent's choice of effort has all the characteristics of a moral hazard problem. In each of the four markets, they find that agents tend to deliver a lower level of service than specified in their offer. However, there are fewer substandard deliveries than predicted by the principal–agent model. They find evidence that the lower frequency of substandard deliveries can be explained by reputation and quality-assuring price models.

Auditing and Monitoring

DeJong *et al*. (1985b) investigate whether liability rules and the possibility of costly investigation by the principal, and whether public disclosure of investigation findings, can mitigate moral hazard problems, using the same design as DeJong *et al*. (1985a) described earlier. In the costly investigation treatment, in the event of a loss, the principal has the option to pay to determine the level of service delivered, and the results are publicly disclosed. In the costly investigation and the negligence liability rule treatments, with either public or private disclosure of the findings, if the principal finds that the agent delivered a level of service below the 'due care' standard, then the agent bears the loss. They find that costly investigation partially deters substandard deliveries as long as the principal continues to investigate. When costly investigation is combined with the negligence liability rule, substandard deliveries are almost completely eliminated. They also find that public disclosure is a more effective deterrent to substandard deliveries than private disclosure, suggesting that agents perceive that there are incentives for them to develop a reputation for supplying high quality. In addition, they find some evidence to support an explanation of quality-assuring price, where the principals pay a premium to agents who have a reputation for delivering higher levels of service.

Mayhew (2001) examines reputation building by auditors, and the incentives provided by managers' decisions to hire auditors. In the experiment, there are two layers of moral hazard: both the manager and the auditor send reports to the investors about the quality of the asset. First, the manager chooses whether to invest in a higher quality product. If the manager invests, the product will be higher quality with probability 0.55. Prior to learning the investment outcome, the manager chooses which, if any, auditor to hire. Then the manager learns the investment outcome and makes a report to the investors. Once hired, the auditor chooses whether or not to engage in costly investigation without knowing the manager's investment decision. If the auditor investigates, he learns the true outcome and makes a truthful report. Otherwise, the auditor agrees with the manager's report. The investors receive both reports, and bid for the outcome in a first-price sealed-bid auction. All participants observe the winning bid, the manager's and auditor's reports, the auditor's identity, and the actual outcome. Mayhew finds that when investors reward managers for hiring reputable auditors, the managers respond by hiring reputable auditors, and auditors form reputations for high-quality audits. However, auditors do not form reputations in those sessions where the rewards to reputation do not manifest early in the session. Mayhew's findings support King's (1996) conjecture that the formation of reputations for truthful reporting is path dependent, and more likely to form when honest reporting is less costly early in the session.

Nagin *et al*. (2002) conducted a field experiment examining the role of monitoring on truthful reporting at a telephone solicitation company. The employees are paid a modified piece rate, where they receive a bonus for each reported successful solicitation. Some of their reported successful calls are monitored by 'call backs' and at the end of each week the employees are informed of the number of 'bad' calls, where the donor claims they did not make a pledge, which are deducted from their incentive pay. Since some donors renege on their pledges, bad calls are a noisy indicator of false reporting. At four of the company's 16 sites, the firm audited 25 percent of the successful calls, but they manipulated the audit rate observed by employees, so it appeared between 0 to 10 percent. In contrast to the theoretical prediction that all employees will shirk more when monitoring declines, they find that a substantial portion of the employees did not respond to manipulations in the monitoring rate. Consistent with predictions that employees are motivated by trust and reciprocity, they find that the employees who exploit the reduction in the monitoring rate also perceive the employer to be uncaring and unfair.

Reciprocity and Fairness

Fehr *et al*. (1997) examine whether reciprocity motives can act as a contract enforcement device when the firms offer a fixed wage contract. They compare worker and firm behavior in a no-reciprocity-treatment (NRT) where the firms post contracts and the workers' effort is exogenously determined by the experimenter, a weak-reciprocity-treatment (WRT) where the firm can fine the worker if it can verify that the worker shirked (they can verify the worker's choice 50 percent of the time), and, finally, a strong-reciprocity treatment (SRT) where, after the firm observes the worker's choice of effort, the firm can, for a cost, penalize or reward the worker. They prevent the formation of reputations by making the trading partners anonymous, so that any reciprocation is due to the trading partners' actions in the current period, rather than in previous periods. Comparing WRT to NRT, they find that firms are more

generous to the workers when the workers have the option to reciprocate, and the workers respond by shirking less frequently. Comparing SRT to WRT, their results suggest that if both parties in a transaction have the opportunity to reciprocate, then reciprocity motivations have a strong impact on the enforcement of contracts. Furthermore, the gains from trade are larger in SRT than WRT.

Fehr and Gächter (2002) find that incentive contracts which punish shirking may crowd out reciprocity-driven voluntary cooperation where the agent exerts excess effort. They compare a trust treatment where the principal offers a fixed wage and states a desired level of effort and an incentive treatment where the principal has the additional possibility of fining the agent if the principal can verify shirking (they can verify one-third of the time). If shirking cannot be verified, then the principal is committed to pay the fixed wage. Again, the principals and agents are not identified, in order to prevent the formation of individual reputations. They find that principals in the trust treatment offer higher wages and higher rents, and demand higher effort levels than in the incentive treatment. Principals in the incentive treatment frequently choose the maximum fine, suggesting that they are relying on the threat of punishment to induce agents to supply the desired effort. In the trust treatments, they find that agents cooperate voluntarily, on average supplying more effort than the principal's stated desired level when they are offered a larger rent. In the incentive treatments, they find almost no voluntary cooperation and, further, incentive compatible fines did not prevent shirking.

Rigdon (2002) examines how workers respond to fixed wage contracts, comparing the principal–agent model prediction of shirking and the fair wage–effort hypothesis prediction of voluntary cooperation in response to a generous contract. The experiment uses a variation of the Fehr and Gächter trust treatment with two significant changes: first, the experiment is double blind, eliminating all experimenter–subject interaction and, second, the agents face substantial costs associated with supplying high effort. In contrast to Fehr and Gächter, Rigdon finds that the workers chose to shirk 79 percent of the time, fulfilled the contract 18 percent of the time, and only cooperated voluntarily 3 percent of the time. In addition, though employers initially offered the workers generous contracts demonstrating trust when the workers did not reciprocate, the contracts converged to the competitive equilibrium of compensating workers for the lowest effort level. Rigdon postulates that the contradicting results can be explained by the elimination of interaction between the subject and experimenter; the experimental economics literature has demonstrated that subjects are more self-interested when their actions are anonymous. (*See* **Economics, Experimental Methods in**)

Incentive Compatibility versus Reciprocity

Guth *et al*. (1998) pair subjects in a principal–agent relationship and examine whether trust and reciprocity motivations are as effective at inducing high effort as incentive compatibility. In their experiment, the principal designs the contracts, specifying the composition of a fixed wage and a share of the dividend payment. The rational response to a fixed wage is for the agent to shirk, so that a high effort response is explained by reciprocity motives. In this setting, an incentive compatible contract would offer a relatively large profit share and no fixed wage. They find that principals initially offer contracts with large fixed wages and profit shares that are too small to be incentive compatible. The principals can offer up to three contracts, and most choose to offer at least two. They observe that the agents' contract choice appears to signal their intended work effort. In addition, the agents' work effort is positively influenced by more generous contracts, either higher profit shares or higher fixed wages. However, high effort in response to a generous fixed wage contract appeared in the initial period, while generous profit sharing induced high effort in later periods. These results suggest that incentive compatibility needs to be learned.

CONCLUSIONS

As predicted by the principal–agent model, and confirmed by experimental evidence, moral hazard is a problem. Berg *et al*. (1990, 1992) find that when faced with a moral hazard problem, the principal chooses a risk sharing contract, and the agents respond to the incentives as predicted. DeJong *et al*. (1985a) find that reputation may reduce the incidence of shirking but certainly does not eliminate moral hazard. DeJong *et al*. (1985b) and Nagin *et al*. confirm that monitoring and agent liability (ex post risk sharing) are effective in alleviating the moral hazard problem both in the laboratory and in the field. Mayhew finds that agents choose to hire reputable monitoring services when the principal is willing to pay more for assets verified by a reputable auditor. In contrast, Fehr and Gächter find that

increased monitoring and liability may reduce efficiency by destroying reciprocity. Fehr *et al*. and Guth *et al*. find that reciprocity motives reduce shirking, and even motivate the agent to deliver excess effort. Rigdon questions the results regarding the efficacy of reciprocity and comments that experimental procedures matter to the level of reciprocity across a wide variety of settings, including issues with moral hazard.

While principal–agent theory focuses on the role of risk sharing as the most effective incentive compatibility mechanism, most of the experiments have ignored risk sharing. Instead the majority of the experiments, including the experiments testing the effectiveness of reciprocity motives, offered the agent a fixed wage. In a risk sharing contract, depending on the outcome, an agent could be punished for high effort or rewarded for low effort. In contrast, the reciprocity experiments prevent the principal from punishing the agent when the agent has taken the correct action.

Games: Sequential Bargaining

Intermediate article

Glenn W Harrison, University of South Carolina, Columbia, South Carolina, USA
E Elisabet Rutström, University of South Carolina, Columbia, South Carolina, USA

CONTENTS

Sequential bargaining games involve one player responding to the offers from another player. They provide a structured opportunity to test game-theoretic hypotheses about subject motivation and cognitive processes.

INTRODUCTION

Sequential bargaining games are particularly interesting objects to analyze since they offer economists a rich context in which to study the way in which humans form expectations about the behavior of others. Traditional game theory provides a crisp series of predictions if one accepts that subjects have common expectations about the rationality of others, as well as about the game being played. Observed behavior in controlled experiments often deviates from those crisp predictions.

Three general hypotheses compete to explain these discrepancies between observed behavior and the prediction of theory. One popular view is that subjects have some desire for fairness with respect to the pay-offs to their opponents, and avoid the extreme outcomes predicted by game theory for this reason. Another popular view is that subjects do not know how to apply the idea of backward induction, or that their application of the idea of backward induction is flawed. A third view is that the subjects simply do not perceive the game in the way the experimenter does.

This article considers the nature of the process of formation of expectations found in these games. This process provides one cognitive window on the second and third explanations for observed behavior, without ruling out the first. Sequential bargaining games require subjects to undertake 'backward induction thought experiments' about the behavior of others, in which they look to the end of the game and figure out what is going to happen, then use that information to figure out what is going to happen in the penultimate stage, and so on. The outcomes of these thought experiments appear to be very sensitive to the context of the experimental design. This suggests that the cognitive process by which people apply backward induction is not 'hard-wired' in an unconditional manner, and that expectations depend on numerous variables in the bargaining environment.

NEGOTIATING A DISTRIBUTIVE OUTCOME

Bargaining occurs more often than many would expect. Whenever a contract is evaluated, an implicit bargaining session has been concluded. This is apparent when the contract price is a subject for negotiation, but even 'take it or leave it' settings entail bargaining in the broader sense in which the term is used by economists.

There are two popular formal approaches to the bargaining task. The first is to characterize the outcome of the bargaining process, remaining agnostic as to the bargaining process itself. A series of axioms are typically proposed as characterizing the outcome of a bargaining process, and the outcomes implied by those axioms derived (Davis and Holt, 1993; Kagel and Roth, 1995). The second approach is to write out the precise rules of the bargaining process, and characterize the game-theoretic equilibria of such games. (The first approach was introduced in Nash (1950), and the second in Nash (1953). See Binmore (1992) for a careful exposition of the relationship between the two.)

Sequential bargaining models provide a rich framework for the second approach, which depends on the expectation formation process. Although there is an infinite range of possible bargaining games that could be specified, extensive study has been generally limited to two broad

classes: 'alternating offer' and 'ultimatum' bargaining games.

SEQUENTIAL BARGAINING GAMES DESCRIBED

Alternating offer and ultimatum bargaining games are strategically similar. In an ultimatum bargaining game, one player makes an offer which the other player either accepts or rejects. In an alternating offer bargaining game, one player makes an offer and the other player then reacts to it by accepting it or making a counter-offer. The ultimatum bargaining game is a proper sub-game of the alternating offer bargaining game that occurs over a finite horizon. Most of the issues that arise in the more complex alternating offer bargaining game can be most directly studied through the ultimatum bargaining game. The latter is also worthy of study in itself since it arises in many other economic settings. (*See* **Games: Ultimatum**)

The Ultimatum Bargaining Game

The ultimatum game involves two agents in a seemingly transparent bargaining setting. One player, 'sender', decides on a proposed division of a pie. The other player, 'receiver', then decides whether to accept the proposal. If the proposal is accepted, the players receive pay-offs according to the proposal. If it is rejected, they each receive some disagreement outcome, typically zero.

Backward induction helps identify the sub-game perfect Nash equilibrium prediction. (For an introduction to game-theoretic terminology and concepts, see Fudenberg and Tirole (1991) or Binmore (1992).) If the receiver is not satiated in pay-offs, then any amount offered by the sender should be accepted providing it exceeds the pay-off the receiver would get in the disagreement outcome. Expecting this behavior in the sub-game, the sender can then ask for virtually all of the pie in the first stage. Backward induction is the thought process by which the sender uses the rules of the bargaining game, as well as his beliefs about the likely actions that the responder will then take, to identify his best strategy.

There have been many experimental studies of ultimatum bargaining: see Güth *et al*. (1982) for the earliest study, and Güth and Tietz (1990) for a review. The interesting behavioral outcome is that the sender does not ask for virtually all of the pie. Instead, we tend to observe average offers of just less than 50% to the receiver, with a common mode being precisely 50%. This result does not appear to be affected by standard treatment variations, such as the level of experience in the game, the level of pay-offs, or repetitions.

Figures 1 to 4 illustrate the main results from four series of ultimatum bargaining games. In each case the data have been normalized in terms of the percentage offer to the receiver. The graphs gloss over several treatments which do not appear to be crucial to the basic behavioral outcome.

Figure 1 shows the data from the experiments of Güth *et al*. (1982). It shows the data from the first series of 'inexperienced' play as well as the data from 'experienced' play with the same subject pool. The distributions of offers are similar, with means of 35% and 31% respectively. There is an apparent tendency to offer 50% or slightly less, with 23 of the 42 pooled observations being centered around 40% or 50%. Experience, in the sense of being able to think about the game for a week, does not make a great difference. Although there is a shift in the distribution towards the equilibrium with a new mode emerging at offers of 20%, the distribution is still skewed much further to the right than predicted by game theory.

Figure 2 displays the results of Prasnikar and Roth (1992), which allow us to observe the effect of repeated play against shuffled opponents. The individual period data of the experiment are pooled into two groups: rounds 1 to 5, and rounds 6 to 10. The distribution is again skewed well to the right of the prediction of game theory, with most of the offers again being over 35%. In this case experience seems to slightly worsen the results from the perspective of game theory, with the mean offer increasing from 39% over the first five rounds to 44% over the last five rounds.

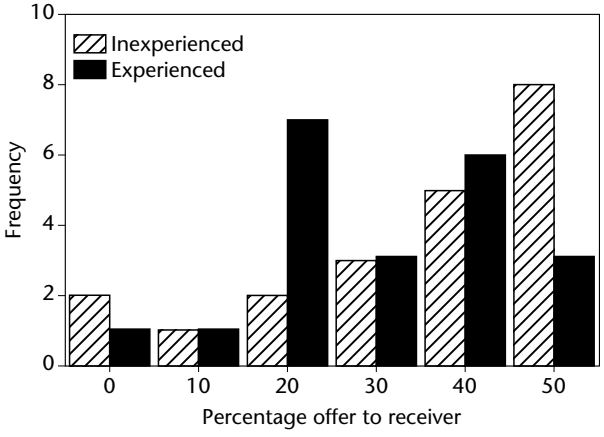

Figure 1. Ultimatum bargaining games: results from Güth *et al*. (1982).

