If words are the focus of research on lexical development, we need to know what a word is. Languages vary in how they package lexical information: in languages such as Navajo, American Sign Language and Spanish, a 'word' may represent all of a sentence's major elements (e.g. subject, verb and object, as in Spanish *commelo*, 'you eat it'). Such examples reflect a language's syntax and morphology, e.g. whether the language permits null subjects or objects and, if so, whether the verb marks such arguments. Let us consider English. Literate English users might define a word as a meaningful group of letters with space on either side. But that definition is of no use to the preliterate, word-learning machine inside your typical 2-year-old human. It runs into trouble elsewhere as well. Consider 'greenhouse' and 'green house'; 'the' and 'of'; the ambiguous word 'bank'; or the idiom 'pushing up daisies' (meaning 'dead'). Consider 'hood', as in 'neighborhood': in some dialects of English, 'hood' meaning 'area of residence' can stand alone without 'neighbor'. Is it then a word? Perhaps we will agree that it is a word only when it appears in our favorite dictionary. In a decade then, 'hood' may be a word. In the meantime, are such elements targets of lexical development? In other words, do children learn them? Yes! Indeed, children's ability to learn words of dubious official status may even contribute to language change. These and related puzzlers are why this article is called 'lexical development' rather than 'word development'. The latter would focus on an object of doubtful definition and force out too much of great interest (especially if cognitive science aims to understand cognition across languages and cultures). (*See* **Idioms, Comprehension of**; **Syntax**; **Morphology**)

The term 'word' is just shorthand then – often useful, but not very precise. Distinctions from linguistic theory provide greater precision. The distinction between lexical and functional categories is emphasized because these categories are probably learned in different ways (Pinker, 1991). The lexical categories include elements such as nouns (e.g. 'house'), verbs (e.g. 'slap'), and adjectives (e.g. 'green'). The functional categories include elements such as complementizers (e.g. 'that'), determiners (e.g. 'the') and inflections (e.g. '-ing'). In English, lexical categories are usually free morphemes (words, if you will), and their semantic content is relatively clear. Functional categories are either free or bound, and their grammatical function is relatively clear while their semantic content is less obvious. If you think children can only learn meaningful elements, then you must think they start with words; but if you think children can pick up any linguistic pattern, then you must allow that they start with whatever occurs often enough to be a pattern. Questions about what comes first do interest researchers, so we will return to this issue below.

To a large extent, the fundamentally syntactic distinction between lexical and functional categories rests on the notions of selection and phrase structure. That is, one way to define a verbal inflection or a noun is by its associations with other elements. This approach contrasts with the kind of referent-based definition many of us learned in school, e.g. 'a noun is a person, place, or thing'. Some such associations are very strong. For example, all verbs can host '-ing'. The relatively new nouns 'email' and 'fax' easily became 'emailing' and 'faxing' as soon as English speakers began to use them as verbs. This example shows an association of two categories, one lexical and the other functional. As we shall see below, linguistic elements select for or prefer association with a variety of kinds of syntactic or semantic information. For now, consider the significance of such associations for learners. For one thing, if cross-category relations characterize the target system, learners must do much more than link the form of each word with its meaning. They must also acquire each element's selectional restrictions. If an element is at least partly defined by such associations, then learning the element includes learning its associations. (*See* **Phrase Structure and X-bar Theory**)

Interestingly, most research on lexical development has emphasized children's acquisition of the lexical categories and links to semantic and conceptual development. See Bloom (2000) for a review of this emphasis. There is less research on children's acquisition of the functional categories. What there is links to syntactic and morphological development. A number of interesting questions that cannot be addressed here should nevertheless be noted. For example, one might ask whether all children map the same initial set of concepts onto words or whether all languages draw from the same full set of category options. For the purpose

of this article, it is important just to appreciate that the target lexicon contains subclasses of elements (i.e. several different types of information). It should be clear that the business of lexical development is challenging. We proceed now to theoretical explanations of that challenge. (*See* **Semantics, Acquisition of**; **Concept Learning**)

TARGET LEXICON

At a general level of description, a lexicon is a person's mental dictionary. It lists the meaningful and/or grammatical elements known by that individual: some of these elements are well-behaved words like 'green' and 'the', some are word parts like '-ing' or perhaps '-hood', and some are collections of both, such as 'pushing up daisies'. If lexical and functional elements are represented separately and processed differently, then it is reasonable to presume that such elements are also learned differently. To put it another way, these classes of linguistic elements may be influenced by distinct learning mechanisms. (*See* Pinker, 1991 for a comparison of associationist learning to rule-and-representation learning.) A particularly striking finding from this research area is the speed of word learning. Many researchers have concluded that young children go through a period of unusual lexical development when they average a new word every waking hour (sometimes called the vocabulary spurt or the naming explosion). However, the existence of such a stage has been challenged, for example by Bloom (2000). For one thing, unlike some other areas of linguistic development, word learning is lifelong. Let us thus focus on the feat itself rather than the question of whether children differ from adults in this domain. Lexical acquisition is undoubtedly fast. How does it work? (*See* **Lexical Acquisition**; **Lexicon**; **Word Learning**)

Lexical Categories and Meaning

The question of how children learn the meanings of words has been in the scientific spotlight for a long time. The seventeenth-century philosopher John Locke, for example, described children's language learning as a consequence of adults pointing out and naming things like 'white' and 'dog'. As Gleitman (1990) emphasized, this view of language acquisition persists both in common sense and in scientific theory. Regarding the latter, she characterized the theory of semantic bootstrapping as reflecting a modern version of Locke's view (e.g. Grimshaw, 1981; Pinker, 1984). While semantic bootstrapping is primarily a theory about children's acquisition of syntax, not about their lexical development, it begins with word learning. During semantic bootstrapping, words link to syntactic categories through their meanings, which are hypothesized to be observed in the world and associated with lexical categories. This hypothesis narrows the learner's initial focus to meaningful elements, perhaps even to concrete and imageable objects. In some sense then, semantic bootstrapping assumes that words are first (i.e. lexicon precedes syntax). Syntactic bootstrapping, on the other hand, is a theory about children's acquisition of word meaning. It does not address children's very first linguistic steps. Because its central hypothesis is that word learning is informed by observation of a word's syntactic context (i.e. the range of its associations with other linguistic elements), it applies only after some acquisition of syntax has already occurred. So semantic and syntactic bootstrapping explain different aspects of language acquisition. Interestingly, they both focus on lexical categories. While Locke's and Pinker's paradigm examples involve nouns – perhaps more properly noun phrases; see Bloom (1994) – where the link to observable referents is plausible, Gleitman's paradigm examples are verbs. It is less obvious that word-to-world mappings will work for verbs (or any other category that is complexly related to the observable world). We return to this point in the section on argument structure below. (*See* **Syntax, Acquisition of**)

Developmentalists' focus on words, especially nouns, has shaped many theoretical questions. For example, the semantics suggested to mediate the learner's progress towards the target lexicon has emphasized features of objects (e.g. animate versus inanimate, countable versus substance). This emphasis is most obvious in hypotheses aimed at explaining the speed of early word learning.

Constraints on Word Learning

There are many proposals for principles or biases that restrict the learner's initial hypotheses about words. Note that these are not general restrictions. Rather, they are specific to word learning. They include – among others – the whole object constraint (Markman, 1989), the shape bias (Landau *et al.*, 1988), and the principle of contrast (Clark, 1993). To clarify the motivation for such constraints, let us examine Clark's principle of contrast. The idea here is that children will learn more if they assume that difference in form entails difference in meaning. One source of evidence for

children's use of this principle comes from how they retreat from overextension errors. In an overextension of the word 'dog', the speaker uses it to refer to dogs as well as to animals that share features with dogs (e.g. other four-legged, fuzzy animals like cats and sheep). When children who overextend 'dog' observe the word 'cat' referring to what they previously called 'dog', they stop referring to cats as 'dogs'. The principle of contrast forces the learner to adjust the meaning of 'dog' when a word with a different form overlaps in reference. This brief mention of how developmental errors can motivate constraints on word learning relates to an earlier point. It is likely that some such errors reflect performance failures rather than being direct reflections of lexical competence.

Argument Structure

We turn now to a topic that might at first seem minimally related to word learning. Recall the hypothesis that lexical elements encode information about other elements. These associations might affect linear relations (as in the strict word-order rules found in English) or morphological relations (as in the rich inflections found in Spanish). That information is part of what learners must master – in addition to more obvious information about a word, such as its form (which could be instantiated as sounds in a spoken language or signs in a signed language). To further appreciate the complexity of lexical development, let us turn to more detailed consideration of selectional restrictions. I will exemplify the notion with some verbs. Recall that these restrictions or associations can involve different kinds of linguistic information. To exemplify syntactic restrictions, compare intransitive verbs (e.g. 'sleep'), transitive verbs (e.g. 'devour') and ditransitive verbs (e.g. 'give'). The examples 1 to 3 show these three subcategories (an asterisk precedes example sentences that are considered to be ungrammatical or ill-formed). A subcategory can be defined in terms of the types and functions of the phrases that are associated with it. These phrases are a verb's arguments, so the argument structure of a verb helps define it. In 3a, for example, we see that a ditransitive verb can have two noun phrase arguments. Words can also encode semantic restrictions. For example, the verb 'drink' prefers its direct object to be liquid, while 'break' prefers it to be rigid. Such preferences help define these words. Poetic use of words, however, can involve fiddling with such restrictions, as in 'drinking a fragrance' or 'breaking a silence'.

1. sleep
   a. Carol is sleeping.
   b. *Carol is sleeping the bed.
2. devour
   a. Carol devoured the casserole.
   b. *Carol devoured.
3. give
   a. Carol will give me a book.
   b. *Carol will give me.

This brief illustration of selectional restrictions re-emphasizes the complexity of lexical development. It also illustrates that syntax and semantics are related. An opportunistic learner should use such relations, which idea drives both bootstrapping hypotheses. Philosophers and linguists think that the meaning of 'sleep' is to some extent reflected by its lexical type and its argument structure. Syntactic bootstrapping exploits this idea by maintaining that the range of argument structures that a verb participates in narrows the hypothesis space that learners consider for its meaning. Read example 4 and guess at the meaning of 'VERB'.

4. Zonk VERBs that the blick is floopy.

Many readers will guess a translation like 'think' (i.e. some mental verb). Perhaps this guess reflects what we know about an argument structure that is typical of such verbs. Interestingly, getting the syntax of the sentence in 4 requires mastery of functional elements like '-s' and 'the'. Let us consider such elements in more detail.

Functional Categories and Grammar

The functional categories are better described by their roles than their referents: that is, a determiner such as 'the' functions to mark and modify noun phrases (e.g. 'the white dog') and an inflection such as '-ing' functions to mark and modify verbs (e.g. 'sleeping'). It is also important to note that the functional categories of any particular language encode its grammar: that is, sentence-level phenomena such as ordering of phrases and agreement between phrases is affected by the language's choice of functional elements. Many researchers maintain that children's development of functional category knowledge lags behind their knowledge of lexical categories. This claim is based, to a large extent, on children's errors or the differences between their behavior and that of adults (who we assume to be finished products of development). Children's development of functional categories illustrates two types of errors: omission of obligatory elements, such as 'is' and '-ing' in 5a, and overt but misused inflectional morphology, such as '-ed' and '-s' in 5b.

5. a. Dog sleep now (to refer to a dog that is sleeping)
   b. breaked, sheeps

The study of lexical development has to some extent ignored functional categories, and this may be because developmental psycholinguists tend to emphasize production data and children's early errors. A wonderful exception to this trend is Gerken *et al*. (1989), whose research is especially instructive with respect to our interpretation of children's errors of omission. In this study, young children responded to commands such as 'Find the bird for me' by pointing to pictures. Phrases like 'the bird' were compared with 'was bird', 'gub bird', and '—bird' (the wrong functional element, an invented functional element and an omitted functional element, respectively). Interestingly, children whose own utterances lacked the target element 'the' were most accurate when responding to commands containing it. The other error type illustrated in 5 also invites interesting conclusions. The child who starts with 'breaked' appears to be applying the regular '-ed' rule to a lexical element requiring a different inflection, and will eventually replace that word with 'broke'. As an aside, it is interesting to speculate about what happens if such replacements do not occur. Could persistent developmental errors drive language change? Might, for example, the shifts in American English from 'learnt' and 'dove' to 'learned' and 'dived' be explained in developmental terms? Returning to the question of what overregularization errors tell us about linguistic development, many have taken children's production of such errors as evidence that they do not know the irregular or exception morphology while they do know the regular morphology. Perhaps regular patterns are learned before irregular patterns.

Thus, study of the development of both lexical and functional elements reveals a busy and sophisticated learner. The learner may produce errors on the way to the target lexicon (e.g. meaning-based overextension of words, omission or overuse of grammatical elements), but when we probe past the obvious, even the errors point to early mastery of extraordinarily complex information and information processing. Returning to the question raised at the beginning of this section, there are many reasons to think that children's knowledge of functional elements develops alongside and in synchrony with their knowledge of lexical elements. For one thing, children's language comprehension precedes their language production. This fact lacks explanation if we attribute to children grammar that is as primitive as their utterances suggest. In addition, crosslinguistic comparisons reveal that children of the same age who are learning different languages produce varying indications of mastery of functional elements (McKee, 1994). English is a relatively isolating language. The omission of a functional element in English often leaves well-formed words. That is not true in all languages (e.g. compare *eats/eat* in English with *mangia/*mang* in Italian). Study of what English learners omit may reveal more about English than it does about lexical development, and children's initial grammatical competence may be richer than their utterances suggest.

OTHER ASPECTS OF COGNITIVE DEVELOPMENT

Finally, children's lexical development raises many philosophical questions. One of these is the extent to which language depends on or even just interacts with extralinguistic cognition. For example, how might the learning of a linguistic label (e.g. 'yak' or plural '-s') affect one's mental representations and processing? In a different direction, consideration of children's developing theory of mind also bears on their learning of linguistic labels. We must also ask where linguistic categories come from, a question that should be aimed both at children and at the evolution of language in our species. If linguistic categories are not selected from an innate list, how do learners discover them? How does the frequency of an element affect its learning? What about the frequency of crosslinguistic associations between the meanings of individual elements and classes of argument structure? How does language in the individual learner differ from the external target language? Can lexical development bring on language change over decades and centuries? Relations between language and other aspects of cognition also bring to mind questions about how language itself is affected by lexical development. Study of this exciting topic thus bears on many domains of cognitive science.

Lexical Semantics

Introductory article

Chris Barker, University of California, San Diego, California, USA

CONTENTS

Word meaning mediates between conceptualization and language: simply put, words name concepts. Studying which concepts can have names – and how the fine-grained structure of those concepts interacts with the linguistic structures that contain them – reveals something important about the nature of language and cognition.

WHAT CAN WORDS MEAN?

To a first approximation, lexemes are words, so lexical semantics is the study of word meaning. The main reason why word-level semantics is especially interesting from a cognitive point of view is that words are names for individual concepts. Thus lexical semantics is the study of those concepts that have names. The question 'What can words mean?', then, amounts to the question 'What concepts can have names?'

There are many more or less familiar concepts that can be expressed by language but for which there is no corresponding word. There is no single word in English that specifically names the smell of a peach, or the region of soft skin on the underside of the forearm, though presumably there could be. Furthermore, it is common for one language to choose to lexicalize a slightly different set of concepts from another. American speakers do not have a noun that is exactly equivalent to the British *toff*, an 'upper-class person', nor does every language have a verb equivalent to the American *bean*, 'to hit on the head with a baseball'.

The situation is quite different for other concepts, however. To adapt a famous example from philosophy, there is no word in any language that refers specifically to objects that were green before 1 January 2000 but blue afterwards. Of course, we can artificially agree to assign this concept to a made-up word; in fact, let's call it *grue*. But doing so doesn't make *grue* a legitimate word, let alone a genuine one. Could there be such a word? That is, is naming the grue concept truly unnatural, or merely unlikely? (*See* **Meaning**)

Identifying systematic patterns governing the meanings of related words can provide convincing answers to such questions. Furthermore, the insights go in two directions simultaneously: on the one hand, natural classes of words that resemble each other syntactically (for instance, the class of nouns) have similar kinds of meaning. This places bounds on the set of possible word meanings. On the other hand, natural classes of words that resemble each other semantically (for instance, the class of words whose meanings involve the notion of causation) behave similarly from a syntactic point of view. Thus studying how the fine-grained conceptual structure of a word's meaning interacts with the syntactic structures that contain it provides a unique and revealing window into the nature of language, conceptualization, and cognition.

POLYSEMY

Lexemes are linguistic items whose meaning cannot be fully predicted based on the meaning of their parts. Idiomatic expressions by definition, then, are lexemes: the expression *kicked the bucket* (as in the idiomatic interpretation of 'My goldfish kicked the bucket last night') means essentially the same thing as the word *died*. (Although it is convenient to draw examples from English in this article, it gives an unfortunate English-centric perspective to the discussion. Those readers familiar with agglutinative languages such as Turkish or West Greenlandic should consider whether 'morpheme' might be a more accurate term than 'word' in the general case.) Other articles in this encyclopedia discuss cases in which lexemes do not correspond exactly to words, but this article will adopt the simplifying assumption that lexemes are words. (*See* **Construction Grammar**; **Lexicon**)

But how many distinct words are there? We can feel comfortable deciding that homonyms (words that sound the same but have completely different meanings) should be counted as different lexical items: *bat* the flying mammal versus *bat* the wooden stick used in baseball certainly ought to be considered as two different words. It is more difficult to be confident of such judgments, however, when the two meanings seem to be closely related. Is *wave* in reference to a beach a different concept than *wave* in 'He experienced a wave of anger'? What about verbal uses such as 'The infant waved' or 'The policeman waved us through'? Words that have multiple related but distinct meanings are 'polysemous'. Identifying and dealing with polysemy is a hotly debated and difficult problem in lexical semantics.

Some polysemy seems to be at least partly systematic. Pustejovsky proposes that language users rely on *qualia*, which are privileged aspects in the way they conceptualize objects. The four main qualia are the object's constituent parts, its form (including shape), its intended function, and its origin. Thus a fast car is fast with respect to performing its intended function of transporting people, but fast food is fast with respect to its origin. We can recognize the polysemy of *fast* as indeterminacy in selection of the most relevant qualia, without needing to postulate two lexical entries for *fast*, let alone two distinct kinds of fastness.

In addition, qualia provide a way to understand how to coerce a conventional meaning into a variety of extended meanings. In 'The ham sandwich at table 7 is getting restless' (spoken by one waiter addressing another in a restaurant), *the ham sandwich* refers not to the material parts of the sandwich, but to the person involved in specifying the sandwich's intended function (i.e. to be eaten by someone).

LEXICAL RELATIONS (MEANING IN RELATION TO OTHER WORDS)

There are two main modes for exploring word meaning: in relation to other words (this section), and in relation to the world (see below). The traditional method used in dictionaries is to define a word in terms of other words. Ultimately, this strategy is circular, since we must then define the words we use in the definition, and in their definitions, until finally we must either run out of words or reuse one of the words we are trying to define.

One strategy is to try to find a small set of *semantic primes* or basic constituent elements: Wierzbicka identifies on the order of 50 or so concepts (such as *good*, *bad*, *before*, *after*, *I*, *you*, *part*, *kind* …) that allegedly suffice to express the meaning of all words (in any language). Whether this research program succeeds or not has important implications for the nature of linguistic conceptualization.

In any case, speakers clearly have intuitions about meaning relations among words. The most familiar relations are synonymy and antinomy. Two words are synonyms if they mean the same thing, for example *filbert* and *hazelnut*, *board* and *plank*, etc. Two words are antonyms if they mean opposite things: *black* and *white*, *rise* and *fall*, *ascent* and *descent*, etc. One reason to think that it is necessary to recognize antinomy as an indispensable component of grammatical descriptions is because at most one member of each antonymous pair is allowed to occur with measure phrases: *tall* is the opposite of *short*, and we can say 'Bill is 6 feet tall', but not '*Tom is 5 feet short'. (Asterisks denote a deviant construction.)

Other major semantic lexical relations include hyponymy (names for subclasses: *terrier* is a hyponym of *dog*, since a terrier is a type of dog), and meronymy (names for parts: *finger* is a meronym of *hand*).

Words whose meanings are sufficiently similar in some respect are often said to constitute a 'semantic field', though this term is rarely if ever given a precise definition. Terms such as *red, blue, green*, etc., are members of a semantic field having to do with color.

Miller and associates have developed a lexical database called WordNet, a kind of multidimensional thesaurus, in which these types of lexical relations are explicitly encoded. Thus WordNet is an attempt to model the way in which a speaker conceptualizes one kind of word meaning.

DENOTATION (MEANING IN RELATION TO THE WORLD)

Defining words in terms of other words or concepts will take us only so far. Language talks about the world, and ultimately, in order to know what a word such as *horse* or *despair* means, it is necessary to know something about the world. One way of getting at the connection between meaning and the world is to consider 'truth conditions': what must the world be like in order for a given sentence to be true? In general, words participate in most of the kinds of truth-conditional meaning that sentences do, plus one or two more of their own.

'Entailment' is the most concrete aspect of meaning: one sentence entails another just when the

truth of the first sentence is sufficient to guarantee the truth of the second. For instance, the sentence 'I have four children' entails the sentence 'I have at least two children'. We can extend this notion to words by assuming that one word entails another in cases where substituting one word for the other in a sentence produces an entailment relation. Thus *assassinate* entails *kill*, since 'Jones assassinated the President' entails 'Jones killed the President'. Similarly, *whisper* entails *spoke*, *devour* entails *ate*, and so on.

'Presuppositions' are what must already be assumed to be true in order for a use of a sentence to be appropriate in the first place. For instance, *and* and *but* mean almost the same thing, and differ only in the presence of a presupposition associated with *but*. If I assert that 'Tom is rich and kind', it means exactly the same thing as 'Tom is rich but kind' as far as what Tom is like; the only difference is that the use of the sentence containing *but* presupposes that it is unlikely for someone who is rich also to be kind.

'Selectional restrictions' are a kind of presupposition associated exclusively with words. The verb *sleep* presupposes that its subject is capable of sleeping; that is, it selects a restricted range of possible subjects. One reason why the sentence '*Green ideas sleep furiously' is deviant, then, is because ideas are not capable of sleeping, in violation of the selectional restriction of *sleep*.

'Implicature' is weaker than entailment. If you ask me how a student is doing in a course, and I reply 'She's doing fine', I imply that she is not doing great (otherwise, I would presumably have said so). Yet the sentence 'She's doing fine' does not entail the sentence 'She's not doing great', since it can be true that a student is doing fine work even if she is actually doing spectacular work. The implicature arises in this case through contrast with other words that could have been used. Interestingly, such lexical implicatures favor the formation of lexical gaps: because *fine* implicates *not good*, there is no word that means exactly *not good* (for instance, *mediocre* entails both *not good* and *not bad*). Similarly, because *some* implicates *not all*, there is no single word (perhaps not in any language) that means exactly *not all*.

'Connotation' is the part of the meaning of a word that adds a rhetorical spin to what is said. More specifically, connotation signals the attitude of the speaker towards the object or event described. If I describe someone as *garrulous* rather than *talkative*, the described behavior may be exactly the same, but *garrulous* conveys in addition the information that I disapprove of or dislike the behavior in question.

'Vagueness' is perhaps the quintessential problem for scientific theories of word meaning. Imagine a person with a full head of hair; clearly, this person is not bald. Now imagine pulling out one hair at a time. Eventually, if this process is continued long enough, the person will qualify as bald. But at what point precisely does the switch from not-bald to bald occur? It's impossible to say for sure. But if we can't answer this simple question, then how can we possibly claim to truly understand the meaning of the word *bald*? A little reflection will reveal that virtually every word that refers to objects or events in the real world contains vagueness: exactly how tuneless must a vocal performance get before the claim 'She is singing' is no longer true? Is that short sofa really a chair? The pervasiveness and intractability of vagueness gives rise to profound philosophical issues. (*See* **Vagueness**)

KINDS OF WORDS, KINDS OF MEANING

One of the most important principles in lexical semantics (part of the heritage of Richard Montague) is that words in the same syntactic class (e.g. noun, verb, adjective, adverb, determiner, preposition, etc.) have similar meanings. That is, the meaning of a determiner like *every* differs from the meaning of a verb like *buy* in a way that is qualitatively different from the difference in meaning between two verbs like *buy* and *sell*.

The overarching division in word classes distinguishes function words from content words. Function words (determiners, prepositions, conjunctions, etc.) are shorter, higher-frequency words that serve as syntactic glue to combine words into sentences. Content words (nouns, verbs, adjectives, adverbs) carry most of the descriptive payload of a sentence. In the sentence 'He asked me to give her a haircut', the content words are *asked*, *give*, and *haircut*.

Semantically, function words are much closer to being able to be expressed as a mathematical or logical function. We can write a rule that gives a good approximation of the contribution of *and* to truth conditions in the following way: 'A sentence of the form [S1 and S2] will be true just in the case where S1 is true and S2 is also true.' Thus the sentence 'It was raining and it was dark' will be true just in the case where the sentence 'It was raining' is true and the sentence 'It was dark' is also true.

Among function words, the meaning of determiners such as *every*, *no*, *most*, *few*, *some*, etc. (but crucially excluding noun phrase modifiers such as *only*) have been studied in exquisite detail, especially from the point of view of their logical properties. One of the most celebrated results is the principle of 'conservativity': given any determiner D, noun N, and verb phrase VP, sentences of the form [D N VP] are guaranteed to be semantically equivalent to sentences of the form [D N be N *and* VP]. For instance, if the sentence 'Most cars are red' is true, then the sentence 'Most cars are cars and are red' is also true, and vice versa; similarly, 'Some cars are red' is equivalent to 'Some cars are cars and are red', and so on. It is conjectured that every determiner in every language obeys conservativity. These equivalences may seem so obvious that it is hard to appreciate just how significant this generalization is; it may help, therefore, to imagine a new determiner *antievery* as having a meaning such that a sentence 'Antievery car is red' means the same thing as 'Everything that is not a car is red'. The claim is that there could be no such determiner in any natural language; that is, *antievery* (or any determiner that violated conservativity) is an impossible thing for a word to mean.

There is a class of lexemes whose behavior is especially fascinating from a cognitive point of view. In English this class includes expressions such *ever*, *anymore, budge an inch*, and many others. These items can only be used in sentences that exhibit certain properties related to the presence of negation. For instance, it is possible to say 'She doesn't ever go to the movies anymore', but it is impossible to say '*She ever goes to the movies anymore'. It is the presence of the negation in the first sentence that licenses the words in question, and it is because of this affinity for negation that they are called 'negative polarity items'. Not only are NPIs interesting in their own right, they provide clues about the internal structure of the meaning of other words. Consider the following contrast: 'I doubt that she ever goes to the movies anymore' is fine, but '*I think that she ever goes to the movies anymore' is deviant. Because negative polarity items are licensed by *doubt* but not by *think*, we can conclude that the meaning of *doubt* contains negation hidden within it, so that *doubt* means roughly *think that not* (i.e. *think that it is not the case that*).

EVENTS

The main linguistically important divisions among event types are as shown in Figure 1. Stage-level

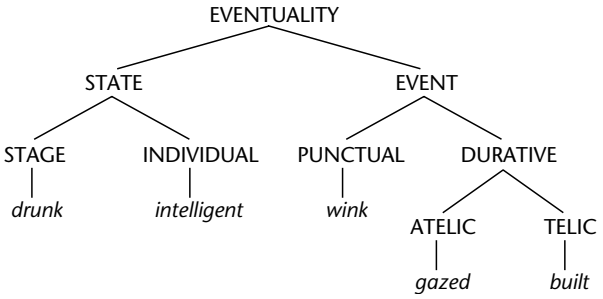

Figure 1.

adjectives such as *drunk* correspond to temporary stages of an individual rather than properties that are (conceived of as being) permanent properties of individuals, such as *intelligent*. Telic activities differ from atelic ones in having a natural end point. Crucially, these semantic distinctions correspond to systematic differences in syntactic behavior. For instance, assume that the temporal use of the preposition *for* requires the absence of an end point, but *in* requires a definite end point. If *gaze* is naturally atelic but *built* is telic, this explains why it is possible to say 'He gazed out to sea for an hour' but not '*He gazed out to sea in an hour'; and conversely, why it is impossible to say '*He built the raft for an hour' at the same time that 'He built the raft in an hour' is perfectly fine.

Although many lexical predicates are naturally atelic or telic, the telicity of the sentence in which they occur can be determined by other elements in the sentence. For instance, some verbs (*drink*, *write*, *draw, erase, pour*, etc.) have meanings that establish a systematic correspondence between the physical subparts of one of their arguments and the described event. Consider the verb *mow*: the subparts of an event of mowing the lawn correspond to the subparts of the lawn. If the event of mowing the lawn is half over, then roughly half the lawn will have been mown. This contrasts with a verb like *interview*: if an interview with the President is half over, that does not mean that half of the President has been interviewed. Because of the systematic correspondence between the internal structure of the noun phrase (NP) denotation and the internal structure of the described event, semantic properties of this special type of verbal argument-NP (which is called an 'incremental theme') can project to determine semantic properties of the described event. In particular, the telicity of sentences containing incremental theme verbs depends on whether the incremental-theme argument is conceived of as quantized (*a beer* is quantized,

compared with just *beer*): 'John drank a beer in/*for an hour' versus 'John drank beer for/*in an hour'.

THEMATIC ROLES

Decomposition

Sentences have internal structure in which the basic unit is the word. For instance, the sentence 'The girl hit the boy' has for its coarse-grained structure [[the girl] [hit [the boy]]]. Words have internal structure as well, in which the basic unit is the morpheme. For instance, *undeniable* = [un [deni [able]]]. Just as the meaning of a sentence must be expressed as a combination of the meaning of its parts and their syntactic configuration, we expect the meaning of a word (in the normal case) to be a combination of the meanings of its parts, and indeed *undeniable* means roughly *not able to be denied*. The internal structure of words can be quite complex, as in agglutinative languages like Turkish, in which there is no principled limit to the number of morphemes in a word. (*See* **Morphology**; **Syntax**)

Yet in general, word structure is qualitatively less complex than syntactic structure in a variety of measurable ways. If the structure of word meaning mirrors the way in which words are built up from morphemes, then we might also expect that word meaning will be simpler than sentence meaning in some respects. However, as discussed in the next section, many scholars believe that the meaning of words has internal structure that does not correspond to any detectable morphological structure.

Argument Structure and Conceptual Structure

One of the main ways in which words in the same main syntactic class differ in their syntax and in their meaning is in terms of 'argument structure'. *Fall*, *hit*, and *give* are all verbs, but differ in the number and arrangement of noun-phrase arguments they occur with: intransitive verbs have one argument ('John fell'); transitive verbs have two arguments ('John hit the ball'), and ditransitive verbs have three arguments ('John gave the book to Mary'). Thus it is necessary to annotate each word with its argument structure, and the meaning of the verb will refer to elements in the argument structure.

'Conceptual structure' defines the connection between argument structure and meaning. According to Jackendoff, for example, the transitive verb *drink* corresponds to the following (simplified) lexical entry:

Word:	*drink*, verb (transitive)
Argument structure:	$\langle NP_i, NP_j \rangle$
Conceptual structure:	CAUSE (NP_i, GO (NP_j, TO (IN (MOUTH-OF (NP_i)))))

In the sentence 'John drank the soda', then, NP_i = *John*, NP_j = *the soda*, and the sentence as a whole means 'John caused the soda to go into John's mouth'.

Note that the conceptual structure is considerably more complex than the syntactic structure in which the verb participates: the concept named by *drink* has been decomposed into five separate predicates (CAUSE, GO, TO, IN, and MOUTH-OF), and there are three arguments at the conceptual level (John, the soda, and John's mouth) instead of two, as at the overt syntactic level.

Levin and others show how separating conceptual structure from argument structure provides a framework for explaining a type of polysemy that gives rise to various syntactic 'alternations': cases in which a single word can be used with a variety of argument-structure configurations. The basic idea is that when a verb like *break* occurs in a transitive sentence such as 'The girl broke the window', it has a conceptual structure that explicitly involves causation – perhaps (CAUSE (THE-GIRL, BECOME (BROKEN, THE-WINDOW))). When the same verb occurs with a single argument, as in 'The window broke', it takes for its conceptual meaning a proper subpart of the transitive structure – (BECOME (BROKEN, THE-WINDOW)). Crucially, the substructure omits mention of the causing entity.

A particularly interesting kind of alternation is known as an 'implicit argument'. For instance, when comparing the meaning of 'John ate something' versus 'John ate', the omitted argument in the shorter version is intuitively still present conceptually. In this case the two senses of *eat* differ only in argument structure but not in conceptual structure.

Thematic Roles and Linking

It is not an accident given the meaning of the word *drink* that the entity that causes the drinking event is expressed as the subject of the sentence: in 'John drank the soda', we know that John is consuming the soda, and not vice versa. More generally, to some degree at least, the meaning of verbs clearly

interacts with the syntactic form of sentences containing those verbs. The various theories developed to characterize the connection between verb meaning and syntactic structure are called 'linking theories', and in many linking theories the connection depends on 'thematic roles'. A verb like *kiss*, for instance, describes events that have two main conceptual participants, which we can call the kisser (the entity that does the kissing) and the kissee (the entity that gets kissed). When *kiss* occurs as the main verb in a sentence of English, the kisser is always syntactically realized as the subject and the kissee is realized as the direct object:

Syntactic structure:	[The girl]	kissed	[the boy]
Syntactic function:	Subject		Direct object
Verb-specific roles:	kisser		kissee
Thematic roles:	Agent		Patient

Thus the linking rules for English must guarantee that the verb-specific kisser role always comes to be associated with the grammatical subject of the sentence. (Passive sentences such as 'The boy was kissed by the girl' are a systematic variation on the basic pattern in which the normal basic linking is deliberately reversed for discourse purposes.)