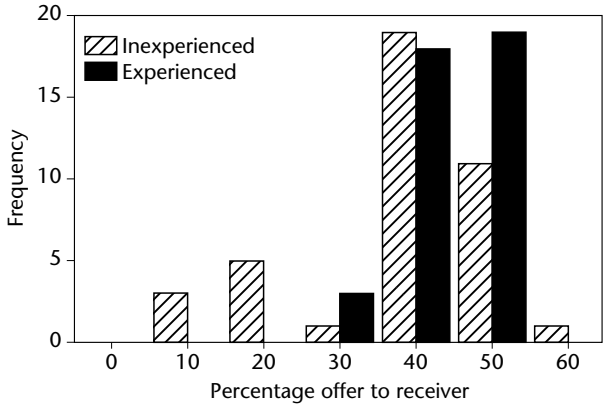

Figure 2. Ultimatum bargaining games: results from Prasnikar and Roth (1992). 'Inexperienced' data are from rounds 1–5, and 'experienced' data are from rounds 6–10.

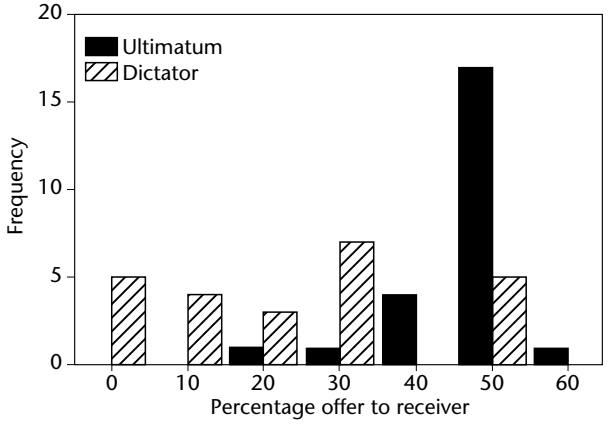

Figure 3. Ultimatum and dictator bargaining games: results from Forsythe *et al*. (1994). $10 games only are shown.

Figure 3 displays the results of Forsythe *et al*. (1994). Their ultimatum bargaining game results are comparable to those discussed already. But in order to study the role of the senders' expectations of responders' behavior, they also implemented a truncated version of the ultimatum game, known as the dictator game. In this game, the sender simply writes down his or her demand, with the receiver getting the residual. Unlike the ultimatum bargaining game, the dictator game does not require the receiver to agree or disagree.

Why conduct such a trivial game as the dictator game? The purpose was to see whether the results from ultimatum bargaining games can be attributed to senders having a 'taste for fairness', in the sense of a bias towards making a 50% offer. If they do have such a taste, then one should observe similar distributions of offers in the dictator and ultimatum games. If, however, the results of ultimatum games primarily reflect an expectation, on behalf of senders, that receivers will reject low offers, we would predict a difference in the distribution of offers between ultimatum and dictator games.

The results, displayed in Figure 3, strongly confirm the latter 'expectational' interpretation of the ultimatum game outcomes. There is little doubt that the distribution of offers in the dictator game is skewed much further to the left than in the ultimatum game. Thus one can conclude that at least some subjects in the ultimatum game are driven to offer large amounts to the receiver because they expect that the receiver will reject small amounts.

Other evidence of the role of expectations can be found in Hoffman *et al*. (1994), where offers are found to be significantly lower when market terminology is used instead of the terminology of splitting a pie. The terminology used may have an effect on expectations by encouraging a focus on common past experiences. When subjects had to earn the right to be the first mover through their performance in a task before the game, offers were found to be even lower. Modal offers were reduced from 50% to 30% of the $10 pie, and the proportion of equal-split offers dropped to 10%.

The Alternating Offer Bargaining Game

The alternating offer bargaining game is conducted over a sequence of periods, in each of which there is a proposer and a responder. If the responder in the first period rejects the offer, the game continues into the second period and the players switch roles. Players normally negotiate over the division of a pool of money, and the value of this pool gets discounted for each period that the game is extended.

Binmore *et al*. (1985) conducted a two-period alternating offer bargaining experiment where the money pool dropped from 100 pence in period one to 25 pence in period two. The sub-game perfect Nash equilibrium prediction is for the first mover to demand 75 pence in the first round, and for the second mover to accept the 25 pence offered. Binmore *et al*. found that, with some experience, subject behavior was consistent with the theory. Subsequent experiments (Neelin *et al*., 1988; Spiegel *et al*., 1994; Harrison and McCabe, 1992; Güth and Tietz, 1988; Ochs and Roth, 1989) have shown that behavior is fully consistent with theory only for some parameters; otherwise deviations from theory predictions are in the direction of equal splits.

Attempts have been made to test the explanatory power of both the fairness hypothesis and the expectations hypothesis. According to the fairness hypothesis, the reactions of subjects reflect a preference for fairness. According to the expectations hypothesis, senders react to responder behavior off equilibrium, and sender behavior is determined primarily by strategic considerations. Binmore *et al*. (1991) and Prasnikar and Roth (1992) find that strategic considerations are important, although they cannot rule out the existence of fairness preferences.

Prasnikar and Roth (1992) studied the 'best shot' game of public goods provision introduced by Harrison and Hirshleifer (1989). In this game the first mover makes an offer, after which the second mover makes an offer, and the pay-offs to each player are determined by the maximum of the two offers (multiplied by some redemption value) minus that player's own offer (multiplied by some cost parameter). The sub-game perfect Nash equilibrium prediction in this game is for the first mover to offer zero. In repetitions over 10 periods, Prasnikar and Roth found that by period 7 all first movers were making the equilibrium offers. They conclude that it is the off-equilibrium experiences, where first-mover offers above zero are countered by offers of zero by the second mover, which drive the adjustment of behavior in these games. Off-equilibrium offers by first movers clearly lead to lower earnings than equilibrium offers, contrary to findings in ultimatum games, where responders' propensity to reject declines with the amount offered so that proposers' earnings often increase with the amount offered. These observed behavioral differences are therefore consistent with the expectations hypothesis.

FORMING COMMON EXPECTATIONS

One way to appreciate the importance of common expectations for the interpretation of these results is by undertaking a simple arithmetic thought experiment with the observed experimental data. Pool all of the data from Figures 1, 2, and 3, generating a discrete distribution of 3, 5, 19, 12, 62, 82, and 6 observations of offers to the receiver of 0%, 10%, 20%, 30%, 40%, 50%, and 60%, respectively. The corresponding distribution of rejections is 2, 3, 9, 4, 16, 2, and 0, resulting in a distribution of the probability of an offer being accepted of 0.33, 0.40, 0.53, 0.67, 0.74, 0.98, and 1.00.

Now imagine that you were asked to play the ultimatum game knowing this history of acceptances. Also imagine that you have no feelings of altruism towards your opponent whatsoever. What is your best strategy as sender? Assuming local risk neutrality, your *expected* percentage of pie from each offer is 33, 36, 42, 47, 44, 49, and 40, respectively. Thus your best strategy (by a small margin) is to ask for only 50% of the pie, just as if you were playing fairly.

One problem with this numerical exercise is that the data are drawn from several experiments which differ in various ways, and this could contaminate the results. Figure 4 presents the data from Carter and Irons (1991). Their study matches our conceptual experiment much better. They asked each subject to submit strategies for both sender and receiver. The roles they played were determined after all strategies were submitted. The method used to allocate each subject to a role was to randomly pair subjects and then to let the winner of a word game be sender.

This is a particularly useful experiment for the purposes of our thought experiment. Firstly, we have data on the distributions of unconditional strategies over the whole subject pool. Secondly, the data are drawn from the same subject pool, supporting our interpretation of them as reflecting the distribution of expectations of the subject pool.

The experiment was not repeated; so subjects had no way to update their expectations. We assess the importance of this issue later in relation to the experimental design of Harrison and McCabe (1996), which addressed it directly.

Applying the same arithmetic as used earlier, the expected pay-off (percentage of pie) to a sender of demanding 100%, 90%, 80%, 70%, 60%, and 50% is 15, 36, 40, 42, 50, or 50, respectively, in this experiment. Again, assuming that the distribution of rejections is invariant, a sender seeking to maximize

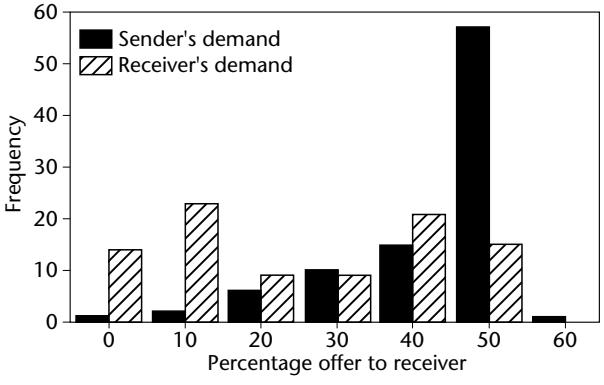

Figure 4. Ultimatum bargaining games: results from Carter and Irons (1991). The data are pooled over economists and non-economists and over first-year and fourth-year students.

expected pay-off would be led to ask for only 50%, just as if he or she had been motivated by fairness considerations.

The only conclusion one can draw from these simple numerical exercises is that one cannot reject out of hand the notion that subjects are bringing expectations into the experiment that are consistent with the distribution that is actually observed. To the extent that mere repetition of the game does not change behavior (and Prasnikar and Roth, 1992, have shown that it does not do so drastically), their posterior distributions during the experiment will continue to reflect their initial priors. They might then have no sense of playing equitably, but still look as if they do. On the other hand, without some control over subject expectations we cannot test the fairness and expectations hypotheses against each other in these experiments.

The critical experiment, then, is one that can control those expectations during the experiment and try to move them in one direction or another. In one sense, this is what was done with the dictator games, where it was found that expectations of rejections explained some, but not all, of sender behavior. Nevertheless, since receivers have no power at all over the outcome in dictator games, it is likely that other factors may cause the observed off-equilibrium sending behavior. Below we review two experimental games which were intended to shift players' expectations, but with the two players' relative positions of power unaffected. The natural direction in which to move expectations, given the priors that are reflected in the behavior exhibited in Figures 1 to 4, is towards the game-theoretic prediction. In this way one can try to generate data that test the fairness and expectations hypotheses against each other.

THE ROLE OF SUB-GAME EXPERIENCE

In the standard extensive form of the ultimatum bargaining game, the receiver gets to know what proposal the sender has chosen before selecting his strategy. A simple modification of this extensive form has the receiver selecting his strategy without knowing what proposal the sender has made. In this case the receiver would simply be asked at what threshold offer he would switch from rejecting to accepting. It is apparent that the equilibrium predictions of these two games are identical.

By eliciting strategies from the receiver, rather than just choices, subjects have an incentive to contemplate strategies that apply both on and off any equilibrium path. Considerations of appropriate actions off the equilibrium path are necessary for the application of backward induction. Essentially the same logic underlies the design in Harrison and McCabe (1992), in which subjects were given experience in the sub-games of an alternating offer bargaining game. Harrison and McCabe put subjects in three-period games in every even round, and in the final two-period sub-game in every odd round. Knowledge of the outcomes of these two-period sub-games was hypothesized to be needed for subjects to properly evaluate strategies for the full game, at least according to game theory, even though the equilibrium of the full game called for the sub-game to never be played. (This behavioral outcome is well known from experimental asset markets, and is referred to as the 'swingback hypothesis' by Forsythe *et al*. (1982) and Friedman *et al*. (1984).) As subjects gained knowledge of the sub-game outcomes in the experiment they indeed successfully managed to apply backward induction and select strategies for the full game consistent with game theory.

We can extend the idea of eliciting complete strategies one step further, and modify the extensive form ultimatum game again so that each subject does not know whether he will be sender or receiver in any given round. This determination is known by the subjects to be made by nature at random, with an equal chance of each subject being selected to be one or the other type. Again, it is apparent that the equilibrium strategies of this game are identical to those of the standard ultimatum bargaining game.

Harrison and McCabe (1996) undertook several experiments with this basic design. Their first experiment, called U1, had subjects submitting their strategies for 15 periods. No information on other players' strategy choices in any period was provided until the end of the session. At that point, each subject was told of the period that had been selected at random for payment purposes. Their second experiment, called U2, was identical to U1 except that subjects were given information on the strategy choices of all subjects after every period. The complete history of these period-specific strategy distributions was also displayed on a blackboard at the front of the room.

Their third experiment, called U3, was the same as U2 except that the human subjects were joined in the first five periods by an equal number of simulated opponents. A simulated player would ask for a percentage of the pie between 86% and 99% when playing sender, and between 1% and 14% when playing receiver. The random distribution of

simulated strategies was uniform within these intervals. The simulated strategies were included in the reported distribution of strategies during the 10 periods in which there were simulated players. For all subsequent periods the reported distribution included only the strategies of the human players, since no simulated players were present. This device for controlling the expectations of subjects is due to Roth and Schoumaker (1983).

Figures 5 and 6 present the results from the experiments of Harrison and McCabe (1996). The average percentage that human senders allocated to themselves is shown in Figure 5. The average percentage that human receivers requested as a minimum is shown in Figure 6.

The results are consistent with the hypothesis stated earlier: that allowing subjects to form common expectations will act as a behavioral surrogate for the common knowledge assumed in the game-theoretic prediction. The control experiment U1, in which there was no public information, produced behavior much like that observed in previous experiments, with the sender asking for slightly more than 50% of the pie. On the other hand, the minimum demands of the receiver in experiment U2 decay in the direction of the game-theoretic prediction. This indicates that expectations are affected by the provision of public information. However, in early periods they are also very close to 50% of the pie. Demands by the sender in experiment U2 are similar to those observed in the control experiment for the first five or so periods, but from period 9 onwards they diverge markedly, moving towards the game-theoretic prediction. By the end of the experiment, average demands by the sender were about 87% of the pie, compared with 56% in the control.

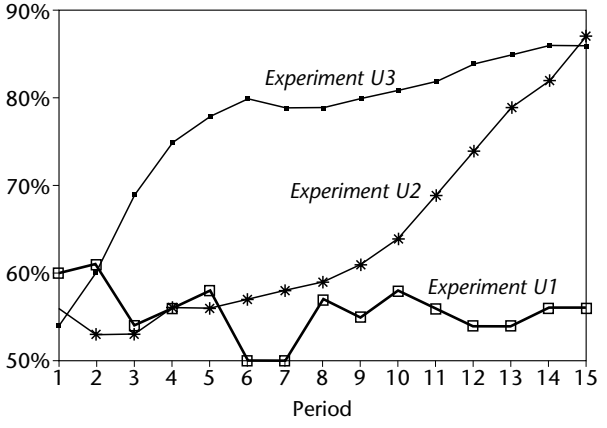

Figure 5. Demands by senders in the Harrison and McCabe (1996) experiments. The graphs show the average percentage that senders allocate to themselves.

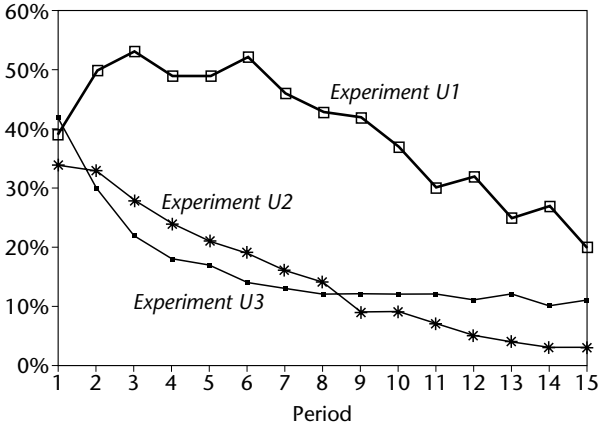

Figure 6. Demands by receivers in the Harrison and McCabe (1996) experiments. The graphs show the average minimum percentage required by receivers.

THEORETICAL EXPLANATIONS

What appears to be driving this behavior is the relatively rapid decline in minimum demands by the receiver in experiment U2. As early as period 2 they are well below those observed in the control, and they steadily decline to around 24% by period 4. Since all subjects are aware of this average requirement by the receiver when they come to enter their period 5 strategies, it is not surprising that subjects re-evaluate the wisdom of sticking with a period 4 demand of 56% on average when they need to give the receiver only 24% on average. A typical risk-neutral subject could increase his sender demand to 76%, assuming that receivers would again ask for only 24%. (A more complete calculation would account for the distribution of offers around the average of 24%.) Moreover, the steady decline in receiver demands is obvious (from 34% to 33% to 28% to 24% over periods 1 to 4), so assuming that receivers would continue with a 24% demand (or less) in period 5 looks like an even safer bet for our risk-neutral subject.

If sender behavior is primarily driven by expectations in this sense, we would expect to see changes in amounts offered as well. This is indeed what happened in experiment U3. Demands by the sender were much higher than observed in the appropriate control (experiment U2), at least for all periods except the first few and the last few. Expectation formation appears to be driven in periods 1 to 5 by the reported behavior of the simulated players, as indicated by the rapid increase in demands by senders. What is particularly

interesting about the results of U3 is the lack of a significant and persistent decline in demands by the sender once this treatment is removed after period 5. Although demands do not continue their rapid increase, they do remain quite stable and settle at an average demand in period 15 of 86% of the pie. Despite the differences in the demands of the sender in experiment U3, the demands of the receiver are virtually identical to those observed in the control experiment U2.

Additional evidence for the changes in receiver behavior over time can be gleaned from some ultimatum game experiments conducted in Japan, Israel, Yugoslavia, and the United States by Roth *et al*. (1991). Three sessions were conducted in each country. In Israel, Japan, and Yugoslavia only one experimenter was used for all sessions. Each of these three experimenters conducted one session in the United States. Thus it is possible to identify experimenter effects and country effects. No data were collected on the ages or sexes of the participants. However, some sessions did have identified differences in the subject pool. Two differences are noted by Roth *et al*.: in one of the Israeli sessions, and in one of the Yugoslavian sessions. Each subject participated in a session lasting 10 rounds, with very few exceptions where only 9 or 8 subjects turned up. Each subject faced a random opponent in each round. Thus the data consist of balanced panels of individuals responding over each of 10 rounds.

The response data in these experiments can be studied using a simple panel logit regression model, in which individual random effects for each subject are estimated. (The data and programs needed to replicate these calculations can be obtained from Harrison (2001). Alvin Roth kindly approved the use of the data, which were supplied by Miguel Costa-Gomes.) In addition to the individual random effects, explanatory variables for the response in period t include the offer received in period t, dummy variables for the country of the experiment, dummy variables for each of the experimenters, dummy variables for the two sessions identified as having unique subject recruitment procedures, and a variable keeping track of the period. The only statistically significant variables in this simple specification are the offer level, the country effect for Israel, and the variable keeping track of the period. A 1% increase in the amount offered in the current period increases the probability of acceptance in the current period by 2.2 percentage points; the Israeli subjects accepted with a probability that was 22 percentage points higher than those in the United States; and the probability of an acceptance increased by roughly 0.7 of a percentage point every period. These acceptance probabilities are conditional on the offer received, since one would expect unconditional acceptance probabilities to increase as the amount offered increased, possibly masking the effect of experience. On the sender side we find significant effects on the current offers from lagged accepted offers, and from just having had an offer accepted, using a panel regression estimated using feasible generalized least squares. We also find that these effects differ across countries.

These results, obtained across a wide sample of experimental data, confirm that there does appear to be a dynamic path to the behavior of receivers in the ultimatum game. The question of the exact form of that dynamic, and whether it corresponds to coherent learning behavior, awaits a more sophisticated econometric characterization.

CONCLUSION

These experimental results demonstrate that much of the observed behavior in sequential bargaining is consistent with an expectations-based explanation, and that it is possible to control these expectations to some extent. Moreover, by manipulating the expectations we can alter observed bargaining outcomes in predictable ways. This experimental control enables us to test the 'fairness' and 'common expectations' hypotheses. The results of Harrison and McCabe (1996) provide a strong refutation of the hypothesis that considerations of fairness drive bargaining outcomes independently of subject expectations, and this is consistent with the conclusions drawn in Binmore *et al*. (1991) and Prasnikar and Roth (1992). This is not to deny a possible role for fairness considerations when applied to subjects who do not have common knowledge of the rationality of opponents. In such environments the predictive power of noncooperative game theory is understandably weak.

Games: Signaling

Intermediate article

Colin F Camerer, California Institute of Technology, Pasadena, California, USA

CONTENTS

In a signaling game, a player who is informed privately about an unobservable quality that he or she has chooses an observable signal, which an uninformed player observes and reacts to. Game theory describes how players' choices and beliefs match ('equilibrium'). Experiments show that behavior generally conforms to an equilibrium after players gain experience.

INTRODUCTION

A 'signal' is an observable action a person takes that can reveal something about the person. The idea was borrowed from the theory of international relations and formalized by Spence (1974), who shared a Nobel Prize in 2001. Spence's prime example was education. He theorized that employers cannot directly observe a person's intelligence, but can observe whether the person graduated from college. If college is too difficult for people who do not have the qualities the employer wants, finishing college 'signals' the presence of those qualities to the employer.

Many other examples share this underlying logic. A cheap warranty signals to consumers that a product isn't likely to break down often; if it was not so, the firm could not afford the costs of frequent product replacement. Giving flowers and small gifts (without the reminder of a splashy holiday like Valentine's Day) means that a person is thinking about his or her lover.

Signals are credible if they satisfy the following two properties. Firstly, signals must be affordable by certain types of people, for whom the cost of the signal is less than the benefit of the 'receiver' decoding the signal. (Note that signals may be free, but have a 'cost' because of the consequences of choosing one signal or another.) Education pays because it gets students jobs; credible warranties get firms eager customers; flowers are well worth it if she knows what they mean. Secondly, signals must be too expensive for players of the wrong type. Students who hate schoolwork cannot stand the pressure and boredom of a demanding university. People selling fake Rolexes from briefcases on the streets of New York cannot afford to offer warranties.

Combining these two properties, a logical observer can conclude that if one person buys the signal, and another does not, then the two people are of different types. This is called a 'separating' equilibrium. A Nash equilibrium is a pattern of mutual best responses, in which all players are making the best choices, knowing that all the others are doing so.

In an equilibrium, actions and beliefs match: signalers' beliefs about what will happen after they buy the signal turn out to be right; and the inferences that the observers of the signal draw about the 'type' of the person who chose the signal are correct. If actions and beliefs are not in equilibrium, then either somebody's belief is wrong or somebody is failing to extract information from what they see. In the education example, if intelligent students go to college but do not get better jobs as a result, then their guess about how employers would react was wrong and employers don't think that college graduates make better employees. Economists study equilibria in which these mistakes are not made, because they believe that players will adjust their behavior over time until consistency occurs.

Signaling is one way to explain actions that might otherwise seem irrational. Some armies build and test soldier loyalty with inefficient tasks, like digging a hole then filling it again. Digging and filling wastes valuable time and produces nothing. But it signals the soldier's willingness to obey orders. Another example is provided by labor strikes. The prevailing theory of why strikes occur is that a company's managers and workers can only credibly signal that they won't pay more, or won't work for less, by agreeing to stop paying and working. A strike is a way for both sides to signal their seriousness.

Signaling models have also begun to influence biology and anthropology. The theory of 'costly signaling' in biology (e.g., Zahavi, 1975) explains apparently fitness-reducing activities by asking what type of information they convey. Male animals often develop physical features that seem to be handicaps, such as a peacock's lush tail-feathers or an elk's heavy antlers, but these 'handicaps' may in fact signal fitness.

SENDER–RECEIVER GAMES

In a sender–receiver game, a sender observes her own 'type' and chooses a message. A receiver observes the message, but not the type, and chooses an action. The pay-offs of both players depend on the type, the message, and the action. (Types are features that the player knows about but are not perfectly evident to others.) All the games described above – signaling intelligence through education, signaling profits or wage requirements through strikes, signaling product quality through warranties or advertising – can be put into this general framework.

The first careful experiments on sender–receiver games were conducted by Brandts and Holt (1992) and Banks *et al*. (1994). Let us begin with game 1 from Brandts and Holt, shown in Table 1. Each cell in the table shows the pay-offs to a sender (the first number) and a receiver (the second number), depending on the sender's message and type (row), and the receiver's subsequent action (C or D). For example, if the sender is of type L and sends message S, and the receiver responds with action C, then the sender earns 140 and the receiver earns 75.

The pay-offs can be thought of as reflecting gains from education. Consider the following scenario: a worker draws her type, either L (low intelligence) or H (high intelligence). There is a common prior probability that her type is L with probability ⅓ and H with probability ⅔. (Everyone knows this probability distribution, and that the worker knows her own type.) After observing her type, the worker can either skip education (S) or invest in education (I). A prospective employer does not observe the worker's type (L or H), but does observe whether she invested in education (S or I). Then the employer assigns the worker to either a dull (D) job, which requires little skill, or a challenging (C) job, which requires more skill.

Table 1. Payoffs in sender–receiver game 1 (Brandts and Holt, 1992)

	Action after message S ('skip')		*Action after message I ('invest')*	
	C	*D*	*C*	*D*
Type L ('low')	140,75	60,125	100,75	20,125
Type H ('high')	120,125	20,75	140,125	60,75

The employer's pay-offs are simple: she wants to assign L employees to the D job, and H employees to the C job. Those assignments produce an employer pay-off of 125; the opposite assignments are mismatches and yield only 75.

The worker's pay-offs create a different incentive. Workers get pay-offs from both wages and 'psychic income'. Both types earn 100 from the challenging job C and only 20 from the dull job D. In addition, L types get an added pay-off of 40 if they skip college (S), and H types get an added pay-off of 40 if they invest in education and go to college (I). In addition, suppose the H types who skip college get an extra payoff of 20 from the challenging job C, perhaps reflecting on-the-job learning from the challenging job which is a substitute for what they would have learned in college. Adding up these pay-offs gives those in Table 1.

There is a conflict of interest between senders (workers) and receivers (employers) in this game. Employers would like to know the workers' types so that they can assign the Ls to job D and the Hs to job C. Since the probability that the worker's type is H is ⅔, if the employer doesn't learn anything about the worker's type from her choice of S or I, she will assign the worker to job C. (Assigning to C gives an expected pay-off of 108.3 and assigning to D gives 91.7.) Essentially, since H is more likely than L, it pays for the employer to take a chance and assign everyone to the more challenging job C.

Both types of workers prefer job C. Since the employer will assign a worker to job C unless she becomes fairly convinced (probability more than ½) that the worker is of type L, the type L workers have an incentive to 'pool' with the type H workers and mimic whatever the Hs do, so that they can get the lucrative C job assignment.

As in many signaling games, there is more than one equilibrium. In one 'pooling' equilibrium, both types choose S and employers respond with C. In addition, a complete 'Bayesian-Nash' equilibrium must specify how employers respond to unexpected messages ('off the equilibrium path'). In the equilibrium described above, to keep H types from breaking out of the pool and choosing I, employers must think that an unexpected choice of I is evidence that the worker is of type L, so that they assign a worker who sends message I to the dull job D. That is, in the S–C equilibrium, the

employer's belief about the worker's type, after the out-of-equilibrium choice I, is that the worker is more likely to be L than H. (That is, $P(L|I) > ½$.) Since the pay-offs from D after choosing I are lower for both types than the pay-offs from C after choosing S, neither type will deviate, and so the pattern of choosing S and getting job C is an equilibrium.

There is a problem with this equilibrium pattern. Imagine a country in which nobody gets advanced education for decades, and then one person does choose to get educated. Everybody knows that L types don't like education – they are bored and frustrated by college – but H types love it (they earn a higher psychic pay-off, reflected by the bonus of 40 in the game). Then why would an employer think that the person who went abroad to college is an L type? L types cannot possibly benefit, but H types might (if their education is taken as a clue that they are H types). The belief that L types are the ones to get educated first violates the 'intuitive criterion' proposed by Cho and Kreps (1987). Game theorists have proposed other criteria for when inferences are plausible or not. These criteria, called 'refinements', narrow the set of multiple equilibria by imposing further mathematical restrictions that only some equilibria satisfy. There is a second sequential equilibrium in which workers pool by choosing I, employers assign everybody who chooses I to job C, and a worker who deviates by choosing S is assigned job D. This equilibrium does satisfy the intuitive criterion because the H types cannot possibly earn a higher pay-off by deviating (by choosing I and getting job C they earn their maximum pay-off of 140), but L types might earn a higher pay-off.

Refinement concepts like the intuitive criterion were developed mathematically to resolve the question of which equilibrium is likely to occur if there are multiple equilibria (a difficult problem which has perplexed theorists). Whether refined equilibria are more likely to occur than unrefined ones is ultimately an empirical question. Experimental data show that only the simplest of these 'refinement' criteria match behavior closely.

Table 2 shows some experimental results along with equilibrium predictions. (The equilibrium predictions are the proportions of players predicted to choose the messages or actions shown in the column headings, according to the two different intuitive and unintuitive equilibrium criteria.) The relative frequencies of I messages and intuitive-equilibrium actions tend to support the intuitive equilibrium. The strongest evidence against it is a low frequency (25%) of I choices by L types in the early periods 1–4, but they quickly learn to pool with the Hs (who always choose I) by choosing I most of the time in later trials.

REPUTATION FORMATION

In game theory, a player's reputation is defined as the probability that he or she is a certain privately-observed type. Camerer and Weigelt (1988) explored these reputation models carefully, using a 'trust', or borrower–lender, game. In each eight-period repeated game, a single borrower drew a random type, either 'normal' (X) or 'nice' (Y). The type was the same for all eight periods. The same borrower played a series of eight-stage games, with a different lender player each time. The lender could either lend or not lend; if choosing to lend, the borrower then decided whether to default or repay. The pay-offs are shown in Table 3. Not lending gives the lender 10, and lending pays 40 if the loan is repaid or −100 if the borrower defaults. A normal borrower prefers to default, and then get 150, instead of getting 60 from repayment. A nice borrower gets 0 from defaulting and thus prefers to repay.