Building on ideas of Davidson that emphasize the importance of events in the semantics of verbs, Parsons accounts for linking regularities by providing thematic roles as primitive notions, and stipulating that when a verb assigns a noun phrase the role of Agent, that NP must appear in subject position. The sentence 'Brutus stabbed Caesar with a knife' would be rendered as [STABBING(e) & AGENT (BRUTUS, e) & PATIENT (CAESAR, e) & INSTRUMENT (KNIFE, e)], which asserts that e is a stabbing event, Brutus is the agent of the stabbing event, Caesar is the patient, and the knife is the instrument.

Other linking theories attempt to derive thematic roles from independently motivated aspects of meaning. In a theory that recognizes conceptual structure, we can hypothesize that for any verb that contains as part of its meaning the conceptual primitive CAUSE, the first conceptual argument of the CAUSE predicate will be an agent. Put another way, the hypothesis is that the syntactic subject is the participant that the speaker conceptualizes as taking the more active causal role in the event.

Both the neo-Davidsonian approach and the conceptual-structure approach rely on defining the meaning of a word in terms of other more basic concepts. Dowty approaches the issue from the point of view of the relation between word meaning and the world. In particular, he suggests that it suffices to consider the entailments of the verb in question. The verb *kiss* entails that the kisser participant must have lips, that those lips must come in contact with the kissee participant, and the kisser must intentionally cause the contact to occur. In contrast, it is not an entailment that the kissee has lips, since it is perfectly possible to kiss a clam, or a rock, nor is there an entailment that the kissee intentionally causes the kissing event to occur (imagine kissing a sleeping child). On entailment-based theories of thematic roles, if a verb entails that a participant intends for the event described by the verb to come about, or causes it to come about, then that participant will (be more likely to) be expressed as the subject rather than as the direct object.

All theories that recognize the existence of thematic roles provide at least two basic thematic roles: Agent and Patient (the term 'Patient' is often collapsed with the term 'Theme', whence the cover term 'thematic roles'). Agents tend to be subjects; Patients, which are conceived of as undergoing an action (alternatively, are entailed to undergo an action, or which are incremental themes) make good direct objects. Among the other thematic roles that play a prominent part in many linking theories are Experiencer, Source, Goal, and Instrument.

Linking theories make strong predictions about possible and impossible words. Assume we are presented with a verb *glarf* that is allegedly a previously unknown transitive verb of English. We are told the following concerning its meaning: it describes situations in which one participant comes into violent contact with the foot of another participant. Furthermore, we know that it is the participant that possesses the foot who initiates or causes the touching event to occur. Now we encounter the following sentence: 'The ball glarfed the player', which is used as a description of an event in which a football player kicked a football for a goal. (In other words, *glarf* seems to be the verb *kick* but with subject and direct object reversed.) At this point, we can conclude that *glarf* is not a legitimate word of English (and in fact, is not a legitimate basic verb in any human language that recognizes the grammatical relations of subject and object), because it associates the volitional participant with the direct object and the more passive undergoer participant with the subject, contrary to the predictions of linking theories.

In fact, thematic roles can provide insight even into the syntactic behavior of verbs that have only one argument. The 'unaccusative hypothesis', due largely to Perlmutter, was a breakthrough in the use of lexical semantics to explain syntactic patterns. The hypothesis claims that intransitive verbs whose sole argument is semantically an Agent (predicates like *sing*, *smile*, or *walk*) behave differently cross-linguistically from so-called 'unaccusative' verbs, whose one argument is semantically a Patient (e.g. *fall*, *bleed*, or *die* – crucially, these activities are conceived of as not being done intentionally). For instance, unaccusative verbs in Italian generally take *essere* ('to be') as a past auxiliary rather than *avere* ('to have').

Like the correspondence between thematic roles and argument linking, the unaccusativity pattern is systematic enough to be quite compelling. However, as with virtually every attempt to derive syntactic behavior directly from semantic distinctions, examination of a wider range of data has revealed a considerable number of complications and exceptions. Nevertheless, there can be no doubt that meaning and form are deeply and inextricably connected, and that lexical semantics is the place at which they come into contact with one another. Therefore understanding lexical semantics is critical to understanding the yin and yang of language and conceptualization.

Lexical-Functional Grammar

Introductory article

Mary Dalrymple, Xerox PARC, Palo Alto, California, USA

CONTENTS

Lexical-functional grammar is a linguistic theory that explores the nature of the various aspects of the structure of language and the relations between them.

INTRODUCTION

Lexical-functional grammar (LFG) is a theory of the structure of language. The theory views the overall structure of language in terms of substructures representing different aspects of linguistic organization, each with its own organizing rules and principles. For example, the ordering and grouping of words into phrases, and of phrases into larger phrases, is represented by a 'constituent structure tree'. Traditional abstract syntactic roles like 'subject' and 'object' are represented by a 'functional structure', different from but related to the constituent structure. Other subsystems of linguistic organization have also been explored, including semantic structure, argument structure, and information structure. LFG provides an explicit theory of the structure and function of each subsystem as well as a detailed specification of the relations among the different systems, enabling a clear, well-grounded and well-motivated theory of the organization of human language. (*See* **Semantics and Pragmatics: Formal Approaches**; **Categorial Grammar and Formal Semantics**)

CONSTITUENT STRUCTURE AND FUNCTIONAL STRUCTURE

LFG had its beginnings in the 1970s, when linguists became dissatisfied with the then-current transformational theory of syntactic structure. According to transformational theory, complex sentences result from the application of a series of transformations that change or combine simple sentences into more complex sentences. In contrast, early LFG research showed that a psychologically more realistic, conceptually simpler, computationally more tractable, and theoretically more satisfactory theory results from abandoning transformations and adopting a lexical view: different sentences with similar meaning are related because the words in the sentences are related. LFG also proposed a finer-grained view of syntactic structure than was assumed in transformational theories. In the LFG view, the syntactic organization of every well-formed sentence is represented in terms of two separate but closely related syntactic structures. The constituent structure tree is like the tree structures commonly used in transformational theories: it represents the organization of words into phrases, and of phrases into sentences. The functional structure represents more abstract functional roles like 'subject' and 'object'.

Well-formed sentences are organized hierarchically: the words in the sentence form phrases, which in turn form larger phrases. For the sentence *David is eating an apple*, the result is the constituent structure tree shown in Figure 1. This tree represents a great deal of information about the phrasal structure of the sentence. The two most important aspects of the tree are the categories of the nodes in the tree and the phrasal groupings represented by the hierarchical structure: phrasal categories are represented as node labels like VP, NP, N, I′, and so on, and phrasal groups are sequences dominated by a single tree node.

In this tree, the word *eating* is dominated by a V node, indicating that it is a verb. Categories like V (for verb), N (for noun), and I (for inflection) are heads of phrases, and are dominated by their corresponding 'single-bar-level' category: V′ (pronounced 'V-bar'), N′ ('N-bar'), and I′ ('I-bar'). The single-bar categories are distinguished in that they can also dominate complements of the head: in this example, the V′ node dominates the V head as well as the NP complement *an apple*; similarly, the I′ category dominates the inflectional auxiliary *is*

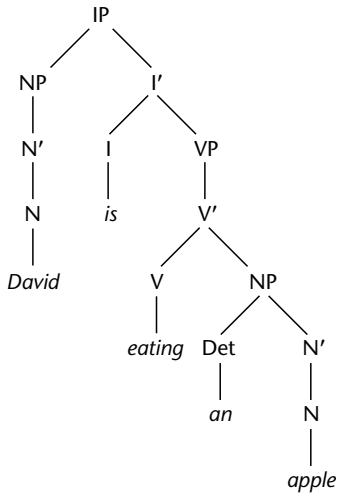

Figure 1. The constituent structure tree for the sentence *David is eating an apple.*

and its VP complement *eating an apple*. Categories like VP ('verb phrase') and NP ('noun phrase') are full phrases, containing both modifiers and complements of the head, and can appear in various places in the sentence according to their syntactic role; their appearance in Figure 1 is governed by basic phrase-structure principles as well as by the particular constraints relevant for English phrase structure. (*See* **Phrase Structure and X-bar Theory**; **Phrase Structure Grammar, Head-driven**; **Parsing: Overview**)

The tree in Figure 1 also indicates that several sequences of words are phrasal units, or 'constituents', dominated by a single node in the tree: *an apple* is an NP constituent, *eating an apple* is a VP constituent, and *is eating an apple* is an I′ constituent. These units also play an important role in other English sentences, since the phrasal rules of English tell us that an NP constituent can appear in any one of a number of phrase-structure positions: the NP *an apple* can appear at the beginning of the sentence, just after the verb, or as the object of a preposition:

[An apple] makes a good snack.
David gave [an apple] to Ken.
He nibbled at [an apple]. (1)

As we would expect, other NPs can also appear in these positions. The phrase *a delicious piece of fruit* is also an NP:

[A delicious piece of fruit] makes a good snack.
David gave [a delicious piece of fruit] to Ken.
He nibbled at [a delicious piece of fruit]. (2)

Rules of constituent structure in English govern where such phrasal units can appear. (*See* **Syntax**)

Some other languages also have consitutent structures like those described above. For example, Chinese, a language unrelated to English, has a constituent structure that is similar in some ways to that of English. However, many languages are unlike English in constituent structure. The constituent structure of Warlpiri, an Australian language, is very different from that of English: there is no VP category, for example, and a noun and its modifier need not form a single phrase. The sentence in Figure 2 means 'the two small children are chasing the dog' in Warlpiri. The noun *kurdu-jarra-rlu* ('two children') and its modifier *wita-jarra-rlu* ('small') do not form a phrasal unit in the constituent structure: *kurdu-jarra-rlu* appears as the first word of the sentence, and *wita-jarra-rlu* is the last word. This is not possible in English (an asterisk in front of a sentence means that it is not an acceptable sentence of standard English):

*[Fruit] David is eating [a piece of delicious]. (3)

In fact, in Warlpiri the words of the sentence can appear in almost any order, with no change to the basic meaning of the sentence. In the two sentences below, the words appear in different orders, reflecting differences in information structure – what is emphasized, assumed to be common knowledge, or presented as new information – but with no change to the basic meaning ('the two small children are chasing the dog'):

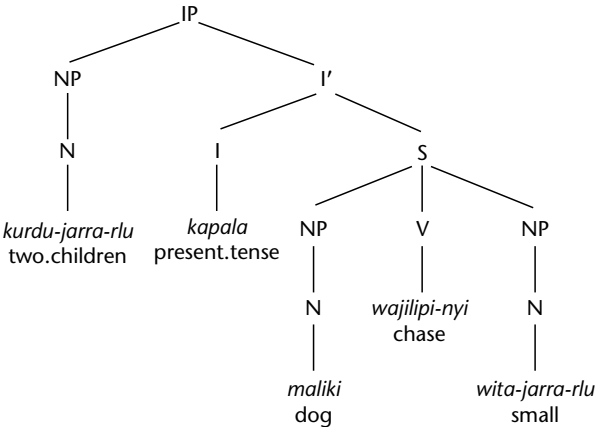

Figure 2. The constituent structure tree for the Warlpiri sentence *kurdu-jarra-rlu kapala maliki wajilipi-nyi wita-jarra-rlu*, which means 'the two small children are chasing the dog'.

maliki	kapala	kurdu-jarra-rlu	wita-jarra-rlu	wajilipinyi
dog	present tense	two.children	small	chase

wajilipinyi	kapala	kurdu-jarra-rlu	maliki	wita-jarra-rlu
chase	present tense	two.children	dog	small

In contrast, changing the order of words in a English sentence does change the meaning, and some orders are impossible:

A delicious piece of fruit ate David.
*A fruit delicious David piece of ate. (5)

Languages can vary a good deal in constituent structure: some, like English, have a more or less rigid word order, so that changing the order of the words changes the meaning of the sentence, while other languages are more like Warlpiri in allowing different word orders to correspond to the same meaning.

However, languages vary much less in functional structure, which represents more abstract syntactic information. Every well-formed sentence in a language has a functional structure that indicates the grammatical roles of the parts of the sentence: what is the subject (SUBJ), what is the object (OBJ), and so on. In LFG, grammatical relations like SUBJ and OBJ are not assumed to be defined in terms of particular constituent-structure-tree configurations, or in terms of particular participant roles in an event such as 'agent' or 'undergoer'; instead, these relations are primitives of the theory, manifested in terms of a cluster of properties that tend to go with particular grammatical roles.

English and Warlpiri are much more alike in functional structure than their very different constituent structures might lead us to expect. The English sentence *David eats apples* has a subject (*David*), a main predicate (*eats*), and an object (*apples*). These traditional grammatical roles are represented in LFG by the functional structure. The functional structure for the sentence *David eats apples* is given in Figure 3. The diagram shows that the sentence has a main PRED, 'eat', which requires a SUBJ and an OBJ. The SUBJ functional structure has a PRED, 'David'; it also contains the information that 'David' has singular number, represented by the number feature NUM with value 'singular'. The OBJ functional structure has a PRED, 'apple', and a NUM feature whose value is 'plural', since 'apples' is a plural phrase referring to more than one apple. A list of functional-structure features is given in Table 1. For simplicity, the functional structures we display here are abbreviated:

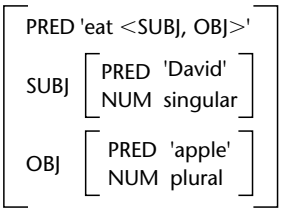

Figure 3. The functional structure for the sentence *David eats apples*.

Table 1. Functional-structure features

Concept	*Feature*	*Values*
Person	PERS	first, second, third
Gender	GEND	masculine, feminine, neuter, …
Number	NUM	singular, plural, …
Case	CASE	nominative, accusative, …
Surface form	FORM	[surface word form]
Verb form	VFORM	pastpart, prespart, …
Tense	TENSE	present, past, …

for example, we have displayed only the number of the subject 'David', omitting features like person and gender.

Several pieces of evidence show that *David* is the subject and *apples* is the object in the sentence *David eats apples*. In English the subject comes before the verb, and the object comes after the verb. If we switch *David* and *apples*, we get a sentence with a different meaning, where *apples* is the subject and *David* is the object:

Apples eat David. (6)

Verb agreement in English provides another way of identifying the subject of a sentence. An English third-person verb ends with 's' if its subject is singular, but not if it is plural:

David eats, apples.
*David eat, apples.
*Apples is eaten by David.
Apples are eaten by David. (7)

English tag questions such as *doesn't he* or *isn't he* appear after the main sentence and show agreement with the subject. If the subject is singular (and masculine), we use a tag question like *doesn't he* or *isn't he*, whereas if it is plural we use *don't they* or *aren't they*:

David eats apples, doesn't he?
*David eats apples, don't they?
*Apples are eaten by David, isn't he?
Apples are eaten by David, aren't they? (8)

This and other evidence shows that *David* is the subject of the sentence *David eats apples* and *apples* is the object. Although the sentence *Apples are eaten by David* has the same meaning, its syntactic structure is different: *apples* is the subject of the sentence, and *David* is the object of the preposition *by*. (*See* **Agreement**; **Local Dependencies and Word-order Variation**; **Linguistic Evidence, Status of**)

Some of these tests for subjecthood are also relevant in other languages. Verb agreement is an indicator of subjecthood in many (though not all) languages; likewise, in many (though not all) languages it is possible to determine the grammatical role of a phrase from its position in the sentence. Although evidence for grammatical functions can differ from language to language, LFG research has shown that functional structure is relevant in every language, and that functional roles and features can be identified in every well-formed sentence in every language. Conversely, if a sentence is ill-formed or ungrammatical, the explanation for its ill-formedness often lies in a violation of functional requirements, as in the examples above.

Now let us consider a sentence meaning 'David eats an apple (or 'apples')' in Japanese, a language that indicates subjecthood and objecthood in a different way from English:

David ga ringo o taberu
David nominative apple accusative eats
'David eats apples.' (9)

The subject of this sentence is *David* and the object is *ringo*; therefore, the functional structure of this sentence is almost the same as the functional structure of the English sentence *David eats apples*. The only difference is that Japanese does not indicate the number of noun phrases like *ringo*, which can mean either 'apple' or 'apples', so that the number feature NUM and its value are not present in the OBJ functional structure.

As in Warlpiri, word order does not help us identify the subject and object in a Japanese sentence; the subject and object can be reordered without affecting the functional structure or the meaning of the sentence. The sentence below has the same functional structure and meaning as the sentence above, even though the object comes first, followed by the subject:

ringo o David ga taberu
apple accusative David nominative eats
'David eats apples.' (10)

In Japanese, unlike English, grammatical roles are identified by the case marker they appear with: the subject is usually marked with *ga*, the nominative case marker, and the object is usually marked with the accusative marker *o*. This case-marking appears regardless of whether the subject is before or after the object, and helps to determine the grammatical role of each part of the sentence and the appropriate functional structure for the sentence.

English and Japanese exemplify two different ways that languages can encode information about grammatical roles: by position and by case-marking. Although sentences in the two languages have very different constituent structure, they exhibit an underlying unity in functional structure.

SYNTACTIC RELATIONS

We have seen that an English sentence like *David eats apples* and a Japanese sentence like *David ga ringo o taberu* have a constituent structure representing phrasal organization and a functional structure representing abstract functional roles and features. We now turn to an examination of the relation between the constituent structure and the functional structure.

In English, grammatical roles are correlated with phrase-structure positions: for example, the phrase appearing as the first daughter of the IP phrase is the subject. There is a mathematical function that defines the relation between each node of the constituent structure tree and the functional structure it corresponds to. We call this function ϕ ('phi'), and we represent it by means of a line pointing from a constituent-structure node to the functional structure it corresponds to, as in Figure 4. In other languages, the relation in different. We have seen that in Japanese and Warlpiri, word order does not correlate with grammatical role: the words in a sentence can appear in different orders without affecting the functional structure. In these languages, the subject can appear in various places in the constituent structure tree. The constituent structure and functional structure for the Warlpiri sentence meaning 'the man is spearing the kangaroo' are shown below. The subject *ngarrka-ngku* ('man') is the third word in the sentence, appearing as the first daughter of the S node in the constituent structure tree (see Figure 5), while the object appears in initial position in the sentence:

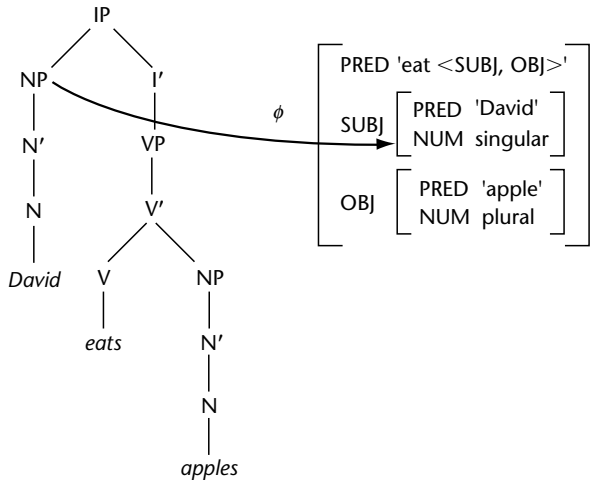

Figure 4. The relation ϕ between the nodes of the constituent structure tree and the corresponding functional structures, for the sentence *David eats apples*.

wawirri ka ngarrka-ngku panti-rni
kangaroo present.tense man spear
'The man is spearing the kangaroo.' (11)

LFG research has explored the relation between constituent structure and functional structure in a number of languages, establishing universally valid constraints on the function ϕ from constituent structure nodes to functional structures, as well as exploring language-particular constraints on the ϕ function. These constraints fully determine the ϕ function. A full specification of the relation between the constituent structure and the functional structure for the sentence *David eats apples* is given in Figure 6.

CONSTRAINTS ON SYNTACTIC STRUCTURES

So far, we have discussed the syntactic structures that LFG assumes – the constituent structure and the functional structure – and we have seen how they are related by the ϕ function from nodes of the constituent structure tree to functional structures. We will now show how constraints on these structures are specified in a linguistic description of languages like English, Japanese, or Warlpiri.

The phrase-structure rule below states that a node labeled V′ can dominate two nodes labeled V and NP:

$$V' \rightarrow V \quad NP \tag{12}$$

LFG allows more complex characterizations of well-formed constituent structure configurations by the use of 'regular expressions' on the right-hand side of a phrase-structure rule. The following more complete V′ rule uses the Kleene star operator ('*') to state that a node labeled V′ can dominate a V node, an optional NP node, and any number (including zero) of prepositional phrase nodes labeled PP:

$$V' \rightarrow V \ (NP) \ PP^* \tag{13}$$

We must also specify the relations between the functional structures corresponding to these nodes. We can do this by using the 'up arrow' $\uparrow$ and the 'down arrow' $\downarrow$ in annotations on the daughter nodes in a phrase-structure rule to refer to the functional structures of the mother node and the daughter node. In the annotated rule below, the up arrow $\uparrow$ refers to the functional structure of the mother node V′, and the down arrow $\downarrow$

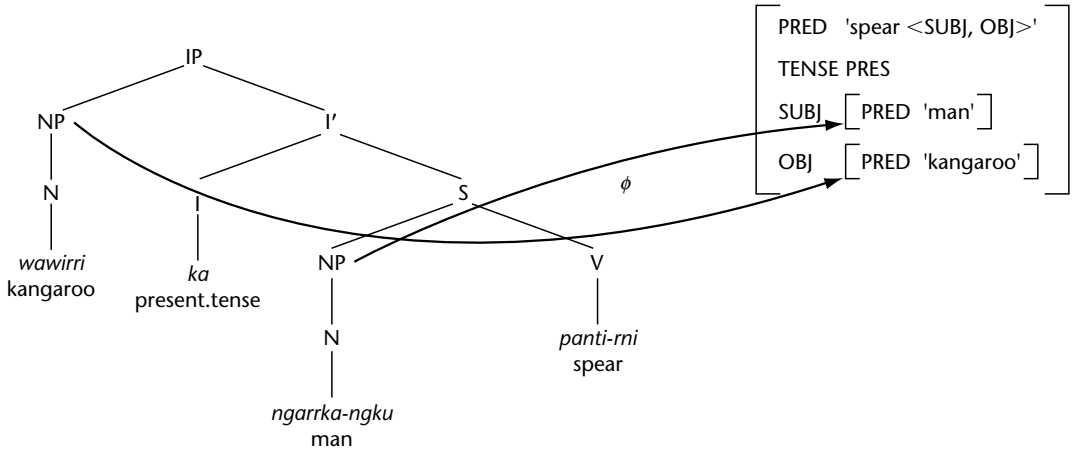

Figure 5. The relation ϕ between the nodes of the constituent structure tree and the corresponding functional structures, for the Warlpiri sentence *wawirri ka ngarrka-ngku panti-rni*, meaning 'the man is spearing the kangaroo'.

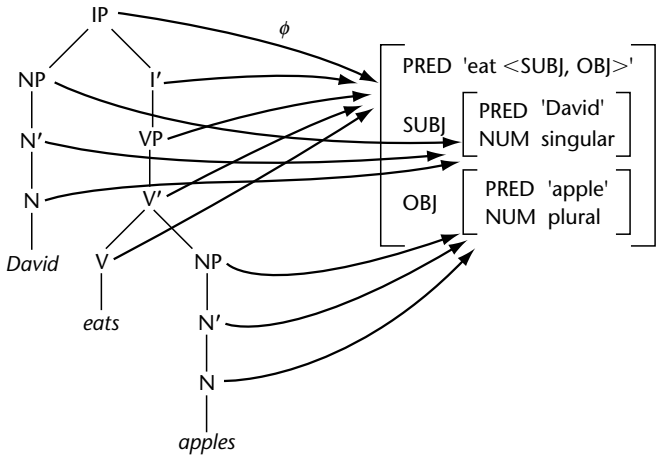

Figure 6. Complete specification of the relation ϕ between the constituent structure tree and the functional structure for the sentence *David eats apples*.

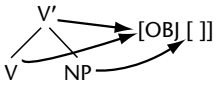

Figure 7. A simple mapping from constituent structure to functional structure, which obeys the constraint $\begin{matrix} V' \rightarrow & V & & NP \\ & \uparrow = \downarrow & & (\uparrow \text{OBJ}) = \downarrow \end{matrix}$.

refers to the functional structure of the V. The equation $\uparrow = \downarrow$ means that the functional structure for the V′ must be the same as the functional structure for the V:

$$\begin{matrix} V' \rightarrow & V \\ & \uparrow = \downarrow \end{matrix} \qquad (14)$$

The more complete annotated rule below tells us that a V′ node dominates a V node and an NP node, that the functional structure for the V is the same as the functional structure for the V′, and that the functional structure for the NP bears the OBJ function in the functional structure for the V′:

$$\begin{matrix} V' \rightarrow & V & & NP \\ & \uparrow = \downarrow & & (\uparrow \text{OBJ}) = \downarrow \end{matrix} \qquad (15)$$

The pairing between constituent and functional structures (constituent structure–functional structure pair) in Figure 7 obeys this constraint. The annotation $\uparrow = \downarrow$ on the V node is satisfied, since the functional structure of the V′ node $\uparrow$ is the same as that of the V node $\downarrow$; the annotation $(\uparrow \text{OBJ}) = \downarrow$ on the NP node is satisfied, since the functional structure of the V′ node $\uparrow$ has an OBJ attribute whose value is the functional structure of the NP node $\downarrow$. Similar rules for IP, I′, NP, and so on can be written, to describe and constrain a complete constituent structure–functional structure pair like Figure 6.

Words also contribute information about their constituent-structure and functional-structure properties. The lexical entry below contains information about the word *apples*:

$$\begin{matrix} \textit{apples}\ \text{N} & (\uparrow \text{PRED}) = \text{'apple'} \\ & (\uparrow \text{NUM}) = \text{plural} \end{matrix} \qquad (16)$$

According to this lexical entry, the word 'apples' is of phrase-structure category N; it contributes the feature PRED with value 'apple', and the number feature NUM with value 'plural'. This constraint is satisfied by the constituent structure–functional structure pair in Figure 6. All constituent-structure configurations, all functional-structure features and values, and the ϕ function from constituent structure nodes to functional structures, must be justified by rules like rule 15 or by information in lexical entries like entry 16. (*See* **Lexicon, Computational Models of**)

Besides basic equations like '$\uparrow = \downarrow$' or '$(\uparrow \text{NUM}) = \text{plural}$', LFG allows a range of other constraints on functional structures. Existential constraints are used to require the presence of a feature without constraining its value; negative constraints are used to forbid the appearance of a feature with any value; set-membership constraints require a set of functional structures to contain a member with particular characteristics; and constraining equations require that some other word or rule in the sentence contribute a particular basic equation in order for the overall functional structure to be well-formed. (*See* **Constraint-based Processing**)

OTHER LINGUISTIC STRUCTURES

'Morphosyntactic structure' represents morphosyntactic dependencies between words that are not reflected in the functional structure. For example, the form and sequence of auxiliary verbs in English is fixed:

David has been eating apples. (17)

Other orders or forms are not possible:

*David been has eating apples.
*David have being eat apples. (18)

Such dependencies are represented and constrained in the morphosyntactic structure. (*See* **Syntax and Semantics: Formal Approaches**)

'Semantic structure' is important in determining the meaning of an utterance and the conditions under which it is true. Meanings of sentences are obtained by logical deduction from a set of semantic premises contributed by the words and syntactic structures in the sentence. These semantic premises are stated in a resource logic, 'linear logic', and they specify how the meanings of the parts of a sentence can be put together to produce the meaning of the full sentence. Different deductions from the same premises can correspond to different meanings: the phrase *alleged criminal from London* is ambiguous, referring either to someone who is alleged to be a criminal from London, or to someone who is actually from London and who is alleged to be a criminal. These two meanings correspond to different orders in which the modifiers *alleged* and *from London* are combined.

'Argument structure' represents the semantic information that is relevant for determining which participant in an event is the subject, which is the object, and so on. Consider a predicate that requires two arguments, one an active participant or instigator (an 'agent') and one that is acted upon (a 'patient'). In an active English sentence with such a predicate, the agent is always the subject and the patient is always the object. In the following English sentences, the kicker or thrower is an agent, and is the subject; the thing that is kicked or thrown is a patient, and is the object:

David kicked the ball.
David threw the javelin. (19)

There are no active sentences in English in which the kicker or thrower is the object and the thing that is kicked or thrown is the subject. The sentence below cannot mean the same thing as the sentence *David kicked the ball*:

The ball kicked David. (20)

However, in the related passive sentence, the thing that is kicked can in fact be the SUBJ:

The ball was kicked by David. (21)

The role of argument structure in determining functional syntactic roles like SUBJ and OBJ, and the nature of relation alternations as exhibited by active–passive pairs (like *David kicked the ball* and *the ball was kicked by David*), has been extensively explored in a number of languages.

'Information structure' represents how the information that the speaker intends to convey is presented and structured according to the topic of conversation, the focus of attention of the utterance, the common assumptions of the speaker and hearer, and what part of the information the speaker intends to emphasize to the hearer. Information structure has been shown to be closely related both to functional structure and to constituent structure; and so constraints on information structure are stated in terms of properties of both syntactic levels of structure. (*See* **Natural Language Processing**)

FUTURE PROSPECTS

Two recent developments in LFG deserve particular attention: a new view of language acquisition and processing in an LFG setting, and the combination of optimality theory with an LFG syntactic base.

'Data-oriented parsing' (DOP) views language acquisition as the analysis of a pool of linguistic structures that are presented to the language learner. The learner breaks up these structures into their component pieces, and new utterances are assembled from these pieces. The likelihood of assigning a particular analysis to a new sentence depends on the frequency of occurrence of its component parts in the original pool of structures. (*See* **Natural Language Processing, Statistical Approaches to**,)

LFG–DOP specializes DOP theory to LFG assumptions about linguistic structures and the relations between them: the body of linguistic evidence that a language learner is presented with consists of constituent structure–functional structure pairs, and language acquisition consists in determining the relevant component parts of these structures and then combining these parts in different ways to produce constituent structure–functional structure pairs for novel sentences.

Much recent research in phonology, morphology, syntax, and semantics has been conducted in the framework of optimality theory (OT). OT-based analyses assume that the grammar of a language consists of a 'generator' component, which proposes candidate linguistic structures for an input, and an 'evaluation' component, which selects the optimal structure from these candidates. The evaluation component consists of a ranked set of universally valid constraints that the optimal analysis must meet.

In OT–LFG, the input is taken to be an underspecified functional structure, and the generator component is a 'universal' LFG grammar that generates all well-formed constituent structure–functional structure pairs that are compatible with the input. The evaluation component determines the optimal candidate in a particular language from this set.

CONTENTS

Natural language processing systems require information about individual words which is stored in the lexicon. Computational lexical representation techniques have been developed to model lexical knowledge.

INTRODUCTION

At the most basic level, a computational lexicon is a mapping from orthography or phonology to some combination of syntactic, semantic and pragmatic information. Its ultimate role is to deliver information to a system which analyzes or generates text or speech. This is in contrast to an electronic dictionary, which provides information to a human user (although there are some resources which combine the functions of lexicon and dictionary). Exactly what information is in the computational lexicon depends on the application: the lexicon for a part of speech tagger is likely to be considerably simpler than one for a natural language interface for instance.

A quite detailed lexicon is required by most computational systems, especially those based on linguistically motivated frameworks such as tree-adjoining grammar (TAG), lexical-functional grammar (LFG), head-driven phrase structure grammar (HPSG), dependency grammar (DG) or categorial grammar (CG). Although there are considerable differences between the various approaches, the main issues that concern lexical representation are common to all of them. In particular, they all require some way of representing generalizations about lexical behavior and some way of dealing with lexical ambiguity.

LEXICAL REPRESENTATIONS, LEXICAL HIERARCHIES AND INHERITANCE

Since the role of a lexicon is to provide information to an analyzer or generator, the precise nature of lexical representation depends on the requirements of those components. However, it is possible to think of all the commonly used approaches to lexical representation as forms of attribute-value representations. In such a formalism, information is expressed as pairings of attributes (or paths, consisting of lists of attributes) and associated values (which may be unspecified). Within this very broad characterization there is considerable variation in detail, but there are common organizational principles. Figure 1 shows a simplified example of an attribute-value representation for the lexeme (i.e. uninflected) transitive verb *tolerate*. The path-value notation is used explicitly at the top of the figure, while the bottom shows the same structure in attribute-value matrix (AVM) notation. In the examples in this article, an attribute, SUBCAT, will be used to represent the subcategorization properties as a whole, with attributes such as SUBJ, COMP1, COMP2 indicating the properties of the subject and individual complements. Such a representation could be used directly in a grammar expressed in a unification-based formalism, such as the PATR formalism (Shieber, 1986), which can be used to encode most of the grammar frameworks mentioned in the introduction. Although some systems maintain hard dividing lines between orthography/phonology, syntax and semantics, it is now common to assume a sign-based approach, in

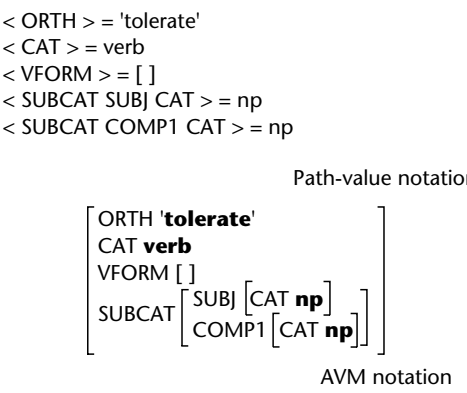

Figure 1. A simplified attribute-value representation for *tolerate* shown in two alternative notations. [ ] expresses an underspecified value.