The equilibrium can be calculated by working backwards from the end. In the last period, normal borrowers will always default. Lenders who anticipate this will lend only if the chance that the borrower is nice is above some threshold (0.79). Moving back to the seventh period, normal borrowers know that if they default in period 7 they will reveal their type and lenders will be afraid to lend to them in period 8. It pays for them to *sometimes* repay (using a 'mixed strategy'). Working

Table 2. Results in sender–receiver game 1 (Brandts and Holt, 1992)

Periods	*Message given type*		*Action given message*		*Equilibrium predictions*	
	I|H	I|L	C|I	D|S	*Intuitive*	*Sequential (unintuitive)*
1–4	1.00	0.25	1.00	0.74	1	0
5–8	1.00	0.58	0.00	1.00	1	0
9–12	1.00	0.75	0.98	0.60	1	0

Table 3. Pay-offs in the borrower–lender (trust) game (Camerer and Weigelt, 1988)

Lender strategy	*Borrower strategy*	*Pay-off to lender*	*Pay-off to borrower*	
			normal (X)	*nice (Y)*
Lend	Default	−100	150	0
	Repay	40	60	60
Don't lend	No choice	10	10	10

Table 4. Lending and repayment rates (Camerer and Weigelt, 1988)

	Experiments	*Period (1 = start, 8 = end)*							
			1	*2*	*3*	*4*	*5*	*6*	*7*	*8*
Conditional frequency of lending	3–5	Predicted	1	1	1	1	0.64	0.64	0.64	0.64
		Actual	0.94	0.94	0.96	0.91	0.72	0.59	0.38[a]	0.67
	6–8	Predicted	1	1	1	0.64	0.64	0.64	0.64	0.64
		Actual	0.96	0.99	1.00	0.95[a]	0.85[a]	0.72	0.58	0.47
	9–10	Predicted	1	1	1	0.64	0.64	0.64	0.64	0.64
		Actual	0.93	0.92	0.83	0.70	0.63	0.72	0.77	0.33
Conditional frequency of repayment by normal (X) types	3–5	Predicted	1	1	1	0.81	0.65	0.59	0.44	0
		Actual	0.95	0.97	0.98	0.95[a]	0.86[a]	0.72	0.47	0.14
	6–8	Predicted	1	1	0.73	0.68	0.58	0.53	0.40	0
		Actual	0.97	0.95	0.97[a]	0.92[a]	0.85[a]	0.70[a]	0.48	0
	9–10	Predicted	1	1	0.73	0.67	0.63	0.56	0.42	0
		Actual	0.91	0.89	0.80	0.77	0.84[a]	0.79[a]	0.48	0.29

[a]Significant difference ($|z| > 2$) between predicted and actual frequencies.

further back, it pays to repay early in the game, because defaulting means that the borrower will never get a loan to repay ever again in that eight-period sequence. For example, defaulting immediately means that the normal borrower earns 150 plus a string of seven payoffs of 10, a total of 220. But repaying for the first three periods earns at least $3 \times 60 + 5 \times 10 = 230$, which is better than defaulting right away and getting no more loans. Table 4 shows the predicted and actual frequencies of lending and repaying in each of the eight periods (assuming there has not been a default earlier in the sequence). Note that these predictions are precise, and derived with no free parameters.

Two patterns in the data are of particular interest. Firstly, what is the rate of lending and default across periods? And secondly, does lending and repayment in each period of an eight-period sequence reflect prior history in that sequence, as the theory predicts?

The table shows the conditional frequencies of lending and repayment (by normal types), from the last two-thirds of all the sequences, pooled together. Actual frequencies significantly different from the predictions are marked.

One prediction is that lending should drop off sharply in period 5 (for experiments 3–5) or 4 (experiments 6–10). Lending does drop off, but not quite as sharply as predicted. For example, in experiments 3–5 the overall frequencies of lending in all early and late periods are 0.95 and 0.62 (predicted to be 1 and 0.64); in experiments 6–8 the corresponding figures are 0.98 and 0.80 (same predictions).

Repayment rates do fall, from close to 100% in the first couple of periods, to nearly zero in the last period, but repayment is generally more common than predicted. This deviation can be explained by the hypothesis that some subjects who earn normal pay-offs simply prefer to reciprocate by repaying.

Camerer and Weigelt concluded that 'sequential equilibrium predicts reasonably well, given its complexity'. That is, while the equilibrium predictions are not perfectly accurate, they vary across periods in the correct direction and are not far off in magnitude. Replications by Neral and Ochs (1992) and Brandts and Figueras (1997) support this basic conclusion.

Camerer *et al*. (2002a) propose a boundedly rational explanation of how players learn to

approximate the equilibrium. In their theory, some players learn what strategies work best from experience. Other players are 'teachers', who realize that others are learning, and choose strategies that change what the learners do in the future to benefit themselves (the teachers). In the trust game, teachers repay in early periods because they are trying to 'teach' the lenders that lending is profitable. But late in the game, the payback period from teaching is too short, so teachers eventually default. The teaching theory retains strategic foresight, but relaxes the requirement in equilibrium models that players all correctly guess what strategy others will follow.

CONCLUSION

In signaling games, one player observes private information and takes an action that may signal that information to a 'receiver' player (who knows the probability distribution of the private information, but does not know the information). The logic that underlies predictions about patterns of mutually-consistent equilibrium play is complex and depends subtly on players' own choices and beliefs and the choices and beliefs of others.

Experiments are particularly useful for testing signaling models, because the predictions depend delicately on variables that are difficult to observe directly. Early experimental results are supportive of equilibrium predictions, but equilibration seems to take time. Some recent experiments have been modeled on specific phenomena: political lobbying (Potters and van Winden, 1996, 2000), firms issuing shares of stock (Cadsby *et al*., 1998), and aggressive pricing to crush competition (Cooper *et al*., 1997a; Jung *et al*., 1994). In most games, players show limited strategic sophistication at first, followed by learning. That is, players often take actions that 'tip their hands', revealing their types to other players in a way that can be exploited.

Cooper *et al*. (1999) conducted an experiment on 'ratchet effects' in planned economies (Chaudhuri, 1998). (In a planned economy, firms are instructed to meet a quota, but do not earn more if they exceed the quota. Productive firms are effectively penalized for doing well because their quotas are raised in the future. Clever managers therefore deliberately underproduce to avoid having their quota ratcheted up.) Cooper *et al*. studied students and factory managers in China to see whether experience in a planned economy taught the managers to underproduce to avoid being ratcheted. When the games were described in the familiar language of production and quotas, the managers played closer to the game-theoretic prediction (that is, the high-productivity managers produced 'too little', to avoid being ratcheted) than the students.

While approximate equilibrium emerges over time, early behavior is constrained by cognitive limits: players do not initially anticipate how their choices reveal information; and players do not make immediate inferences from other players' choices, as equilibrium theories require. New models that incorporate limited cognition (Camerer *et al*., 2002b) and learning are a promising way to understand how players behave. Cognitive science could inform game theory further. As Van Damme (1999) concluded: 'At present our empirical knowledge is inadequate and it is an interesting question why game theorists have not turned more frequently to psychologists for information about the learning and information processing processes used by humans.'

CONTENTS

Trust and investment games are experimental methods for assessing behaviorally the presence of trust and reciprocity.

THE NATURE OF INVESTMENT, POSSIBLE INEFFICIENCIES, AND REMEDIES

In economic environments, an investment is an advance payment to earn future productive returns and benefits. The agent who makes the investment must have the appropriate incentives. For instance, a company involved in scientific research is willing to pay for the costs of the research only if there is a reasonable probability that adequate benefits and profits may be reaped in the future. This might not be the case if competitors are allowed to copy a new design at no cost. Patents are a way to guarantee such a return.

When prospects of future benefits are not reasonably large and reasonably assured to the person making the advance payment, then the potential investor may decide that the investment is not convenient; then, the productive capability of the investment is lost. This outcome is inefficient, since the total amount of resources available reflects a forgone opportunity.

One way of overcoming this inefficiency is the institution of complete, binding, irrevocable contracts. The contract has to be binding, or it has no power; it has to be complete, or the uncertain outcome in some event might destroy the incentive to invest. And it must be irrevocable: the person who makes the advance payment in the form of investment is in an unfavorable bargaining position once the payment is made.

Clearly, contracts with such stringent requirements are hard to realize, and when they are realized they are typically costly and complex. In many informal or infrequent interactions, a contract is either not feasible or not convenient. A second way to insure the appropriate investment in repeated situations is building a reputation through the threat of future sanctions. An informal agreement to return something to the investor is credible if the situation is going to be repeated. The investor may threaten to stop the investment in future periods. The promise of future benefits, and the threat of their loss, may induce the trustee to honor his or her dues today.

When contracts are impossible, and the exchange is not repeated, investments are likely to be inefficient. The loss may be considerable. Yet often in real exchanges we observe investments even when these two solutions are unavailable. It is important to understand why investment still occurs. Recent research in experimental economics addresses this issue precisely.

The investment game is an effective tool in this research. It is a simple game, specifically designed for a laboratory environment. Its aim is to investigate whether observable investment occurs if agents cannot write binding contracts and cannot create reputations.

THE EFFECTIVENESS OF TRUST

The investment game is a tool to study how widespread and effective trust is in social interactions. Consider any situation in which one agent is giving another the power to make a decision that affects the utility of both. Trust occurs if, in pursuing an outcome that is potentially favorable to the two players, one of the two puts himself or herself willingly in a situation of vulnerability. It is far from clear whether trust has any effect in economic interactions between selfish agents. It is also far from clear how different factors may affect trust if it does

exist. The investment game allows a controlled study of the effectiveness and nature of trust in economic interactions.

THE STRUCTURE OF THE INVESTMENT GAME

In the basic investment game, or trust game, two players move in sequence. Player 1 has an initial monetary endowment A. Player 1 decides the amount x of A to transfer to player 2. The transfer x is a productive investment; it increases by a factor of R ($R > 1$) before reaching player 2. Then, player 2 decides how much, a, of Rx to return to player 1. Player 1 leaves with $[A-x+a]$ and player 2 leaves with $Rx-a$. For example, if the multiple is 3, and player 1 has an initial \$10 and decides to transfer \$5, player 2 would receive \$15. If player 2 decides to return \$8 out of the \$15, the final pay-offs for the players are \$13 and \$7 respectively.

Several features of the game deserve comment. Firstly, there is no possibility of writing binding contracts, so that player 2 cannot be penalized for not sending something back to player 1. Secondly, there is no opportunity for reputation formation, at least provided the game is played only once and the subjects are never going to meet again. Similarly, the threat of a zero transfer in future periods, which might be effective in situations where the game is repeated by the same subjects in the same roles, is ineffective. Given the assumption that each subject prefers more money to less, then the second player should not return any of the Rx that he was sent. Given that player 1 knows that player 2 follows the same principles of behavior as player 1, then player 1 knows he will receive nothing back, thus player 1 will send nothing. In summary, the investment game is a strategic situation in which, under standard economic modeling assumptions, no investment should occur.

This conclusion is valid even for very large R. Yet if the first player rationally decides to make no initial transfer, the two players completely forgo the potential benefits of the productive technology represented by R: the total amount they receive is A, rather than RA, which would be technically feasible. It is clear that if they could sign binding and irrevocable contracts before the beginning of the game, then the rational course of action would prescribe a transfer equal to the total amount A by the first player. This choice would maximize the total amount available to them, and they could bargain on its final allocation.

EXPERIMENTAL EVIDENCE

The original experiment implementing this game was run with very tight controls (Berg *et al.*, 1995). Two features were crucial. Firstly, the anonymity from the experimenter, as well as subjects' anonymity from each other, was guaranteed. Secondly, each subject was matched with only one other subject. The values chosen for the parameters were $A =$ \$10 and $R = 3$.

While the prediction of the sub-game perfect equilibrium is a zero transfer of the first player and a zero amount returned, the average amount sent was \$5.16, and the average amount returned was \$4.66. Very few subjects among the first movers sent zero (2 out of 31). The amount sent was highly variable, with a distribution statistically similar to a uniform distribution over the range of possible transfers. Many among the second movers who had received an amount of \$1 or more returned less than \$1 (12 out of 29). But 11 of the same 29 subjects returned more than they had received. It has become customary to call player 1's behavior 'trusting behavior' and player 2's 'positive reciprocity'.

This finding leads to the conclusion that new assumptions about individual behavior need to be incorporated in modeling activities in industrial organization, such as the modeling of asymmetric information, to better explain observed phenomena. Several related games, with similar designs, have produced the same experimental outcomes.

RELATED GAMES

In the investment game, the first mover has to make a decision that is costly to him or her, but potentially beneficial for both players. The benefits to the first mover, however, come only after a similar costly decision for player 2: so player 1 cannot insure that he will get some of the benefits. On the contrary, purely selfish motivations of the second player would imply that the first mover cannot derive any benefit from his payment; so he should not make any positive transfer. The same dilemma exists in several related games that have been tested. The general result, that an advance positive payment of player 1 is made, is confirmed (with some important exceptions). We now review some of these variations.

The Gift Exchange Game

As in the investment game described above, two players move in sequence. Player 1 has to propose

a wage w, in a given interval. Player 2 can accept or refuse. If player 2 refuses, both players get a zero pay-off. If player 2 accepts, he or she has to choose a costly effort e. Then the game is over, and the first player gets a pay-off of $Re-w$ while the second gets $w-c(e)$, where c is a function that is increasing at an increasing rate. The transfer, or investment, in the basic investment game is replaced by the commitment of the first player to pay a wage w, irrespective of the effort of the second player; the return payment is replaced by the effort e and its cost $c(e)$ to the second player, $c(0) = 0$. The opportunity for both players is represented by the productive factor R.

As in the investment game, a rational selfish first player should anticipate a minimum effort of the second player, and should promise a minimum wage. With wage, effort, and cost of effort all equal to zero, both players get zero equilibrium pay-off, even though $Re-c(e)$ is achievable (and hence divisible to each) with a feasible effort e.

Experimental evidence

This game was introduced and tested in Fehr *et al*. (1993, 1998); see also (Charness, 1996, 2000). In contrast to the equilibrium prediction of minimum effort and minimum wage (the market clearing levels of the competitive labor market), the observations in the experiment were consistent with a fair wage hypothesis. This hypothesis can be formulated as three statements: the effort level is increasing in the wage; the average wage is higher than the minimum necessary to assure employment; and the average effort is higher than the minimum. These outcomes persist after replications of the same (one-off) game.

The Moonlighting Game

In the investment game, player 1 can transfer only positive amounts of money to player 2. In the moonlighting game, both players begin with a positive endowment. Player 1 can give an amount g or take away an amount t from the second player. An amount given increases by a factor of R; an amount taken away is simply transferred to player 1. Player 2 can then return money or take money away from the first player: an amount b given back costs b to player 2, while the punishment in the form of an amount p penalizes player 1 $3p$. Player 1 is a moonlighter, his activity cannot be contracted upon. The game allows the study of positive and negative reciprocity.

Experimental evidence

The moonlighting game was introduced and tested in 'one-off' experiments by Abbink *et al*. (1999). They found that three-quarters of subjects transferred a positive amount g; on average, this transfer induced a positive return b. An amount taken away t is heavily punished with a positive p. Retribution is thus considered to be stronger and more effective than reciprocity. Player 2 was also allowed to propose a non-binding contract. These contracts increased trust but did not encourage reciprocity.

The Peasant–Dictator Game

In the peasant–dictator game, player 1 is a peasant and player 2 a dictator. The peasant decides the amount k he or she will invest out of an available amount W. The investment produces income $(1 + r)k$. Then the dictator moves: he or she can impose a tax on the income produced, and the amount $t(1 + r)k$ goes to him or her; $(1 - t)(1 + r)k$ returns to the peasant, and is added to $W - k$.

Two treatments are possible. In one, the dictator may commit to a level of taxes before the peasant decides. In another (slightly different but economically equivalent), the dictator announces the level of taxes before the investment, but is not committed to the announcement. When the announcement has no binding force, the economically rational choice for the dictator for any level of investment is to tax the entire amount. When the announcement is binding, the dictator knows that too high a tax will induce the peasant to make no investment.

The peasant–dictator game with no commitment is equivalent to the investment game: the amount invested by the peasant is equivalent to the transfer made by player 1 in the investment game, and the amount left after taxation corresponds to the amount returned by player 2 in the investment game. The specific parameters used by Berg *et al*. correspond to a rate of return $r = 2$ in the peasant–dictator game, with W equal to the initial endowment of the first mover. A possibly important difference in the description of the game is the nature of the amount decided by the first mover. In the instructions for the peasant–dictator game the amount is described as an investment, while in the investment game it is described as a transfer from the first to the second mover.

Experimental evidence

The game was introduced and tested by Van Huyck *et al*. (1995). The game with commitment played by rational selfish individuals would have an outcome where positive investment is made, while in the game without commitment the

peasant would not invest anything. Van Huyck *et al*. emphasized the difference in behavior between the commitment and no-commitment games. Their qualitative results correspond to the game-theoretical analysis: in the games where no commitment was possible, the average investment, and aggregate earnings, were lower.

No direct comparison was made between the results in Berg *et al*. (1995) and Van Huyck *et al*. (1995). From the evidence available it is not clear that the level of trust in the peasant–dictator game is lower than that in the investment game. In both games there is a positive level of investment without available commitments.

RECIPROCAL BEHAVIOR AND ITS REASONS

The results described above prompt certain questions. What is the reason for such behavior? Why, in particular, do we observe the deviation from predictions based on the assumption of selfish rational behavior – assumptions that are supported in different contexts? Are these deviations robust and meaningful? Important approaches to these questions can be found in various manipulations of the basic game that have been tested experimentally.

Manipulations

Social history

In a variation of their main experiment, Berg *et al*. (1995) showed subjects a report on the outcome of the same experiment run a few months earlier in the same university. The report showed, for each level of transfer, the number of subjects who had chosen that transfer, the average amount returned, and the average profit (average amount returned minus average amount sent). The behavior in the two treatments (with and without seeing a social history) was different, and statistically significant at the 6 percent level, suggesting an increase, among those subjects who had seen a social history, in the correlation between the amount sent and the amount sent back.

Induced strategic reasoning

Boeing *et al*. (2000) asked whether informing subjects of the theoretical logic of sub-game perfection makes them perform more consistently with the theory. They modified the way in which information was presented to participants and, through a questionnaire, prompted strategic reasoning. None of the various treatments led to a significant reduction in the amounts invested. The results of these experiments suggest that the findings of Berg *et al*. (1995) are robust to changes in information presentation and to cues about strategic reasoning.

Mood induction

A large literature in psychology has shown that mood and emotions can affect altruism, defined as the propensity to help unknown people with no material reward. The common finding is that good mood increases altruism. Reviews of these findings and their methodology can be found in Lewis and Haviland-Jones (2000) and Gilbert *et al*. (1998): in particular, see Isen (2000) and Zajonc (1998). An illuminating review of the main hypothesis and explanations is in Carlson *et al*. (1988).

The effect of mood on reciprocity, however, is not clear. An experimental analysis of this question was attempted by Kirchgeister *et al*. (2001). Their experiment was based on the investment game. Before the game, however, subjects in the role of player 2 underwent a mood induction phase. There were two treatments: to a first treatment group, a 'sad' film was shown (a five-minute sequence from *Schindler's List*); to a second treatment group, a 'happy' film was shown (a five-minute sequence from *City Lights*).

The mood induction was effective. The behavior of players in the two different moods was significantly different. The return transfer of 'happy' subjects was relatively insensitive to the original investment. 'Happy' subjects who received a low transfer x replied with a higher a than 'sad' subjects, while 'happy' subjects who received a high transfer x replied with a lower a than 'sad' subjects.

Personal and social interactions

The original investment game captures what can be called 'direct reciprocity'. However, in various social exchanges, reciprocity may not directly involve the subject who first makes the investment, but other members of a group. Subjects are called indirectly reciprocal if they are willing to reciprocate even if the originator of the transfer is not the target of the reciprocity, but belongs to the same group. Buchan *et al*. (2001a) devised and tested a variation of the original trust game to examine the extent to which subjects are willing to trust for the benefit of a group or a community.

The original design is called the 'direct condition'. In the 'group condition', a sender A transfers money to a responder B, and a sender C transfers money to a responder D. The money is multiplied

by 3, as in the original experiment of Berg *et al*. (1995). Responder *B* can then return some proportion of her wealth to sender *C*, while responder *D* can return some proportion of his wealth to sender *A*. In the 'society condition', sender *A* sends money to responder *B*, while responder *D* receives money from a different, randomly chosen, sender in the same room as sender *A*. Responder *D* then returns some proportion of his wealth to sender *A*, while responder *B* returns some proportion of her wealth to a randomly chosen sender in the same room as sender *A*. Subjects are said to engage in indirect trust by sending money even when they are not the recipients of potential reciprocation.

Out of a total amount normalized to 1000, the mean amounts sent were 782.14 units in the direct condition, 488.64 units in the group condition, and 505.46 units in the society condition. Thus, even in the society condition, where there is no possibility of personally benefiting from reciprocation, the amounts sent far exceed the equilibrium prediction.

Both the trust of the first mover and the reciprocity of the second mover, for both the group and the society conditions, are significantly reduced as the reciprocation becomes more indirect. But there is strong evidence of reciprocity even when the reciprocation is indirect. The mean proportions returned (fraction of the money returned compared with the total amount available to the two players after the productive investment) are 0.319 in the direct condition, 0.114 in the group condition, and 0.130 in the society condition. The situation for the amount sent is similar. For both the amounts sent and the amounts returned, there was no significant difference between the group and society conditions.

Choice of partner

Eckel and Wilson (2000) designed a variation of the basic investment game to study the partners people choose in investment enterprises. In their design, subjects were allowed to choose between two trust games. These games could be slightly different, or identical. The games had a marker represented by an icon, a stylized image of a face, which could appear to be friendly, unfriendly, or neutral. The first mover could choose the icon (hence the game), and then make the first move. The second mover could then observe the game chosen (and the icon) and the first move of the sender. (Eckel and Wilson interpret the choice of icon as the choice of the type of partner that the first mover would like to meet. This interpretation would not necessarily be made by subjects: for example, the choice of an angry icon might be interpreted by both players as a signal that the first mover would be angry at a lack of reciprocation of the second player.) Eckel and Wilson found that people chose partners who appeared to be most trustworthy. A choice of the neutral icon was usually followed by a more trusting choice of investment.

There were some counterintuitive results. For instance, a choice of angry icon was followed by a high level of trusting behavior; and reciprocation by the second player was higher when the icon chosen by the first was angry. These results might be explained on the basis of the interpretation of the choice of icon as a signal sent to the second mover.

Factors Affecting Behavior

Male and female behaviors

One dimension of analysis of the trust game is the study of the behavior of players of different sexes in the trust game. It is known that there are significant differences. For instance, in the peasant–dictator game, Bolton and Katok (1995) and Eckel and Grossman (1998) found that women gave more than men. The difference was significant in the second paper. Andreoni and Vesterlund (1998) compared differences in behavior between men and women in dictator games for different monetary values of the tokens to be divided. They found that women gave more overall and were more likely to divide tokens evenly despite changes in monetary value, while men became less generous as the value of their tokens increased.

For the trust game, Croson and Buchan (1999) examined this issue in a study extending over four different countries. The design of the experiment was the same as in Berg *et al*. (1995). Men and women sent approximately the same amount as first movers. But women were more reciprocal. The proportion of money returned grew by approximately one-third per dollar, and for women this factor was increased by approximately one-eighth. In Croson and Buchan (1999), the sex of the opponent was unknown. Buchan *et al*. (2001) varied the information that subjects had about the sex of the opponent. When subjects knew the sex of the opponent, the difference between men and women in observed trust and reciprocity became more apparent: men sent more than women (to subjects of either sex) when they were first movers; both men and women sent more to men than to women; and men sent significantly more to other men than to women.

Culture and environment

The trust game has been applied in different countries, providing a test of the possible importance of cultural and social factors. Bond and Hwang (1996) found evidence of face-saving behavior (investing to avoid appearing selfish) among subjects, a fact that makes even more desirable the use of double-blind procedures.

A more systematic study was conducted by Buchan *et al*. (2001b), who used the experiment designed to test direct and indirect trust and reciprocity to look for differences in behavior in four different countries. The study involved students from China (Beijing), Korea (Seoul), Japan (Osaka) and the United States (Madison, Wisconsin).

The differences in the levels of trust were significant and sizeable. Japanese and Korean subjects extended significantly less trust than did American subjects. Also, the amounts sent by American and Chinese subjects significantly differed from the amounts sent by Japanese and Korean subjects.

Expectations

Morrison and Rutstrom (2000) studied the effect that beliefs have on behavior. They used a discrete version of the trust game, in which the first mover could choose only between sending or not sending and the second could choose only between returning and not returning.

Morrison and Rutstrom focused on the prior belief of the second mover that the first mover will send money. A second mover is surprised if he or she was expecting no money to be sent yet receives a transfer. The main finding is that a surprised second mover is less likely to return the money.

The Need for New Theories

How can we give a unified explanation of these different phenomena? Probably the most widely used approach is to attempt to adjust standard theories of preferences to address the trust issue. Such an approach would introduce additional arguments to the utility function and then ask whether observed data can be accounted for. A common assumption is that individuals' preferences are defined in terms of their own and other people's pay-offs. This is systematically investigated in Fehr and Schmidt (1999). For example, reciprocation in the trust game occurs because player 2's preferences do not just depend on his or her own wealth but also on player 1's final wealth. If this approach is correct, then other traditional means of analysis remain valid. There is no doubt that this approach will continue to provide useful insights.

However, rather than viewing trust as something to be incorporated into existing models, it is possible that a more basic understanding of trust could arise from a more general attempt to trace behavioral regularities in strategic situations back to structures and functions of the brain. Neuronal structures are generally understood to be at the basis of all behavior; yet they may defy the application of the traditional mathematical structures used by decision scientists to examine choice. McCabe *et al*. (2001) have begun to examine the behavior of subjects in multiple-person settings using functional magnetic resonance imaging. They have found brain activation patterns for trusting players when they play against other humans that are different from when they play against computers. Their study is a first step in attempting to unravel the anatomical underpinnings of the trust phenomenon. It is not yet fully clear how such phenomena can easily be subsumed in any traditional account of choice. A major question still to be answered is how activation varies as a function of the level of observed trust. A hint at how this question might be addressed is provided by Smith *et al*. (2001). Their study finds that relatively more brain activation can be traced to ventromedial (dorsomedial) areas depending on the presence of ambiguous (risky) stimulus comparisons. The ventromedial area corresponds to areas that are evoked in the presence of emotional factors, while the dorsomedial area evokes areas that are associated with computation.

As we have noted, levels of trust are not independent of factors like social history, sex, and culture. The results in Kirchgeister *et al*. (2001) show that the prior viewing of a film sequence which contains no relevant information can significantly alter behavior in an investment game, suggesting that mood and emotion are involved in the way trusting behavior and reciprocity are regulated. This in turn suggests the following conjecture: the same ventromedial area that is associated with emotional factors in conjunction with ambiguous stimuli may also be associated with morally based emotional choice which is sensitized by such things as seeing *Schindler's List* or observing social history. Furthermore, this area would be activated in different degrees for men and women and for people of different cultures. Of course, it is possible to incorporate such factors as social history and sexual and cultural differences into a traditional functional representation, as in Fehr and Schmidt (1999), but such factors may be so far removed from human

deliberation that it may be more parsimonious to invoke notions of automaticity.

Games: Ultimatum

Advanced article

Terence C Burnham, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

The ultimatum game is a simple, two-person strategic situation. Human behavior in the ultimatum game and the economic prediction of behavior diverge in a robust manner with profound significance for economics.

INTRODUCTION

The ultimatum game is a simple strategic situation between two people. One person, called the proposer, divides a fixed amount of money into two parts. This division is presented to the second person, termed the responder, as a 'take it or leave it' offer (hence the name 'ultimatum'). The responder has two options: to either accept or reject the proposed division. If the responder accepts, then the two parties divide the money according to the proposal. If the responder rejects, then both parties receive nothing. In either case the game ends with the responder's decision. In most experimental settings, the proposer and responder communicate through the experimenter and never learn each other's identity.

Many of the experiments that are discussed below were played for cash stakes of the order of 10 US dollars. For example a proposer might offer a split of $7 for the proposer and $3 for the responder. If the responder accepts this division, the $10 is allocated as the proposer suggested: $7 to the proposer and $3 to the responder. If the responder rejects this division, then neither the responder nor the proposer receives any money. The game ends at this point; responders who reject the first offer (the 'ultimatum') are not allowed to make a counter-proposal.

THE IMPORTANCE OF THE ULTIMATUM GAME IN ECONOMICS

The ultimatum game has been the subject of hundreds of articles and fierce debate within economics. This prompts the question of why such a simple game should be so important. The answer is both empirical and theoretical. As we will see, there is no widely accepted theory to explain the way people behave in the ultimatum game, and this has broad and deep implications for economics. Two areas of research, discussed below, relate the ultimatum game structure and results to economics.

Game Theory

The use of game theory within the social and natural sciences is now widespread. Indeed, the 1994 Nobel Prize for Economics was awarded to John Nash, Reinhardt Selten, and John Harsanyi for their work in game theory.

Game theory deals with situations where the outcome of one party depends both on that party's own behavior and on that of another party. Thus, the province of game theory includes such diverse topics as employer and employee relations, predator and prey interactions, and global political situations. Whenever there are strategic interactions between parties, the analysis should include game theory.

The ultimatum game is one of the simplest game-theoretic situations. There is just a single proposal; the game has only two players; and each player has only one decision. Furthermore, the proposer and the responder can communicate only through the offer of the proposer. In contrast to the simple structure of the ultimatum game, most situations outside the laboratory have many parties, myriad terms, long histories, and undefined sets of choices for the parties.

For example, consider the relationship between a farmer and the people who pick the farmer's crops. The two parties negotiate over pay, hours, health insurance, unemployment compensation, and so on. The individuals in this strategic situation will often be involved with each other for decades. The

tactics range from cool-headed financial proposals to strikes, boycotts, lockouts, and violence.

The ultimatum game provides a check of the predictive and normative power of game theory in an extremely simplified setting. If game theory fails in this setting, its applicability to more complex situations is questionable.

Self-interest in Economics

In addition to game-theoretic interactions between parties, the ultimatum game involves the question of basic human motivation. Economic theory is predicated on the notion that individuals pursue self-interest. What is self-interest, and how does it relate to the ultimatum game? In answering these questions, there is a division between theoretical and applied economists.

When economic theorists define self-interest, the term has little predictive power. For example, a person who commits suicide could be maximizing utility and pursuing self-interest. Or a person may maximize utility by giving money away to others. Thus, an economic theorist may see self-interest in many acts that most lay people would call altruism or even self-destruction.

An example may clarify the economist's view of altruism. Consider a typical day of Mother Theresa, in which she tended to the needs of others. Was Mother Theresa an altruist? To most people the answer is 'yes', but to economists the answer is 'no'. Economics assumes that all people ruthlessly and efficiently seek happiness. Any behavior that a person performs is assumed to make that person happier than alternative, feasible actions. In this view, when Mother Theresa nursed a sick person she was just as self-interested as a landlord who evicts a tenant for not paying rent.