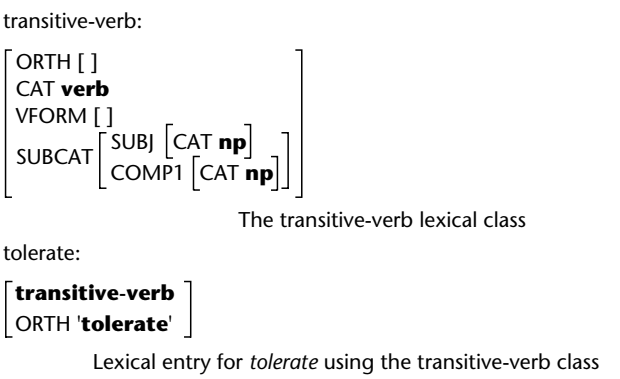

Figure 2. Using lexical classes to simplify lexical entries.

which a single representation combines information about all three levels (see, for instance, Jurafsky (1996), for discussion of why this is relevant to psycholinguistically plausible models). Pragmatic information might also be included, but in current practice pragmatic processing is nearly always application-specific and pragmatic information is omitted from the lexicon. For simplicity, Figure 1 omits semantics, and the discussion of lexical organization in the next sections concentrates on syntactic information, but the reader should bear in mind that the principles also apply to semantics.

Lexical Entries and Lexical Classes

The most basic form of organization is the lexical class. Notice that Figure 1 contains several individual pieces of structure. Rather than repeat all this for each transitive verb, the lexical entry (that is, the information stipulated for *tolerate*) should only contain the information that is idiosyncratic: generally the phonology/orthography and the semantic relation. It is therefore desirable to define a class for all simple transitive verbs, shown at the top of Figure 2, and used by the revised lexical entry for *tolerate* shown at the bottom of the figure. Note the contrast between the lexical entry and the structure to which it expands (i.e. Figure 1), which is what is accessed by the grammar rules when parsing or generating.

From an engineering viewpoint, the use of a class avoids many errors that might arise if a more complex structure had to be created directly (manually or automatically) and allows changes to be made in the representation without affecting the individual entry. Because the class expresses generalizations, it can add extra information. For instance, most entries in the COMLEX lexicon (Grishman *et al*., 1994) distributed by the Linguistic Data Consortium can be automatically converted into an HPSG lexicon by mapping them into predefined classes. This involves adding considerable extra information when considered in terms of the expanded lexical structures, but this is not problematic, because the extra information is predicted by the class. From a theoretical viewpoint, the class captures generalizations about lexical structure, for instance that simple transitive verbs have a subject and object position, and the inventory of lexical classes delimits the possible structures of the linguistic theory.

It is necessary to have a formal specification of the function that takes as input the individual entry together with its class and yields the expanded structure. Many systems which use unification in parsing also use unification for this operation, although this is not a necessary assumption.

Inheritance Hierarchies

The use of lexical classes can be seen as one-step inheritance. However, it is also desirable to capture relationships between the classes themselves by relating them in a hierarchy. The underlying idea is the same as inheritance in object-oriented programming: common information should be expressed in one place and inherited by subclasses. There is an indirect relationship to the use of IS-A links in semantic networks, but there are also differences: most importantly, lexical inheritance in modern representation languages is formally specified in such a way that the number of links in the hierarchy has no effect on behavior.

A portion of an inheritance hierarchy is sketched in Figure 3. Notice that some classes inherit from more than one parent. In a monotonic inheritance hierarchy, all information from all parents is combined with the information on the node itself:

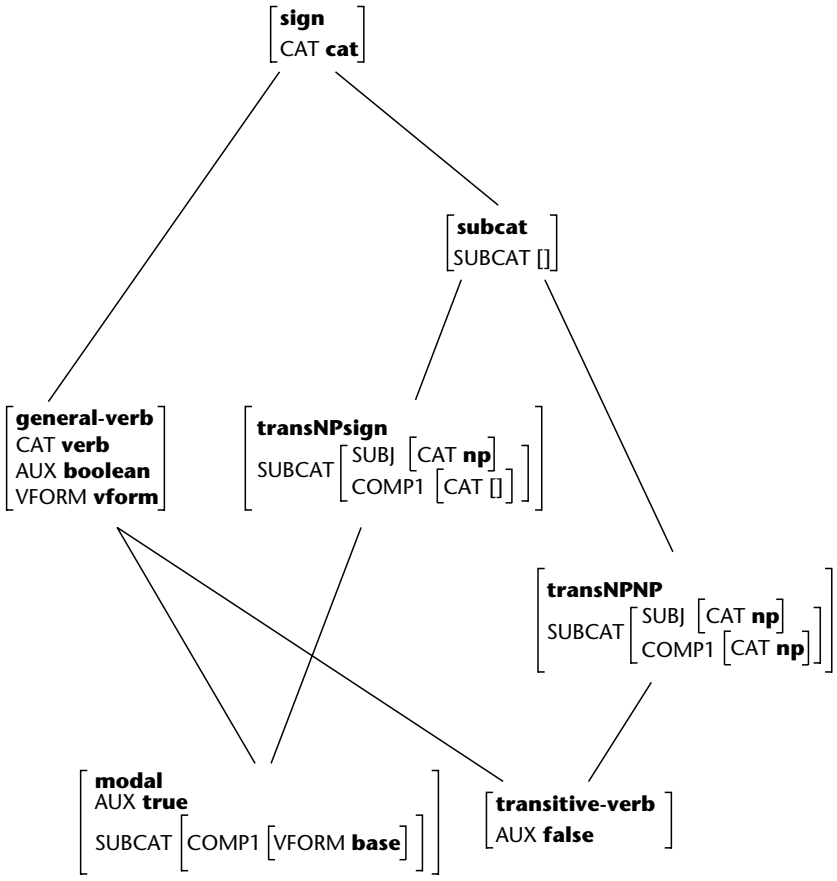

Figure 3. A fragment of a lexical inheritance hierarchy. Only the information local to each node is shown.

conflicts mean there has been an error in defining the hierarchy.

HPSG has made extensive use of inheritance in lexical description, following Flickinger *et al*. (1985), but all the frameworks mentioned in the introduction adopt it to some extent. HPSGs are often encoded using typed feature structures: in such formalisms, a type hierarchy is used for inheritance and to constrain the allowable structures.

Realistic lexical hierarchies are much bigger than Figure 3 would suggest and may easily involve many hundreds or thousands of classes. Cross-classification can be very helpful because it allows different parts of the hierarchy to be developed semi-independently of each other. It is worth noting that inheritance can be useful in the description of grammar rules and lexical rules as well as lexical structures, because the same principles of capturing generalizations are relevant.

Default inheritance

Many systems assume monotonic inheritance, which means that all information has to be mutually consistent. But there are some phenomena for which a purely monotonic account is problematic. The hierarchy in Figure 3 includes a class **modal-verb**, which specifies a single verbal complement which must have VFORM **base**. This is valid for most modal verbs, but *ought* is an exception (in most dialects of English): it patterns like a modal verb in most respects (it inverts, it can be negated without *do*, it takes the contracted negation *oughtn't* and it does not have distinct inflected forms) but it takes a *to*-infinitive complement. The distinction is demonstrated in the following examples:

1. I ought to go to bed.
2. *I ought go to bed.
3. *I should to go to bed.
4. I should go to bed.

In a formalism where inheritance is purely monotonic, the only option would be to split the class of modal verbs into two classes, one of which specifies VFORM **base** and another which specifies the *to*-complement. But this complicates the hierarchy and does not capture the intuition that *ought*

is the exceptional case. An alternative is the use of defaults, which is possible in the DATR representation language (Evans and Gazdar, 1996) and in various extensions of unification-based formalisms. For this particular example, the class for modal verbs specifies by default that the complement is a base form, but this is overridden by the entry for *ought*. This is shown in Figure 4. In this figure, only information after the '/' is default, so the only information about the modal verb class that can be overridden is the value of VFORM on its complement. In other variants of default inheritance, all information is potentially overridable.

Morphological Relationships and Lexical Rules

Lexical representation and morphology interact when representing inflected and derived forms of words. The syntactic and semantic effects of inflection may be captured in a simple inheritance hierarchy, on the assumption that inflection involves a fixed number of slots for number, gender, case etc., which take simple values, and that the base form is unmarked. Alternatively, lexical rules may be used, see below. It is also possible to specify slots for the stem and affix(es), with default inheritance being used for irregular verbs, for instance. This requires separate spelling rules to combine stem and affix to capture effects such as loss of *e* (e.g. *love* plus *ed* combine to give *loved*, not *loveed*). However in many computational systems, the phonological/morphological effects of affixation are captured with a finite-state approach or other device which involves a different formalism from the rest of the lexical representation. One exception is DATR, which can be used to define a finite-state transducer (Evans and Gazdar, 1996). Bird and Klein (1994) discuss the representation of phonology in a typed feature structure formalism.

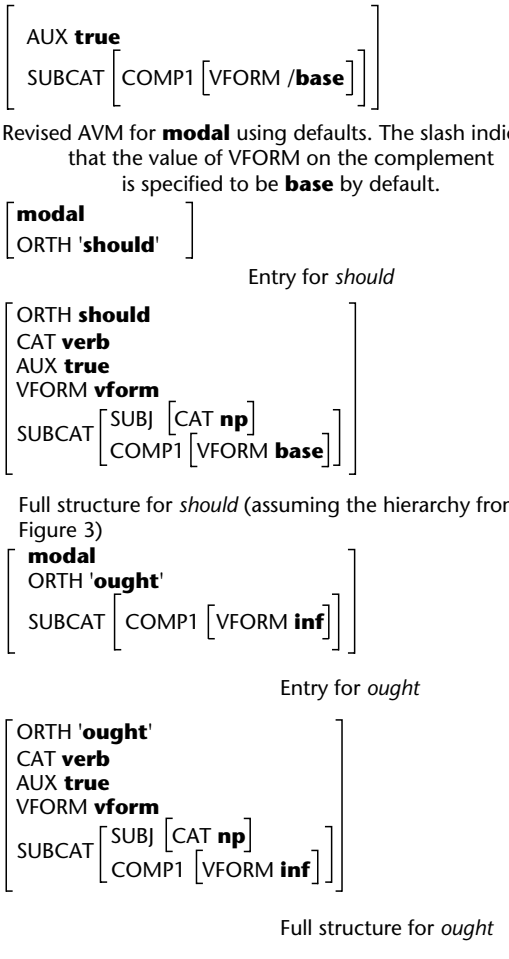

Figure 4. Default inheritance for *ought*.

Representation of derivational morphology is more complex, because it cannot be seen as instantiating a fixed number of simple attributes. For instance, the ending *ize/ise*, can convert an adjective X into a verb meaning (roughly) 'cause to become X' (e.g. *modern/modernize*). The number of derivational affixes does not in principle have an upper bound (e.g. *modernize/modernization/overmodernization/antiovermodernization*…), affixes do not have a fixed order of application (*godli-ness-less, god-less-ness*) and there is potential for multiple application of affixes (e.g. *antiantimissile*). This means that derivational morphology cannot in general be adequately represented using a simple inheritance hierarchy but requires some device capable of supporting recursive application.

Most commonly, derived forms are assumed to be related by some variety of *lexical rule*. Lexical rules are most straightforwardly thought of as having an input and an output which correspond to lexical classes, with some information being shared between the two parts. The rules are instantiated by individual lexemes: for derivational morphology, the output will be the affixed form. A sketch of a lexical rule for *+er* affixation of verbs to form agentive nominals is shown in Figure 5. The rule itself is very simple, because it makes use of the same lexical classes as the lexical entries do. The boxed integer tag indicates that the stem orthography is the same in the input and the output.

A complicating factor is that derivational morphology is semi-productive. This shows itself in two ways: a derived form may not have exactly the behavior predicted by the rule, or it may not occur at all. To avoid generating incorrect forms, lexical rules may be used as redundancy rules: that is, derived forms are explicitly listed in the lexicon

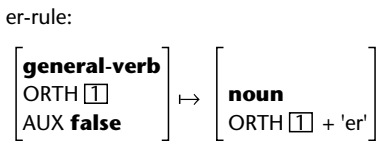

Figure 5. A lexical rule for affixation with *+er*.

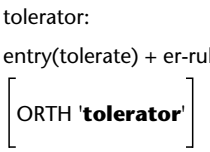

Figure 6. Using a lexical redundancy rule in a lexical entry.

but the lexical rule is used as part of the description. See Figure 6, for example. If default inheritance is available, the entry may specify that some part of the rule output is overridden. The disadvantage of this approach is that it does not predict novel forms: thus, faced with a previously unseen word *cloner*, the system has no way of relating it to *clone*. Theoretically, it is clear that productive derivational morphology is required at some level, although it might be seen as similar to acquisition of completely novel lexical entries rather than as analogous to inflection. Practically, no system can ever include all words in its lexicon: even after hundreds of millions of words of text have been processed, previously unseen forms still arise. But whether to treat some cases of derivational morphology as productive or not depends on the application. For a language generator, it is generally better to avoid making derivational morphology productive, since nonce formations are often regarded with some degree of distaste by hearers. On the other hand, for an analyzer, accepting previously unseen forms is essential for robustness.

There is a close relationship between derivational morphology and some cases of lexical ambiguity, discussed later in this article.

Multi-word Expressions

The lexical entries considered so far concern single (orthographic) words of a language, though possibly with internal morphological structure. There will also be entries that can be considered as corresponding to words which happen to be spelled with spaces (e.g. *ad hoc*). However, the lexicon must also contain entries for genuine multi-word expressions, including compounds (e.g. *house boat*), verb particle constructions (e.g. *tidy up*), idioms and collocations. The challenge to lexical representation is that many multi-word expressions are partly but not wholly compositional. For instance, the use of *tidy* in *tidy up* is clearly related to the verb *tidy* and *up* has a comparable use in *clear up, wash up* etc. In the extreme case of idioms such as *pull strings*, parts of the idiom may occur in different clauses: *The diplomatic strings that the ambassador pulled got the company the contract*. The representation of such idioms must therefore involve at least some aspect of the representation of compositionally constructed phrases. Several approaches have been proposed, most notably within TAG (Abeillè and Schabes, 1989), but this aspect of lexical representation is still very much an open issue. This is also true of the treatment of collocations such as *heavy sea* (note that *heavy swell* and *strong swell* are also collocations, but *strong sea* is unidiomatic). Collocations are the focus of much work within Meaning-Text Theory (MTT), some of which is computational in orientation (e.g. Mel'čuk and Polguère, 1987).

Semantic Representation

Unfortunately there is little agreement about the amount of semantic information that should be included in the computational lexicon, and even less about the way it should be represented. There has been much discussion about the distinction between lexical and real-world knowledge, but no consensus as to where the dividing line might be drawn or even if there is a theoretically motivated dividing line. At one extreme, semantic information in the lexicon is limited to predicate-argument structure. For instance, Figure 7 shows an entry for *tolerate* containing a semantic representation which links the subject and object to argument positions in the semantic representation (the linking is indicated by the boxed integers in the AVM). But by itself this says very little about the meaning of *tolerate* and it misses generalizations about the syntax–semantics interface. The representation in Figure 7 uses the semantic roles EXPERIENCER and EXPERIENCED but there is no agreed inventory of such roles. However, the FrameNet project (Baker *et al*., 1998) is developing frames that encode basic conceptual structures for a variety of semantic domains.

Unfortunately, attempting to fully represent word meaning leads into complex knowledge representation issues which are theoretically and computationally intractable. Even apparently simple information, such as selectional restrictions, can be problematic. For instance, it would seem

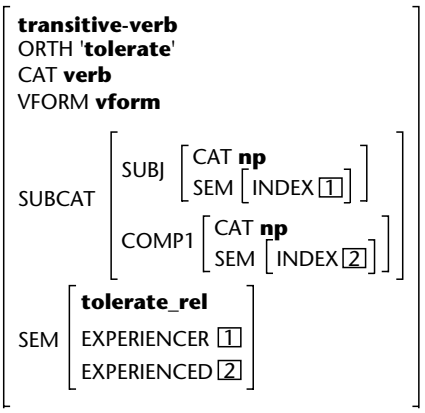

Figure 7. Lexical entry for *tolerate* including a very simple predicate-argument representation.

that the subject of *tolerate* (i.e. the experiencer) should be sentient, but, like many other similar verbs, *tolerate* is also used of plants, for instance: *Azaleas cannot tolerate alkaline soil*. If selectional restrictions are encoded as hard constraints, this sentence cannot be parsed. Selectional restrictions are thus generally used to guide processing by means of preferences rather than to completely rule out parses.

Practically, much depends on the application and on the system architecture: for instance, it is often possible to make semantic relationships domain-specific. There is considerable scope for utilizing statistical techniques to provide an approximation of (some aspects of) meaning: this is discussed further below, in the context of ambiguity and disambiguation.

One compromise position is to restrict semantic information in the lexicon itself to that which is necessary to capture generalizations about syntax or morphology. The representation tools described so far are generally adequate for this, since the need is for inheritance rather than full logical inference. For instance, in typed feature structure formalisms, a hierarchy of semantic types which includes predicates such as **tolerate_rel** can be defined.

Taxonomic information of a more general sort is also of proven utility in some applications, such as retrieval from document databases, and other uses are being very actively investigated. Much of this work uses domain-specific taxonomies but researchers requiring general-purpose taxonomies often rely on WordNet (Fellbaum, 1998). Taxonomic links are generally not formally defined: WordNet's hyponymy links, for instance, cover traditional taxonomic information, such as the relationship between a species and a family in biology, but are also used for relationships between verbs, which raises the question of argument mapping. Both WordNet and FrameNet are resources which can be utilized by a range of systems, rather than as computational models in their own right.

LEXICAL AMBIGUITY

Discussions of ambiguity are frequently motivated by examples such as *bank*: financial institution versus *bank*: geographical feature. It is clear that there are two quite distinct senses of *bank* and there is nothing interesting to say about the synchronic relationship between them, even if there is a historical relationship. A corresponding computational representation would be to have two lexical entries for the noun *bank* which are unrelated apart from having the same spelling.

There are several reasons why computational models of ambiguity are less straightforward than this would suggest. The first is that most ambiguity actually concerns related senses: for instance *bank*: financial institution versus the verb *bank*: to carry out transactions at a bank. Here the senses are clearly related, though they have different parts of speech. As illustrated below, different types of lexical ambiguity require different computational models (Copestake and Briscoe, 1995). Furthermore, the distinctions made between related senses in conventional dictionaries are not mutually consistent and do not offer a particularly good guide to a computational lexicographer. The second issue is more related to the engineering issues of computational lexicography: representing lexical ambiguity with multiple entries is computationally expensive, since it expands the search space required by parsing. This leads to the use of various techniques to pack ambiguity into one lexical entry. Many computational lexicons do not in fact have completely distinct lexical entries for the two distinct nominal senses of *bank*, either because the representations for the senses are packed together or because the semantics is so coarse-grained that the distinction is not representable. Finally, it is important both theoretically and practically to consider the relative frequencies of different senses.

Classes of Ambiguity

The classical *bank* ambiguity is an example of homonymy, which technically refers to totally unrelated senses. From the computational perspective, words which intuitively have some relationship but where the meaning difference is unpredictable are treated with distinct entries in the same way as homonyms proper. An example is *bank*: geographical feature

and *bank*: to turn an airplane. Many people intuitively feel there is a relationship between these senses, since both involve a slope, and there is a clear historical connection, but there is no generalization to be made about the relationship.

More interesting cases involve some regularity in the polysemy. For example, the nouns *heap*, *pile*, *mound* etc., referring to a raised mass of some type, have corresponding verbs, which (roughly) mean to construct such an object. This class of polysemy is very similar to derivational morphology (compare this example with the suffixes *-ize*, *-ify*, for instance) and can be represented computationally by a lexical rule in a comparable way. Issues of semi-productivity arise here, much as they do with derivational morphology.

A subtle form of polysemy is exemplified by the noun *cloud*, which can be used not only for the weather phenomenon, but also for similar amorphous masses made up of dust, flies, etc. Usually the non-weather use is made explicit by compounding (*dust cloud*) or an *of*-PP (*cloud of flies*). A similar pattern is found in many other nouns, for example *belt/belt of snow*, *ribbon/ribbon of sauce*. Effectively there is one relatively specific sense and a range of other more general uses which contain only part of its meaning. Such examples may be classed as figurative but they are conventionalized and quite common in standard corpora. Furthermore, the syntactic properties sometimes differ, since the general uses subcategorize for the of-PP. It is therefore necessary to account for these senses in a computational lexicon. One approach is to assume a general (underspecified) structure for *cloud*, which by default refers to weather clouds, but which can be contextually specialized to get the other uses, overriding default information about composition. Copestake and Briscoe (1995) discuss such examples and relate them to the examples of *logical metonymy* which have been discussed in detail by Pustejovsky (1995).

There are many cases where some conventional dictionaries split senses where there may well be no reason to make any sense distinction in a computational lexicon. For instance, many dictionaries distinguish between *bank*: mound and *bank*: river bank as separate senses but most computational lexicographers would not split the uses. In this particular case, that decision could be justified by examples such as the following: *Removal of vegetation may destabilize banks*. If *banks* here refers to both mounds and river banks, then there must be a single lexical structure which encompasses them both (although this could be an underspecified structure, with specializations corresponding to the two dictionary senses). But, in general, if the computational lexicon gives the same structure for two senses, there is little point in having two entries.

Practically speaking, the sense distinctions made in many systems are driven by the application. For instance, a natural language interface may use the ontology of the underlying system for guidance in distinguishing senses while a machine translation lexicon might use distinctions in the target language. But this can produce problems if the systems are extended. For instance, if another target language was added that shared the ambiguity found in the source language, the strategy of multiplying lexical entries would mean that an unnecessary disambiguation step was required for the new language pair. On the whole it is best to arrange the system architecture so that choices are made at the latest possible processing stage.

Lexical Probabilities

Lexical representation is not necessarily entirely symbolic – many systems include some probabilistic or frequency information. This is most apparent in statistical approaches. A lexical entry for a statistical part-of-speech tagger contains all possible tags for the string plus associated probabilities, which are acquired automatically while training the tagger on text. For instance, the entry for *bank* might look as follows (based on data adapted from the tagged British National Corpus): bank: V 0.002 NP 0.214 N 0.784. Lexical probabilities are important in statistical tagging and statistical parsing, since, as the example illustrates, the distribution of parts of speech is very uneven. This is true of senses more generally: usually some are much more frequent than others, although the particular frequencies will depend on the domain of the text. Relative lexical frequency metrics are also important in some analyzers based on manually constructed grammars, although these are generally implemented as weights rather than genuine probabilities because of the difficulty of producing probabilistic grammars for non-context-free formalisms. Developing lexicons which have accurate estimates of probabilities for finer-grained information than a simple part-of-speech is an ongoing research goal: constructing such lexicons manually is unrealistically time-consuming, but automatic acquisition techniques run into difficulties because of data sparseness and ambiguity. Lexicons with accurate frequency information can be expected to lead to more psychologically plausible models of processing, in particular with respect to ambiguity and the treatment of multi-word expressions.

Disambiguation and Lexical Representation

Disambiguation is dependent on lexical representation in a very basic way since it is only required to the extent that the lexicon makes a sense distinction. However, because of the need to compare results, much research has involved disambiguation with respect to some external standard, such as a dictionary or WordNet. Disambiguation algorithms in complete systems can take advantage of the lexical information required for other aspects of processing, but many researchers also use some external information source to guide disambiguation. For example, information about word co-occurrences (acquired either manually or automatically) is an important source of information for many disambiguation algorithms. Arguably, at least, this is lexical information, but it is of a somewhat different type from the sort of information needed by a conventional parser. Lexical disambiguation is inevitably imperfect: it is easy to invent examples which require arbitrary amounts of world knowledge and reasoning. But human hearers sometimes make errors due to lexical ambiguity too! What is important is whether the disambiguation rate that can be achieved with the available knowledge sources is acceptable for a given application and whether it is possible to recover from errors.

Some research on disambiguation uses meaning representations automatically derived from corpora. Given the discussion of sense distinctions above, it seems plausible to assume a model of meaning where individual uses of words have different degrees of relatedness, and senses are clusters of uses, which naturally leads to a notion of a sense distinction as a cline, rather than a hard boundary. This fits in quite naturally with models of meaning based on local context of individual uses acquired automatically from corpora, which have become much more attractive in recent years because of the availability of large amounts of text in machine-readable form and increases in computing power. Schütze (1996) describes one approach that uses a relatively simple notion of co-occurrence to give representations which consist of very high dimension vectors, but there are many ways in which this basic idea might be refined. Work along these lines is promising because it may address some of the weaknesses of purely qualitative approaches to lexical representation. Specifically, it may provide an approach to obtaining a fine-grained meaning representation automatically in a way that allows for different sense frequencies and for collocations. But this is unlikely to entirely supersede symbolic attribute-value representations and the challenge will be to combine the two in a way that realizes the strengths of both.

CONTENTS

The lexicon of a grammar must provide a systematic and efficient way of encoding information about the words in a language.

WHAT IS A WORD?

Methodological Preliminaries

Linguistic computation requires access to knowledge about words. In this article, the requirements on the lexicon are examined in terms of the information required for syntax, and in terms of the knowledge needed for semantic interpretation.

Although there is little agreement on the exact nature of what should go into a lexicon, there are some important common assumptions held by researchers in linguistics on the form of a lexical entry. It is generally assumed that there are four necessary components for the structure of a lexical item. These are: syntactic information (e.g. what part of speech the word is); semantic information (i.e. how the word is interpreted); orthographic and morphological information (i.e. how the word is spelled and what form it takes); and phonetic and phonological information (e.g. how the word is pronounced and stressed).

But the lexicon is not merely a collection of words with their associated phonetic and orthographic forms. Words are structured objects that participate in larger operations and compositions, acting as signatures to semantic entailments and implicatures in the context of discourse and text. So we need to address the following four questions when designing a computational lexicon or modeling our mental lexicon:

- What information goes into a single lexical entry?
- How do lexical entries relate to one another?
- How is this information exploited by the grammar?
- How is this information available to general reasoning?

As regards all of these questions views on lexical knowledge vary in the linguistic sciences. To a large extent, the nature of the grammar itself is determined by what information the lexicon contains for the other grammatical components. Nevertheless, the lexicon is often viewed as the most passive module of grammar. Since the 1970s, the amount of information that is associated with lexical items, as well as what is taken to be a lexical item in the first place has changed considerably. What started as a passive repository of pure stems, with active word-formation rules generating everything from inflected forms to derivational compounds, has developed into a distributed library of lexically based syntactic encodings, generative operations, and object-oriented processes.

There are essentially two reasons for the changing perspective on the lexicon in recent years. Firstly, there is now a tighter integration of compositional operations of syntax and semantics with the lexical information structures that bear them. Secondly, lexical researchers have become more concerned with how lexical types reflect the underlying ontological commitments of the grammar. The field has moved towards addressing more encompassing problems in linguistic theory, such as polysemy, global lexical structure, syntactic linking, and the relation between lexical and world knowledge. In this article, we review briefly the conventional view of the lexicon and then contrast this with newly emerging theories of lexical information.

The conventional view of the lexicon is of a file of words, acting in the service of the more dynamic components of the grammar. This view has its origins in the generative tradition (Chomsky, 1975) and has been an integral part of the notion of the lexicon ever since. While the *Aspects*-model of selectional features (Chomsky, 1965) restricted the relation of selection to that between lexical items, work by Jackendoff (1972) and McCawley (1968) showed that selectional restrictions must be available to computations at the level of derived semantic representation rather than at deep structure. Subsequent work by Pollard and Sag (1994) and others extends the range of phenomena that can

be handled by the projection and exploitation of lexically derived information in the grammar. Recently, with the convergence of several areas in linguistics (lexical semantics, computational lexicons, type theories), several models for the determination of selection have emerged that put even more compositional power in the lexicon, making explicit reference to the paradigmatic systems that allow for grammatical constructions to be partially determined by selection. Examples of this approach are 'generative lexicon theory' (Pustejovsky, 1995), and to a certain extent 'construction grammar', combinatory categorial grammar (CCG), and Jackendoff's recent work. These developments have helped to characterize approaches to lexical design in terms of a hierarchy of semantic expressiveness. There are at least three such classes of lexical description (see Pustejovsky, 1995): 'sense-enumerative' lexicons, where lexical items have a single type and meaning, and ambiguity is treated by multiple listings of words; 'polymorphic' lexicons, where lexical items are active objects, contributing to the determination of meaning in context, under well-defined constraints; and 'unrestricted sense' lexicons, where the meanings of lexical items are determined mostly by context and conventional use. The most promising direction of study seems to be a careful and formal elucidation of the polymorphic lexicons, and this will form the basis of our discussion below of both the structure and the content of lexical entries.

Multi-Word Expressions

If we assume that a word can be viewed as a data structure associating a specific orthography and phonology with syntactic behavior, meaning, and conventions of usage, then arguably the lexicon is populated by not just single morphemes but multiword expressions as well. There are two major classes of multi-word expressions that we will consider here: collocations and idioms.

It is often merely an historical accident that a language (or dialect) lexicalizes a concept as a single morpheme rather than a multi-word expression: compare the British English *hoover* with American English *vacuum cleaner*, for example. The latter type of compound word is commonly referred to as a 'collocation', of which there are two kinds:

- A collocation that makes up a single, non-phrasal constituent. Examples include proper names such as *George Miller* and *Arlington Heights*, and grammatical formatives such as *in addition to* and *such that*. There is a single, non-phrasal category associated with the entire expression.
- A collocation that makes up more than one non-phrasal category. This happens in the case of lexical items that must co-occur with a particular word, rather than an entire category. Examples include so-called 'verb–particle' combinations, such as *blow up* and *write down*, and verbs that select a prepositional phrase headed by a particular preposition, such as *look for* and *wait for*. Note that, in the verb–particle case, material may intervene between the verb and the particle (*blow the building up*). In both cases, inflectional material appears on the first word of the expression (*blew up, looked for*).

Idioms might be considered a special case of collocations, having many constituents. They are, however, distinguished from collocations by a number of criteria. Firstly, they have a noncompositional semantics. Typically, the interpretation of an idiom is not derivable from its component parts: *kick the bucket*, *the cat's got his tongue*. Secondly, they exhibit 'fixedness'. Often an idiom, unlike a collocation, is a fixed expression, specifying an entire complement structure, rather than some subsidiary element. Contrast *kick the bucket* (idiom) with *look for him* (collocation). This is not universally true of idioms, since some do allow unfixed elements to appear as part of the complement structure: *the cat's got his tongue*, *take advantage of him*. Note, however, that even in these cases, much more of the complement structure is specified than in cases of collocation. Also, lexical items, and not merely grammatical formatives (such as determiners), are specified in these examples. Finally, they violate grammatical constraints. The idiom *take advantage of* presents a good example of this. Firstly, it violates the normal subcategorization frame of *take*, which does not permit *of* as the preposition following the object NP (*John took books from/to/*of Bill*). Secondly, *advantage* appears without a determiner in this idiom, though it normally requires one (*I can see *(the) advantage in that*).

If collocations and idioms are stored as units in our mental lexicon, then there are several related issues that linguistic theories must deal with. How are multi-words indexed? And how much internal morphological or syntactic structure do multiwords have or allow access to?

THE PROBLEM OF POLYSEMY

Given the compactness of a lexicon, relative to the number of objects and relations in the world and the concepts we have for them, lexical ambiguity is inevitable. Add to this the cultural, historical, and linguistic blending that contributes to the meanings

of our lexical items, and ambiguity can appear arbitrary as well. Hence, homonymy – where one lexical form has many meanings – is to be expected in a language. Examples of homonyms are illustrated in the sentences below.

(a) Mary walked along the *bank* of the river.
(b) FleetBank is the largest *bank* in the city. (1)

(a) Drop me a *line* when you are in Boston.
(b) We built a fence along the property *line*. (2)

(a) First we leave the gate, then we *taxi* down the runway.
(b) John saw the *taxi* on the street. (3)

(a) The discussion *turned* on the feasibility of the scheme.
(b) The bull *turned* on the matador. (4)

(a) The judge asked the defendant to approach the *bar*.
(b) The defendant was at the *bar* in the pub. (5)

Weinreich calls such lexical distinctions 'contrastive ambiguity', where the senses are distinct and generally unrelated. For this reason, it is generally assumed that homonyms are represented as separate lexical entries within the organization of the lexicon. This accords with a view of lexical organization that has been termed a 'sense-enumeration' lexicon (Pustejovsky, 1995). A lexicon L is a sense-enumeration lexicon if and only if for every word w in L, having multiple senses $s_1,\ldots,s_n$ associated with it the lexical entries expressing these senses are stored as $\{w_{s_1},\ldots,w_{s_n}\}$. Words with multiple senses are simply listed separatedly in the lexicon. This does not seem to compromise or complicate the compositional process (how words combine in the interpretation of a sentence).

This model becomes difficult to maintain, however, when we consider the phenomenon of polysemy. Polysemy is the relationship that exists between different senses of a word that are related in some logical manner, rather than arbitrarily, as in the above examples. We can distinguish four broad types of polysemy, each presenting a distinct set of challenges to linguistic theory:

- Deep semantic typing: single-argument polymorphism.
- Syntactic alternations: multiple-argument polymorphism.
- Dot objects: lexical reference to objects that have multiple facets.
- Terms of generalization: light verbs and general predicates.

The first class refers mainly to functors allowing a range of syntactic variation in a single argument. For example, aspectual verbs (*begin, finish*), perception verbs (*see, hear*), and most propositional attitude verbs (*know, believe*) subcategorize for multiple syntactic forms in complement position, as illustrated in example 6 below.

(a) Mary began to read the novel.
(b) Mary began reading the novel.
(c) Mary began the novel. (6)

(a) Bill saw John leave.
(b) Bill saw John leaving.
(c) Bill saw John. (7)

(a) Mary believes that John told the truth.
(b) Mary believes what John said.
(c) Mary believes John's story. (8)

What these and many other cases of multiple selection share is this: the underlying relation between the verb and each of its complements is essentially identical. Thus, in example 8, the complement to the verb *believe* in all three sentences is a proposition; in example 6, what is begun in each sentence is an event of some sort; and in example 7, the object of the perception is (arguably) an event in each case. This observation has led some linguists to argue for semantic selection and others to argue for structured selectional inheritance. In fact, these perspectives are not very distant from one another (Pustejovsky, 1995): on either view, there is an explicit lexical association between syntactic forms which is formally modeled by the grammar.

The second type of polysemy mentioned above (syntactic alternations) involves verbal forms taking arguments in alternating constructions, the so called 'verbal alternations'. These are true instances of polysemy because there is a logical (typically causal) relation between the two senses of the verb. As a result, the lexicon must either relate the senses through lexical rules, as in head-driven phrase structure grammar, or assume that there is one lexical form that has multiple syntactic realizations.

(a) The window opened suddenly.
(b) Mary opened the window suddenly. (9)

(a) Bill began his lecture on time.
(b) The lecture began on time. (10)

(a) The milk spilled onto the table.
(b) Marry spilled the milk onto the table. (11)

The final form of polysemy we will review here is encountered mostly in nominals, and has been termed 'regular polysemy' (Apresjan, 1973) and 'logical polysemy' (Pustejovsky, 1991) in the literature. It is illustrated in the sentences below.

(a) Mary carried the book home.
(b) Mary doesn't agree with the book. (12)

(a) Mary has her lunch in her backpack.
(b) Lunch was longer today than it was yesterday. (13)

(a) The flight lasted three hours.
(b) The flight landed on time in Los Angeles. (14)

Notice that in each of the pairs above, the same nominal form is assuming different semantic interpretations relative to its selective context. For example, in sentence 12(a) the noun *book* refers to a physical object, while in sentence 12(b) it refers to the informational content. In sentence 13(a), *lunch* refers to the physical manifestation of the food, while in sentence 13(b) it refers to the eating event. In sentence 14(a), *flight* refers to the flying event, while in sentence 14(b) it refers to the plane. This phenomenon of polysemy is one of the most challenging in the area, and has stimulated much research recently. In order to understand how each of these cases of polysemy can be handled, we must first familiarize ourselves with the structure of individual lexical entries.

BASIC PROPERTIES OF A LEXICAL ENTRY

As stated above, it is generally assumed that there are four components to a lexical item: phonological, orthographic, syntactic, and semantic information. We now focus on what syntactic and semantic information must be encoded in an individual lexical entry.

There are two types of syntactic knowledge associated with a lexical item: its 'category' and its 'subcategory'. The former includes traditional classifications of both the major categories (such as nouns, verbs, adjectives, adverbs, and prepositions) and the minor categories (such as adverbs, conjunctions, quantifier elements, and determiners). Knowledge of the subcategory of a lexical item is typically information that differentiates categories into distinct, distributional classes. This sort of information may be usefully separated into two types: 'contextual features' and 'inherent features'. The former are features that may be defined in terms of the contexts in which a given lexical entry may occur. Subcategorization information marks the local syntactic context for a word. It is this information that ensures that the verb *devour*, for example, is always transitive in English, requiring a direct object; the lexical entry encodes this requirement with a subcategorization feature specifying that an NP appear to its right. Another type of context encoding is collocational information, where patterns that are not fully productive in the grammar can be tagged. For example, the adjective *heavy* as applied to *drinker* and *smoker* is collocational and not freely productive in the language (Mel'čuk, 1988). 'Inherent features', on the other hand, are properties of lexical entries that are not easily reduced to a contextual definition, but rather refer to the ontological typing of an entity. These include such features as count versus mass (e.g. *pebble* versus *water*), abstract, animate, human, physical, and so on.

Semantic, information can also be separated into two categories: 'base semantic typing' and 'selectional typing'. While the former identifies the semantic class that a lexical item belongs to (such as entity, event, or property), the latter specifies the semantic features of arguments and adjuncts to the lexical item. We turn first to semantic typing. (*See* **Lexical Semantics**)

Word Classes and Types

Lexical items can be systematically grouped according to their syntactic or semantic behavior in the language. There have thus been two major traditions of word clustering. Broadly speaking, for those concerned mainly with grammatical behavior, the most salient aspect of a lexical item is its argument structure; for those concerned with a word's entailment properties, the most important aspect is its semantic class. We will examine these two approaches and see how their concerns can be integrated into a common lexical representation.

Conventional approaches to lexicon design and lexicography are relatively informal regarding the taxonomic structures for the word senses in the language. For example, the top concepts in Word Net illustrate how words are characterized by local clusterings of semantic properties. As with many ontologies, however, it is hard to discern a coherent

global structure for the resulting classification beyond a weak descriptive labeling of words into extensionally defined sets.

One of the most common ways to organize lexical knowledge is by means of type or feature inheritance mechanisms (Pollard and Sag, 1994). Furthermore, Briscoe *et al*. (1993) describe a rich system of types for allowing default mechanisms into lexical type descriptions. Similarly, type structures can express the inheritance of syntactic and semantic features, as well as the relationship between syntactic classes and alternations (Sanfilippo, 1993; Davis, 1996; Alsina, 1992) and other relations (Pustejovsky and Boguraev, 1993). (*See* Figure 1.)

Next, we will examine the approach to characterizing the weak constraints imposed on a lexical item according to its arguments. Then, we will examine attempts to model lexical behavior by means of internal constraints imposed on the predicate itself. Finally, we will show how, in some respects, these are very similar enterprises, and how both sets of constraints may be necessary to model lexical behavior.

Argument Structure

Once the base syntactic and semantic typing for a lexical item has been specified, its subcategorization and selectional information must be encoded in some form. There are two major techniques for representing this type of knowledge:

- Associate 'named roles' with the arguments to the lexical item (Jackendoff, 1972).

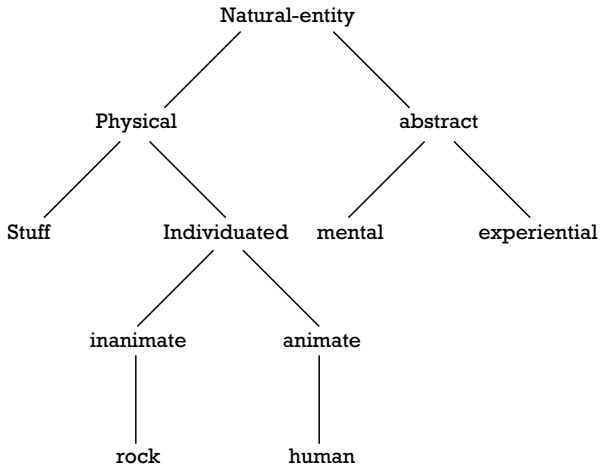

Figure 1. Inheritance of features between types of natural entity.

- Associate a logical decomposition with the lexical item. Meanings of arguments are determined by how the structural properties of the representation are interpreted (Hale and Keyser, 1993; Levin and Rappaport Hovav, 1995).

One influential way of encoding selectional behavior has been the theory of 'thematic relations' (Gruber, 1976; Jackendoff, 1972). Thematic relations are now generally defined as partial semantic functions of the event being denoted by the verb or noun, and behave according to a predefined calculus of role relations. For example, semantic roles such as agent, theme, and goal, can be used to partially determine the meaning of a predicate, when they are associated with the grammatical arguments to a verb.

(a) put < AGENT, THEME, LOCATION >
(b) borrow < RECIPIENT, THEME, SOURCE >
(15)

Thematic roles can be ordered relative to each other in terms of an implicational hierarchy. Universal subject hierarchies such as shown below are often used.

AGENT > RECIPIENT/BENEFACTIVE > THEME/PATIENT > INSTRUMENT > LOCATION (16)

Many linguists have questioned the general explanatory coverage of thematic roles, however, and have have chosen alternative methods for capturing the generalizations they promised. Dowty suggests that theta-role generalizations are best captured by entailments associated with the predicate itself. A theta-role can then be seen as the set of predicate entailments that are properties of a particular argument to the verb. Characteristic entailments might be thought of as prototype roles, or '*proto-roles*'; this allows for degrees or shades of meaning associated with the arguments to a predicate. Others have opted for a more semantically neutral set of labels to assign to the parameters of a relation, whether it is realized as a verb, noun, or adjective. For example, the theory of argument structure as developed by Williams (1981), Grimshaw (1990), and others can be seen as a move towards a more minimalist description of semantic differentiation in the verb's list of parameters. The argument structure for a word can be seen as the simplest specification of its semantics, indicating the number and type of parameters associated with the lexical item as a predicate. For example, the verb *die* can be represented as a predicate taking one argument, *kill* as taking two arguments, and *give* as taking three arguments:

(a) die($\underline{x}$)
(b) kill($\underline{x}, y$)
(c) give($\underline{x}, y, z$) (17)

What began as the simple listing of the parameters or arguments associated with a predicate has developed into a sophisticated view of the way arguments are mapped onto syntactic expressions. Williams's (1981) distinction between 'external' arguments (the underlined arguments above) and 'internal' arguments, and Grimshaw's (1990) proposal for a hierarchically structured representation, provide us with the basic syntax for one aspect of a word's meaning. Similar remarks hold for the argument list structure in head-driven phrase structure grammar (Pollard and Sag, 1994) and lexical-functional grammar.

The interaction of a structured argument list and a rich system of types, such as that presented above, provides a mechanism for semantic selection through inheritance. Consider, for instance the sentence pairs below:

(a) The man/the rock fell.
(b) The man/*the rock died. (18)

Now consider how the selectional distinction for a feature such as animacy is modeled so as to explain the selectional constraints of predicates. For the purpose of illustration, the arguments of a verb will be identified as being typed from the system shown above.

(a) λx[fall($\underline{x}$: physical)]
(b) λx[die($\underline{x}$: animate)] (19)

In example 18, it is clear how rocks cannot die and men can, but it is not obvious how this judgment is computed, given what we would assume are the types associated with the nouns *rock* and *man*, respectively. What accomplishes this computation is a rule of subtyping, Θ, that allows the type associated with the noun *man* (i.e. human) to also be accepted as the type animate, which is what the predicate *die* requires of its argument as stated in equation 19(b).

$$\Theta[\texttt{human} \sqsubseteq \texttt{animate}] : \texttt{human} \rightarrow \texttt{animate} \quad (20)$$

The rule Θ applies since the concept human is subtyped under animate in the type hierarchy. Parallel considerations rule out the noun *rock* as a legitimate argument to *die* since it is not subtyped under animate. One of the concerns mentioned above about how syntactic processes can systematically keep track of which 'selectional features' are entailed and which are not is partially addressed by such lattice-traversal rules as the one presented here.

Event Structure and Lexical Decomposition

The second approach to lexical specification mentioned above is to define constraints internally to the predicate itself. This is commonly called 'lexical decomposition'. We will now review the motivations for decomposition in linguistic theory, and the proposals for encoding lexical knowledge as structured objects. We will then relate this to the way in which verbs can be decomposed in terms of eventualities.

Since the 1960s, lexical semanticists have attempted to formally model the semantic relations between lexical items, such as those between the adjective *dead* and the verbs *die* and *kill* in the sentences below (McCawley, 1968).

(a) John killed Bill.
(b) Bill died.
(c) Bill is dead. (21)

Assuming that the underlying form for a verb like *kill* directly encodes the stative predicate in sentence 21(c) and the relation of causation, generative semanticists have posited representations such as:

$$\text{CAUSE } (x, (\text{BECOME } (\text{NOT } (\text{ALIVE } y)))) \quad (22)$$

Here the predicate CAUSE is represented as a relation between an individual causer x and an expression involving a change of state in the argument y. Carter proposes a similar representation shown here for the causative verb *darken*:

$$x \text{ CAUSE } (\ (y \text{ BE DARK}) \text{ CHANGE}) \quad (23)$$

Although there is an intuition that the cause relation involves a causer and an event, neither Lakoff nor Carter make this commitment explicitly. In fact, it has taken several decades for Davidson's observations regarding the role of events in the determination of verb meaning to find their way convincingly into the major linguistic frameworks. Recently, a new synthesis has emerged which attempts to model verb meanings as complex predicative structures with rich event structures (Pustejovsky, 1991; Hale and Keyser, 1993). This research has developed the idea that the meaning of a verb can be analyzed into a structured representation of the event that the verb designates, and

has furthermore contributed to the realization that verbs may have complex internal event structures. Recent work has converged on the view that any complex event is structured into an inner and an outer event, where the outer event is associated with causation and agency, and the inner event is associated with telicity (completion) and change of state.

Jackendoff (1990) develops an extensive system of what he calls 'conceptual representations', which parallel the syntactic representations of sentences of natural language. These employ a set of canonical predicates, including CAUSE, GO, TO, and ON, and canonical elements, including Thing, Path and Event. Verb meaning is represented by decomposing the predicate into more basic predicates. This work owes an obvious debt to the innovative work within generative semantics illustrated by McCawley's (1968) analysis of the verb *kill*. Recent versions of lexical representations inspired by generative semantics can be seen in the 'lexical relational structures' of Hale and Keyser (1993), where syntactic tree structures are employed to capture the same elements of causation and change of state as in the representations of Carter, Levin and Rapoport Hovav, Jackendoff, and Dowty. The work of Levin and Rappaport Hovav (1995), building on Jackendoff's lexical conceptual structures, has been influential in further elucidating the internal structure of verb meanings.

Pustejovsky (1991) extends the decompositional approach presented in Dowty (1979) by explicitly reifying the events and sub-events in the predicative expressions. Unlike Dowty's treatment of lexical semantics, where the decompositional calculus builds on propositional or predicative units (as discussed above), a 'syntax of event structure' makes explicit reference to quantified events as part of the word meaning. Pustejovsky further introduces a tree structure to represent the temporal ordering and dominance constraints on an event and its sub-events. For example, a predicate such as *build* is associated with a complex event such as that shown below.

$$[_{\text{TRANSITION}}\ [e_1\text{:PROCESS}]\ [e_2\text{:STATE}]\ ] \qquad (24)$$

The process consists of the building activity itself, while the state represents the result of the object being built. Grimshaw (1990) adopts this theory in her work on argument structure, where complex events such as *break* are given a similar representation. In such structures, the process consists of what *x* does to cause the breaking, and the state is the resultant state of the broken item. The process corresponds to the outer causing event, as discussed above, and the state corresponds in part to the inner change-of-state event. Both Pustejovsky and Grimshaw differ from other authors in assuming a specific level of representation for event structure, distinct from the representation of other lexical properties. Furthermore, they follow Higginbotham in adopting an explicit reference to the event place in the verbal semantics.

Recently, Levin and Rappaport Hovov have adopted a large component of the event-structure model for their analysis of the resultative construction in English. Event decomposition has also been applied to properties of adjectival selection, the interpretation of compounds, and stage-and individual-level predication.

Qualia Structure

Thus far, we have focused on the lexical information associated with verb entries. All of the major categories, however, are encoded with syntactic and semantic feature structures that determine their constructional behavior and subsequent meaning at logical form. In 'generative lexicon theory' (Pustejovsky, 1995), it is assumed that word meaning is structured on the basis of four generative factors, or 'qualia roles', that capture how humans understand objects and relations in the world and provide the minimal explanation for the linguistic behavior of lexical items. (These are inspired in large part by Moravcsik's interpretation of Aristotelian *aitia*.) These are: the FORMAL role (the basic category that distinguishes the object within a larger domain); the CONSTITUTIVE role (the relation between an object and its constitutent parts); the TELIC role (its purpose and function); and the AGENTIVE role (factors involved in the object's origin or 'coming into being'). Qualia structure is at the core of the generative properties of the lexicon, since it provides a general strategy for creating new types. For example, consider the properties of nouns such as *rock* and *chair*. These nouns can be distinguished on the basis of semantic criteria, which classify them in terms of general categories such as `natural_kind` and `artifact_object`. Although very useful, this is not sufficient to discriminate semantic types in a way that also accounts for their grammatical behavior. A crucial distinction between *rock* and *chair* concerns the properties which differentiate *natural kinds* from artifacts: functionality plays a crucial role in the process of individuation of artifacts, but not of natural kinds. This is reflected in grammatical behavior, whereby *a good chair* and *enjoy the chair* are well-formed expressions reflecting the

specific purpose for which an artifact is designed, but *good rock* or *enjoy a rock* are semantically ill-formed since for *rock* the functionality (i.e. TELIC) is undefined. Exceptions arise when new concepts are referred to, for example when the object is construed relative to a specific activity, as in '*the climber enjoyed that rock*': *rock* itself takes on a new meaning, by virtue of having telicity associated with it, and this is accomplished by integration with the semantics of the subject NP. Although *chair* and *rock* are both physical_object, they differ in their mode of coming into being (i.e. AGENTIVE): artifacts are man-made, while rocks develop in nature. Similarly, a concept such as 'food' or 'cookie' has a physical manifestation or denotation, but also a functional grounding, pertaining to the relation of 'eating'. These apparently contradictory aspects of a category are orthogonally represented by the qualia structure for that concept, which provides a coherent structuring for different dimensions of meaning.

GLOBAL LEXICAL DESIGN

The view of what computational resources are available to the mental lexicon has changed significantly in recent years. It is now believed that lexical storage and access capabilities are considerably higher than originally imagined by early grammatical theorists. It now seems that combinatorial aspects of grammar that could once only be accounted for by phrase-structure rules and transformations can be handled (in part) by the lexicon directly. This has been a general trend in the generative tradition. The various approaches to lexical encoding can be analyzed using two strategies: precompiling the information into lexical items or forms; and computing or generating new forms or senses during the compositional process. As discussed above, idioms are examples of multiple words of possibly diverse lexical categories behaving as one lexical unit. They thus lend themselves to the first strategy above. Perhaps an even better example of precompiled lexical entries might be noun–noun compounds in English: *pencil sharpener* and *coffee cup* are arguably compositional in nature, but there is enough semantic drift in each form to merit consideration as precompiled lexical entries (Choueka, 1988).

Some linguistic frameworks have adopted this idea as fundamental for the entire compositional operation. The best example of this is CCG. CCG has recently been articulated in enough detail to handle most of the major linguistic phenomena using a library of precompiled lexical types, together with the combinatoric rules of categorial syntax. If the grammar utilizes representations with such nonlocal dependencies, then there must be additional mechanisms for unifying these representations; these are provided in the form of function composition rules and lexical rules.

Lexical rules have also been invoked in head-driven phrase structure grammar to explain the relationship between the various senses for lexical items, from grinding and packaging operations (such as that relating the animal and food senses of *chicken* and *lamb*), to the relation between logically polysemous items, such as *book* and *lecture*, as discussed above. In generative lexicon theory such relations are represented explicitly in the type itself, by means of a typing construction, called 'dot objects', and are disambiguated in context (Johnston, 1995). It is very likely, however, that language makes use of both types of devices: namely, complex types, such as dot objects, and lexical rules. In any case, both types of devices must be seriously constrained by the grammar in order not to overgenerate forms and interpretations.

Independently of the issue of precompiled versus generated forms and senses, there is no question that the mental lexicon is large, containing arguably as many as 350 000 lexical entries. This figure is based on fairly conservative estimates of speaker competence with active and passive vocabularies. For example, an average speaker lexicon might contain 5 000 distinct verbs, 30 000 distinct nominal forms, and 5 000 adjectives. Combine this with an additional 10 000 compound forms and 300 000 distinct proper names. Obviously, the psychological (and hence computational) demands of these classes are quite distinct. There are two parameters that can help us distinguish these classes: the degree of combinatoric (functional) complexity of the lexical item; and whether the lexical item is part of active or passive lexical knowledge. Most closed-class items, for example, are functionally complex, as are many open-class verbs and relational nouns. The majority of the open-class items will also involve a fair amount of information regarding combinatoric possibilities. However, the class of names, although it is by far the largest class of lexical items, is the least demanding in terms of computational resources.

We should view the lexicon neither as a listing of the morphemes in the language, nor as a passive database of items used in other grammatical processes. The lexicon is a dynamic module of grammar, incorporating as well as dictating essential components of syntactic and semantic composition and interpretation. Furthermore, it acts as the

interface to deeper and wider aspects of inference and reasoning.

Linguistic Evidence, Status of

Intermediate article

Carson T Schütze, University of California, Los Angeles, California, USA

CONTENTS

Linguistics concerns itself in principle with any kind of evidence that seems capable of informing us about the human language faculty, though individual researchers may find certain kinds of evidence more fruitful for their goals than others. A survey of the major sources of evidence used by linguists leads to an assessment of their relative merits and consideration of the kinds of explanations of linguistic phenomena this evidence can lead to.

INTRODUCTION

The evidence used by linguists can be roughly divided into three categories: language data that exist independent of the linguist's desire to study then (corpora); language behavior induced with the specific intent of studying knowledge of language (behavioral experiments); and unconscious reflections of linguistic knowledge or processes (brain measures). Within the second category there is in practice a dichotomy between grammaticality judgments, which constitute the everyday staple of data, and controlled experimentation in the psychological tradition. Since no single kind of evidence is ideal in all respects, an efficacious approach to linguistic investigation is to seek convergence from a wide array of techniques. The discussion that follows chiefly concerns evidence relevant to theories of linguistic competence rather than, for example, evidence concerning how people parse sentences. Points are illustrated mainly with examples from syntax, but most can be easily translated to other levels (e.g. phonology, morphology, semantics, pragmatics). (*See* **Syntax**; **Phonology**; **Morphology**; **Categorial Grammar and Formal Semantics**; **Pragmatics, Formal**)

Any discussion on the status of linguistic evidence would be incomplete without noting that much of it is disappearing: at least 20 per cent and perhaps as many as 50 per cent of the languages spoken in the world as of the year 2000 are not being learned by children and will thus cease to be spoken at all by 2100, unless dramatic changes occur (Krauss, 1996). This state of affairs has led to the suggestion that the field of linguistics should devote greater attention to documenting and helping to preserve endangered languages. This undertaking typically includes fieldwork with native speakers, for instance by elicitation, a specialized interview-style technique (e.g. Munro, 2000).

CORPUS DATA

Corpus data can be characterized as (a collection of) pre-existing samples of language, that is, language that was (or could have been) originally produced for some purpose other than directly answering linguists' questions.

Benefits

Corpus evidence has the following benefits. The contents of corpora cannot have been biased by the researcher. They may bring to our attention phenomena that would not otherwise have come to mind as relevant. Because they typically contain extended passages of continuous language, they allow for study of phenomena not testable in sentences in isolation, for example, how referents are identified throughout a narrative or discourse. They include records of languages no longer spoken. The ability to search and calculate statistics by computer makes detailed quantitative analysis possible. (Ideally, one would like to search both for strings of words and for particular structural configurations of phrase types; this is beginning to be possible.) Finally, they may provide samples of language as produced when the speaker/writer was not consciously reflecting on the form of the utterance. This last point is nontrivial: Labov (1975) has documented that speakers who denied that they would ever produce a given construction

went on to do so spontaneously during the very same interview.

Increasingly, corpus data are being used to show that constructions that tend to sound artificial and awkward when presented as examples in linguistics articles nonetheless occur and sound natural in everyday language situations. A further advantage to corpora of spontaneous language use is reflected particularly in studies of acquisition and speech production: one can find 'errors' in such corpora, whether they be systematic productions by children that are not possible for adult speakers, or spontaneous speech errors (slips of the tongue). (*See* **Discourse Processing**; **Statistical Methods**; **Syntactic Form Frequency: Assessing**; **Language Acquisition**; **Speech Production**)

Drawbacks

There are concomitantly certain limitations to corpus data. Most importantly, the absence of some phenomenon from a corpus is hard to interpret – its nonoccurrence may have been accidental or systematic. There is thus an asymmetry in corpus findings. The presence of some phenomenon indicates that it is part of the language, at least for one speaker/writer (although there is no standard for how frequently a structure must occur before it is considered attested), and this can be a valuable tool in theorizing: if one finds in real text systematic violations of, say, island constraints, this could demand some change in the theory. On the other hand, if one wishes to confirm the impossibility of some structure, failure to find that structure in a corpus constitutes only weak evidence for ungrammaticality, even if one can argue that sufficient opportunities arose for it to appear. Additional difficulties arise in interpreting written corpora. In the composing or editing of text it is possible to make piecemeal alterations to a sentence without being forced to re-read it to verify that it still hangs together as intended (as well as, of course, making typos). Editing may also introduce structures that would not be producible in real time, such as complex embeddings (cf. sentence (4) below), and especially in old texts we must allow for the possibility that systematic 'corrections' and random errors may have been introduced during reproduction. (*See* **Constraints on Movement**)

GRAMMATICALITY JUDGMENTS

So-called grammaticality judgments involve explicitly asking speakers whether some particular string of words is a possible utterance of their language, with an intended interpretation either implied or explicitly stated. The term is misleading in at least two respects (Schütze, 1996). First, since a grammar is a mental construct not accessible to conscious awareness (or a formal model of that construct), speakers cannot have any intuitions about the status of a sentence with respect to that grammar; rather, in Chomsky's (1965) terms one might say their intuitions are about acceptability. Second, they are not judgments, inasmuch as they need not involve the speaker reasoning consciously about an appropriate answer (as opposed to, say, judging whether a defendant is guilty of some crime). Thus, a more accurate and less loaded term might be 'acceptability reactions', but for familiarity's sake I continue to use the traditional label. Grammaticality judgments are potentially the richest sort of information about knowledge of language, but at the same time they are the kind most susceptible to distortion.

A simple judgment that a string is a possible sentence, with no mention of what it would mean, is virtually worthless. For this reason, whenever there could be confusion, the presentation of judgment data typically includes an indication of crucial interpretive features, for example the use of subscripts to indicate intended co-reference relationships in (1):

$$\text{John}_i \text{ believes himself}_i \text{ to be in danger.} \qquad (1)$$

In the general case it can also be important to know what prosody the utterance is meant to have, and possibly the linguistic or situational context; both of these considerations are especially important in judging topic and focus structures, for example. (It is sometimes claimed that syntactic well-formedness can be judged without one being able to identify what a sentence means, as in Chomsky's celebrated example 'Colorless green ideas sleep furiously', or Lewis Carroll's poem *Jabberwocky*. This claim is misleading, however. One actually knows perfectly well what the sentences *should* mean; in the former case, some nonliteral interpretations of content words are required for the meaning to be coherent, and in the latter case one would be able to determine the meaning of the sentence upon receiving the meanings of the nonsense content words.) (*See* **Anaphora**; **Prosody**)

Benefits

Grammaticality judgments have the following benefits. They provide evidence about the status of phenomena that occur so rarely in spontaneous

language use that we could not learn about them from studying corpora; in particular, they distinguish possible from impossible utterances among those that have never been naturally produced. Establishing which utterances are impossible has become increasingly important as the development of restrictive theories of possible human languages has become a priority, along with the observation that language learners apparently do not receive systematic negative evidence, so that their knowledge of what is impossible demands nontrivial explanation. The opposite situation also arises: rare and scattered attestations of some structure could be artefacts of the production situation and might not be felt to be appropriate upon reflection, even by the very speaker who produced them. Grammaticality judgments sometimes demonstrate knowledge of language in speakers whose behavior on other tasks does not evince the same degree of knowledge (e.g. Linebarger *et al*., 1983); this has also been observed anecdotally in the fact that children will sometimes reject an adult's faithful repetition of an utterance they have just produced, apparently realizing that their own productions are not hitting the intended target (e.g. Berko and Brown, 1960).

Drawbacks

Turning to drawbacks of grammaticality judgment data, the most systematic source of confusion is the semantic content of a sentence – it can be difficult to separate a well-formed expression of incoherent content from an ungrammatical sentence. Young children often respond to truth-value when asked to judge well-formedness (e.g. Hakes, 1980). Another common source is parseability: it can be hard to distinguish parsing difficulty from grammatical ill-formedness, for example, for clausal embeddings like that in (2), claimed to be strictly ungrammatical by Koster (1978) but possible by Delahunty (1983):

If [that John likes Mary] surprises you, you obviously haven't been paying much attention. (2)

An example of the opposite kind, where the parser seems to make a structure spuriously sound grammatical, is the comparison between (3) and (4):

The patient that the nurse the clinic had hired met Jack. (3)

The patient that the nurse the clinic had hired admitted met Jack. (4)

Sentence (3) often seems grammatical when considered next to (4), although in fact only (4) is well formed (Frazier, 1985, attributed to Janet Fodor). An example whose explanation is less obvious is (5):

More people have been to Russia than I have. (5)

Sentence (5) often sounds fine on initial presentation, a feeling that changes after it is pointed out that this sentence has no possible meaning.

Although there are strings of words that seem unequivocally completely well formed (e.g. 'Mary saw John') and strings that seem completely ill formed (e.g. 'Fred the the this'), most strings of theoretical interest lie in a vast gray area in between these two extremes. This means that theories are necessarily concerned with distinctions among strings in the gray area; for this reason, simply eliciting yes/no grammaticality judgments is of limited use. Two solutions are to elicit responses on a multi-valued scale (e.g. 1–7, as is typical in psychology), or to elicit relative judgments that compare minimal pairs of sentences. The notation used to indicate the status of sentences has evolved to allow numerous gradations of well-formedness to be indicated, but it should be kept in mind that even so, the *relative* status of examples is primarily what matters; the same notation does not always convey the same absolute level of well-formedness. The most common symbolization, marked at the beginning of a sentence, is as follows, from most to least well formed: unmarked, (?), ?, ??, ?*, *, **. These symbols are combined in a nonobvious way with the use of parentheses to indicate optionality: symbols inside parentheses mark the status of a sentence with the optional element present, as in (6), while symbols immediately preceding a parenthesis indicate the status of omitting the parenthesized element, as in (7):

This sentence (*might) has a problem with verbs. (6)

This sentence requires *(a) determiner. (7)

A possible objection to the use of grammaticality judgments that has often been raised is that their metalinguistic nature makes them artificial and hence undermines their external validity; they may, the objection goes, have little to do with how people actually use language. One response is to suggest that similar metalinguistic behaviors are part of everyday language use, for instance, in forming opinions about people based on how they

talk. Another response is simply to note that to the extent that grammaticality judgment data are systematic, it is highly unlikely that their underlying cognitive source would be something unrelated to grammar – the existence of a separate system that duplicates many aspects of language use but is invoked only for metalinguistic judgment seems highly improbable.

Because there are many ways in which one's judgments can be misled, the question has arisen whether it is possible to obtain useful judgments on subtle issues from naive speakers with no linguistic training. In some cases it is difficult to replicate relatively agreed-upon judgments of linguists while testing naive subjects (e.g. Gordon and Hendrick, 1997). Partly for this reason, and partly for sheer convenience, linguists rely increasingly on other linguists for judgment data on some languages. It is not clear whether data obtained from linguists should be taken as in any way more desirable (cf. Spencer, 1973). Valian (1982) makes a case in favor of using such 'expert' judgments, based on analogy to another domain: she notes that wine tasting, for example, relies on the acquired ability to detect subtle distinctions that inexperienced wine drinkers simply cannot make. One practice that is clearly undesirable, however, is for investigators to use their own judgments as the primary basis for theorizing. There is no reason to believe that people with a stake in the outcome of such judgments can remain unaffected by their theoretical stance.

Interpretation of Judgment Data

Some researchers have raised the possibility that gradience in our judgments of sentences implies that grammar itself does not make categorical distinctions between the possible and the impossible. This does not follow, however. For one thing, we know that humans can give systematic gradient judgments about virtually any phenomenon, including ones such as *even number* whose only meaning is formally defined as categorical (Armstrong *et al*., 1983; Barsalou, 1987). This observation does not entail that our knowledge of mathematics fails to make a perfectly sharp distinction between even and odd numbers. Rather, our judgments can evidently be sensitive to factors other than our underlying competence. Moreover, even within the grammar it is possible that numerous separate components are implicated in the structuring and interpretation of a sentence (e.g. the modules of Government–Binding theory); one might expect that a violation in any single component should lead to a lesser degree of overall deviance than violations at multiple levels. (*See* **Government–Binding Theory**)

The nature of grammaticality judgments has sometimes been characterized with reference to traditions in psychology that might lead one to worry about the wisdom of using them as evidence in linguistics: they have been described as 'introspective' judgments or 'intuitions', but neither of these terms applies accurately (Carr, 1990; Schütze, 1996). They have more in common with the responses in psychophysics experiments, having the character of sensations, reactions to stimuli, or reports about mental states. There is also no basis for the occasionally encountered view that grammaticality judgments are somehow related to competence while spontaneous production and comprehension data are related to performance; all are behaviors, hence performance data, but all can in principle bear on competence. (*See* **Introspection**; **Performance and Competence**)

EXPERIMENTAL DATA

It has sometimes been suggested that claims made exclusively on the basis of grammaticality judgment data do not necessarily bear on how the human language faculty is actually constructed unless their 'psychological reality' has been tested by means of some other sort of data, typically a formal experiment. This view belies a misunderstanding: grammaticality judgments are, as noted above, themselves data about human behavior that need to be accounted for; they are not intrinsically less informative than, say, reaction-time measures (one might argue that they are more informative). The elicitation of grammaticality judgments is itself a behavioral experiment on a speaker, albeit one whose generally casual nature may leave it susceptible to certain kinds of misinterpretation. (These can be due, for example, to the limited number of types and tokens of items tested, the small number of participants questioned, lack of randomized order of presentation, etc.)