As this example demonstrates, the economic assumption of self-interest cannot be contradicted by behavior. Whatever someone does is assumed to be motivated by self-interest. The term 'revealed preference' is used to describe this view of human behavior. People have preferences, and seek to be as happy as possible given those preferences and the choices they face. An outsider can understand motivation only by observing behavior, which reveals the underlying preferences.

While economic theorists take a very general definition of self-interest, economic practitioners are more specific. For economists who make predictions in the world, and those who make normative judgments on policy matters, self-interest means consuming goods and leisure. In this materially self-interested version of economics, Mother Theresa would be considered an altruist, but altruists are assumed not to exist.

The ultimatum game results discussed below suggest that human motivations are more subtle than is assumed by this second, more commonly used, definition of economic self-interest. In a variety of settings, people show deep concern for the impact of their actions on others. Sometimes people act altruistically to help others, but they also show a spiteful willingness to damage others. Both altruism and spite are inconsistent with the standard economic model of human nature. The implications of the divergence between the economic theory of human nature and actual human nature are profound.

PREDICTED AND ACTUAL BEHAVIOR IN THE BASIC ULTIMATUM GAME

Predicted Behavior in the Ultimatum Game

Standard economic theory makes a precise prediction of behavior in the ultimatum game (Stahl, 1972; Rubinstein, 1982). The standard analysis is based on the game-theoretical concept of 'sub-game perfection' (Selten, 1975).

To understand the standard analysis, first consider the position of the responder deciding whether to accept the proposer's offer. If the responder rejects the offer, the responder will receive zero and the game will end. The standard assumption of economics is that a responder will care only about the money that he or she will receive. The choice of an ultimatum game responder is thus clear. Rejection results in zero money for the responder while acceptance means the responder will take home whatever amount has been offered. A responder who behaves as predicted by standard economic theory will accept any offer greater than zero.

Consider an ultimatum game played for $10. Standard economic theory predicts that the amount the proposer proposes to take will have no effect on the responder's behavior. So at an extreme in the $10 game, responders are predicted to accept one cent and allow the proposer to take home the rest.

Now that the prediction for the responder's behavior is clear, consider the behavior of the proposer. The outcome of any proposal depends on the responder's behavior; thus the proposer must have an implicit or explicit model of the responder. If the responder will behave as predicted by economic theory, the responder will accept any offer that is more than zero. If the proposer assumes that

the responder will act as predicted by economic theory, and if the proposer cares only about his or her own monetary pay-off, then the offer should be the smallest possible positive amount.

In other words, a selfish proposer who anticipates a selfish responder proposes to take the whole financial pie. The selfish responder faced with a crumb or nothing, accepts the crumb. Returning to our $10 ultimatum game, the standard economic prediction is that proposers will offer the smallest possible positive amount and all offers will be accepted by responders. If the proposals are constrained to whole numbers of dollars, the prediction for a $10 game is an offer of $1 to the responder and acceptance of the offer.

Actual Behavior in the Ultimatum Game

The first experimental ultimatum game study was conducted by Guth *et al*. (1982). They had people play the ultimatum game for 10 deutschmarks. The money was actually paid according to their choices.

Guth *et al*. found that actual human behavior differed from the economist's prediction of behavior in two significant ways. Firstly, 20 percent of the responders rejected offers. (Recall that self-interested responders are predicted to accept all offers greater than zero.) Secondly, the average amount offered to responders was 30 percent of the total. Economic theory predicts offers close to zero, so the human proposers in this study were significantly more generous than predicted.

These data present a challenge, for the reasons discussed above. Firstly, if economics generally assumes material self-interest, why are responders walking away from money? Secondly, if game theory fails to predict behavior in this setting, how applicable is it to more complex situations? Finally, game theory fails in both its predictive role and its normative role. The behavior of both proposers and responders differs from the prediction. Furthermore, proposers who follow the theoretical advice make less money than proposers who ignore this advice.

Because of these important implications, this landmark study led to a series of related experiments that continues to this day. We summarize below some of the experimental evidence.

Replication of Guth et al.

The original data have been widely replicated using subjects drawn from industrialized countries (often college students). Summarizing across many experiments: (1) the most common proposal is an equal split, (2) the average amount offered to responders is between 40 and 50 percent, and (3) responders are more likely to reject proposals that give them a smaller percentage of the money, and frequently reject proposals that give them less than 20 percent. (See Camerer and Thaler (1995) and Roth (1995) for excellent summaries.)

Economic theory predicts an extreme division, with proposers taking almost all of the money. As noted, the actual outcome is always closer to an equal split than this prediction. However, the proposer very rarely ends up with less than half the money, so there is a substantial advantage to being the proposer (Bolton, 1991).

The effect of stake size

One common reaction to the initial study of Guth *et al*. was that the results were due to the relatively small amount of money at stake. Defenders of the standard economic theory predicted that the deviations from theory would disappear as the stakes became larger. And in their paper, Guth *et al*. suggested that an important test of their results would be to raise the stakes substantially to the level of 100 deutschmarks.

Hoffman *et al*. (1996a) had 50 pairs of subjects play the ultimatum game for $100 (all pairs were paid). The behavior of people in this $100 game was compared with that of previous participants in a $10 game. There was no significant difference between the two games. In the $100 game, three out of four offers of $10 were rejected, and two out of five offers of $30 were rejected.

Hoffman *et al*. did find, however, that there was a difference between ultimatum games played for no money (where people are just asked for their decisions, without any monetary consequences) and games for $10 or $100. Specifically, they found that in games for no money the rejection rate was 17 percent, and this dropped, with statistical significance, to 4 percent for games with stakes of $10. So in this study, money did matter, and increasing the stakes from zero to $10 did induce behavior closer to the economic prediction. The original findings of Guth *et al*. were, however, replicated, and increasing the stakes from $10 to $100 did not change behavior towards that predicted by economic theory.

Another approach to raising the effective value of the stakes was taken by Cameron (1999), who travelled to Indonesia. Because of the lower average income there, this study was able to use stakes equal to three months' worth of an average person's salary. The result was that responders were more willing to accept smaller percentages of the

total as the stakes increased. However, proposer behavior did not change with the increase in stakes, and behavior did not converge to the prediction of economic theory.

The Indonesian proposer behavior highlights an important theme in ultimatum games. Recall the two most salient differences between actual and predicted behavior: 'generous' proposers offer more than predicted, and 'proud' responders reject low offers when theory predicts invariable acceptance.

The initial reaction to these results focused on the generosity of proposers. Given that responders reject small offers, however, proposers' generosity redounds to the benefit of both parties. Similarly, when the stakes are increased a proposer risks more financial loss, so proposers might temper their demands out of aversion to risk rather than altruism. The finding that proposers do not alter their behavior as the stakes increase, even though responders become more willing to accept low offers, is consistent with this assessment.

So the deviation from the economic prediction exists when the stakes are raised to $100 in the US and three months' salary in Indonesia. What about even higher stakes? Even in poor countries, it is difficult to raise the funds for experiments with extremely high stakes.

Some evidence from outside the laboratory bears on the question of extremely high stakes. Cohen *et al*. (1996) suggest that potentially violent arguments between strangers are characterized by high costs of disagreement and no material costs of concession and withdrawal. They write, 'approximately 20 000–25 000 Americans will die in homicides this year, and tens of thousands more will be injured in stabbings or gunfights that could have ended in death'. In these interactions, people are willing to bear even the chance of death rather than accept an outcome they deem unfair or humiliating.

Cultural variation

While many of the ultimatum game experiments have been conducted in the US and Western Europe, several studies have been performed to examine how play varies across cultures. The general conclusion is that actual human behavior in the ultimatum game does not conform to the standard economic prediction of play in any culture studied.

Roth *et al*. (1991) ran identically structured ultimatum games in Israel, Slovenia (in Ljubljana, which was then part of Yugoslavia), the US, and Japan. The experiment was carefully constructed to reveal cultural differences. For example, the instructions were all translated from the same script, the different experimenters all had the same training, and the stakes were set to have equivalent purchasing power (slightly above $10 in the US). In contrast to many other experiments, this study had each participant play ten games, each with a different counterpart.

In all four countries, the most common offer ranged between 40 and 50 percent of the stake. There were cultural differences in both responder and proposer behavior. Israeli responders were more willing to take small offers, and Israeli proposers did indeed make smaller offers. In the first round of play, the most common offer was 50 percent in all four countries. By the tenth round of play, the most common offer in Israel was 40 percent, the most common offer in the US and Slovenia remained at 50 percent, and the most common offers in Japan were 45 percent and 40 percent. These differences were statistically significant.

In summary, this first cross-cultural study found differences in ultimatum game play between cultures, but behavior in all cultures was similar to the original findings and different from that predicted by standard economic theory.

Henrich (2000) went further and took the ultimatum game to the Machiguenga of South America, who subsist on hunting, fishing, gathering, and small-scale horticulture. Then, together with other researchers, he studied ultimatum game behavior in 15 small-scale societies around the world (Henrich *et al*., 2001).

The ultimatum game results from these 15 small-scale societies confirm that actual human behavior in the ultimatum game deviates from the prediction of the standard economic model. The authors write that the standard model 'is not supported in *any* society studied' (emphasis added). The lowest average offer was among the Machiguenga, where it was 26 percent, and this is significantly higher than the standard economic prediction of zero.

The small-scale societies exhibited two behaviors not previously documented. Firstly, participants from the Achuar, Ache, and Tsimané accepted 100 percent of the offers. In the case of the Achuar, this may be because there was only one offer of under 20 percent. However, all five offers of under 20 percent were accepted among the Tsimané, as were all eight such offers among the Ache. Secondly, among the Au and Gnau cultures, offers were frequently for more than half, and these offers were frequently rejected. Among western populations, offers above 50 percent are very rare, and larger offers are more likely to be accepted. The authors explain that the Au and Gnau are

gift-giving cultures in which acceptance of gifts requires reciprocation.

Informational treatment

Kagel *et al*. (1996) investigated fairness by running ultimatum games and manipulating the stakes and what the proposer and the responder knew about the stakes. (For related experiments, see also Prasnikar and Roth (1992), Mitzkewitz and Nagel (1993), and Croson (1996).) Specifically, they used an ultimatum game played for 100 chips, each worth 30 cents or 10 cents, and varied which players know the value of the chips.

In the basic version, chips are worth the same to both players and the values are common knowledge. This is a standard ultimatum game, and Kagel *et al*. replicate other studies with the most common offer being 50 percent. In one variant, chips are worth 30 cents to proposers and 10 cents to responders, and this is known only to the proposers. In this setting, proposers can achieve equal monetary outcomes by offering 75 chips. What the proposers actually do, however, is to exploit their informational advantage by offering close to 50. Responders generally accept these 50–50 splits in chip terms and (unknowingly) give 75 percent of the money to the proposer.

The outcome differs, however, when the game is played with the same pay-off conditions (30 cents' value to the proposer and 10 cents' value to the responder), but where the responder knows about the asymmetry in value. In this case, 50–50 splits of chips tend to be rejected, and over time proposers increase their offers.

Context-dependent effects

Hoffman *et al*. (1994) take issue with the notion that 'fairness' is the source of the observed behavior in the ultimatum game. They designed experiments in which the right to be the proposer in an ultimatum game is earned by correctly answering questions on a trivia quiz. When the right to propose is earned – and the instructions reinforce this 'property right' aspect – ultimatum game behavior is significantly more self-regarding. Specifically, half the proposers offer equal splits when the right is assigned randomly, versus one in ten when the right is earned.

RELATED GAMES

Multistage Games

Researchers have examined the motivation for rejections in the ultimatum game. In particular, why do responders reject positive amounts and so end up with zero? Some insight comes from looking at slightly more complicated multistage games. Recall that the ultimatum game derives its name from the finality of the first offer. In other games, the responder is allowed to make a counter-proposal from a smaller financial 'pie'.

One interesting feature was discovered in these multistage games with shrinking stakes. Responders often make counter-proposals that earn them less money than the offer they have just rejected. For example, a responder may reject \$4 out of \$10, then turn around and propose to take home \$3 out of \$5. Roth (1995) summarizes four independent studies, and finds that between 65 percent and 88 percent of the counter-proposals would result in less money for the responder than the just-rejected offer. This fact is strong evidence that many subjects care about more than just their own material pay-off.

Dictator Games

To explore the role of altruism in the ultimatum game, Kahneman *et al*. (1986) had subjects play a different game in which the proposers had no strategic motive to be generous. The dictator game has the same structure as the ultimatum game except that the second player does not have the right to refuse the division. The first player's decision is unilaterally imposed (hence the name 'dictator'). Because of this difference, the second player is called the 'recipient' in dictator games, as opposed to the 'responder' in ultimatum games.

Kahneman *et al*. used 161 dictators, of which 122 divided \$20 evenly, consistent with an altruistic interpretation. In this study, however, only 8 of the dictators were paid. Forsythe *et al*. (1994) ran dictator games in which all subjects were paid for stakes of \$5 and \$10. They found that 64 percent of \$5 dictators and 79 percent of \$10 dictators give at least \$1. The average amount given was approximately 25 percent. So dictators in these experiments were more generous than predicted by standard economic theory. These allocations are, however, less generous than those observed in comparable ultimatum games, so there is a strategic component in the behavior of ultimatum game proposers.

THEORETICAL EXPLANATIONS

Roth and Erev (1995) looked at the evolution of play in ultimatum games that continued for several rounds, as well as data from other repeated games. In the repeated versions of the ultimatum game,

their model has proposers learning to make generous offers because their less generous offers get rejected. The model also captures an important asymmetry in the ultimatum game: rejections cause larger losses for proposers than for responders. In this model of adaptive learning, behavioral adjustments happen faster in the context of large losses. Thus, proposers learn to moderate their demands faster than responders learn to accept.

This learning model provides insight into the dynamics of adjustment, but it is not designed to explain why play starts where it does. For such explanations, other models are required. One important approach involves what are called 'other-regarding' preferences. Economists use the term 'preferences' to describe an individual's likes and dislikes. The standard assumption about preferences is that people derive satisfaction only from their own lives and not from the lives of others. The ultimatum game results are inconsistent with these standard, materially self-interested, preferences.

While human behavior deviates in a significant and robust manner from that predicted by self-interested preferences, economic theory has no difficulty constructing preferences with an interpersonal component. These other-regarding preferences can be defined in a manner that is consistent with the ultimatum game.

Since the late 1980s several models of other-regarding preferences have been proposed. These models have inspired empirical tests, which have in turn stimulated new models and more experiments.

Bolton (1991) posits other-regarding preferences that include a term for relative consumption. In the context of two-person games, Bolton's model suggests that people care about both the amount of money they receive and the percentage of the total that they receive. The ultimatum game data are consistent with a utility function of this form. Specifically, a responder's dislike for low relative pay-off may outweigh the value of an offer. Granted that the responder is willing to reject, the offers of the proposer are understandable: proposers anticipate the possible rejection and temper their behavior accordingly.

In the light of Bolton's model, consider two games. The first is the standard ultimatum game, and the second is identical except that a computer generates the proposed split. In the second game, with a computer-generated proposal, the responder is presented with a 'take it or leave it' offer exactly as in the ultimatum game. The material repercussions for both individuals are identical regardless of the origin of the ultimatum.

What is the prediction for the new game? Bolton's model predicts that players will react identically to an offer generated by a human or a computer. Blount (1995) performed this experiment and found that, in the computer-generated game, rejection rates approach zero. In this case, then, materially self-interested preferences more accurately predict behavior than does Bolton's model.

As with Bolton's model, economic theory has no difficulty incorporating Blount's results into different specifications of other-regarding preferences.