Behavioral Measures

The most direct behavioral experiment one can conduct to assess the status of sentences is essentially a more rigorous version of grammaticality judgment collection, typically carried out using a written questionnaire with a multi-valued response scale. A special variant is the speeded grammaticality judgment task, which requires participants to

respond with a yes/no button-press decision within a very short time, and is thereby intended to get at their earliest reactions. (The appropriateness of this task for assessing grammar is debatable; however, it can be useful in the study of sentence processing.) Beyond this and similar types of experiments that ask participants for their reactions to sentences directly, a large variety of experimental paradigms used in psychology can be employed to assess participants' knowledge of language in more indirect ways. These generally involve a trade-off between reducing the influence of conscious reflection about language and making response measures more difficult to interpret *vis-à-vis* linguistic competence. (*See* **Sentence Processing**)

Brain Measures

Recent years have shown the promise that we might learn about details of linguistic knowledge by direct measurements from the brain, in some cases bypassing the need for participants to perform any task other than simply comprehending or producing language. Techniques used in this way have included event-related potentials (ERP), functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and magnetoencephalography (MEG). The trade-off for not requiring conscious attention to an additional task is, of course, the difficulty of interpreting results of such experiments. Even a relatively fine-grained characterization of which parts of the brain are involved in processing certain aspects of linguistic stimuli is not terribly helpful for uncovering the particulars of linguistic competence. Dissociations of the sort obtained from lesion studies can be informative with respect to the architecture of the grammar, but are not especially so with respect to its contents. More provocative have been suggestions (mostly in the ERP literature) that the grammaticality status of certain classes of utterance types might be reflected in characteristic patterns of activity (e.g. Neville *et al*., 1991). For example, it has been claimed that syntactic versus semantic anomalies have distinct signatures, and that violations of different grammatical constraints pattern differently. Interpretation of these claims is still open to debate, however, in that it is not established whether a full range of superficially diverse sentence types that by hypothesis share a common grammatical property (e.g. violating Subjacency) have a detectable commonality in brain signals; if it turns out that each kind of ungrammaticality produces a different ERP pattern, the value of these methods for theoretical purposes may be limited. (*See* **Neuroimaging**; **Syntax and Semantics, Neural Basis of**; **Constraints on Movement**)

NATURE OF EXPLANATION IN LINGUISTIC THEORY

A central goal in linguistic theory is to explain numerous disparate language phenomena using as few grammatical principles as possible, and in turn to seek to ground the grammar in terms of properties of the mind/brain.

Phenomena To Be Explained

Linguistics as a whole seeks to explain much more than simply adult linguistic competence, though this remains the focus of a large amount of research. Increasingly, additional phenomena are part of the enterprise, as potential sources of evidence about the nature of linguistic knowledge and as phenomena that theories of grammar could in turn be used to help explain. The aforementioned three kinds of data sources (corpora, judgments, and experiments) largely cross-cut these areas of investigation. The kinds of behaviors studied include first and second language acquisition, the typology of existing and nonexisting languages, patterns of historical change and creolization, multilingualism and intrasentential code-switching, language disorders in adults and children, and speech errors. Each of these has been hypothesized to be characterizable to some degree by grammar. (*See* **Language Acquisition**; **Second Language Acquisition**; **Typology**; **Language Disorders**; **Speech Error Models of Language Production**)

Kinds of Explanations

There are essentially two kinds of answers to the question of why human languages are the way they are: (1) given other facts about the nature of human beings, they could not be any other way; and (2) they are accidents of history that could just as easily have come out some other way. Most likely, each of these answers is correct for some aspects of language, but we have little idea which ones are which.

Learning- and processing-based explanations

The possible human languages may be constrained by limits on the procedure by which language is acquired – that is, some hypothetically possible languages fail ever to come to be spoken because

a child would never reach them as the target of acquisition (even if such a language were being spoken around the child), because the finite amount of evidence available to the child would be consistent with other, less marked grammars, or because the acquisition system affords no learning path that would reach the target. The nonoccurrence of other types of languages may be explained because those languages would not be processable to a degree sufficient to express common ideas. Lack of processability might in turn be explained either by the inherent architecture of the parsing mechanism or by other (not purely linguistic) cognitive limits such as the capacity of short-term memory. Results from theories of computation and learnability are thus relevant to determining the form of human linguistic knowledge. If we can formally prove that a system lacking property X would be unlearnable, not parseable in reasonable time, etc., then human language must have X (e.g. Wexler and Culicover, 1980; Berwick and Weinberg, 1984). (*See* **Sentence Processing: Mechanisms**; **Sentence Comprehension, Linguistic Complexity in**; **Computability and Computational Complexity**)

Historical and biological accidents

There are certainly properties of particular languages whose only explanation lies in the course of human history; for example, the fact that English has a huge Latinate vocabulary with distinctive properties is traceable to the Norman conquest. But many linguists believe that there are limits on what a language *could be* like, regardless of the course of human events, limits not of the sort discussed in the previous paragraph, but rather, strictly properties of the language competence system, imposed by human biology in its determination of brain structure, often referred to as Universal Grammar (UG). In what sense can we explain facts about languages by hypothesizing that they are properties of UG? The utility of appeals to UG would seem to depend on a notion that some kinds of properties are of the right character (say, being constructed from sufficiently simple primitives) to plausibly be part of the human innate genetic endowment. Unfortunately, we have almost no idea yet what this character really is, so for now, successful explanations in linguistics mostly involve reduction of numerous, superficially unrelated facts within and across languages to fewer principles that are consistent with what is known about all languages. (*See* **Innateness and Universal Grammar**)

Even more speculatively, we might seek to explain why the genetic underpinning of UG is the way it is. While having a system of communication obviously has evolutionary benefits, many of the details of how human language works do not seem to carry adaptive advantages. For this reason some researchers suspect that UG has 'piggy-backed' on other systems, where the counterparts of these properties might have made a difference. There remains the possibility that some aspects of UG are the result of random evolutionary events that played no role in natural selection, in which case they might have no explanation in any interesting sense.

Individual Differences

In addition to explaining what is apparently common to every human's language faculty, a problem linguists face every day is how to explain apparently conflicting evidence about grammars, most commonly, situations where different speakers of 'the same language' or even 'the same dialect' report different grammaticality judgments for identical stimuli. On the one hand, from a cognitive perspective we are investigating what is in the mind/brain of each individual (I-language), rather than some purported object out in the world called a language (E-language), so there would be no contradiction in finding that no two speakers have identical grammars. In this sense, *idiolects* are expected to exist.

On the other hand, it is worrying if too many such differences are found, because it might be a sign that the judgments are reflecting, in heterogeneous ways, individual differences *outside* the grammar. The conundrum arises because any data collected from a single individual are liable to random interference or misinterpretation; the best way to eliminate such complications is to consider multiple speakers and hope for convergence. Still, an important emerging finding stressed by Cowart (1997) is that while individuals may differ widely in how they use any given response scale, so that a particular sentence might be rated 5/7 by one participant and 3/7 by another, for instance, there is much less individual variation in the *patterns* of responses, that is, how sentences rate relative to one another. This is the reason why linguists are primarily concerned with contrasts, say between a sentence marked '??' and one marked '*', but not about how good or bad '??' really is in any absolute sense. The more we learn based on patterns agreed upon by substantial numbers of speakers, the more

we may hope to understand what is and is not plausibly a locus of cross-speaker grammatical variation, and therefore to become more secure in our interpretation of individual differences. (*See* **Individual Differences**)

Local Dependencies and Word-order Variation

Intermediate article

Gereon Müller, Institut für Deutsche Sprache, Mannheim, Germany

CONTENTS

Certain syntactic displacement operations target clause-internal positions. These movement types are typically clause-bound, and they are responsible for word order variation within and across languages.

INTRODUCTION

Certain syntactic displacement operations target clause-internal (IP-internal, where IP = inflection phrase) positions; among them are noun phrase (NP)-movement, scrambling, pronoun movement, and extraposition. A conspicuous common property of these movement types is that they are clause-bound: they cannot cross a complementizer phrase (CP) and target an IP-internal position in a higher clause. Because of this strict locality property, it is more difficult to establish the existence of a syntactic movement operation (and a trace) than in the case of movement types that target IP-external positions and are not clause-bound (such as *wh*-movement to SpecC). Accordingly, analyses that do without syntactic displacement have been proposed for all local dependencies addressed below (see, e.g., Williams (1994) on NP-movement, Fanselow (2001) on scrambling, and Culicover and Rochemont (1990) on extraposition). In what follows, a movement analysis will nevertheless be presupposed throughout – first, because there is a growing body of empirical evidence in support of this view (see the Further Reading); second, because a displacement analysis is forced under a general, conceptually attractive assumption, the *Uniformity of Theta Assignment Hypothesis* (UTAH; Baker, 1988) according to which identical thematic relationships between items must be represented by similar structural relationships between those items at deep structure (D-structure). (*See* **Phrase Structure and X-bar Theory**; **Constraints on Movement**; **Government–Binding Theory**)

NOUN PHRASE MOVEMENT

Passive

The core property of passive constructions is that the external argument of a verb cannot be realized as an NP in the subject position SpecI (specifier of the IP). This argument reduction effect typically goes hand in hand with a morphological reflex (e.g. special passive morphology on the verb, presence of a passive auxiliary). In some languages (e.g. in Ukrainian), this is all there is to say; a remaining internal argument receives objective Case, and SpecI can remain empty. However, in many languages (e.g. in English), argument reduction is accompanied by Case absorption – a passivized verb cannot assign objective Case any more. An internal argument that receives objective Case in active sentences (see (1a)) is moved to the subject position SpecI in passive sentences (see (1b)), where it is assigned nominative Case. This operation is called NP-movement. Chomsky (1981) argues that NP-movement is possible in (1b) because SpecI is not a Theta-position (so that a general ban on movement into Theta-positions is respected); and it is necessary because NP_2 would otherwise violate the Case Filter (that demands that every NP is assigned Case).

a. $[_{IP}$ John$_1$ I$[_{VP}$ kissed Mary$_2]]$
b. $[_{IP}$ Mary$_2$ was$[_{VP}$ kissed $t_2]$ (by John)$]$ (1)

The thematic relations between the two arguments are identical in (1a, b). Hence, the UTAH not only implies that the argument bearing the Theta-role Theme (NP_2) is base-generated in VP in (1b); it also requires a syntactic representation of the argument bearing the Theta-role Agent in this sentence. Proposals as to what acts as the external argument in (1b) include the passive morphology itself, the

by-phrase, and various kinds of empty categories (pro, PRO).

Some languages (e.g. German) behave like Ukrainian in that NP-movement is not required, and like English in that an internal argument is assigned nominative rather than objective Case. The question arises of which Case is absorbed by passivization in double object constructions. In English, it is normally the object Case assigned to the first NP in double object constructions that is absorbed by passivization (see (2a, b)); but there is considerable variation in this domain, and even closely related languages (like Norwegian and German) may behave differently.

a. $[_{IP}$ Mary$_1$ was $[_{VP}$ given t_1 a book$_2$]]
b. $^*[_{IP}$ A book$_2$ was $[_{VP}$ given Mary$_1$ t_2]] (2)

Raising to Subject, Exceptional Case Marking, and Control

NP-movement is also involved in raising constructions like (3).

$[_{IP}$ John$_1$ $[_{VP}$ seems $[_{IP}$ t_1 to be a fool]]] (3)

The matrix predicate *seem* shares two properties with passivized verbs: it does not take an external argument NP, and it does not assign objective Case. Given that the SpecI position of an infinitive is not assigned nominative Case by nonfinite I in English, NP$_1$ in (3) can and must move to the matrix SpecI position, where it is assigned nominative Case by finite I. Raising to subject must be distinguished from two related constructions. *Exceptional Case Marking* (ECM) differs from raising in that the matrix verb takes an external argument (hence, raising is not possible), and in that the matrix verb 'exceptionally' assigns objective Case to an embedded subject that it does not Theta-mark (hence, raising is not required); see (4):

$[_{IP}$ Mary$_2$ $[_{VP}$ believes $[_{IP}$ John$_1$ to be a fool]]] (4)

It seems that a verb's ability to assign objective Case and the presence of an external NP argument go hand in hand; this observation is known as 'Burzio's generalization'.

Raising and ECM constructions have in common that the infinitive is transparent (for movement and Case assignment, respectively). This is often accounted for by assuming that raising and ECM infinitives possess less structure than other clauses: they are bare IPs, not CPs. A CP destroys the transparency of an infinitive, whereas an IP does not. Accordingly, exceptional Case assignment is impossible in *control* constructions like (5) (where the matrix verb takes an external NP argument) if we assume that a CP projection with a phonologically empty complementizer C is present.

$[_{IP}$ Mary$_1$ $[_{VP}$ tries $[_{CP}$ C $[_{IP}$ PRO$_1$ to work hard]]]] (5)

The embedded CP is a *barrier* for exceptional Case assignment. Hence, the subject of the embedded infinitive cannot be realized as an overt NP (which would violate the Case Filter). A possibility that is often entertained is that the infinitive's external argument is nevertheless realized syntactically, albeit as an empty category PRO; PRO is confined to ungoverned positions. (Chomsky (1981) suggests that this can be derived from independent assumptions; hence, the restriction on PRO is sometimes referred to as the *PRO theorem*.)

More on Control

PRO is co-indexed with the matrix subject (which acts as its controller) in (5) and (6a), but depending on lexical and structural factors, PRO may also be co-indexed with a matrix object (as in (6b)), or may receive an arbitrary, generic, or discourse-based interpretation (as in (6c, d)).

a. $[_{IP}$ Mary$_1$ $[_{VP}$ promised John$_2$ $[_{CP}$ C $[_{IP}$ PRO$_{1/*2}$ to leave]]]]
b. $[_{IP}$ Mary$_1$ $[_{VP}$ persuaded John$_2$ $[_{CP}$ C $[_{IP}$ PRO$_{*1/2}$ to leave]]]]
c. $[_{IP}$ $[_{CP}$ C $[_{IP}$ PRO$_x$ To behave oneself in public]] would help John]
d. $[_{IP}$ John$_1$ does not know $[_{CP}$ C $[_{IP}$ how PRO$_x$ to prove the theorem]]] (6)

Examples like (5) and (6a, b) are often said to involve *obligatory control* (OC); examples like (6c, d) show *non-obligatory control* (NOC). It has been argued that the theory of control can be based on the assumption that PRO is an anaphor that obeys an appropriately revised version of principle A of the binding theory (Manzini, 1983; Koster, 1987): PRO must be bound within its binding domain if it has one. The next-higher clause is the binding domain in OC contexts; however, there is no binding domain for a PRO in subject clauses and *wh*-clauses, which are therefore NOC contexts. A complication is that control tends to be even more local than predicted by the binding theory: with the exception of certain verbs like 'promise' (see (6a)), the interpretation of PRO follows a *Minimum Distance Principle* (MDP) according to which PRO picks the minimally c-commanding NP as its antecedent in OC contexts. (*See* **Anaphora**; **Binding Theory**)

Another kind of approach is developed by Hornstein (2001). He argues that the locality of control in OC contexts results from the fact that movement rather than anaphoric binding is involved. Under this view, PRO is a trace of NP-movement, and control and raising are similar after all, the main difference being that movement is to a Theta-position in OC, but not in raising contexts. (Note that this analysis is incompatible with the ban on movement into Theta-positions mentioned above.) MDP effects are traced back to the *Minimal Link Condition* (MLC), which is independently known to restrict movement (Chomsky, 1995). Furthermore, NOC contexts are assumed to involve an empty pronominal (pro) that is inserted as a last resort operation in syntactic environments that block movement.

At present, it is an open question to what extent such structural explanations (based on binding or movement) can succeed in accounting for the varieties of control, and to what extent non-structural properties (such as the thematic properties of matrix predicates) play a role (Culicover and Jackendoff, 2001).

General Properties

NP-movement has several characteristic properties, some of which distinguish it from movement types that target an IP-external position, such as *wh*-movement. First, like *wh*-movement, NP-movement obeys the *Relativized Minimality* constraint (Rizzi, 1990), according to which α-movement must not cross an intervening α-position. Thus, NP-movement must be successive-cyclic if a SpecI position intervenes between the base position and the target SpecI position (see (7a, b)); note that a passivized ECM verb behaves in every respect like an ordinary raising verb).

a. *A man$_1$ seems/is believed [$_{IP}$ there to have been kissed t$_1$]
b. A man$_1$ seems/is believed [$_{IP}$ t$_1'$ to have been kissed t$_1$] (7)

However, in contrast to *wh*-movement, NP-movement is clause-bound: it cannot cross a CP. Thus, NP-movement from a finite clause (*super-raising*) is impossible in English (see (8a)), whereas *wh*-movement is not (see (8b)):

a. *[$_{IP}$ Mary$_1$ seems [$_{CP}$ (t$_1'$) that [$_{IP}$ t$_1$ likes John]]]
b. [$_{CP}$ Who$_1$ do you think [$_{CP}$ t$_1'$ that [$_{IP}$ Mary likes t$_1$]]]? (8)

A second difference concerns *binding of anaphors* (i.e. reflexive and reciprocal pronouns). NP-movement creates new possibilities for anaphoric binding (see (9a)), whereas *wh*-movement does not (see (9b)).

a. [$_{IP}$ The students$_1$ seem [$_{PP}$ to each other$_1$] [$_{IP}$ t$_1$ to be intelligent]]
b. *[$_{CP}$ Which man$_1$ does himself$_1$ think [$_{CP}$ t$_1'$ that Mary likes t$_1$]]? (9)

Third, there is a difference with respect to *weak crossover*. In a weak crossover configuration, a quantified NP has been moved across a co-indexed personal pronoun that does not c-command the trace of NP. This configuration leads to ungrammaticality with *wh*-movement, but not with NP-movement; see (10a, b):

a. [$_{IP}$ Every girl$_1$ seems [$_{PP}$ to her$_1$ mother] [$_{IP}$ t$_1$ to be intelligent]]
b. *[$_{CP}$ Which girl$_1$ does [$_{NP}$ her$_1$ mother] think [$_{CP}$ t$_1'$ that John likes t$_1$]]? (10)

Fourth, NP- and *wh*-movement diverge with respect to *parasitic gaps*. A parasitic gap is a trace (noted here as 'e') in a position that is typically not accessible to regular movement (because of locality constraints). However, e is permitted if it is in a sufficiently local relation with a well-formed movement chain with the same index. As shown in (11a, b), NP-movement does not license parasitic gaps in English, whereas *wh*-movement does (Chomsky (1982), who also notes that (11a) is grammatical with *them* in place of e, which implies that the construction is not ill formed because of a control failure with the PRO subject of the *without* phrase).

a. *[$_{IP}$ The books$_1$ can be sold t$_1$ [$_{CP}$ without reading e$_1$]]
b. [$_{CP}$ Which books$_1$ did they sell t$_1$ [$_{CP}$ without reading e$_1$]]? (11)

Further Dissociation of Case-positions and Theta-positions

In NP-movement constructions, the first member of the movement chain is in a position to which Case is assigned, and the last member occupies a Theta-position. NP-movement has so far been motivated on the basis of passive and raising (also recall the above remarks on an NP-movement approach to control), but it has also been argued to underlie other constructions.

The VP-internal subject hypothesis

The assumption that an external argument of a verb is base-generated in the verb phrase (VP)-external SpecI position has been called into question in recent years. The alternative (suggested by Sportiche (1988) and many others, and now widely adopted) is that all arguments of V are base-generated in a VP-internal position; this is known as the *VP-Internal Subject Hypothesis* (VISH). (Since this assumption is usually taken to hold for all predicates, a more adequate term is *Predicate-Internal Subject Hypothesis*.) Under this view, the 'external' argument of V is base-generated VP-internally, in SpecV. Given that SpecI is the position to which nominative Case is assigned in English, NP-movement to SpecI must then take place in active sentences as it does in passive sentences; see (12):

$[_{IP}$ John$_1$ I $[_{VP}$ t$_1$ wrote the book$_2$$]]$ (12)

The VISH raises a question concerning the structure of double object constructions, where there are three argument NPs but, it seems, only two VP-internal positions (specifier and complement). The most widely adopted approach to this problem is one that relies on a *shell* (Larson, 1988; Chomsky, 1995): on top of the lexical VP, there is a vP shell with an empty head v. Two internal arguments can now be base-generated in VP, and the remaining external argument is base-generated in Specv. Obligatory V-to-v movement and Case-driven NP-movement to SpecI yield the correct surface string. (13) is a possible analysis of an English double object construction.

$[_{IP}$ John$_1$ I $[_{vP}$ t$_1$ gave$_2$ $[_{VP}$ Mary $[_{V'}$ t$_2$ a book$]]]]$ (13)

The vP shell analysis is usually extended to simple transitive and intransitive verbs, such that an external argument is base-generated in Specv throughout; it thereby qualifies as 'external' in the literal sense again.

Raising to object

There is an alternative analysis of ECM constructions that goes back to Postal (1974). Under this view, (4) does not involve exceptional Case assignment of the matrix verb to the subject position of the infinitive, but raising of the embedded subject to the object position of the matrix clause, as in (14).

$[_{IP}$ Mary$_1$ I $[_{vP}$ t$_1$ believes John$_2$ $[_{IP}$ t$_2$ to be a fool$]]]$ (14)

As before, the construction would then depend on the transparency of IP, but it would be transparency for movement, not for Case assignment.

The empirical evidence that might decide between the two possibilities is not decisive. On the one hand, adverbials that belong to the matrix clause may usually not intervene between the lower external argument and the rest of the infinitive; see (15). This is an argument for the ECM analysis.

*John believed Mary sincerely to have left (15)

On the other hand, the external argument of the infinitive c-commands a matrix adverbial that follows the infinitive, as shown by binding of the reciprocal in (16). This piece of evidence supports the raising to object analysis.

The DA proved the defendants$_1$ to be guilty during each other's$_1$ trials (16)

The raising to object analysis has been refined and generalized in such a way that all NPs that bear objective Case must undergo raising to a Case-related position provided by a functional head (e.g., the specifier of an 'object agreement' phrase AGR_OP). In such an approach, there is a complete dissociation of Theta-positions and positions to which structural Case is assigned; see Johnson (1991) and Chomsky (1995).

SCRAMBLING

Many languages exhibit a considerable amount of clause-internal free constituent order. For instance, all permutations of three argument NPs in a double object construction can result in well-formedness in German (on which the following discussion will focus). Given the UTAH, only one of the orders can be base-generated; the remaining orders are derived by *scrambling*, a movement type introduced by Ross (1967). For present purposes, we can assume (following what is arguably the standard view) that subject → indirect (dative) object → direct (accusative) object is the base order in German. Thus, (17b–f) are derived from (17a) by scrambling.

a. dass $[_{IP}$ die Frau$_1$ dem Mann$_2$ das Buch$_3$ gegeben hat$]$
   that the woman$_{nom}$ the man$_{dat}$ the book$_{acc}$ given has
b. dass $[_{IP}$ die Frau$_1$ das Buch$_3$ dem Mann$_2$ t$_3$ gegeben hat$]$
c. dass $[_{IP}$ das Buch$_3$ die Frau$_1$ dem Mann$_2$ t$_3$ gegeben hat$]$

d. dass [$_{IP}$ dem Mann$_2$ die Frau$_1$ t$_2$ das Buch$_3$ gegeben hat]
e. dass [$_{IP}$ dem Mann$_2$ das Buch$_3$ die Frau$_1$ t$_2$ t$_3$ gegeben hat]
f. dass [$_{IP}$ das Buch$_3$ dem Mann$_2$ die Frau$_1$ t$_2$ t$_3$ gegeben hat] (17)

An independent argument for a scrambling approach is provided by the fact that clause-internal word order variation is not confined to co-arguments of a predicate in German. Scrambling can also move an item that is base-generated within an object NP to a clause-internal position. This is shown for extraction of a pronoun *da* (lit. 'there', here 'it') from a prepositional phrase (PP) embedded in an object NP in (18).

dass [$_{NP}$ da]$_1$ keiner [$_{NP}$ eine Ahnung [$_{PP}$ t$_1$ von] gehabt hat]
that it no one$_{nom}$ a notion$_{acc}$ of had has (18)

There are different views as to what the landing site of scrambling is. Data such as (17e, f) show that scrambling can be iterated. This requires either additional functional categories that provide a unique landing site for each scrambling operation, or a general mechanism that produces as many landing sites as are needed in one domain. Assuming the latter, we can postulate that scrambling in German (where NP-movement to SpecI is not obligatory) is movement within the vP domain – adjunction to vP (as was standardly assumed), or substitution in (outer) specifiers of v (see Chomsky (1995) on the possibility of multiple specifiers).

Scrambling (in German) differs from NP-movement (in English) in being optional. It has so far proven difficult to find a trigger for scrambling, which is required in syntactic theories that adopt economy principles and thereby require each movement operation to be forced in some way. Triggers that have been suggested include abstract features and information-structural requirements.

Much recent work has focused on how scrambling fits into the typology of movement operations that is based on the distinction between NP-movement and *wh*-movement. (This distinction is often generalized to a dichotomy of *A*- versus *A-bar movement*, with NP-movement an instance of the former, and *wh*-movement an instance of the latter.) In some respects, it does not seem to fit at all. For instance, since scrambling can cross an intervening scrambled item (see (17e, f)), it appears to be exempt from Relativized Minimality effects. In most cases, however, scrambling patterns with either NP-movement or *wh*-movement.

First, in many languages, scrambling is clause-bound. Thus, scrambling in German can never leave a finite CP (see (19a)), like NP-movement and unlike *wh*-movement. Depending on the nature of the matrix verb, scrambling may or may not take place from a nonfinite clause. This is often taken to show that so-called *restructuring* verbs select a bare IP infinitive, whereas *non-restructuring* verbs select a CP infinitive (see (19b, c)).

a. *dass den Fritz$_1$ keiner sagt [$_{CP}$ (t$_1'$) dass Maria t$_1$ mag]
that ART Fritz$_{acc}$ no one$_{nom}$ says that Maria$_{nom}$ likes
b. *dass den Fritz$_1$ keiner [$_{CP}$ (t$_1'$) C t$_1$ einzuladen] abgelehnt hat
that ART Fritz$_{acc}$ no one$_{nom}$ to invite rejected has
c. dass den Fritz$_1$ keiner [$_{IP}$ t$_1$ einzuladen] versucht hat
that ART Fritz$_{acc}$ no one$_{nom}$ to invite tried has (19)

However, in some languages (among them Russian, Persian, Korean, and Japanese), long-distance scrambling across a CP is possible, like *wh*-movement in English.

Second, scrambling at first glance seems to pattern with NP-movement as regards the binding of anaphors. (20a) shows that a direct object can bind an indirect object that follows it; given that the reverse order is base-generated, this implies that scrambling creates new possibilities for anaphoric binding. However, it is then unclear why an indirect object can never bind a direct object; see (20b). Furthermore, scrambling in front of a subject cannot license a nominative anaphor, like *wh*-movement; see (20c). All this might be taken to show that anaphoric binding is not solely regulated by structural factors, but relies on linear precedence and dominance on a thematic hierarchy, in which case the evidence is neutral between an NP-movement and a *wh*-movement analysis (see Jackendoff, 1990; Williams, 1994).

a. dass der Fritz die Gäste$_1$ einander$_1$ t$_1$ vorstellte
that ART Fritz$_{nom}$ the guests$_{acc}$ each other$_{dat}$ introduced
b. *dass der Fritz den Gästen$_1$ einander$_1$ vorstellte
that ART Fritz$_{nom}$ the guests$_{dat}$ each other$_{acc}$ introduced
c. *dass den Fritz$_1$ sich$_1$ t$_1$ mag
that ART Fritz$_{acc}$ self$_{nom}$ likes (20)

Third, German scrambling does not give rise to (clear) weak crossover effects, like NP-movement; see (21)

dass jeden Jungen$_1$ [$_{NP}$ seine$_1$ Mutter] t_1 liebt
that every boy$_{acc}$ his mother$_{nom}$ loves (21)

Fourth, scrambling licenses parasitic gaps, like *wh*-movement; see (22):

dass das Buch$_1$ jeder [$_{CP}$ ohne e$_1$ zu lesen] ins Regal t$_1$ zurückgestellt hat
that the book$_{acc}$ everyone$_{nom}$ without to read into the shelf put has (22)

Thus, scrambling in German seems to share some properties with NP-movement, and some with *wh*-movement. To preserve the strict A-/A-bar dichotomy mentioned above, scrambling must be assimilated with either NP-movement or *wh*-movement, and conflicting pieces of evidence must be explained away. Alternatively, the non-homogeneous evidence can be taken to indicate that the A-/A-bar distinction should be dispensed with, and be replaced by a finer-grained system according to which, for example, scrambling forms a natural class with NP-movement insofar as it targets an IP-internal position, and with *wh*-movement insofar as it is not Case-driven. Syntactic constraints can then refer to these distinctions. (*See* **Anaphora**, **Binding Theory**)

PRONOUN MOVEMENT

Object Shift

Unstressed object pronouns move out of the vP to a clause-internal position in Scandinavian languages, thereby crossing vP-external material such as adverbs and negation; this operation is known as *object shift*. The landing site follows the canonical subject position SpecI; see the contrast between (23a) and (23b) in Danish.

a. Hvorfor købte$_3$ [$_{IP}$ Peter$_2$ den$_1$ ikke [$_{vP}$ t$_2$[$_{v'}$ t$_3$ t$_1$]]]?
why bought Peter it not
b. *Hvorfor købte$_3$ [$_{IP}$ Peter$_2$ — ikke [$_{vP}$ t$_2$[$_{v'}$ t$_3$ den$_1$]]]?
why bought Peter not it (23)

The nature of the landing site is not generally agreed on; a possibility is that it is the specifier of a functional projection like AGR$_O$P that intervenes between IP and vP. Similarly, it is unclear whether pronominal object shift is phrasal (XP) movement or head (X^0) movement. (*See* **Phrase Structure and X-bar Theory**)

While being confined to unstressed pronouns in the Mainland Scandinavian languages, object shift can also affect non-pronominal NPs in Icelandic, the main difference being that movement of the latter is optional. Furthermore, object shift can (and, in the case of two unstressed object pronouns, must) be iterated, as we have seen with scrambling. However, Scandinavian object shift differs from scrambling in German (and other languages) in a number of respects. First, in contrast to scrambling, object shift requires movement of the main verb to a higher position ('Holmberg's generalization'; see Holmberg, 1999; Chomsky, 2001). This is ensured by V-to-C movement in (23a), but not in a minimally different sentence where *købte* ('brought') is replaced by the perfect form *har købt* ('has bought'), such that *har* is in C and *købt* stays within vP. Consequently, object shift is impossible in the latter case. (Dependence on main verb movement also explains why object shift is strictly local and cannot even leave restructuring infinitives.) Second, unlike scrambling, object shift does not seem to pattern with *wh*-movement in any respect (e.g. it does not license parasitic gaps). Third, while scrambling typically reverses the D-structure order of arguments, object shift is strictly order-preserving: a shifted direct object can never show up in front of an indirect object.

Pronoun Fronting

German also exhibits obligatory fronting of unstressed object pronouns to a clause-internal position; see (24a, b). This position precedes the scrambling domain vP. However, it can in turn optionally be preceded by the subject; see (24c):

a. dass es$_1$ [$_{vP}$ der Fritz der Maria t_1 gegeben hat]
that it$_{acc}$ ART Fritz$_{nom}$ ART Maria$_{dat}$ given has
b. *dass —[$_{vP}$ der Fritz der Maria es$_1$ gegeben hat]
that ART Fritz$_{nom}$ ART Maria$_{dat}$ it$_{acc}$ given has
c. dass der Fritz$_2$ es$_1$ [$_{vP}$ t$_2$ der Maria t$_1$ gegeben hat]
that ART Fritz$_{nom}$ it$_{acc}$ ART Maria$_{dat}$ given has (24)

Pronoun fronting in German is local in the same way that scrambling is: a finite CP can never be crossed, and movement from an infinitive is possible with restructuring verbs, but not with others:

a. *dass es_1 keiner $[_{CP}$ (t'_1) C t_1 zu lesen]
abgelehnt hat
that it_{acc} no one_{nom} to read
rejected has
b. dass es_1 keiner $[_{IP}$ t_1 zu lesen] versucht
hat
that it_{acc} no one_{nom} to read tried
has (25)

It seems desirable to analyse German pronoun fronting and Danish object shift in the same way. Under this view, the fact that subject NPs precede fronted pronouns optionally in German, and obligatorily in Danish, would result from an independently motivated difference with respect to optional versus obligatory NP-movement to SpecI. Furthermore, multiple pronoun fronting results in a fixed order that is reminiscent of the order-preservation effect with object shift. Still, there are many differences. First, the fixed-order effect is not the same: the order is indirect object → direct object with object shift, but direct object → indirect object with pronoun fronting. Second, pronoun fronting can cross an intervening non-pronominal NP, which object shift cannot. Third, main verb movement does not seem to be required with pronoun fronting. Finally, pronoun fronting in German shares some properties with *wh*-movement (e.g. it licenses parasitic gaps).

Cliticization

Unstressed pronouns may be (pro- or en-) *clitic* in the sense that they must attach to the left or to the right of a suitable phonological host, usually V. Pronominal cliticization is widespread in the Romance and Slavic languages. (26a) is an example from French.

Jean les_1 mange t_1
Jean them eats (26)

The trigger for cliticization is arguably phonological, given the clitic pronoun's need to form a phonological word with an appropriate host. Since nothing can intervene between a clitic pronoun and its host, cliticization is often analyzed as involving head movement (*incorporation*) into the X^0 position in which the verb shows up. However, whereas head movement is extremely local (Baker, 1988), clitic movement seems to obey roughly the same locality constraints as scrambling and pronoun movement in German: a finite CP cannot normally be crossed, but cliticization from an infinitive (*clitic climbing*) is permitted in some languages, where a restructuring verb occurs in the matrix clause. Clitic climbing is impossible in French, but applies optionally in Italian: see (27a, b) (alternatively, in (27a), *lo* can attach as an enclitic to *leggere*):

a. Mario lo_1 vuole $[_{IP}$ leggere $t_1]$
Mario it wants to read
b. *Mario lo_1 odia $[_{CP}$ (t'_1) C $[_{IP}$ leggere $t_1]]$
Mario it hates to read (27)

In view of this dual nature, it has been argued that a moved clitic pronoun simultaneously acts as an X^0 category and as an XP.