One second-generation model of other-regarding preferences modifies the utility function to include a term for 'fairness' (Rabin, 1993). If a player believes his or her counterpart is being fair (this is defined precisely), then the player's happiness increases as the counterpart's pay-off increases. Conversely, if a player believes his or her counterpart is being unfair, then the player's happiness decreases as the counterpart's pay-off increases.

In Rabin's model, rejections in the standard ultimatum game come from the responder perceiving the proposer as acting unfairly. In Blount's computer-generated game, there is no unfairness on the part of the proposer, hence no reason to reject.

The narrow self-interest model, Bolton's model, and Rabin's model share the feature that every person has preferences of the same form. There are no spiteful or altruistic people in these models. Rather, circumstances, and perceptions of circumstances, induce people to act in ways that can be viewed as selfish, spiteful, or altruistic.

In contrast to these universal preferences, Levine (1998) assumes that there are different types of people in the world. Some individuals derive satisfaction from their counterpart's pain and others from their counterpart's pleasure. Furthermore, Levine assumes that players' behavior is conditioned by their expectation of the counterpart's type. People who delight in the counterparts' consumption might, nevertheless, dislike rewarding selfish types. Although the preferences differ between individuals, Levine's model constrains the distribution of spiteful and altruistic types to be constant across all situations.

Levine's model is consistent with the ultimatum game results. In this model, two distinct groups of responders will reject unequal ultimatum splits. The first group contains individuals who derive satisfaction from others' pain. They reject because

the loss to them through their own pay-off is more than compensated for by the pleasure in hurting the proposers. The second group of rejecters is using the offer as a signal of the proposer's type. Proposers who make unequal splits reveal themselves to be people who ought to be punished. In Blount's computer-generated offer game, this second group does not exist, hence the lower rejection rates.

So both the Levine and Rabin models are consistent with both standard and computer-generated ultimatum game behavior. Preferences of these types can also be constructed that are consistent with the observed generosity in the dictator game. However, several variants of the dictator game have been performed experimentally with results that are not consistent with these models.

Hoffman *et al*. (1996b) ran variants of the dictator game that systematically varied the 'social isolation' of the dictators. In the most private treatment, neither the experimenter nor the recipient could identify the behavior of any individual dictator. Recall that dictators who make their allocations known to the experimenter tend to give over 20 percent. In the private treatment, almost two-thirds of dictators kept the entire stake, and the average allocation was $0.80 out of $10.

In summary, dictators' giving is affected by their social isolation, and dictators who make decisions under private conditions keep almost all the money. This result has been replicated by Burnham (2002). Burnham found further that dictators are more generous when their actions are less private. Specifically, dictators give more when they see a photograph of their recipient, or when the recipient sees a photograph of them.

Let us return to the models of other-regarding preferences. Neither the Levine nor the Rabin model predicts any change in dictator behavior as a function of social isolation or anonymity. A new generation of theories has been developed which are more consistent with the existing data (Fehr and Schmidt, 1999; Bolton and Ockenfels, 2000; Fehr and Gachter, 2000). Empirical tests of these theories are under way.

Games: Voluntary Contributions

Advanced article

R Mark Isaac, Florida State University, Tallahassee, Florida, USA

CONTENTS

Voluntary contributions are a common mechanism for individuals to provide public goods to an economy. Standard economic theories suggest problems with the use of voluntary contributions. However, both field data and data collected from controlled laboratory experiments suggest that this pessimism is only partially justified.

INTRODUCTION

A core proposition of neoclassical economic theory is that a competitive equilibrium of a market economy with individually maximizing, selfish agents achieves a desirable efficiency benchmark known as 'Pareto efficiency'. In other words, individually interested maximization is linked to social efficiency. (Briefly, an economy is Pareto-efficient if the only way to make one person better off is to make someone else worse off.) This proposition is often referred to as the 'first fundamental welfare theorem' in economics. However, the first welfare theorem does not hold in all cases. It may fail if there are spillover costs or benefits to economic agents not a part of the original transaction (pollution being the textbook example). And the link between equilibrium and optimality may fail if there are what economists call 'public goods' in the economy, particularly if the mechanism for producing the public goods is by voluntary contributions. In the voluntary contributions world, economic theory demonstrates that individually maximizing behavior is potentially decoupled from social efficiency. Furthermore, a long series of laboratory experiments in public goods decision-making has demonstrated the reality of the efficiency problems with the voluntary contributions mechanism for providing public goods. However, these same experiments have not only demonstrated but have also replicated behavior that some argue to be reflective of attempts by the subjects to substitute cooperative behavior for the inefficient individually maximizing social equilibrium.

MODELING THE PUBLIC GOODS PROBLEM

To set the stage more formally, we note that economists offer two boundary definitions of economic goods: purely public goods and purely private goods, with a wide variety of goods exhibiting intermediate characteristics. The purely private good is defined by the paired characteristics of ability to exclude nonpayers and nonrivalrous consumption. If X represents the total amount of a good available for consumption, and x_i represents the consumption of that good by a single person, then, at the extremes, a good in rivalrous consumption exhibits $X = \Sigma x_i$ while a good in nonrivalrous consumption exhibits $X = x_1 = x_2 = \ldots = x_N$. (Note that nonrivalrous consumption does not mean that each individual gives the same value to the good, but that each person can be represented as consuming the same amount.) Another way of looking at nonrivalry is to imagine a society that adds one new individual in a short run (no production) situation in which there is a fixed amount of the good. If that good has rivalrous consumption, the addition of a new person in society means that either that new person consumes nothing or a reallocation occurs, causing others to consume less. With nonrivalrous consumption, the new person consumes as much as everyone else, which is the same as everyone did before the newcomer's arrival. (Imagine adding one more person on a block to receive satellite TV; other current subscribers suffer no loss).

Obviously, not all goods are either perfectly public (perfectly exhibiting both characteristics) or perfectly private (exhibiting neither). Sometimes one of the characteristics can occur without the

other. For example, the Arizona-Sonora Desert Museum in Tucson (a private, nonprofit zoological institute) can exclude nonpayers but includes exhibits 'inside' that are, in some conditions, nonrivalrous. This is an example of a so-called club good (Buchanan, 1965). Similarly, a good may exhibit one or more of the characteristics of public goods under some circumstances but not under others. A university recreation center swimming pool may exhibit nonrivalry in consumption until the number of people wishing to swim exceeds the number of lanes. This is an example of a so-called crowding good.

The distinction between public and private goods is interesting to economists because of the issue of convergence of individual and group incentives. Competitive markets for private goods tend to coordinate individual incentives and aggregate efficiency. Public goods risk a disconnection between individual and group incentives. In general, several different mathematical representations describe some form of the following statement: in the presence of public goods, it is difficult or even impossible to find institutions and incentives such that each individual following his own interest will yield an outcome that is socially optimal (Samuelson, 1954; Walker, 1980).

One of the most common institutions for providing public goods is the voluntary contributions mechanism, in which N individuals each choose m_i amount of resources to contribute to a fund which will be used to purchase a given level Y of a public good. If the good is nonrivalrous in consumption, then a given level of Y will be consumed not just by one individual but by all N individuals. Increasing the provision of the public good by one unit will yield a vector of increases in well-being of the form $(v_1, v_2, v_3, \ldots, v_n)$. The problem, as modeled by economists, is that each individual bears the entire private cost of his marginal contribution, $c(m_i)$ but receives only his personal marginal benefit, v_i, ignoring the net benefits generated for others, v_{-i}. In addition, individuals who do not support the public good at an optimal level cannot be excluded for consumption. This inability of individual incentives to match social incentives, known as the 'free rider problem', results in a socially nonoptimal level of the provision of the public good. To embed this abstract problem in a more familiar framework, imagine a cul-de-sac of five houses being asked for contributions for mosquito spraying. Each individual homeowner, if making his decision as above, ignores the benefit to others. At the limit, any one homeowner can contribute nothing and yet not be excluded from the benefits of that spraying (which, due to the endemic free riding, cannot be funded).

Notice that this practical example is built on assumptions both about technology and about the legal system. A mosquito spraying device which allowed noncontributors' houses to be missed would dramatically change the public goods nature of the spraying, as would a legal system which provided contributors with a legal right to tax noncontributors (as might be found in many so-called homeowners' associations).

EARLY EXPERIMENTS IN PUBLIC GOODS

The public goods problem has been a part of classical microeconomics training for decades (see Samuelson, 1954 and 1955, citing and referring to Lindahl and Musgrave among others). However, it was in other social science disciplines with older traditions of experimentation that data on public goods environments were first collected. In this work, a pattern emerged of cooperation in providing the public good at levels greater than what might have been expected from standard economics models. Unfortunately, many of these experiments did not control for the incentive structures of most interest to economists, or had other design features that limited their acceptance by economists (this work includes Marwell and Ames, 1979; see Kim and Walker, 1984 and Isaac *et al*., 1985 for critiques and discussion).

In the late 1970s, economists began laboratory experimental tests of behavior in public goods situations. Smith (1980) worked on the design of a process that sought to achieve efficient outcomes in a public goods environment. Kim and Walker, and Isaac *et al*. (1985), each conducted new public goods experiments providing real economic incentives and altering design features to which economists had objected in earlier work by noneconomists. Both research groups created experimental environments in which there was a clear distinction between private incentives to underprovide the public goods (to free ride) and group optimal behavior. Both groups used a variant of the voluntary contributions mechanism, where the only resources available for the provision of the public good are those voluntarily transferred by the economic agents. The results were both surprising and not surprising. The results were not surprising in that conditions could be obtained in which the level of free riding was substantially closer to economic predictions than had been observed before. The results were surprising in that,

even when utilizing a design that addressed economists' concerns about previous work, unpredicted cooperation still occurred and, in some settings, was still economically significant.

Isaac *et al*. (1984) and Isaac and Walker (1988) began the first systematic investigation as to why there was this divergence in results. After almost 20 years, the twin pillars of the original results remain. The prediction that individuals by and large ignore individual incentives to free ride and instead adopt socially maximizing strategies is wrong. Just as we observe that communally provided day use bicycles seem to disappear, even in politically correct university towns, so, too, can we observe free riding behavior in the laboratory. How severe the free riding is, how far the outcome is from the social optimum, varies. This will be discussed in more detail below. Equally, a prediction that individuals by and large make free riding decisions based solely upon an individual maximization model is also wrong. Just as we observe significant charitable contributions of both money and time in our society, so, too, we observe levels of public goods provision in experiments that are significantly above the free-riding predictions of economists. The task for the last 20 years or so is still the task today: what conditions, environmental or institutional, lead people to behave more like individual maximizers, and which conditions lead people to behave more like social maximizers? In attempting this analysis, I must return a favor and acknowledge John Ledyard, whose early survey on public goods (1995) is still a standard reference.

Hence forth, I shall assume, unless otherwise stated, that we are considering a standard, linear, voluntary contributions public goods model of the following form: there are N individuals, each individual in possession of z_i units of wealth (tokens). The simultaneous decision facing each individual is how to 'invest' each token. A token may be invested in an individual exchange where it earns p_i (assume that $p_i = 1$ cent for all i) or it may be invested in a group exchange. Letting m_i represent individual i's investment in the group exchange, every individual, regardless of their personal m_i, earns the following from the group exchange: $1/NxGx\ m_i$ cents – this is the linear part of the model. (Changing the linear nature of the return from the public good will change some of the details of the discussion, but not the basic points.) For some examples, see Bagnoli and Mckee (1991), Harrison and Hirshleifer (1989), Isaac *et al*. (1989).

As long as $G/N < 1$, each individual has a dominant strategy to invest all tokens in the group exchange (to free ride), but if $G > 1$ the social optimum is to invest all the group tokens in the group exchange. Furthermore, if the allocation of tokens is sufficiently egalitarian, every individual is better off at the group optimum than at the free-riding equilibrium. In typical experiments, although not in every one, the task is repeated by the same group a known, finite number of times. (And, for those not familiar with the protocols of experimental economics, the earnings from the public good sessions are translated into salient economic rewards.)

DO INCENTIVES AND STRUCTURES MATTER?

A variable or treatment might matter in the sense that a change will alter the theoretical prediction; it might matter in the sense that we observe changes in actual individual behavior. These two may go together, but they need not. The role of individual versus group incentives is a factor that provides a perfect example of the difference in these two definitions. In our standard model, the dominant strategy prediction holds for any values of G, N, and p_i such that $G/N < p_i$. Isaac *et al*. (1984) defined $(G/N)/p_i$ (or G/N when $p_i = 1$ as I will continue to assume) to be the 'marginal per capita return' (MPCR hereafter). As long as the MPCR is less than 1 an individual's single period (noncooperative) dominant strategy is to free ride. Why? Because regardless of the behavior of others, at the margin reducing contributions by 1 token gains 1 cent in earnings in the individual exchange and costs G/N in the group exchange. (If G is not a constant then one looks at $G'(m)/N$). If MPCR > 1, an individual's dominant strategy is to contribute fully to the group good (at MPCR = 1, the individual is indifferent). Thus, there is no predicted difference when MPCR equals .3 as opposed to when it equals .75. A more complicated argument demonstrates that free riding is predicted as a Nash Equilibrium across multiple finite periods whenever the MPCR is less than 1.

The behavioral consequence of the change in MPCR is, however, much different. For groups of 4 and 10, increasing MPCR from .3 to .75 increases contributions to the group good. These effects have been replicated (Isaac *et al*., 1994). The observed MPCR effect in experimental public goods environments is one of the key behavioral anomalies with respect to standard microeconomic theory. It is not the only such anomaly.

There is a well-known conjecture in economics, notably associated with Olson (1965) and Buchanan (1968), that group size (the number of people in the

group) affects the ability of groups to provide public goods; specifically, large groups are thought to have a harder time providing public goods than smaller groups. What does our model say about that? In the basic model, N has an effect only when it lowers the marginal per capita return (G/N); there is no other effect of group size in the model. Isaac and Walker found that the behavioral effect of an increase in N acting to reduce MPCR is completely consistent with the standard conjecture. Reducing G/N by increasing N reduces contributions to the public good. However, when the independent effect of N is sought, there was a surprise in that data. There was no statistically significant independent effect of N (as consistent with the basic model), but the direction of the effect was, surprisingly, positive (that is, holding G/N constant; the qualitative effect of increasing N on contributions to the group good was positive). Isaac *et al*. (1994) were able to pursue these conjectures with more observations and with larger groups. Their data supported the following conclusions about group size. First, they found that, controlling for MPCR, large groups of 40 and 100 were more successful in providing public goods than small groups (4 or 10). In fact, these larger groups mean provision level was about 40 percent of optimum, typically not dipping below 30 percent even in the last period. Second, they found that for the larger groups the change from an MPCR of 0.30 to an MPCR of 0.75 made little difference, in stark contrast to smaller groups. However, even in a group of 40 the MPCR effect could be recaptured when the experimental design was altered to examine MPCR equal to 0.03

DOES LEARNING MATTER?

Perhaps the surprising level of individual decisions which involve 'overcontribution' to the public good (relative to the standard equilibrium theory) simply reflects individuals learning either the single-period (stage game) dominant strategy or the multiple-period Nash equilibrium version of free riding. In a classroom, teaching undergraduates the dominant strategy nature of the single-period decision is relatively straightforward. However, a common report of the same students (and of nonstudents confronted with the same task) is that in a multiple-period setting: 'I am trying to increase contributions by others in the future by my own positive contributions now.' In addition to the fact that this flies in the face of the Nash equilibrium built upon backward induction from the dominant strategy in the final period, it ignores other practical complications such as: 'Just because you raise your contribution in the period, how do you know that this will be reflected in an aggregate increase in contributions?' (It may not.) These arguments may not be transparent, especially to novices in the experimental task. However, this common self-description will be revisited in the discussion on reciprocity below.