EXTRAPOSITION

Whereas NP-movement, scrambling, and pronoun movement involve leftward displacement, extraposition is rightward movement. This movement type is often optional and seems to be motivated at least in part by parsing requirements. Extraposition has been argued to underlie instances of optional rightward PP- and CP-displacement from NP (see (28a, b)), so-called *heavy NP shift* (see (28c)), and argument CP-displacement in languages with subject–object–verb word order (see (28d) from German, which is strongly preferred over the preverbal option).

a. $[_{NP}$ A review $t_1]$ will appear shortly
$[_{PP}$ of his new book$]_1$
b. $[_{NP}$ A woman $t_1]$ came into the room
$[_{CP}$ that no one knew$]_1$
c. She threw t_1 into the wastebasket
$[_{NP}$ the letter which she had not decoded$]_1$
d. dass er t_1 dachte $[_{CP}$ dass sie schläft]
that he thought that she sleeps (28)

Extraposition is clause-bound (Ross, 1967), like NP-movement; see (29a). On the other hand, heavy NP shift has been claimed to license parasitic gaps, like *wh*-movement; see (29b):

a. *John always maintains $[_{CP}$ that $[_{NP}$ a review $t_1]$ will appear shortly] whenever he is asked about it $[_{PP}$ of his new book$]_1$
b. John offended t_1 $[_{CP}$ by not recognizing e_1 immediately] $[_{NP}$ his favourite uncle from Cleveland$]_1$ (29)

Extraposition has a number of peculiar properties that set it apart from other instances of movement. To name just one, subject NPs as in (28a, b)

are barriers for leftward movement; so the well-formedness of these examples is initially surprising. Moreover, rightward movement has been argued to be dubious on purely conceptual grounds (Kayne, 1994).

LOCALITY

There is one fundamental property that all movement types that target an IP-internal position share, and that sets them apart from movement types that target a position in the CP domain: displacement is clause-bound, that is, long-distance movement across a CP is impossible; see (30). (There is evidence that the CP domain can be targeted by scrambling in languages with long-distance scrambling.)

$$^{*} \ldots [_{IP} \ldots \alpha_1 \ldots [_{CP} (t_1') \ldots t_1 \ldots] \ldots \quad (30)$$

Thus, there is a correlation between the position targeted by a movement type (low versus high) and the distance over which it can apply (short versus long). This generalization seems hardly accidental; it can be explained by a conspiracy of two constraints. First, there is a locality constraint that permits extraction from a CP only via SpecC (see, e.g., the *Phase Impenetrability Condition* in Chomsky, 2001). This precludes one-step movement without t_1' in (30). Second, there is a constraint on improper movement according to which movement to an IP-internal position may precede movement to SpecC, but not vice versa; this asymmetry can be taken to reflect the hierarchy of the target positions in the tree. See Williams (1974) for the basic observation, and May (1979), Chomsky (1981), and Müller and Sternefeld (1993) for specific proposals. (*See* **Constraints on Movement**)

Metaphor

Intermediate article

Matthew S McGlone, Lafayette College, Easton, Pennsylvania, USA

CONTENTS

Metaphor is a figure of speech in which a word or phrase is used to describe something it does not literally denote. How we are able to go 'beyond the literal' to understand metaphors is a central question in the study of language and thought.

INTRODUCTION

Metaphor, from the Greek *metapherein* ('transference'), is a figure of speech in which a word or phrase is used to describe something it does not literally denote, for example, 'This encyclopedia is a *feast*'. Whether or not you agree with this characterization of the encyclopedia, you probably had no difficulty understanding it. Furthermore, your understanding did not hinge on a literal reading of the sentence – in other words, at no point in your reading did you contemplate tasting (let alone feasting upon) the book. The meaning of a metaphorical expression does not coincide with the literal meanings of the words comprising it. How then do we go 'beyond the literal' to understand metaphors? There are scholarly contemplations of this question dating back to Aristotle, but only in the twentieth century has it been regarded as an important problem in the study of language and thought.

PHILOSOPHICAL PERSPECTIVES ON METAPHOR

Aristotle's analysis of metaphor in the *Poetics* is generally considered the starting point of the topic's intellectual history. He characterized metaphor as the sign of language mastery and genius. However, he also believed that it was largely ornamental, appropriate for poetry but too enigmatic to use in philosophical or scientific discourse. Few contemporary language scholars agree with his limited view of metaphor's function, but many still endorse his account of metaphor understanding. According to what has become known as the Aristotelian 'comparison view', metaphors of the form *X is a Y* (e.g. 'This encyclopedia is a feast') are understood by converting them into simile form, *X is like a Y* ('This encyclopedia is *like* a feast'). This conversion serves the dual purpose of affording the proposition literal truth (in that any two things, even an encyclopedia and a feast, are literally alike in some respects) and making explicit the analogical comparison Aristotle presumed to be the crux of metaphor. Once converted to a simile, the metaphor is then interpreted by determining in what respects the two things being compared are similar. The comparison view thus (a) treats metaphor as a species of analogy, and (b) asserts that the perception of similarity is the basis of metaphor use and comprehension. These proposals have recently been challenged on theoretical and empirical grounds, but none the less have historically dominated scholarly discussions of metaphor.

Aristotle's relegation of metaphor to ornamentation had the unfortunate effect of leading many subsequent generations of language scholars to ignore the topic altogether. Up until the late nineteenth century, the study of metaphor was primarily the province of rhetoricians who focused almost exclusively on the interpretation of particular metaphors in literary texts. Around the turn of the twentieth century, an English translation of Michel Breal's *Essay de semantique* sparked new interest in the topic among American linguists and philosophers. Breal persuasively argued that metaphor was not mere ornament, but a ubiquitous feature of language and a principal device of linguistic change. I. A. Richards took up this cause in the 1930s and introduced a terminology of metaphor that has become fairly standard: the term used metaphorically is the 'vehicle' (e.g. feast), the term to which it is applied is the 'topic' or 'tenor' (e.g. encyclopedia), and the meaning of the metaphor is the 'ground'.

In his 1962 book *Models and Metaphors*, Max Black articulated an influential alternative to traditional

views of metaphor understanding. He rejected Aristotle's 'comparison view' of metaphor as elliptical comparison, and criticized what he called the 'substitution view' wherein metaphor is assumed to be a fancy substitute for literal language. Building on Richards' work, he argued that the product of metaphor comprehension is a complex 'interaction' of the topic and vehicle concepts. According to this 'interaction view', metaphors are understood by perceiving the topic concept 'in terms of' the vehicle to produce a ground that transcends their literal meanings. The imprecision of the notion of 'interaction' has limited the influence of Black's view on subsequent metaphor theory; however, his claim that the topic and vehicle play asymmetric roles in metaphor understanding (contrary to the traditional comparison view) has endured.

John Searle's 1979 analysis of metaphor in terms of speech act theory focused attention on the question of how a metaphorical interpretation of an utterance is initiated. He assumed that a defective literal meaning was a necessary cue for the hearer to interpret an utterance metaphorically. Searle thus assumed that before one interprets 'This encyclopedia is a feast' metaphorically, you must first contemplate and reject the possibility that the speaker wanted you to think that the book is edible and tasty. This assumption implies a model of metaphor comprehension comprising three stages. First, a literal interpretation of the utterance is derived. Second, the appropriateness of this interpretation is assessed against the context of the utterance. Third, if the literal meaning is deemed defective in context, then *and only then* is an alternative interpretation derived. For Searle (as for Aristotle), this alternative interpretation involved the conversion of metaphor into an analogical comparison.

PSYCHOLOGICAL MODELS OF METAPHOR COMPREHENSION

By the mid-1970s, metaphor had become a topic of interest among cognitive psychologists. Initial research on this topic focused on the question of whether metaphors and other nonliteral expressions (idioms, indirect requests, irony, hyperbole, etc.) required comprehension strategies different from those of literal language. Although Searle's speech act analysis appeared to motivate the postulation of a distinct nonliteral interpretation strategy, this analysis is based on two dubious psychological assumptions. The first is that the literal meaning of an utterance is derived before any possible nonliteral meaning it might have. This claim is contradicted by empirical demonstrations that when people understand nonliteral expressions such as indirect requests (e.g. '*Could* you pass the salt?') and idioms (e.g. 'The old man *kicked the bucket*'), literal meanings are not (and need not be) derived at all. Furthermore, experimental evidence indicating that metaphors are no more difficult to understand than comparable literal expressions suggests that literal meaning does not have interpretational priority.

Second, metaphor comprehension is optional on Searle's analysis, in that a nonliteral meaning of an utterance should not be considered when its literal meaning makes sense in context. This claim is also unfounded. Sometimes a metaphor can be recognized because it is literally false. For example, when a wife asserts that 'My husband is a pig', no one would interpret her assertion as meaning that her husband is a broad-snouted barnyard animal. But a metaphor need not be literally false. The opposite assertion – 'My husband is not a pig' – is literally true; the husband is not a barnyard animal. However, this is not likely to be the speaker's intended meaning or the hearer's interpretation. Thus even when the literal meaning is not defective in context, people go beyond the literal meaning of the utterance to arrive at the speaker's intention. This example is consistent with empirical demonstrations of people's inability to ignore the metaphorical meanings of utterances, even when their literal meanings are contextually appropriate.

Subsequent psychological research on metaphor has focused on how the topic and vehicle concepts 'interact' to produce the metaphoric ground. Two general types of model have been proposed to describe this interaction: similarity models and attribution models. Following Aristotle's lead, similarity models assume that the first step in metaphor comprehension is recognition of the elliptical comparison that the metaphor implies. Once the comparison is recognized, it is interpreted in much the same manner as a literal comparison, by searching for the properties and relations common to the topic and vehicle concepts. The chief difference between literal and metaphoric comparisons is that the metaphoric ground is composed of common properties that are of low salience in the topic and high salience in the vehicle. For example, the ground of 'Religion is a drug' might include properties such as 'soothing' and 'euphoria-inducing', which are highly salient properties of drugs but less salient for religions.

Two important assumptions underlie similarity models of metaphor. The first is that the referential

scope of the topic and vehicle terms is restricted to entities that conform to their conventional dictionary definitions. This assumption is what motivated Aristotle to assert that metaphors are covert comparisons in the first place. If it were possible that a vehicle term such as 'drug' could be understood as referring to a category that can include 'religion' as a member, then it would be unnecessary for people to transform 'Religion is a drug' into a comparison statement to understand it. There are good reasons to question this assumption, which we will consider below. The second assumption is that people are aware of the relevant properties that the topic and vehicle concepts have in common. This assumption is clearly violated when people are able to interpret informative metaphors. For example, consider 'That film was a sermon'. People not familiar with the film in question do not, prior to hearing this utterance, have a representation of the film that includes properties such as 'preachy' or 'moralistic'. Yet these are exactly the sorts of properties that come to mind upon reading the statement, even when the film is not familiar to the hearer. This argument applies with equal force to literal comparisons. If a person knows nothing about Saab sedans, then telling her 'A Saab is like a BMW' will introduce new properties into her mental representation of Saabs (e.g. hand-built, expensive), rather than produce a match between Saab and BMW properties.

Motivated in part by the case of informative metaphor, attribution models characterize metaphors as exactly what they appear to be: class-inclusion assertions of the form *X is a Y*. This claim implies that the referential scope of the terms comprising a metaphor is not as limited as Aristotle and other similarity theorists have assumed. According to attribution models, the vehicle term of a metaphor (e.g. 'sermon') is extended to name a class of things that its literal referent exemplifies (e.g. 'preachy, moralistic discourses'). To say that a film is a sermon is to attribute (i.e. transfer, in the sense of its Greek root) salient properties of the metaphoric category exemplified by sermons and named 'sermon' to this particular film. By virtue of the metaphoric assertion, this particular film is now included in the 'sermon' category and as a consequence of this categorization is now similar in relevant respects to literal sermons. Predicative metaphors, which employ verbs metaphorically, function the same way. For example, the verb 'to fly' literally entails movement through the air. Because flight through the air exemplifies fast movement, expressions such as 'He jumped on his bike and flew home' are as readily understood as nominal metaphors such as 'His bike was an arrow'. Arrows exemplify the category of objects that move at fast speeds; flying exemplifies the category of fast movement. In this manner are nominal and predicative metaphors used to attribute properties to particular topics.

WHY ARE METAPHORS USED?

Metaphors are used because there are often no comparable literal expressions to convey the same proposition. This is frequently the case when metaphorical expressions reflect a complex analogy between domains. For example, there are a variety of metaphorical expressions that reflect an analogy between love and journeys, as in 'Love is a two-way street', 'We've come a long way since we first dated', or 'Our relationship has come to a crossroads'. Once a target domain (e.g. love) has been described in terms of a source domain (e.g. journeys), new correspondences can be introduced, as in 'Let's walk off into the sunset together'. Whether the analogical coherence of metaphorical expressions constitutes conceptual knowledge *per se* (as argued by the linguist George Lakoff and colleagues) or simply an efficient means of communicating about complex domains remains largely an unresolved issue.

Morphological Processing

Intermediate article

R Harald Baayen, University of Nijmegen/Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands
Robert Schreuder, University of Nijmegen, Nijmegen, The Netherlands

CONTENTS

Words with internal morphological structure are processed differently in the mental lexicon than monomorphemic words, both in language comprehension and in speech production. How morphological structure is represented in the brain is hotly disputed. Dissociations between the processing of regular and irregular complex words on the one hand, and gradient morphological phenomena on the other, are key issues in the debate between single and dual route approaches, and between symbolic and connectionist approaches.

INTRODUCTION

Many words have internal morphological structure (e.g. 'walk-ed', 'good-ness', 'key-pad'). Such internal structure is evident from systematic correspondences between the form and meanings of series of words. Some patterns of form–meaning correspondences are pervasive in the language and are easily and readily extended by language users to form new words. Such productive patterns are typically found in inflectional morphology (e.g. person and number marking on verbs, number marking on nouns). Even young children have already internalized such patterns and readily apply them to nonsense words, producing 'memped' as the past tense of 'memp' without difficulty. In linguistics, rules (e.g. add *ed* to form the past tense in English) are used to account for such productive form–meaning patterns. By contrast, other patterns of form–meaning correspondences occur in only a few words; for example, the derivational suffix *-th* that forms nouns such as 'length' and 'strength' from the adjectives 'long' and 'strong'. Unproductive patterns appear to be exceptional instead of governed by an active rule, and linguists generally assume that the words exemplifying such patterns are listed in the lexicon as wholes.

There are two main views in linguistics as to the nature of morphological rules. Linguists in the generative tradition (e.g. Pinker, 1997) regard rules as existing in the mind independently of the data from which they were abstracted. In this approach, any complex word that is predictable by rule (e.g. 'linked') is not stored in the lexicon; only words with unpredictable properties (e.g. 'sang') are listed there. Formally, morphological rules are described in this tradition using the mechanisms of formal grammars.

Others (e.g. Skousen, 1989) argue that rules are analogical in nature. They assume that a great many complex words, both irregular and regular, are available in lexical memory. For a past tense form such as 'linked', assuming that it is not already available in memory, an analogical rule would first look for all verbs in memory that are most similar to the verb 'link' (think, sink, blink, wink). It would then look at the corresponding past tense forms, and select the one that occurs most often with the greatest probability. Every once in a while, a less likely exemplar would be selected, leading to deviant forms such as 'lank'. Explicit computational algorithms have been developed for modeling analogy.

While linguistic theories account for morphological structure using techniques borrowed from computer science, it is not self-evident that these theories provide good descriptions of the computational mechanisms actually used by the human brain.

MORPHOLOGY IN THE MENTAL LEXICON

When considering the question how morphologically complex words are processed in the mental lexicon, it is important to distinguish between speech production and language comprehension. The speaker has to produce the correct morphological form given conceptual input

('walk' + PAST → 'walked'), while readers and listeners receive the correct morphological form and have to unravel its meaning. The different tasks of the speaker and the listener lead to an asymmetry between comprehension and production. For instance, second language learners of German master the comprehension of the complex system of German noun plurals fairly quickly, while getting the plural forms right for production takes considerably more experience.

The most striking evidence of the role of morphology comes from studies of errors in speech production (see, e.g., Stemberger, 1998), which show that during production things can go wrong both with the lining up of morphemes, and with the selection of morphemes. This shows that complex words are constructed online on the basis of their constituent morphemes.

Turning to language comprehension, one key question is whether morphological relationships are represented in the mental lexicon independently of orthographic and phonological relationships. Priming studies (see, e.g., McQueen and Cutler, 1998) have shown that words preceded by morphologically related words are processed faster than words preceded by orthographically, phonologically, or semantically matched control words. Moreover, morphological priming effects persist over many intervening trials, while orthographic and semantic repetition effects fade away rapidly. Another phenomenon pointing to the relevance of morphological structure in the mental lexicon is the morphological family size effect (De Jong *et al*., 2000). Words that occur as a constituent in many other words are responded to faster in visual lexical decision than words occurring as a constituent in just a few other words. This effect is a semantic effect involving the co-activation of semantically related words along lines of morphological similarity. Thus, there is strong evidence that morphological structure is represented in the mental lexicon.

Another key question is whether complex words are necessarily decomposed into their constituent morphemes during recognition, or whether complex words are recognized on the basis of stored forms of the complex words as wholes, without decomposition into the constituent morphemes. It appears that decomposition may take place, depending on a wide range of factors, including the semantic transparency of the complex word (Marslen-Wilson *et al*., 1994), frequency of use, the specific affix under consideration, its possible functional ambiguity, and its productivity (Bertram *et al*., 2000). Decomposition is more likely to occur for transparent, lower-frequency words with productive and functionally unambiguous affixes. However, recognition on the basis of stored forms of complex words seems to be fairly pervasive, not only for compounding and derivation, but also for regular inflection, especially in languages with simple morphological systems such as English.

COGNITIVE MODELS FOR MORPHOLOGICAL PROCESSING

There are four main approaches to the modeling of morphological processing.

Cascaded Dual Route Models

The Cascaded Dual Route approach is similar in spirit to the generative linguistics view. Regular complex words are assumed to be processed by symbolic rules; irregular complex words are supposed to be retrieved from an associative memory. The two routes, the route using morphological rules and the route retrieving irregular complex words from an associative memory, are taken to be subserved by different parts of the brain. The two routes are cascaded in the sense that rules are used only upon failure of memory retrieval (Pinker, 1997; Clahsen, 1999).

This model provides an elegant and simple account for a great many differences that have been reported in the literature with respect to the processing of regular versus irregular inflected words. However, many of the differences that supposedly support it are open to multiple interpretations and some appear, on closer scrutiny, not to exist. For instance, inflected words have been argued to differ with respect to the frequency effect for the inflected form as a whole, with only irregular inflected words showing full form frequency effects. However, various studies (see, e.g., Taft, 1979; Sereno and Jongman, 1997) have reported such full form frequency effects even for fully regular inflected words. This casts doubt upon the linguistic idea that it is only irregular words that are in the lexicon.

Parallel Dual Route Models

In Parallel Dual Route models (see, e.g., Caramazza *et al*., 1988), morphological processing also proceeds on the basis of two routes, a direct route retrieving whole complex words from a (not necessarily associative) memory, and an indirect route

using rules (not necessarily symbolic and potentially analogical in nature). Crucially, the two routes are assumed to run in parallel. Because they may use shared or even competing representations, the two routes are not necessarily independent.

Perhaps the greatest weakness of these models is that they are difficult to falsify without computational implementations that embody explicit mechanisms for lexical look-up and parsing. On the positive side, the Parallel Dual Route approach seems promising for dealing with the resolution of parsing ambiguity. Long complex words can often be segmented into strings of morphemes in a great many ways. In Dutch, for instance, the word 'belangstellende', 'interested party', has some 80 mostly spurious segmentations. Simulation studies suggest that storage protects the parser against such spurious segmentations. In the Parallel Dual Route framework, the relevant constituents of a longer complex word (belang, stellen, de: 'interest', 'to place', INFLECTIONS) may become available without sequences of possible but irrelevant constituents (bel, angst, ellende: 'to ring', 'fear', 'misery') becoming available as well (Baayen and Schreuder, 2000).

Symbolic Single Route Models

In Symbolic Single Route approaches, morphological processing is explained in terms of activation spreading through lexical networks. Standard linguistic insights are translated into activation models driven by general incremental procedures sequentially activating symbolic representations at various cascaded levels. In Levelt's production model (Levelt *et al*., 1999), for instance, a past tense form such as 'walk-ed' is produced by activating the lemma of 'walk' and the diacritical feature PAST TENSE. As the lemma of 'walk' is prespecified for combining with the morpheme *-ed*, the morphemes 'walk' and *-ed* are selected for further processing. The lemma for 'see', when combined with the diacritic PAST TENSE, directly passes on activation to the word form 'saw'.

The strength of this model is that it accounts for a wide range of chronometric data on speech production. With respect to the production of complex words, the model explains in detail how morphemes might be strung together, beginning with the first morpheme to be pronounced and ending with the last morpheme. But it has nothing to say about the production of new complex words. Its main weakness, which it shares with the dual route models, is that in its present form it cannot handle gradient morphological phenomena.

Connectionist Single Route Models

In models that make use of artificial neural networks (ANNs), words no longer have independent representations. Instead, they receive implicit representations in terms of activation weights and patterns of activation distributed in the ANN. Currently, pools of orthographic, phonological, and semantic units are combined in one ANN, an architecture generally referred to as the triangle model. In this approach, morphological effects in lexical processing are considered to be epiphenomena of statistical regularities in the lexicon.

The ability to handle gradient effects is the main strength of distributed connectionist single route models. Various ANN models predict the right kind of regular and irregular past tense forms in English without incorporating explicit rules (Plunket and Juola, 1999). ANN models are not without their own share of problems, however. First, reduplication is widespread in the languages of the world, but ANN cannot be trained to handle reduplicated forms without training individual forms into the network (Sproat, 1992). Second, it is a matter of dispute whether the kind of errors made by ANN models are really similar to the kind of errors made by humans (but see Stemberger, 1998).

CONCLUSION

Morphologically complex words are at the juncture of form and meaning. The complexity of this juncture arises from the absence of a clear and unambiguous mapping of the two domains.

In production, relatively little is known about the underlying conceptual processes that lead to the selection of a sequence of morphemes to be combined into a complex word, while detailed knowledge is available on how these morphemes are sequenced for articulation. For comprehension, it is becoming increasingly apparent that a wide range of linguistic and statistical factors are all jointly exploited in order to extract the intended interpretation from the auditory or visual input. The details of semantic processing are as yet unknown both for comprehension and for production.

The challenge for the cognitive modeling of morphological processing is twofold. On the one hand, cognitive models should capture the linguistic functions of morphology in all its complexity in

a plausible process model. On the other hand, cognitive models should also be sensitive to the many nondeterministic, statistical patterns that are present in the language and the way it is used. Current computational models tend to meet only one of these challenges.

CONTENTS

Computational morphology can be defined as the study of computational analysis and synthesis of word forms in the context of natural language processing with the computer.

INTRODUCTION

Morphology is the study of the structure of words and how words are formed by combining smaller units of linguistic information called *morphemes*. Morphemes can be classified into two groups: free morphemes (e.g. roots) can occur by themselves as a word, while bound morphemes are not words in their own right but have to be attached in some way to a free morpheme. The way in which morphemes are combined, and the information conveyed by morphemes and their combination, differ from language to language. Sproat (1992) details how languages are classified with respect to their morphology (*isolating*, *inflecting*, *agglutinative*, *polysynthetic* languages); discusses morphological processes such as *inflection* (which is used to generate forms of a word as demanded by the syntactic context), *derivation* (which is used to generate new words semantically related to the original word but possibly with a different part of speech), and *compounding* (which is used to generate new words by concatenating two or more word stems); and describes types of morphological combinations, such as *suffixation, prefixation, circumfixation, templatic combination, reduplication,* etc. (*See* **Morphology**)

Computational morphology aims at developing formalisms and algorithms for the computational analysis and synthesis of word forms for use in language processing applications. Applications such as spelling checking and correction, stemming in document indexing, and so on, also rely on techniques in computational morphology, especially for languages with rich morphology.

ASPECTS OF COMPUTATIONAL MORPHOLOGY

Computational morphology has two main computational tasks: *morphological analysis* analyses a word token to extract all linguistically relevant information for later use; *morphological generation* synthesizes a word from a set of features. Morphological analysis has problems analogous to all those in full-blown syntactic parsing, albeit usually on a smaller scale. Words may be ambiguous with regard to their part of speech, or may be divided up in a number of ways, each giving rise to possibly different morphological interpretations. For instance, in English, the word 'books' can be interpreted as:

book + Noun + Plural
  (plural of the noun 'book')
book + Verb + Present + 3PS
  (3rd person singular present of the verb 'to book')

In a morphologically complex language like Turkish, a simple word like 'oyun' can be interpreted in a number of ways, as:

oyun + Noun + Singular + NoPossessive + Nominative	(*game*)
oy + Noun + Singular + Possessive2SG + Nominative	(*your vote*)
oy + Noun + Singular + NoPossessive + Genitive	(*of the vote*)
oy + Verb + Imperative + 2SG	(*carve!*)

Morphological generation deals with the reverse process of producing the correct word form from a set of features. For example, in a machine translation application, say from French to English, one may need to produce the past tense of the verb 'stop' and the morphological generation system should produce the form 'stopped', dealing with the gemination (or doubling) of the consonant *p*.

Computational morphology attempts to model and capture two main aspects of word formation: morphophonology or morphographemics, and morphotactics. Morphophonology and its counterpart for words in written form, morphographemics, refer to the changes in pronunciation and orthography that occur when morphemes are put together. For instance in English, when the derivational suffix *-ness* is affixed to the adjective stem 'happy' to derive a noun, we get 'happiness'. The word-final *-y* in the spelling of 'happy' changes to an *-i*. Similarly, in the present continuous form of the verb 'stop', we need to geminate the last consonant of the root to get 'stopping'. Turkish, for instance, has a process known as *vowel harmony*, which requires that vowels in affixed morphemes agree in various phonological features with the vowels in the root or the preceding morphemes. For instance, *-lar* in 'pullar' ('stamps') and *-ler* in 'güller' ('roses') both indicate plurality; the vowel *-u* in the first word's root forces the vowel in the suffix to be an *-a*, and the *-ü* in the second word's root forces the vowel in the suffix to be an *-e*. Words where such agreement is missing are considered to be ill-formed. Computational morphology develops formalisms for describing such changes, the contexts they occur in, and whether they are obligatory or optional (e.g. 'modeling' and 'modelling' are both valid forms).

MORPHOTACTICS

Morphotactics describes the structure of words, that is, how morphemes are combined to form words as demanded by the syntactic context and with the correct semantics (in the case of derivational morphology). The root words of a language are grouped into *lexicons* based on their part of speech and other criteria that determine their morphotactical behavior. Similarly, the bound morpheme inventory of the language is also grouped into lexicons. If morphemes are combined using prefixation or suffixation, then the morphotactics of the language describes the proper ordering of the lexicons from which morphemes are chosen. Morphotactics in languages like Arabic require more elaborate combinations where roots consisting of just consonants are combined with a vocalization template that describes how vowels and consonants are interdigitated to form the word with the right set of features.

The state-of-the art formalisms for describing morphographemic phenomena are based on the mathematically well developed and understood theory of regular languages and relations, and their computational models of finite state recognizers and transducers (Kaplan and Kay, 1994). Such morphophonological and morphographemic changes are described as either a cascade of *replace rules* or a set of parallel *two-level rules* (Koskenniemi, 1983), both of which are compiled into finite state transducers. The morphotactics for most languages can also be handled by finite state machinery: the ordering of morphemes can be described by relatively simple finite state grammars and can be compiled into finite state transducers. Even for languages like Arabic with complex morpheme combinations, finite state methods can be used (Beesley, 1996; Kiraz, 2000). The use of finite state machinery enables the combination of the finite state transducers for morphographemics and morphotactics into a single finite state transducer, which can process words very fast (Karttunen, 1994). There are, however, certain morphotactical phenomena, notably partial or full duplication (for example, in Indonesian, the plural of 'orang' ('man') is 'orangorang'), which cannot be elegantly described by finite state machinery, apart from full listing of the duplicated forms in a lexicon.

Finite state tools for building wide-coverage morphological analyzers typically let (computational) linguists describe the morphographemics and morphotactics using high-level notational tools which are then compiled into finite state transducers. This compilation may, however, be quite memory-intensive as algorithms for combining finite state transducers rely on operations such as composition that may require large amounts of memory. Another source of complexity which (at least theoretically) comes up in the context of two-level morphology is that the generate-and-test approach employed in some of the earlier two-level morphology implementations (e.g. Antworth, 1990) may be inherently computationally inefficient (Barton *et al*., 1988, chap. 5). However, empirical evaluations have shown that this complexity is not observed in practice (Koskenniemi and Church, 1988).

Another recent thread of research in computational morphology is the use of machine learning techniques for inducing morphophonological transducers (Gildea and Jurafsky, 1996), for two-level rules (Theron and Cloete, 1997), and for bootstrapping full morphological analyzers (Oflazer *et al*., 2001).

Morphology

Introductory article

Stephen R Anderson, Yale University, New Haven, Connecticut, USA

CONTENTS

Morphology, in linguistics, is the study of the forms of words, and the ways in which words are related to other words of the same language. Formal differences among words serve a variety of purposes, from the creation of new lexical items to the indication of grammatical structure.

INTRODUCTION

If you ask most nonlinguists what primary thing has to be learned in order to *know* a language, the answer is likely to be 'the words of the language'. Learning vocabulary is a major focus of language instruction, and while everyone knows that there is a certain amount of 'grammar' that characterizes a language as well, even this is often treated as a kind of annotation to the set of words – the 'uses of the accusative', etc. But what is it that is involved in knowing the words of a language?

Obviously, a good deal of this is a matter of learning that *cat*, pronounced [k^hæt], is a word of English, a noun that refers to a 'feline mammal usually having thick soft fur and being unable to roar'. The notion that the word is a combination of sound and meaning – indeed, *the* unit in which the two are united – was the basis of the theory of the linguistic *sign* developed by Ferdinand de Saussure at the beginning of the twentieth century. But if words like *cat* were all there were in language, the only thing that would matter about the form of a word would be that it differs from the forms of other words (i.e., cat is pronounced differently from *mat, cap, dog*, etc.). Clearly there is no more specific connection between the parts of the sound of cat and the parts of its meaning: the initial [k^h], for example, does not refer to the fur. The connection between sound and meaning is irreducible here.

But of course *cat* and words like it are not the end of the story. Another English word is *cats*, a single word in pronunciation but one that can be seen to be composed of a first part *cat* followed by another part *–s*, with the meaning of the whole made up of the meaning of *cat* and the meaning of *–s* ('plural'). *Cattish* behavior is that which is similar to that of a cat; and while a *catbird* is not itself a kind of cat, its name comes from the fact that it sometimes sounds like one. All of these words are clearly connected with *cat*, but they are also all words in their own right.

We might, of course, simply have memorized *cats, cattish* and *catbird* along with *cat*, even though the words seem to have some sort of relation to one another. But suppose we learn about a new animal, a *wug*, say 'a large, hairy bovine mammal known for being aggressive and braying'. We do not need to learn independently that two of these are *wugs*, or that *wuggish* behaviour is likely to involve attacking one's fellows, or that a *wugbird* (if there were such a thing) might be a bird with a braying call. All of these things follow from the knowledge we have not just of the specific words of our language, but of their relations to one another, in form and meaning. The latter is our knowledge of the morphology of our language.

In some languages, the use of morphology to pack complex meanings into a single word is much more elaborate than in English. In West Greenlandic, for example, *tusaanngitsuusaartuaannarsiinnaanngivipputit* is a single word meaning 'you simply cannot pretend not to be hearing all the time'. Other languages do much less of this sort of thing: Chinese and Vietnamese are often cited in this connection, though Chinese does have rather exuberant use of compounding (structures like *catbird* made up of two existing items). Despite this variation, however, morphology is an aspect of the grammar of all languages, and in some it rivals syntax in the expressive power it permits.

INFLECTION

Traditionally, morphology is divided into several types, depending on the role played in grammar by

a given formation. The most basic division is between inflection and word formation: the latter is easy enough to characterize as 'morphology that creates new words' (*wuggish, wug-like, wugbird*), but inflection (e.g., *wugs*) is rather harder to define. Often, inflection is defined by example: categories like number (e.g., 'plural'), gender (e.g., masculine, feminine and neuter in Latin), tense ('past'), aspect (e.g., the difference between the *imparfait* and the *passé simple* in French), case ('accusative'), person (first *vs* second *vs* third) and perhaps a few others are inflectional while everything else is word formation. But this approach is inadequate, because the same category may be inflectional in some languages, and not in others. In Fula (a West Atlantic language), for example, the category 'diminutive' is fully integrated into the grammar of agreement in the language, just as much as person, number, and gender. Verbs whose subjects are diminutive indicate this with an agreement marker, as do adjectives modifying diminutive nouns etc. In English, in contrast, diminutives appear in forms like *piglet*, but these are clearly cases of word formation. On the other hand, while number is clearly involved in important parts of English grammar (verbs agree with their subjects in number), other languages, like K^{w}ak^{w}'ala (or 'Kwakiutl') treat the category of plural as something that can optionally be added to nouns, or to verbs, as an elaboration of meaning that has no further grammatical consequence.

Despite the intuitively clear nature of the category of inflection, other efforts to define it explicitly do no better. Inflection is generally more *productive* than other sorts of morphology, for instance: virtually every German noun has an accusative, a plural etc., while only a few English nouns have a diminutive formation like *piglet*. But in some languages, categories that we would certainly like to call inflectional are quite limited: in Basque, for example, only a few dozen verbs (the number varying from one dialect to another) have forms that show agreement. In English, on the other hand, the process of forming nouns in *–ing* from verbs (as in *Fred's lonely musings about love*) can take virtually any verb as its basis, despite being intuitively a means of creating new words, not of inflecting old ones. A variety of other attempts that have been cited also fail, either because of ready counterexamples, or because they are insufficiently general: inflectional material is generally found at the word's periphery, while word formational markers are closer to the stem (cf. *piglets* but not **pigslet*), but this property is only useful in words that contain material of both types, and even then, it does not help us to find the boundary in a word like French *im-mort-al-is-er-ait* 'would immortalize'.

In fact, the intuition underlying the notion of 'inflection' seems to be the following: inflectional categories are those that provide information about grammatical structure (such as the fact that a noun in the accusative is likely to be a direct object), or which are referred to by a grammatical rule operating across words (such as the agreement of verbs with their subjects). The validity of other correlates with inflectional status, then, follows not from the nature of the categories themselves, but rather from the existence of grammatical rules in particular languages that refer to them, and to the freedom with which items of particular word classes can appear in positions where they can serve as the targets of such rules.

For any given word, we can organize a complete set of its inflectional variants into a *paradigm* of the word. Thus, a German noun has a particular gender, and a paradigm consisting of forms for two numbers (singular and plural) and four cases (nominative, genitive, dative, and accusative). German adjectives have paradigms that distinguish not only case and number but also gender (since they can agree with nouns of any of the three genders), plus another category that distinguishes between 'strong' and 'weak' declensions (depending on the presence of certain demonstrative words within the same phrase).

All of the word forms that make up a single inflectional paradigm have the same basic meaning. In general, they are all constructed on the basis of a basic shape, or stem, though in many languages with complex inflection, the paradigm of a given word may be built from more than one stem. In French, for example, the verb *pouvoir* 'to be able to' shows different stems in (*je*) *peux* 'I can' and (*je*) *pourrais* 'I would be able to'.

Certain terminology has become more or less accepted in describing facts of these sorts. We refer to a particular sound shape (e.g. [fawnd]) as a specific *word form*; all of the inflectional forms in a single paradigm are said to make up a single *lexeme* (e.g., *find*). A specific *morphosyntactic form* of a particular lexeme (e.g., the past tense of *find*) is realized by a corresponding word form [fawnd]). These terms are all distinct, in their way: thus, the same morphosyntactic form of a given lexeme may correspond to more than one word form (e.g., the past tense of *dive* can be either [daivd] or [dowv]), while the same word form can realize more than one morphosyntactic form (e.g., [hɪt] can be either the past tense of *hit*, the non-third-person present tense of *hit*, or the singular of the noun *hit*).

WORD FORMATION

Inflection, then, is the morphology that distinguishes the various forms within the paradigm of a single lexeme. Some languages, like ancient Greek or Georgian, have a great deal of inflectional morphology, while others (like English) have much less, and some (like Vietnamese) have hardly any at all. Regardless of this, however, essentially all languages have ways of constructing new lexemes from existing ones, or patterns of word formation. These fall into two broad classes: *compounding* is the process of combining two or more independently existing lexemes (perhaps with some additional material as 'glue') into a single new lexeme (as in *catbird*). *Derivation*, in contrast, is the formation of a new lexeme from an existing one by means of material that does not appear by itself as a word. It is common to refer to such non-independent content as *bound*, in contrast with independently occurring or *free* elements.

Derivation

A typical derivational relation among lexemes is the formation of adjectives like *inflatable* from verbs (*inflate*). In this case, the meaning of the adjective is quite systematically related to that of the verb: VERB-*able* means 'capable of being VERB-ed'. It is therefore tempting to say that English contains an element *–able* with that meaning which can simply be added to verbs to yield adjectives. The facts are a bit more complex that that, though.

For one thing, the related adjective may not always be just what we would get by putting the two pieces together. For instance, *navigate* yields *navigable, formulate* yields *formulable*, etc. These are instances of *truncation*, where a part of the base is removed as an aspect of the word formation process. Then there are cases such as *applicable* from *apply*, where we see the same variation (or *allomorphy*) in the shape of the stem as in *application*. These patterns show us that the derivational whole may be more than the simple sum of its parts.

When we consider the class of adjectives in *–able* (or its spelling variant *–ible*), we find a number of forms like *credible, eligible, potable, probable* … which seem to have the right meaning for the class (they all mean roughly 'capable of being [SOMETHING]-ed'), but the language does not happen to contain any verb with right form and meaning to serve as their base. This suggests that derivational patterns have a sort of independent existence: they can serve as (at least partial) motivation for the shape and sense of a given lexeme, even in the absence of the possibility of deriving that lexeme from some other existing lexeme. In some instances, the force of this analysis is so strong that it leads to what is called *back-formation*: thus, the word *editor* was originally derived from Latin *e:dere* 'to bring forth' plus *–itor*, but it fit so well into the pattern of English agent nouns in *–er* (e.g., *baker, driver*) that a hypothetical underlying verb *edit* actually became part of the language.

We may also notice that some *–able* forms do not mean precisely what we might predict. Thus, *comparable* means 'roughly equal', not just 'able to be compared'. In the world of wine, *drinkable* comes to mean 'rather good', not just 'able to be drunk', etc. This shows us that even though these words may originally arise through the invocation of derivational patterns, the results are in fact full-fledged words of the language; and as such, they can undergo semantic change independent of the words from which they were derived. This is the same phenomenon we see when the word *transmission*, originally referring to the act or process of transmitting (e.g., energy from the engine to the wheels of a car) comes to refer to a somewhat mysterious apparatus which makes strange noises and costs quite a bit to replace.

Finally, we can note that in some cases it is not at all evident how to establish a 'direction' of derivation. In Maasai, for example, there are two main noun classes ('masculine' and 'feminine'), and one derivational pattern consists in taking a noun which is 'basically' of one class and treating it as a member of the other. Thus, *en-kérái* is a feminine noun that refers to any child, of either gender; while *ol-kérái* is a corresponding masculine noun meaning 'large male child'. Here it looks plausible to take the feminine form as the basis for the derivational relationship; but when we consider *ol-abáánì* (masculine) 'doctor' vs. *enk-abáánì* 'small or female doctor, quack' it looks as if the direction of derivation goes the other way. In fact, it looks as if what we have here is a case of a relation between two distinct patterns, where membership in the feminine class may (but need not) imply femaleness and/or relatively small size, as opposed to the masculine class which may imply maleness and/or relatively large size. When a word in either class is used in the other, the result is to bring out the additional meaning associated with the class, but there is no inherent directionality to this relationship. The possibility of back-formation discussed above suggests that this interpretation of derivational relationships as fundamentally symmetrical may be applicable even to cases where the formal direction of derivation seems obvious.

Compounding

The other variety of word formation, compounding, seems fairly straightforward, even if the actual facts can be quite complex at times. Compounds are built of two (or more) independent words, and have (at least in their original form) a meaning that involves those of their components. Thus, a *catfish* is a kind of fish sharing some property with a cat (in this case, the whiskers). Like derived forms, compounds are independent lexemes in their own right, and as such quickly take on specialized meanings that are not transparently derived from those of their parts. We need to tell a story to explain why a *hotdog* is called that, why a *blackboard* can be green, etc.

Where it is possible to relate the meaning of a compound to those of its parts, it is often possible to establish a privileged relationship between the semantic 'type' of the whole compound and that of one of its pieces. Thus, a *doghouse* is a kind of *house* (and certainly not a kind of *dog*), *outdoing* is a kind of *doing*, etc. When such a relation can be discerned, we refer to the 'privileged' member of the compound as its head, and speak of the compound itself as *endocentric*.

By no means all compounds would appear to be endocentric, however: a *pickpocket* is neither a kind of pocket nor a kind of picking, and a *sabre-tooth* is a kind of tiger, not a kind of tooth. Traditional grammar provides a variety of names for different types of such *exocentric* compounds, some deriving from the Sanskrit grammatical tradition in which these were of particular interest. A *bahuvrihi* compound is one whose elements describe a characteristic property or attribute possessed by the referent (e.g., *sabre-tooth, flatfoot*); a *dvandva* compound is built of two (or more) parts, each of which contributes equally to the sense (e.g., an *Arab-Israeli* peace treaty).

In some languages, the decision as to which compounds are endocentric and which are not depends on the importance we give to different possible criteria. For instance, in German, *Blauhemd* '(soldier wearing a) blue shirt' is on the face of it a bahuvrihi compound, exocentric because it does not denote a kind of shirt. On the other hand, the gender of the compound (neuter, in this case) is determined by that of its rightmost element (here, [*das*] *hemd* '[the] shirt'). Semantically, *blauhemd* is exocentric; while grammatically, it could be regarded as endocentric with its head on the right.

Languages can vary quite a bit in the kinds of compound patterns they employ. Thus, English compounds of a verb and its object (like *scarecrow*) are rather rare and unproductive, while this constitutes a basic and quite general pattern in French and other Romance languages. English and German tend to have the head, when there is one, on the right (*dollhouse*), while Italian and other romance languages more often have the head on the left (e.g., *caffelatte* 'coffee with milk'). Most English compounds consist of two elements (though one of these may itself be a compound, as in [[*high school*] *teacher*], leading to structures of great complexity such as German [[[[Leben]s-versicherung]s-gesellschaft]s-angestellter], 'life insurance company employee', but many dvandva compounds in Chinese consist of three or four components, as in *ting-tai-lou-ge*, '(pavilions-terraces-upper stories-raised alcoves) elaborate architecture'.

Finally, although we have defined compounds as built from free elements or independent lexemes, this leaves us with no good way of describing structures such as the names of many chemical compounds and drugs (*dichlorobenzene*, *erythromycin*) and words such as *Italo-American*. On the one hand, we surely do not want to say that there is a process that affects a base such as *American* by prefixing *Italo*. On the other hand, *Italo-*, *erythro-*, *chloro-* etc. do not occur on their own, but only in this class of compounds. Even more striking examples occur in other languages: the Mandarin root *yi*, 'ant', freely forms compounds such as *yiwang*, 'queen ant' (literally ant-king); *gongyi*, 'worker ant', *baiyi*, 'white ant, termite'. But *yi* is clearly not a word: the free word for 'ant' in Mandarin is *mayi*. While English *erythro* etc. are always prefixes, in Mandarin, the roots in question occur in both head and non-head position and are therefore like normal compound components in every respect except that they are not free forms. It appears that the very definition of compounding needs more thought than was initially evident.

REPRESENTATION OF MORPHOLOGICAL KNOWLEDGE

So far, we have talked of morphological relationships as existing between whole lexemes (in the case of word formation), or between word forms (in the case of inflection). Much traditional thought about morphology, however, regards these matters somewhat differently. Earlier, it was pointed out that the model of the Saussurean sign as the minimal unit where sound and meaning are connected could not serve as a description of the word, since (proper) parts of words often display their own connection between sound and meaning. It was

this observation, in fact, that led us to explore the varieties of morphology displayed in natural language. But many have felt that the proper place for the sign relation is not the word, but rather a constituent part of words: the *morpheme*. In that view, morphology is the study of these units, the morphemes: how they may vary in shape (the *allomorphy* they exhibit) and how they can be combined (*morphotactics*).

Morphemes and Words

The notion that words can be regarded as (exhaustively) composed of smaller signlike units, or morphemes, is extremely appealing. It leads to a simple and uniform theory of morphology, one based on elementary units that can be regarded as making up a sort of lexicon at a finer level of granularity than that of words. Nonetheless, it seems that this picture of word structure as based on a uniform relation of morpheme concatenation is literally too good to be true.

If morphemes are to serve the purpose for which they were intended, they ought to have some rather specific properties. It ought to be possible, for any given word, to divide its meaning into some small number of subparts, to divide its form into a corresponding number of continuous substrings of phonetic material, and then to establish a correspondence between the parts of meaning and the parts of form. Of course, it is possible to do exactly that in a great many cases (e.g., *inflatable*): hence the intuitive appeal of this notion. But in many other instances, such a division of the form is much more labored or even impossible.

One fairly minor problem is posed by parts of the form that are not continuous. When we analyze words containing circumfixes (e.g., *ke—an* in Indonesian *kebisaan*, 'capability', from *bisa*, 'be able') or infixes (e.g., *-al-* in Sundanese *ngadalahar*, 'to eat several', from *ngadahar*, 'to eat') one or the other of the component morphemes is not a continuous string of material.

Other cases are more serious. For instance, we may find no component of meaning to correspond to a given piece of form (an 'empty morph' such as the *th* in English *lengthen*, 'make long(er)') or no component of form that relates to some clear aspect of a word's meaning (English *hit* 'past tense of *hit*'). Sometimes two or more components of meaning are indissolubly linked in a single element of form, as in French *au* ([o]), 'to the (masc.)' or the ending *–o*: of Latin *amo:* which represents all of 'first person singular present indicative', various categories that are indicated separately in other forms. When we look beyond the simple cases, it appears that the relation between form and meaning in the general case is not one-to-one at the level of the morpheme, but rather many-to-many.

In fact, it seems that even though both the forms and the meanings of words can be divided into components, the relation is still best regarded as holding at the level of the entire word, rather than localized exclusively in the morpheme. We have also seen support for this notion in the fact that entire words, presumably composed of multiple morphemes, develop idiosyncratic aspects of meaning that cannot be attributed to any of their component morphemes individually (e.g., *appreciable* and *considerable* coming to mean not 'capable of being appreciated/considered' but 'substantial, relatively large'). On this basis, many linguists have come to believe that morphological relations are based on the word rather than the morpheme. Actually, we need to take into account the fact that in highly inflected languages like Latin or Sanskrit, no existing surface word form may supply just the level of detail we need, since all such words have specific inflectional material added. For such a case, we need to say that it is *stems* (full words minus any inflectional affixation) that serve as the basis of morphological generalizations, in the sense of representing the phonological component of a lexeme.

Items and Processes

A further difficulty for the notion that morphemes are the basis of all morphology comes from the fact that in many cases some of the information carried by the form of a word is represented in a way that does not lend itself to segmentation. One large group of examples of this sort is supplied by instances in which it is the replacement of one part of the form by another, rather than the addition of a new piece, that carries meaning. Such relations of *apophony* include *umlaut* (*goose/geese, mouse/mice*), *ablaut* (*sing/sang/sung*) and such miscellaneous relations as those found in *food/feed*, *sell/sale, sing/song*, *breath/breathe*, and many others. Terms for these relations often refer to their historical origins and do not reflect any particularly natural category in the modern language (e.g., the categories of *umlaut* as opposed to *ablaut* in modern English).

Sometimes some information is carried in a word's form not by the addition of some material (a morpheme), but by the deletion of something that we might expect. In the Uto-Aztecan language Tohono O'odham ('Papago') for example, the perfective form of a verb can in most instances be

found by dropping the last consonant of the imperfective form (whatever that may be): thus, *gatwid* 'shooting' yields perfective *gatwi* 'shot'; *hikck* 'cutting' yields *hikc* 'cut', etc.

Examples like these (and several others which we cannot consider here for reasons of space) suggest that the relations between words that constitute a language's morphology are best construed as a collection of *processes* relating one class of words to another rather than as a collection of constituent morphemic *items* that can be concatenated with one another to yield complex words. Of course, the simplest and most straightforward instance of such a process is one that adds material to the form (a prefix at the beginning, a suffix at the end or an infix within the basic stem), but this is only one of the formal relations we find in the morphologies of natural languages. Others include changes, permutations, deletions and the like. Linguists set on treating all morphological relations as involving the addition of morphemes have proposed analyses of many of these apparent processes in such terms, but it is possible to ask whether the extensions required in the notion of what constitutes an 'affix' do not in the end empty it of its original theoretical significance.

CONCLUSION

We have seen above that the forms of words can carry complex and highly structured information. Words do not serve merely as minimal signs, arbitrary chunks of sound that bear meaning simply by virtue of being distinct from one another. Some aspects of a word's form may indicate the relation of its underlying lexeme to others (markers of derivational morphology or of compound structure), while other aspects indicate properties of the grammatical structure within which it is found (markers of inflectional properties). All of these relations seem to be best construed as knowledge about the relations between *words*: That is, relations between whole lexemes, even when these can be regarded as containing markers of their relations to still other lexemes; and relations between word forms that realize paradigmatic alternatives built on a single lexeme's basic stem(s) in the case of inflection. These relations connect substantively defined classes in a way that is only partially directional in its essential nature, and the formal connections among these classes are signaled in ways that are best represented as processes relating one shape to another.

Optimality Theory

Intermediate article

Diana Archangeli, University of Arizona, Tucson, Arizona, USA

CONTENTS

Optimality theory proposes that universal grammar consists of a set of constraints, and that language-specific grammars consist of different rankings of these constraints.

INTRODUCTION

Optimality theory was introduced in the early 1990s (Prince and Smolensky, 1993; McCarthy and Prince, 1993a). These early works recognized a class of cases that continued to challenge 'classical' generative phonological theory, and proposed a dramatically different model – optimality theory – with which to address those challenges. Rather than a series of rules for rewriting that change an underlying form into a surface form, the core of optimality theory (OT) is to determine the best pairing between input ('underlying') and output ('surface'), given the requirements of the language in question. This is accomplished through a device known as 'constraint satisfaction'. A very appealing aspect of OT is the nature of these constraints that need to be satisfied. They are proposed as universal statements about language, thereby providing a means for encoding universal language properties directly in the grammar of specific languages. In addition to addressing standard issues of the synchronic nature of language, OT also is proving to be a valuable tool for a deeper understanding of how language works, giving insights into areas such as language acquisition and language change. OT is not without its own challenges, addressed at the close of this article.

CHALLENGES FOR CLASSICAL PHONOLOGICAL THEORY

Classical rule-based phonological theory faces a number of challenges. One class of challenges is that in which the rule-based analysis is mechanical rather than explanatory. For example, Kisseberth (1970) pointed out that in order to account for certain patterns under a rule-based model of phonology, it was necessary that a variety of rules 'conspire' to create a particular type of surface form. The rules participating in such a conspiracy need not have any formal relation to each other, and in fact can be virtual opposites. For example, rules of vowel insertion and vowel deletion work together in Yawelmani to ensure that syllables have one of three forms: CV, CVC, or CVV. Thus, the conspiracy emerges only when the surface forms are compared. Although it is possible to express the phenomena through a complex set of rules, this strategy fails to provide an explanation: it is simply coincidental that the mental representations are such that a particular set of rules produces surface forms of a uniform type.

The second class of challenges to the rule-based system is conceptual. Rule-based models typically include constraints as well as rules, such as constraints on underlying representations (defining the feature inventories from which underlying representations are created, requiring that certain features be unassociated, etc.). If rules alone are inadequate, the challenge, then, is to test whether constraints alone are adequate. This is the goal of OT.

Another important conceptual difference is in the way markedness is characterized in the grammar. Markedness refers to powerful cross-linguistic tendencies, such as the tendency for syllables to have onsets, for heavy syllables to be stressed, etc. Under a rule-based model, markedness is peripheral to the formal model. There are efforts to include markedness somehow, such as the marking conventions introduced in *The Sound Pattern of English* (Chomsky and Halle, 1968). However, the coherence of the rule-based model is not affected by whether or not markedness is incorporated formally. Thus, significant cross-linguistic generalizations are peripheral, not integral, to classical phonological theory. OT, as a theory of constraint satisfaction, places markedness constraints at the core of individual language phonologies.

CONSTRAINT SATISFACTION

The architecture of OT is simple. There are universal primitives of two types, primitive elements and primitive constraints. Phonological elements (or units, such as features, moras, and syllables) are the basis from which representations are constructed. Constraints govern both markedness and faithfulness. Markedness constraints prefer unmarked configurations. Faithfulness constraints prefer a perfect match between input and output.

In addition, there are two universal operations, generate (GEN) and evaluate (EVAL). GEN takes a specific input and randomly adds and deletes elements to construct an (in principle) infinite set of candidates for the output. EVAL examines the candidates and the relations between the candidates and the input in order to select the optimal output for that input. EVAL is composed of a language-particular ranking of the universal constraint set. The mechanism by which EVAL makes this selection is constraint satisfaction.

Candidates are evaluated with respect to the highest ranked constraint first; the candidates which survive for evaluation by the next constraint are those that best satisfy the top ranked constraint (either by fully satisfying the constraint or by violating it less than any other candidates). This procedure is repeated with the next constraint until a single candidate remains.

For example, in numerous languages, sequences of three or more consonants may result from morphological concatenation. Languages vary in their response to such sequences. OT claims that the variation is due to different rankings of the constraints in EVAL. For this case, three markedness constraints are necessary: that syllables have vowels (PEAK), that they not have codas (NOCODA), that at most one consonant appears in the onset or the coda (*CC). In addition, two faithfulness constraints are necessary, one preferring that input and output vowels match (FAITHV) and a similar one for consonants (FAITHC).

Consider, for instance, a language like English, which tolerates codas and tolerates consonant clusters within syllables. Formally, under OT, NOCODA and *CC are relatively unimportant and so are low ranked, indicated by the heavy black bar in the display. Each violation is indicated by an asterisk in the appropriate cell. The exclamation points are added to show the violation that eliminates a particular candidate from consideration. For example, (b) [lɪm.p.nɛs] is eliminated by a violation of PEAK. The ☞ indicates the optimal candidate. The shaded-in cells indicate constraints whose violations are irrelevant in the selection of the optimal candidate.

	/lɪmp-nɛs/	PEAK	FAITHV	FAITHC	NOCODA	*CC
☞a.	lɪmp.nɛs				**/	*
b.	lɪm.p.nɛs	*!			**/	
c.	lɪm.nɛs			*!	**/	
d.	lɪ.mip.nɛs		*!		*	
e.	lɪ.mi.pi.nɛ.si		*!*.*			
f.	lɪ.nɛ			*!**		

A display like this is known as a 'tableau', and is used to demonstrate constraint satisfaction given a particular constraint ranking. The heavy vertical bar indicates the most critical constraint ranking: constraints to the left are all ranked above constraints to the right.

Different constraint rankings produce different languages. For example, should *CC and FAITHC outrank FAITHV, the form with an inserted vowel (d) would be selected: this is the pattern chosen in Yawelmani. Languages like Hawaiian, which tolerate only open syllables, would rank NOCODA above all other constraints. Whether the NOCODA effect were achieved by vowel insertion or consonant deletion would depend on the relative rankings of FAITHC and FAITHV.

More abstractly, given a set of *n* constraints, there are *n*-factorial possible rankings, predicting up to *n*-factorial different languages, known as the factorial typology. As shown in the tableau, where the heavy black bar shows the only critical constraint ranking, many constraint rankings are irrelevant and so the full range of the factorial typology cannot be exploited.

THE UNIVERSAL BASIS FOR CONSTRAINTS

Constraints fall into two classes, markedness constraints and faithfulness constraints, both of which are universal. High-ranked markedness constraints indicate ways in which a language is unmarked. Low-ranked markedness constraints not only indicate ways in which a language is marked (because of being violated) but also the unmarked configurations emerge when higher ranked constraints fail to decide among candidates.

The interplay of two premises of the model, that constraints are violable and that there are markedness constraints, immediately explains the puzzle

that has frustrated earlier attempts to deal with markedness: namely, why many universals are tendencies, not absolutes.

Markedness constraints include constraints such as those noted above which define preferred configurations. In addition to constraints governing syllable structure there are constraints over feature co-occurrence, such as *if [+ round] then [+ back]*, the universal tendency for round vowels also to be back vowels. These constraints all fall into the class defining preferred combinations of primitive elements. There is, however, another large class of markedness constraints: those that prefer anchoring or aligning units with each other. Anchoring constraints may be straightforward phonological constraints, such as aligning the edge of a heavy syllable to the edge of a foot. They also may anchor some phonological unit to some morphological unit. For example, vowel harmony might be characterized by an anchor or align constraint, preferring that the harmonic feature align to the edges of the word. Align and anchor constraints differ from other markedness constraints in that their form is universal, but particular instantiations of the forms vary from language to language (McCarthy and Prince, 1993b).

Faithfulness constraints are also universal under OT. Faithfulness constraints vary along different parameters. On the formal side, faithfulness may either refer to input corresponding to output ('MAX', prohibits deletion) or to output corresponding to input ('DEP', prohibits insertion). (The FAITHV and FAITHC constraints above conflate these two types of faithfulness.) Substantively, faithfulness constraints may refer to phonological units (e.g., MAX[Voice], DEP[High]), or to their organization, such as the order or number of elements in a string (preventing metathesis and merger or breaking, respectively) (McCarthy and Prince, 1995). One advantage of this perspective is that the issue of universality arises with every constraint posited for an analysis, driving us to a broader and deeper understanding of the claims made by an analysis.

EXTENSIONS OF OT

OT, originally proposed as a model of phonology, is being extended in a variety of ways. OT proposes a means of characterizing adult grammars. As such, it is also being explored as a model of syntax (Speas, 1997, and Pesetsky, 1997, in Archangeli and Langendoen, 1997; Grimshaw, 1997; Bresnan, 1999; Barbosa *et al*., 1998 and others), of semantics (Hendriks and de Hoop, 2001), and even of the semantics–pragmatics interface (Blutner, 2000). However, most extensions explore phonological effects in language variation, change, and acquisition. These three classes of phenomena may be closely related, under the view that language variation and change occur, at least in part, due to learning a grammar that is slightly different from the one learned by the previous generation.

The optimality theoretic analysis of both variation and change hinges heavily on the concept of constraint reranking. The idea is that different versions of a grammar (whether synchronic or diachronic) arise due to minimal changes in the ranking of constraints. Research efforts are underway to determine what principles, if any, restrict the types of rerankings that occur. For example, is there a particular distance that constraints must adhere to when reranking? Are there principled limits on the types of constraints that move higher? Lower? How about the types of constraint that remain stationary (Holt, 1997)?

Under OT, language acquisition consists of the problem of determining the correct ranking of the universal constraints. The most convincing models are those which take two things as basic assumptions: (i) anything proposed to be universal under the model (i.e., constraints and primitives) and (ii) anything to which a child has physical access (i.e., adult pronunciations) (Smolensky, 1996).

CHALLENGES FOR OT

Despite the advantages and interest of OT pointed out above, there are challenging issues faced by the model. One of these is its computational and psychological impossibility: if GEN truly creates an infinite set, then in real time we should all be stuck in a GEN state.

There are also empirical challenges: for example a phenomenon known as 'opacity'. Opacity arises in a rule-based system when the environment necessary for an earlier rule to apply is eliminated by application of a later rule: both rules apply, but at the surface the environment for the earlier rule is not present – hence opacity. These cases present a serious challenge to OT because of its reliance on the surface form. Opacity has led to a variety of proposals in efforts to account for these patterns. The most successful of these approaches is known as 'sympathy', wherein the optimal candidate bears a similarity to a (failed) sympathetic candidate (McCarthy, 1998.)

More broadly, the role of phonetics with respect to phonology is being eagerly explored, with some suggesting that the constraint hierarchies should

include phonetic constraints determining exact pronunciations as well as phonological constraints determining a phonological form (see, for example, Hayes, 1996).

Another broad class of empirical challenges arises from the ways in which phonology and morphology interface. The later stages of classical rule-based theory included the theory of lexical phonology (e.g., Kiparsky, 1982) which separated the phonological rules and the morphological operations of a language into distinct strata, pairing certain sets of morphological operations with specific sets of phonological rules. The OT hypothesis might accept this approach, and posit separate constraint hierarchies. However this is counter to the overall effort to simplify the formal mechanisms, for it would require that languages be able to refer to morphological constituents both in constraints and in defining strata. A new challenge introduced by OT is to determine whether it is possible to characterize the different phonological behaviors of specific morphemes through a single constraint hierarchy. Note that if both these efforts are successful, phonetics, phonology, and morphology will all be included in a single constraint hierarchy.

Parsing: Overview

Introductory article

Florian Wolf, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA
Edward Gibson, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

Parsing is the task of determining how the words in a sentence combine to yield a structured representation of the sentence meaning, given a grammar.

INTRODUCTION

To understand a sentence, one has to determine how the words in the sentence are combined to arrive at a meaning for the sentence. Consider the following examples:

a. The dog bites the man.
b. The man bites the dog. (1)

Sentences (1a) and (1b) have the same words. However, the words are combined differently, resulting in two very different sentence meanings. The set of rules governing how words are combined for a given language is called a *grammar* of that language. Sentences (1a) and (1b) are acceptable English sentences, whereas the asterisk preceding (2) indicates that this sentence is unacceptable. Sentences (1a) and (1b) follow the rules of English, whereas sentence (2) does not.

*The dog man bites the. (2)

The task of *parsing* is to determine how the words in a sentence combine to yield a structured representation of the sentence meaning, given a grammar. In contrast to a *parser*, a *recognizer* merely determines whether a sentence is grammatically correct or not, without producing a structured representation for the input sentence. A further contrast holds between *parsers* and *generators*. Whereas a parser takes a sentence as input and provides a representation of the meaning of the sentence as output, a *generator* takes some representation of meaning as input and provides a sentence as output.

This article discusses the process of parsing. The process of parsing is not just retrieving a representation of the sentence's meaning that is already stored in memory. If that were so, we would not be able to understand sentences that we have not heard before. Furthermore, there are an infinite number of possible sentences. Storing a representation of the meaning of each sentence in memory would require infinite memory resources.

This article will give a basic introduction to some parsing strategies that were developed in computational linguistics. It will also describe a method that deals efficiently with *local* (or *temporary*) and *global* ambiguity. Human languages are highly ambiguous. For example, sentence (3) contains both local and global ambiguity:

The man saw the woman on the hill with the telescope. (3)

The word 'saw' is locally ambiguous. That is, without disambiguating context, it could be either a tool or the past tense form of the verb 'see'. Sentence (3) is also globally ambiguous. It has five different readings, because the *prepositional phrases* (*PP*s) in (3), 'on the hill' and 'with the telescope', can modify either the *noun phrase* (*NP*) 'the woman' or the *verb phrase* (*VP*) 'saw the woman'. 'With the telescope' can also modify the *NP* 'the hill'. One of these readings would be equivalent to 'The man used the telescope in order to see the woman who was on the hill'. Another possible reading would be equivalent to 'The man saw the woman who was on the hill and who had a telescope'.

The number of readings of such ambiguities grows exponentially with the number of modifying phrases, PPs in this case. Such ambiguities are very frequent in human languages, but they usually do not present a problem to humans. This is in large part because humans use their knowledge of the world in order to rule out less likely possibilities as they are processing sentences word by word. For instance, humans usually do not get a reading of (3) in which 'with the telescope' modifies 'the hill', because without further context or assumptions we assume that it is unlikely that hills have telescopes.

PARSING STRATEGIES

The task in parsing is to discover how the words of a sentence can combine, using the rules in the grammar. A very simple grammar is presented in Figure 1 (where S = sentence; NP = noun phrase; VP = verb phrase; Det = determiner). The grammar indicates that a sentence (S) expands to a noun phrase (NP) and a verb phrase (VP), and that an NP expands to a determiner (Det) and a Noun, etc. We will refer to the symbol to the left of the arrow as the *left-hand side* (*LHS*) of a rule, and the right side of the arrow as the *right-hand side* (*RHS*) of a rule. The first symbol of the RHS is called the *left corner* of an RHS. The categories on the LHS of rules are sometimes called *nodes* in the grammar. Nodes that expand directly to a word (e.g. Det, Noun and Verb) are called *pre-terminals*. Nodes that do not expand directly to a word (e.g. S, NP and VP) are called *non-terminals*.

Using a grammar like this (much more complex in real applications), a parsing algorithm then establishes a syntactic structure for an input sentence. One possible parsing strategy starts by looking at the rules and seeing what input one can find that is compatible with the rules. Such a strategy is called *top-down*. Alternatively, one might start by looking at the input, and seeing which rules in the grammar apply to that input. This is a *bottom-up* strategy. Still another possibility would be some combination of top-down and bottom-up. The following sections describe these different parsing strategies in more detail.

The parsing algorithms described below process a sentence one word at a time, from left to right, similar to when people read or listen to language. A *stack* data structure (last in, first out) is used by the parser to keep track of the categories that the parser still needs to process to obtain a complete sentence structure. The parser also keeps a record of the structure that it has built so far.

Notice that the grammar in Figure 1 is unambiguous. That is, each left-hand side node has exactly one right-hand side. However, in more realistic grammars, this is not the case. Consider the possible expansions of the category VP in Figure 2. The first rule would be used for intransitive verbs such as 'walk', as in 'I walk'. The second rule would be used for transitive verbs such as 'like', as in 'I like the apple'. The third rule would be used for VPs that are modified by a prepositional phrase, for example, 'I see you with the telescope'. A parsing algorithm can handle ambiguity either by trying one choice at a time – a serial approach – or by following multiple alternatives at once – a parallel approach. Under a serial approach, the parser tries one of the rules first and pursues the resulting structure further, and backtracks and tries the other rule(s) only if the first rule fails, or if the goal is to find all possible parses. The ordering of the rules in the grammar determines which rule is applied first. Under a parallel approach, the parser works on all alternative rules and further pursues the resulting structures in parallel threads. A parallel approach requires some data structure that contains a set of parse trees, one tree for each combination of rules.

S	→ NP VP	Det	→ the
NP	→ Det Noun	Noun	→ man
VP	→ Verb NP	Noun	→ woman
		Verb	→ likes
		Verb	→ meets

Figure 1. A very simple grammar.

VP	→	Verb
VP	→	Verb NP
VP	→	VP PP

Figure 2. Some possible expansions of a *VP*.

Top-down Parsing

In *top-down* parsing, one starts with the assumption that the input will eventually form a sentence. This involves initially positing an S-node and all of the extensions of the S-node specified by the grammar (in our case, only $S \rightarrow NP\ VP$). One keeps expanding nodes, following the rules of the grammar, until one finds some matching input. The stack in a top-down parser keeps track of what still needs to be found in order to get a sentence that is well-formed according to the grammar. The pseudocode in Figure 3 shows a top-down algorithm in a general form. Notice that in the case of ambiguity, that is, if a left-hand side of a rule has more than one possible right-hand side (cf. Figure 2), the parser does not specify an order in which these rules are applied. This is called *non-deterministic* parsing.

In the following, we provide a step-by-step example of how a top-down parser would parse the sentence 'The man likes the woman', assuming the grammar from Figure 1 (cf. Figure 4):

```
FUNCTION top-down-parse (SENTENCE)
    initialize STACK = [S]
    DO
      IF (top-element of STACK = non-terminal N) THEN
        Select a rule N → A B
        Pop N from STACK
        Push A B onto STACK
        Add A B below N in the structure for the input
      ELSE IF (top-element of STACK = pre-terminal P) THEN
        Find next word W in SENTENCE
        IF (there is a rule P → W) THEN
          Pop P from STACK
          Add W below P in the structure for the input
        ELSE
          Fail.
        ENDIF
      ENDIF
    UNTIL STACK = [] AND end of SENTENCE is reached.
    RETURN PARSE-TREES
END top-down-parse
```

Figure 3. Pseudocode for top-down parser.