From the very earliest experiments, there was evidence to support the idea that individuals were learning how to free ride, so to speak. Contributions to the public good generally decayed across time, and individuals returning for a second time seemed to free ride more than subjects making these decisions for the first time. There have been several attempts to disentangle how many of the equilibrium violations may be do to learning. Palfrey and Prisbrey (1997) pointed out that many of the early wave of public goods experiments used an experimental design in which the (dominant strategy and/or Nash) equilibria were at a boundary of the message space – namely, zero contribution to the public good. This meant that, potentially, what had been observed as theory violating contributions to the public good were merely the censored (one-sided) errors of convergence to the standard theory (errors in convergence had to be above the prediction by definition). They constructed a design in which MPCRs differed across individuals and across periods. They concluded that random error played a significant role in explaining positive contributions to public goods in standard experiments. Several other researchers addressed this same question by using an experimental design in which there was a suboptimal interior Nash equilibrium of contributions to the public good (see Andreoni (1993); Isaac and Walker (1998); Keser (1996); Sefton and Steinberg (1996), and others in the Laury and Holt (1998) review). Laury and Holt concluded that 'moving the equilibrium away from the boundary is not sufficient in itself to induce Nash behavior in public goods experiments.'

Finally, on a different front, Houser and Kurzban (2000) used computerized, nonreciprocal partners from which to measure a baseline in confusion in their experiments, finding that it explains about half of the observed 'cooperation'.

Pretty clearly there are at least two things going on here. First, there is some recoverable effect of censored errors in a learning process that may be mistaken for intentional contributions to the public good. Second, there remains a significant amount of that effect in standard experimental designs and in designs in which censoring is not an issue.

DO INDIVIDUAL PREFERENCES MATTER?

Perhaps the unpredicted tendency towards provision of public goods represents incorrect modeling of individuals' supposedly selfish preferences, a phenomenon whose general rubric is often called 'altruism'. Altruism would seem to be high on the list of topics of mutual interest for economists and cognitive scientists. However, this must be approached with some care. First, in the literature of the economics of public goods, altruism refers narrowly to a failure of the assumption that individuals are entirely self-interested. Mutually cooperative behavior based upon self-interested individuals' recognition of the benefits of such behavior is more commonly called 'reciprocity'.

An additional caveat with the concept of altruism is that it has different manifestations. 'Pure' altruism is usually characterized as the phenomenon in which John cares directly about Mary's well-being, variously defined as Mary's utility, income, wealth, or consumption of some commodity. 'Warm glow' altruism (Andreoni, 1995) refers to the idea that John gets utility (a 'warm glow') out of the act of contributing to Mary's well-being, or, perhaps, out of being seen by others to be a generous person, in this way also contributing to Mary's well-being. These are not observationally equivalent. Beyond these two lie numerous other concepts of preferences that, while clearly not selfish, may or may not be distinguishable from altruism; some examples are preferences for fairness, justice, or even duty.

There are other interesting paradoxes regarding altruism. For example, altruism may be significantly dependent upon the institutional context in which people find themselves. I certainly have not seen much evidence in market experiments, as buyers and sellers face off each other for a penny or two of trading profits, of interpersonal overlap in utility functions. Further, in markets with opportunities for collusive behavior by some participants, experimental economists typically observe at least some periods of successful collusion even though this collusion public good clearly makes some people in the room (those on the other side of the market) worse off. Where is the altruism? Likewise, altruistic behavior may be very dependent upon the social context. Would you be an income altruist if the other three people in your public goods experiment were Bill Gates, Rupert Murdoch, and Oprah Winfrey? What if the other three people were young residents of a shelter for battered teens?

There have been numerous attempts, using clever experimental designs, to disentangle how much of the replicable pattern of positive contributions to public goods is due to 'errors and learning' (as above) or to altruism, or to 'warm glow' effects, or to fairness or even to spite, and so forth. The reader is referred to the following representative papers: Anderson *et al*. (1998), Andreoni (1988), Carter *et al*. (1992), Goeree *et al*. (2000), Offerman *et al*. (1996), Palfrey and Prisbrey (1997), Saijo and Nakamura (1995), and with a particularly complete literature review, Croson (1998).

DOES THE WAY WE LOOK AT THE PROBLEM MATTER? OR WHAT IS THE ROLE OF RECIPROCITY?

I find each of the above families of explanations incomplete in order to explain why experimental subjects provide public goods at levels much higher than predicted by standard theories. (It would be worth noting at this point that while we cannot know for sure the equivalent parameters of these experiments in the field, it is clearly the case that the naturally occurring outcome is not zero contributions. Massive amounts of resources are contributed by individuals, using just the United States as an example, to goods that transparently have attributes of publicness and some inherent dangers for free riding.)

While error processes and altruism probably influence individual decisions about public goods provision, I believe that there is something else going on. I argue that this is that individuals are simply not looking at the public goods provision problem in entirely the same way that we economists model it. I use the word 'entirely' deliberately, because I conjecture that in the naturally occurring world, as in the laboratory, free riding does occur; outcomes are neither automatically nor uniformly socially optimal, but public goods are provided. Such a paradigm shift ought to be intriguing to cognitive scientists.

I believe that the vast majority of people who confront a public goods situation recognize, even if in some nontechnical sense, that everyone will be better off if the public good is provided. Furthermore, most believe that there is some individual benefit to be gained from everyone trying to make cooperation successful, even when direct communication is not possible. This concept has several different faces, but it goes by the generic name of 'reciprocity'.

There are a numerous different versions of reciprocity that have been considered. The following are presented in approximately chronological order. Auster (1983) based a theory of 'closed anarchy' upon the hypothesis that each individual in a public goods situation has some expectations about how his contributions will affect the decisions of others, and that this relationship is not the trivial null relationship. Rather, he posits that individuals typically have an expectation that they can lead others. Auster's formulation is very explicit that each person has an expectation belief $E = g(e)$, where e is one's own contribution decision and E is the total of others' contributions.

Sugden (1984) developed several versions of reciprocity. He refers to his 'principle of reciprocity' as Kantian, and it might be also be called 'do the right thing' reciprocity. Sugden states, in his introduction, that he is proposing a theory of the voluntary sector, 'based on the assumption that most people believe that free riding to be morally wrong.' His principle of reciprocity is that individuals should not free ride relative to the level of contributions others are making. Sugden does derive equilibria from this new principle, but for me the most important contribution is not the equilibrium mathematics but the idea that an external moral imperative changes the way we look at the problem. Presumably, if we are looking at the problem differently, it is possible that our calculation, learning, and judgment skills are being applied to the new problem. The cognitive question to which we may be responding may no longer be 'How do I noncooperatively make the most return' but 'How do I make sure that we are all made better off?', or 'How do I fulfill my moral obligations?'

A third concept of reciprocity is what Sugden calls his 'principle of unconditional commitment' and what others might call the 'golden rule': contribute to the public good as you would like others to do so. I believe the drift into the vocabulary of theology is both explicable and meaningful, but that is for another article.

A different definition is that of 'trust reciprocity' (Berg *et al*., 1994). Their concept of reciprocity is distinct, both in theory and in evidence, from what they call 'benevolence'. The key to their concept of reciprocity is trust. Individuals who seem to trust one another irrationally end up with higher payments than those who perfectly follow a backwards induction equilibrium. The shorthand application to public goods is that individuals ignore the backwards induction Nash equilibrium: I contribute today trusting that you will see my contribution and contribute tomorrow.

Isaac *et al*. (1994) propose a 'forward looking' model of individual decisions. Their model has three components. First, each individual believes that his decisions have some signaling content: that is, actions today will have an influence on the actions of others in the future. Second, each individual has a definition for success, say in achieving a cooperative outcome. Third, each individual has some expectations about his signals achieving that success. Isaac *et al*. relate this model to the outcomes of a series of public goods experiments which will be discussed below.

Finally, McCabe and Smith (1999), as elaborated specifically for public goods in Gunnthorsdottir *et al*. (2000), propose a 'goodwill accounting' framework. In their model, the standard public goods model is altered by multiplying the benefits side by a function $P_i(\alpha_{it})$, where the α_{it} is a measure at time t of individual i's expectations about contributions forthcoming from the rest of the group.

Although these models of reciprocity differ, what is striking is that they uniformly posit a decision problem that is neither approached nor solved in the economist's standard paradigm of backward induction equilibrium rationality, built upon assumed dominant strategy free riding in the final period. In fact, from my informal discussions with colleagues, students, and subjects who have participated in public goods experiments, I almost always find that their description of how they approach the problem is typically in terms similar to at least one of these reciprocity models. Very few people say that this is an exercise of backward induction from a dominant strategy. The problem for evaluating this self-reporting is that we do not know whether the way that people talk about a problem has a systematic relationship with the decisions they make. There is a great deal of more formal experimental research that ought to speak to this hypothesis. One of the first direct tests of whether reciprocity might be making a difference was Andreoni's (1988) innovative research in which he altered the traditional iteration scheme so that the groups of individuals rotated in composition. He called the new treatment 'strangers' and hypothesized that the strangers treatment would eliminate the role of reciprocity. Unfortunately, this design has proven problematic. First, Andreoni's own data gave the opposite of the hypothesized effect: strangers were more cooperative. While some experimenters have been able to reproduce Andreoni's results, others have recovered the expected result that strangers free ride more (Croson, 1996; Andreoni and Croson, 1998).

Croson (1998, 2000) also reports direct tests of reciprocity. A standard experimental design is altered so that subjects receive specific information on the pattern of individual contributions to the public goods, allowing subjects to calculate not only the mean (as in traditional designs) but also the minimum, medium, and the maximum contribution in any round. Statistical analysis finds significant positive correlations of current contributions with the contributions of others for 21 of 24 subjects, broadly consistent with reciprocity. The most powerful past effect turns out to be the median of the previous periods contributions. Cox *et al*. (2001) have developed a 'triadic' approach to disentangling behavior consistent with reciprocity from that better explained by altruism. Their paper looks primarily at other game-theoretic environments. Whether their conclusions, generally non-supportive of models based upon altruism, would transfer to something that looked more like the voluntary contributions system is open for further examination.

Next, consider some of the anomalous results discussed earlier:

- Holding other design variables constant, the level of MPCR matters over regions where it should not, according to the standard theory (Isaac *et al*., 1984; Isaac and Walker, 1988).
- The range over which MPCR makes a difference in contributions appears to vary according to group size. For example, changing MPCR from .3 to .75 makes a significant difference for $N = 4$ or 10. However, for $N = 40$, that treatment does not yield a significant difference. Changing MPCR from .03 to .75, however, reproduces the original result (Isaac *et al*., 1994).
- Holding MPCR constant, changing group size in some cases shows the unexpected result that larger groups free ride less than smaller groups (Isaac *et al*., 1994).

Isaac *et al*. (1994) argue that while traditional models cannot explain these phenomena, their 'forward looking' models can. Specifically, in their models, both MPCR and N influence the expected success of contributions, signaling in a manner consistent with the anomalous results just described.

Gunnthorsdottir *et al*. (2000) conducted a standard linear public goods series and then separated the subjects into smaller groups in a later round of experiments. The treatment was whether the later separation would be random or sorted, whether the individuals were grouped together based upon their initial contribution. In the sorted rule, high investors were grouped with high investors, and so forth. They found that the MPCR effect (as reported above) was larger and more significant for subjects classified as cooperators than for subjects with low initial contributions. Furthermore, at each level of MPCR studied, 'cooperators' contributions in the sorted condition become higher than contributions in the random conditions no later than the fourth round, and remain higher through round ten.'

Finally, there are a few other indirect indications. Contributions in public good processes typically decline across time (which, by itself, argues against altruism as a single-dimension explanation for these phenomena). However, contributions very rarely converge to full free riding, even in a known (dominant strategy) end period. The residual, end-period contribution would not be explained by those reciprocity models relying upon influence on future contributions (Auster's 'closed anarchy,' Isaac, Walker, and Williams's 'forward looking models', or McCabe and Smith's 'goodwill accounting'). Those reciprocity concepts that could explain the residual would be Berg *et al*.'s 'trust reciprocity' and Sugden's three concepts.

In summary, the term 'reciprocity' is broad and includes numerous different formulations about how one person will react to the actual or perceived past or future actions of others. This has led to numerous different theoretical formulations and a similar number of experiments which attempt to compare their theoretical usefulness. It would be outside the scope of this article to survey all the results. However, an excellent discussion of experiments that attempt to discern among candidate models of reciprocity is provided by Croson (1998). Despite the differences in the model, a key similarity is that they posit that individuals look at the public goods world differently than the standard non-cooperative equilibrium formulation. By altering the assumption of how individuals look at the world, reciprocity models can provide predictions that, like actual observations of human decision-making, differ from than the usual pessimistic predictions.

SUMMARY AND CONCLUSIONS

After more than 20 years of experimental research regarding the voluntary provision of public goods there is overwhelming support that three overarching conclusions can be drawn:

1. Free riding is not a figment of economists' imagination. It can be observed in the laboratory under controlled conditions.

2. The extent of free riding is much less than is predicted by standard economic models.
3. Where a particular group falls in the continuum between complete free riding and the full social optimum may have some random components but it is not completely random. We can observe replicable effects of the economic environment, economic institutions, and the role of information.

After these general statements and the general replicable effects began to be identified, attention shifted somewhat to the 'why' questions. The three most popular answers each have some implication for the brain, mind, or cognition. Some individuals whose outlook is purely selfish, non-cooperative, and self-maximizing may nevertheless take some time to learn the dominant strategy, or to find the Nash equilibrium. Follow-on questions would include: how do people learn? What cues can accelerate or retard their learning? Other individuals may exhibit preferences (or preferencelike attributes) that are altruistic. Economists typically end their questioning at this level; however, there are other disciplines whose research will continue to ask: 'Why are a person's preferences the way they are?'

The most productive avenue for interchange between economists interested in public goods provision and cognitive scientists may lie in a third category, typically called 'reciprocity'. Reciprocity models, to varying degrees, suggest that potential contributors are looking at the problem in a different way. This statement is intended to transcend the laboratory results and extend to the field. Significant numbers of people do free ride in many naturally occurring circumstances: roadway litter and the failure of 'honors system' payment schemes are two examples, but group efforts to clean up a local park might bring out a significant number of residents. Why does this happen? And why in some circumstances, and not others? Why with some people and not others? Twenty years of laboratory experiments have shown that economic variables suggest as individual return and group size matter but in unexpected ways.

It should not be assumed that cognitive research questions are mutually exclusive among these categories of models explaining public goods provision. For example, consider the 'learning' explanation. Across time, individuals in economics experiments may learn the most starkly functional components of the decision process: how to transmit decisions, how the mathematical relationships (described initially in experimental instructions) actually work, what an 'end period' actually means. On the other hand, the learning may be about key components of one or more of the reciprocity models, especially those that include a parametric representation of each person's expectations about the others. In this world, individuals learn about the state of reciprocity in their community. And, of course, there is the fact that most naturally occurring public goods problems occur on a continuum between a purely one-shot decision and perfect iteration and replication. Furthermore, a group facing a public goods provision problem may be composed of individuals best described by different referenced models. An altruist may interact with a reciprocator. This becomes very interesting very quickly, as cognition applied to the problem of public goods requires a process not simply about the world but about interaction with other potentially dissimilar and complex cognitive beings in the context of specific institutional and social rules.