- Step 1: Push *S* onto the stack. Stack = [*S*]
- Step 2: Apply the rules that have *S* on their LHS. There is only one such rule in our grammar, $S \rightarrow NP\ VP$. Pop *S* from the stack. Push *NP* and *VP* onto the stack. Stack = [*NP VP*]
- Step 3: Apply the rules that have *NP* on their LHS. Here, this is only $NP \rightarrow Det\ Noun$. Pop *NP* from the stack. Stack = [*Det Noun VP*]
- Step 4: Find 'the' in the input and incorporate it into the parse tree. Pop *Det* from the stack. Stack = [*Noun VP*]
- Step 5: Find 'man' in the input and incorporate it into the parse tree. Pop *Noun* from the stack. Stack = [*VP*]
- Step 6: Apply the rules that have *VP* on their LHS. Here, this is only $VP \rightarrow Verb\ NP$. Pop *VP* from the stack. Push *Verb* and *NP* onto the stack. Stack = [*Verb NP*]
- Step 7: Find 'likes' in the input and incorporate it into the parse tree. Pop *Verb* from the stack. Stack = [*NP*]
- Step 8: Apply the rules that have *NP* on their LHS. Here, this is only $NP \rightarrow Det\ Noun$. Pop *NP* from the stack. Push *Det* and *Noun* onto the stack. Stack = [*Det Noun*]
- Step 9: Find 'the' and incorporate it into the parse tree. Pop *Det* from the stack. Stack = [*Noun*]
- Step 10: Find 'woman' in the input and incorporate it into the parse tree. Pop *Noun* from the stack. Stack = [ ]

One of the advantages of a top-down parser is that it never tries to form a structure that will never end up being an *S*, because it starts from *S*. One of the disadvantages of a top-down parser is that it can try to build trees that are inconsistent with the input. This did not happen with our extremely simplified grammar. However, if we also had a rule like $NP \rightarrow Det\ Adj\ Noun$ (*Adj* = Adjective), the parser could have predicted a structure that is inconsistent with the input, one that contains an Adjective.

Another problem with top-down algorithms is left-recursion. A grammar is left-recursive if it has some LHS that can be expanded through a series of rules such that the left corner of one of these expansions is the same LHS category. For example, if a grammar has a rule $VP \rightarrow VP\ NP$, the parser could keep extending the left corner of its RHS, *VP*, and get caught in an endless loop, as shown in Figure 5.

Bottom-up Parsing

Whereas top-down parsing starts with the rules, *bottom-up* parsing first looks at the input and then tries to find rules in the grammar that apply to the input. The stack in a bottom-up parser keeps track of what has been found so far and what still has to be integrated in a parse tree. The bottom-up parser considered here consists of two basic steps – pushing categories on the stack that still need to be integrated into the input structure (*shift*), and applying rules in the grammar to the categories on the stack (*reduce*). This algorithm is therefore also called *shift-reduce* parsing. The pseudocode in Figure 6 shows a bottom-up shift-reduce algorithm in a general form.

In the following, we provide a step-by-step example of how a bottom-up shift-reduce parser would parse the sentence 'The man likes the woman', assuming the grammar from Figure 1 (cf. Figure 7):

- Step 1: Find 'the' and its lexical category, *Det*. Push *Det* onto the stack. Stack = [*Det*]
- Step 2: Find 'man' and its lexical category, *Noun*. Push *Noun* onto the stack. Stack = [*Noun Det*]
- Step 3: Apply the rule $NP \rightarrow Det\ Noun$ to top of stack. Pop *Det* and *Noun* from the stack. Push *NP* onto the stack. Stack = [*NP*]
- Step 4: Find 'likes' and its lexical category, *Verb*. Push *Verb* onto the stack. Stack = [*Verb NP*]
- Step 5: Find 'the' and its lexical category, *Det*. Push *Det* onto the stack. Stack = [*Det Verb NP*]
- Step 6: Find 'woman' and its lexical category, *Noun*. Push *Noun* onto the stack. Stack = [*Noun Det Verb NP*]

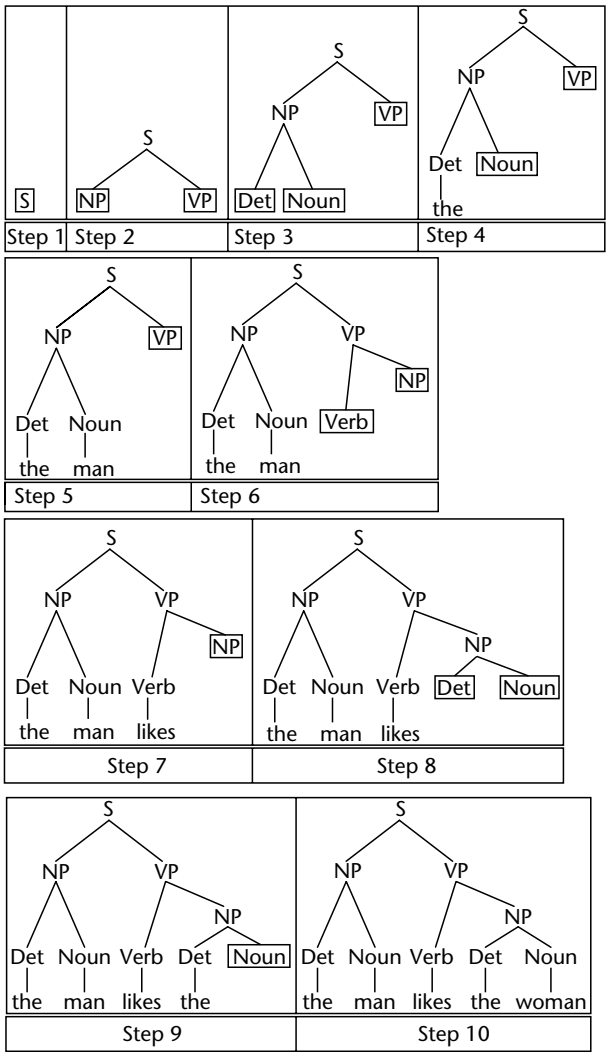

Figure 4. Top-down parsing step-by-step.

- Step 7: Apply the rule $NP \rightarrow Det\ Noun$ to top of stack. Pop *Det* and *Noun* from the stack. Push *NP* onto the stack. Stack = [*NP Verb NP*]
- Step 8: Apply the rule $VP \rightarrow Verb\ NP$ to top of stack. Pop *Verb* and *NP* from the stack. Push *VP* onto the stack. Stack = [*VP NP*]
- Step 9: Apply the rule $S \rightarrow NP\ VP$ to top of stack. Pop *NP* and *VP* from the stack. Push *S* onto the stack. Stack = [*S*]

An advantage of bottom-up parsers is that they do not predict parse trees that are inconsistent with the input. Furthermore, unlike top-down parsers, bottom-up parsers cannot get caught in an endless loop if the grammar contains left-recursive rules. A disadvantage of bottom-up parsers is that they can generate structures that never result in an *S*.

Left-corner Parsing

Left-corner parsing combines some elements from both top-down and bottom-up parsing. In left-corner parsing, only rules consistent with the input are predicted. That is, a rule is only predicted (top-down) if the current input (bottom-up) matches the leftmost node (hence left-corner) of the RHS of a rule. In left-corner parsing, a stack is used to keep track of what input is still needed to complete a predicted rule.

Left-corner parsing is particularly interesting from a cognitive science point of view, because it mirrors human performance in parsing more closely than pure top-down or bottom-up parsers. Consider the following sentences:

John's brother's dog's tail fell off. (4)

The dog chased the cat that caught the mouse that squeaked. (5)

The mouse that the cat that the dog chased caught squeaked. (6)

Sentence (4) has a *left-branching* structure, (5) a *right-branching* structure, and (6) a *center-embedded* structure. Humans do not have difficulty understanding sentences with left-branching structures like (4) or with right-branching structures like (5). However, sentences with center-embedded structures like (6) are hard for humans to process, in spite of the fact that (6) has virtually the same meaning as (5). It is plausible that the difficulty in center-embedded structures like (6) has to do with the quantity of storage space that is required to parse them. Table 1 shows a comparison between the processing complexity, for humans, of different

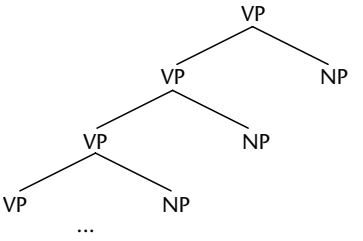

Figure 5. Endless loop due to left-recursion in a top-down algorithm.

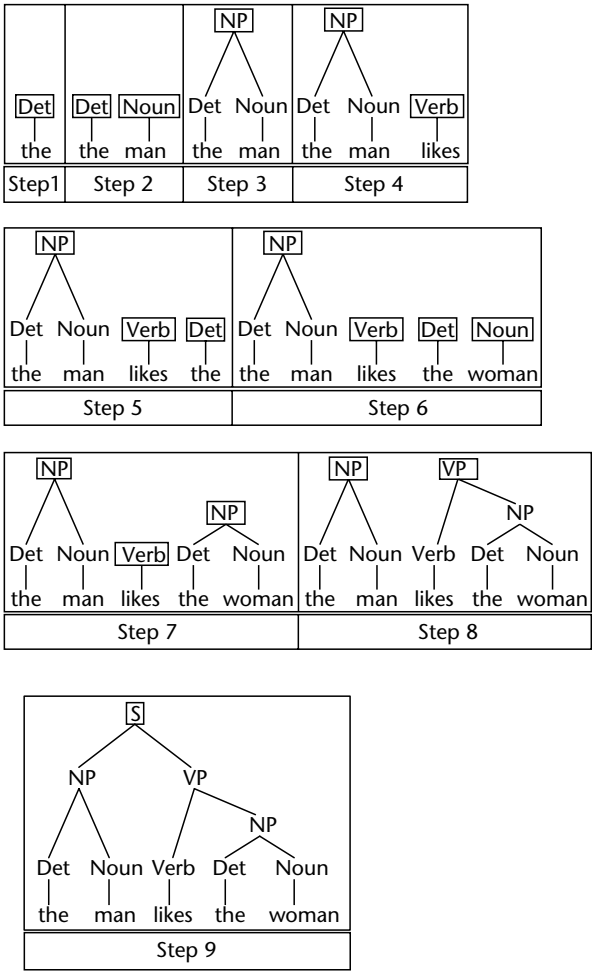

Figure 7. Bottom-up parsing step-by-step.

```
FUNCTION bottom-up-parse (SENTENCE)
  Initialize STACK = []
  DO
    Find next word W in SENTENCE
    IF (there is a rule P ⟶ W) THEN      /* shift */
      Push P onto STACK
    ENDIF
    IF (nodes on STACK = right-hand side of rule N ⟶ A B) THEN    /* reduce */
      Pop from STACK
      Push N onto STACK
      Add N above A B in the structure for the input
    ENDIF
  UNTIL STACK = [S] AND end of SENTENCE is reached
  RETURN PARSE-TREES
END bottom-up-parse
```

Figure 6. Pseudocode for bottom-up parser.

structural types, and the storage space for different parsing algorithms.

Table 1 shows that the stack size in a left-corner parsing algorithm mirrors human performance, but not in a top-down or a bottom-up algorithm. Thus, left-corner parsing algorithms are more psychologically plausible than top-down or bottom-up parsing algorithms.

The pseudocode in Figure 8 shows a left-corner algorithm in a general form.

Here is a step-by-step example parse of the sentence 'The man likes the woman' (cf. Figure 9):

- Step 1: Find 'the' and its lexical category, *Det*. Stack = [*S*]
- Step 2: Apply the rule $NP \rightarrow Det\ Noun$. Push *Noun* onto the stack. Stack = [*S Noun*]
- Step 3: Find 'man' and its lexical category, *Noun*. Pop *Noun* from the stack. Stack = [*S*]
- Step 4: Apply the rule $S \rightarrow NP\ VP$. Push *VP* onto the stack. Stack = [*VP*]
- Step 5: Find 'likes' and its lexical category, *Verb*. Pop *VP* from the stack. Stack = [ ]
- Step 6: Apply the rule $VP \rightarrow Verb\ NP$. Push *NP* onto the stack. Stack = [*NP*]
- Step 7: Find 'the' and its lexical category, *Det*. Pop *NP* from the stack. Stack = [ ]
- Step 8: Apply the rule $NP \rightarrow Det\ Noun$. Push *Noun* onto the stack. Stack = [*Noun*]
- Step 9: Find 'woman' and its lexical category, *Noun*. Pop *Noun* from the stack. Stack = [ ]

Head-corner Parsing

Head-corner parsing is a generalization of left-corner parsing. In left-corner parsing, one looks for the left-corner of the RHS of a rule to make top-down predictions. In head-corner parsing, one looks for the head of a rule. Roughly speaking, the head of a rule is the word at the semantic core of that rule. For example, in the rule $NP \rightarrow Det\ Noun$, *Noun* is at the semantic core. Thus, Noun is the head of NP. The idea behind looking at the head of a rule first is that it contains a lot of useful information (such as subcategorization, thematic roles,

Table 1. Performance of parsing algorithms and humans compared

	Sentence structure		
	Left-branching	*Center-embedded*	*Right-branching*
Stack size, top-down	unbounded	unbounded	bounded
Stack size, bottom-up	bounded	unbounded	unbounded
Stack size, left-corner	bounded	unbounded	bounded
Processing for humans	easy	hard	easy

```
FUNCTION left-corner-parse (SENTENCE)
  Initialize STACK = [S]
  DO
    Find next word W in SENTENCE
    IF (there is a rule P ⟶ W) THEN
      IF ((top-element of STACK = non-terminal N) AND ( P = left-corner
      of rule R ⟶ A B)) THEN
        Pop N from STACK
        Push B onto STACK
      ELSE IF ((STACK = []) AND (P = left-corner of rule R ⟶ A B)) THEN
        Push B onto STACK
      ENDIF
    ELSE
      Fail.
    ENDIF
  UNTIL STACK = [] AND end of SENTENCE is reached
  RETURN PARSE-TREES
END left-corner-parse
```

Figure 8. Pseudocode for left-corner parser.

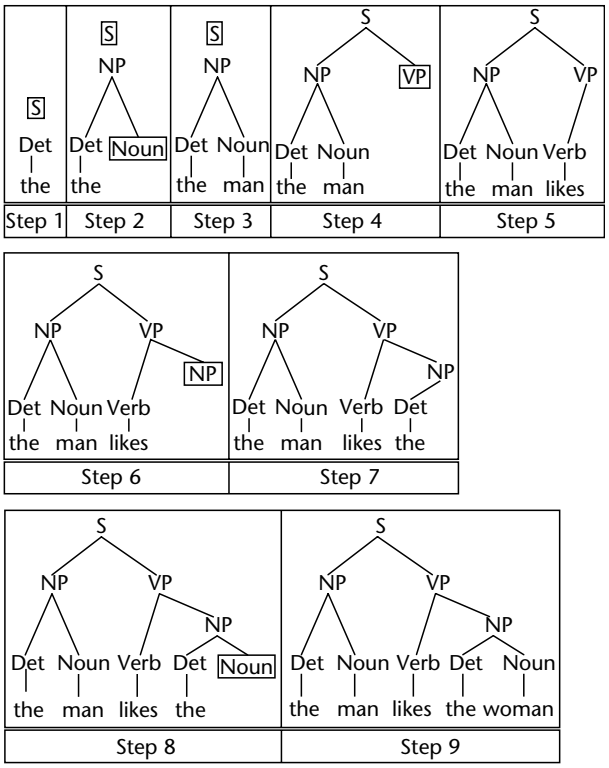

Figure 9. Left-corner parsing step-by-step.

etc.) which can allow for better top-down predictions. For instance, the lexical entry for a verb, which is the head of a VP, contains information about what NPs or PPs are needed to form a complete VP. As an example, consider the verb 'like'. Its lexical entry would contain the information that in order to form a complete VP, it needs an NP that denotes someone or something that is liked. These additional items are called *arguments*.

Having such information about head–argument relations available can improve the efficiency of parsing languages such as Japanese or German, whose word order is less constrained than that of English. Consider sentence (7):

The man likes the woman. (7)

In German, this sentence might also be written as

The woman likes the man. (8)

meaning, 'the man likes the woman'. The subject and object NPs are distinguished by morphological case marking in German. To be able to parse (7) as well as (8) correctly, a left-corner parsing algorithm would need two sets of rules. There would have to be one set of rules for (7) that includes $S \rightarrow NP\ VP$ and $VP \rightarrow Verb\ NP$. Another set of rules for (8) would have to include $S \rightarrow VP\ NP$ and $VP \rightarrow NP\ Verb$. A head-corner parsing algorithm does not require such a complex grammar. It is enough to have one set of rules that includes $S \rightarrow NP\ VP$ and $VP \rightarrow Verb\ NP$. Once a head-corner parser has found the head of the VP, 'likes', it can look for the argument of this head. This can be done bidirectionally – left-to-right or right-to-left – so that word order does not matter. The same applies to the rule $S \rightarrow NP\ VP$.

CHART PARSING

As mentioned in the introduction, human languages are extremely ambiguous. The parsing strategies discussed so far are very inefficient at handling ambiguity, whether they use a serial approach or a parallel approach. Consider the following sentence:

The tall man with brown hair saw the short woman with blond hair. (9)

Remember that 'saw' is ambiguous between a *Noun*-reading (a tool) and a *Verb*-reading (past tense of 'see'). This means that 'the tall man with brown hair' would have to be processed twice – once for the *Noun*- and once for the *Verb*-reading – although this segment gets the same structure in both parses. In realistic large-scale applications with big grammars, this can lead to efficiency problems that paralyse the whole application.

A way out of this situation is to give the parser a memory. With a memory, the parser can keep a record of all the parses it has attempted so far, and look them up instead of reparsing them. In parsing, such a memory is called *chart*. The chart keeps a record of partially as well as completely parsed rules from the grammar. In a chart, these rules are called *edges*. Partially parsed edges are called *incomplete* or *active*. Completely parsed edges are called *complete* or *inactive*. Once an edge is entered into the chart, it stays there. This is because we want to keep a record of all possible parses of a sentence, to facilitate backtracking. The following information about all edges (both active and inactive) is contained in a chart:

- the syntactic category of the edge, e.g. *NP*
- where in the sentence the edge begins (the *left end*)
- where in the sentence the edge ends (the *right end*)
- pointers to further inactive edges, e.g. to *Det Noun* for *NP*
- The following information is also included for active edges: a list of what categories are still needed to complete the active edge (to make it inactive).

A chart parser functions by combining active edges with inactive edges via the *Fundamental*

Rule. The Fundamental Rule looks for matches between categories that are needed in an active edge and the set of inactive (complete) edges. In order to start a parse, one has to specify a top-down or bottom-up strategy. This is accomplished by initializing the chart by adding either an empty active edge for an S (top-down) or inactive edges for the words in the sentence (bottom-up). The algorithm presented in Figure 10 uses a bottom-up strategy.

During the parse, when a match is found, a new edge is constructed by adding the inactive edge to the contents of the active edge. The original edges are left in the chart to allow reanalysis. The edges in the chart are labeled as follows:

```
STRUCTURE EDGE {
      CATEGORY
      CHILDREN
      LEFT-END
      RIGHT-END
      REQUIRED-CATEGORIES
}
FUNCTION chart-parse (SENTENCE)              /* the top-level function */
      initialize-chart SENTENCE, returning CHART-ACTIVES, CHART-INACTIVES,
      PARSE-TREE
      IF ((CHART-INACTIVES contains node S) AND (distance (left-corner (node S)
      AND to right-corner (node S)) = length (SENTENCE))) THEN
          RETURN PARSE-TREES
      ENDIF
END chart-parse
FUNCTION initialize-chart (SENTENCE)
      FOR (all words W in SENTENCE) DO
          add-new-edge LEXICAL-ENTRY (W)
      END
      RETURN (PARSE-TREE, CHART-ACTIVES, CHART-INACTIVES)
END initialize-chart

FUNCTION add-new-edge (EDGE)
   IF (EDGE = inactive) THEN
     FOR (all CHART-ACTIVES) DO
       fundamental-rule EDGE, CHART-ACTIVES
       add EDGE to CHART-INACTIVES
       add-null-active-edges EDGE
     END
   ELSE IF (EDGE = active) THEN
     FOR (all CHART-INACTIVES) DO
       fundamental rule EDGE, CHART-INACTIVES
       add EDGE to CHART-ACTIVES
     END
   ENDIF
END add-new-edge
```

```
FUNCTION fundamental-rule (ACTIVE-EDGE, INACTIVE-EDGE)
  IF ((left-end of INACTIVE-EDGE matches right-end of ACTIVE-EDGE) AND
  (INACTIVE-EDGE satisfies first category requirement of ACTIVE-EDGE))
  THEN
    NEW-EDGE = INACTIVE-EDGE incorporated in ACTIVE-EDGE
    IF (NEW-EDGE = active) THEN
      add NEW-EDGE to CHART-ACTIVES
    ELSE IF (NEW-EDGE = inactive) THEN
        add NEW-EDGE to CHART-INACTIVES
    ENDIF
  ENDIF
END fundamental-rule

FUNCTION add-null-active-edges (INACTIVE-EDGE)
   FOR (each rule from GRAMMAR whose rhs is initiated by INACTIVE-EDGE) DO
     NEW-ACTIVE-EDGE = rule in GRAMMAR with rhs initiated by INACTIVE-
     EDGE
     add-new-edge NEW-ACTIVE-EDGE
   END
END add-null-active-edges
```

Figure 10. Pseudocode for chart parser.

[category]/[what is already there]. [what is still needed]

Examples:

- *S/NP. VP*: category is S, an NP has been processed already, a VP is still needed, so the edge is active.
- *NP/Det Noun.* : category is NP, a Det and a Noun have already been processed, so the edge is inactive.

Active edges are printed above the words, inactive edges below. Furthermore, there are solid circles that denote stages of the parser.

Here is a step-by-step example, parsing the sentence 'The man likes the woman' (cf. Figures 11–21; to keep the figures legible, only the more important edges are shown):

- Step 1: Find 'the' and its lexical category, *Det*. Push an inactive edge, [*Det* / the .], onto chart-inactives. Chart-actives = [ ], chart-inactives = [*Det* / the .]
- Step 2: Make null-active-edge, [*NP*/. *Det Noun*]. Chart-actives = [*NP*/. *Det Noun*], chart-inactives = [*Det* / the .]
- Step 3: Apply Fundamental Rule to inactive edge, [*Det* / the .], and incorporate it into null-active-edge, [*NP*/. *Det Noun*]. Push active edge, [*NP* / the . *Noun*], onto chart-actives. Chart-actives = [[*NP* / the . *Noun*] [*NP*/. *Det Noun*]], chart-inactives = [*Det* / the .]
- Step 4: Find 'man' and its lexical category, *Noun*. Push an inactive edge, [*Noun* / man .], onto chart-inactives. Apply Fundamental Rule to inactive edge, [*Noun* / man .], and incorporate it into active edge, [*NP*/*Det* . *Noun*]. Push inactive edge, [*NP*/*Det Noun*.], onto chart-inactives. Chart-actives = [[*NP* / the . *Noun*] [*NP*/. *Det Noun*]], chart-inactives = [[*NP* / the man .] [*Noun* / man .] [*Det* / the .]]
- Step 5: Make null-active-edge, [*S*/. *NP VP*]. Chart-actives = [[*S*/. *NP VP*] [*NP* / the . *Noun*] [*NP*/. *Det Noun*]], chart-inactives = [[*NP* / the man .] [*Noun* / man .] [*Det* / the .]]
- Step 6: Apply Fundamental Rule to inactive edge, [*NP* / the man .], and incorporate it into active edge, [*S*/. *NP VP*]. Push active edge, [*S* / the man . *VP*], onto chart-actives. Chart-actives = [[*S* / the man. *VP*] [*S*/. *NP VP*] [*NP* / the . *Noun*] [*NP*/. *Det Noun*]], chart-inactives = [[*NP* / the man .] [*Noun* / man .] [*Det* / the .]]
- Step 7: Find 'likes' and its lexical category, *Verb*. Push an inactive edge, [*Verb* / likes .], onto chart-inactives. Chart-actives = [[*S* / the man . *VP*] [*S*/. *NP VP*] [*NP* / the . *Noun*] [*NP*/. *Det Noun*]], chart-inactives = [[*Verb* / likes .] [*NP* / the man .] [*Noun* / man .] [*Det* / the .]]
- Step 8: Make null-active-edge, [*VP*/. *Verb NP*]. Chart-actives = [[*VP*/. *Verb NP*] [*S* / the man . *VP*] [*S*/. *NP*

Noun]], chart-inactives = [[*NP* / the woman .] [*Noun* / woman .] [*Det* / the .] [*Verb* / likes .] [*NP* / the man .] [*Noun* / man .] [*Det* / the .]]

- Step 11: Apply Fundamental Rule to inactive edge, [*NP* / the woman .], and incorporate it into active edge, [*VP* / likes . *NP*]. Push inactive edge, [*VP* / likes the woman .], onto chart-inactives. Apply Fundamental Rule to inactive edge, [*VP* / likes the woman .], and incorporate it into active edge, [*S* / the man . *VP*]. Push inactive edge, [*S* / the man likes the woman .], onto chart-inactives. Chart-actives = [[*NP* / the . *Noun*] [*NP* /. *Det Noun*] [*VP* / likes . *NP*] [*VP* /. *Verb NP*] [*S* / the man . *VP*] [*S* /. *NP VP*] [*NP* / the . *Noun*] [*NP* /. *Det Noun*]], chart-inactives = [[*S* / the man likes the woman .] [*VP* / likes the woman .] [*NP* / the woman .] [*Noun* / woman .] [*Det* / the .] [*Verb* / likes .] [*NP* / the man .] [*Noun* / man .] [*Det* / the .]]

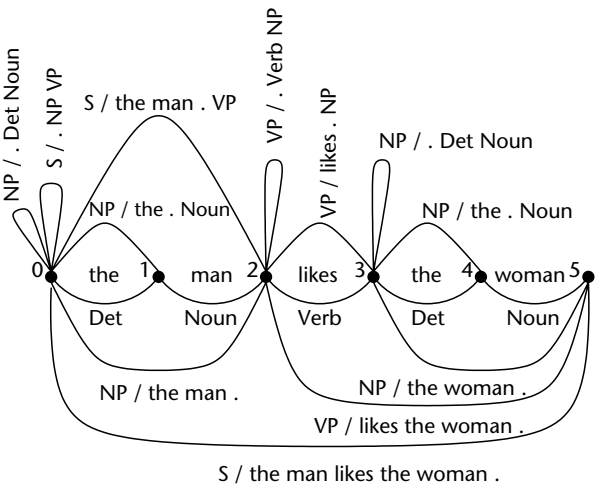

Figure 21. Chart parsing, step 11.

SUMMARY

Parsing – determining the structure of a sentence, given a grammar – is a crucial aspect of establishing meaning in language processing. There are two basic sets of constraints in parsing. One set of constraints is top-down: the rules in the grammar constrain which structures sentences can have in a given language. The other set of constraints is bottom-up: the input sentence to the algorithm constrains which rules from the grammar can apply. Parsing algorithms differ with respect to the constraints they use more prominently: bottom-up, top-down, or a combination of both (left- and head-corner).

An important issue in parsing is efficiently dealing with structural and lexical ambiguities. In an ambiguity, if the later disconfirmed alternative reading is pursued initially, a standard parser has to backtrack and re-parse parts of the input sentence. Re-parsing can be avoided by using a chart, a data structure that stores partially parsed input, so that it can be looked up during backtracking.

Parsing

Introductory article

Martin J Pickering, University of Edinburgh, Edinburgh, UK

CONTENTS

Parsing refers to the way that people assign a syntactic (grammatical) analysis to a sentence as they hear or read it.

INTRODUCTION

Our understanding of language is normally extremely efficient and often appears effortless. However, the underlying processes are extremely complex and sophisticated. They clearly make use of very specific information, as is apparent from the inability we have to perform any kind of analysis on an utterance in a language we are unfamiliar with. Researchers in the area assume that comprehension can be broken into several components, including word recognition and comprehension of entire discourses. Between such 'early' and 'late' stages lies a component that is concerned with processing combinations of words. Psycholinguists normally refer to this component as the 'parser'.

As a first approximation, parsing is concerned with assigning a syntactic analysis and a semantic interpretation to a sentence (or complete utterance). Hence, it is sometimes referred to as 'sentence processing'. The most important source of linguistic information that it employs is knowledge of syntax and semantics – in other words, the information that is discussed in most linguistic textbooks concerned with grammar. However, instead of simply describing analyses that can be assigned to sentences, a theory of parsing is concerned with understanding how people actually convert an uninterpreted string of words into a syntactic analysis and associated meaning.

Many studies of parsing involve reading or listening to sentences containing some syntactic ambiguity. Consider, for example, *The farmer hit the tramp with the stick*. According to linguistic theory, this sentence is ambiguous, not because a word has two meanings, but because the phrase *with the stick* can modify either the verb phrase *hit the tramp* or the noun phrase *the tramp*. In the former case, the sentence means that the farmer used the stick to hit the tramp; in the latter, it means that the farmer hit the tramp who had the stick. Theories of parsing attempt to determine how people analyze sentences, and they often use evidence about the processing of syntactically ambiguous sentences to do this. In order to do this, they examine what happens while (and sometimes after) people are reading or listening to such sentences.

One thing that we can now be certain of is that sentence comprehension begins almost immediately. We know this because a 'unified' interpretation is assigned to each sentence fragment as every word is encountered. For instance, people are disrupted by a word whose interpretation is incompatible with preceding context as soon as that word is encountered. But can information such as semantic plausibility be used to 'guide' parsing in cases of ambiguity? This has been the dominant question in parsing research and is motivated, ultimately, by the question of whether parsing constitutes an autonomous process that occurs before true interpretation takes place. In other words, answering this question may help resolve one aspect of the 'modularity' debate that has played such an important role in cognitive science. This article first considers the evidence for and against an autonomous parser, and then briefly considers ways in which parsing research is currently reaching beyond this question.

AUTONOMOUS ACCOUNTS

The 'classic' autonomous account is the 'garden-path' theory. On this account, the parser makes initial parsing decisions using some syntactic information and very little else. It uses a core principle known as 'minimal attachment' to decide which analysis to pursue in cases of ambiguity. This says adopt the simplest analysis, which is defined as the one involving fewest nodes in a phrase structure tree. According to Frazier's syntactic assumptions, the verb-phrase analysis of *The farmer hit the tramp with the stick* is simpler than the noun-phrase analysis, and so that analysis is initially adopted. In this

case the sentence is globally ambiguous (because the sentence has two interpretations). But the parser applies the principle as soon as an ambiguity emerges, and so the principle affects the processing of sentences that are locally ambiguous but which are eventually disambiguated. An example of a local ambiguity occurs in *The defendant examined by the lawyer turned out to be unreliable*, where *examined by the lawyer* is a 'reduced relative' that modifies *the defendant*; however, after *examined*, it might continue as a simple 'main-clause' sentence (e.g. *The defendant examined the jurors*). Because the main-clause analysis involves fewer nodes, the garden-path theory predicts that readers initially adopt this analysis. This analysis turns out to be incompatible with the words after *examined*, and so readers are 'led up the garden path': they experience processing difficulty and are forced to re-analyze (or fail to parse the sentence at all) (e.g. Frazier and Rayner, 1982).

If the two analyses have the same number of nodes, another principle, known as 'late closure', is applied. This says, when possible, attach new words into the phrase that is currently being processed. So for instance, in *John said Fred died yesterday*, the word *yesterday* is preferentially attached to *died* (i.e. Fred died yesterday). Neither minimal attachment nor late closure draws upon any information apart from phrase-structure geometry. According to garden-path theory, initial parsing pays no attention either to the relative frequency of the analyses or to whether the interpretation of one analysis is more compatible with background knowledge than the others (in other words, to plausibility). According to garden-path theory, information like frequency or plausibility can be used during subsequent processing. In other words, they can affect re-analysis, but not initial analysis. Thus, the model is called a 'two-stage' account, because the stages of initial analysis and re-analysis employ different sources of information. Additionally, notice that this theory assumes that the processor always adopts a single analysis at a time. Because alternative analyses are only ever considered if the initial analysis is abandoned, the garden-path theory is often called a serial account (i.e. one analysis at a time). Other autonomous accounts exist (including ones that make reference to thematic role assignment), but the garden-path theory is by far the best known.

Early experimental evidence provided strong support for the garden-path theory. For example, some work found that people had difficulty with sentences like *The spy saw the cop with a revolver*, where the verb-phrase analysis is implausible. This suggested that they initially adopted the verb-phrase analysis and then re-analyzed. Similarly, people appeared to have difficulty with reduced-relative sentences. But reduced-relatives are generally fairly rare types of sentence, so an alternative explanation for this result is surely that people have adopted the more frequent analysis.

INTERACTIVE ACCOUNTS

More recently, a great deal of experimental work has critiqued autonomous parsing accounts. In general, such research has attempted to show that a source of information, such as frequency or plausibility, plays a role in initial parsing decisions. This work supports 'interactive' accounts, in which all potentially relevant sources of information can be drawn upon at the same time. Although interactive accounts have a long history in language comprehension, the recent resurgence in their popularity has been associated with so-called constraint-based theories. These theories are broadly based on connectionist models and assume that language comprehension involves the integration of a large number of 'soft' constraints and that alternative analyses compete for activation. Importantly, such models assume that many analyses can be considered in parallel.

To explicate such accounts, consider a study that contrasted sentences like (a) *The defendant examined by the lawyer turned out to be unreliable* with (b) *The evidence examined by the lawyer turned out to be unreliable*. As in most good parsing research, the sentences are very closely related (only one critical word differs between them, and between other pairs of sentences used in the study). According to garden-path theory, people should initially adopt the reduced-relative analysis in both (a) and (b), because they are syntactically identical. But notice that while a defendant can examine things, evidence cannot. This means that the main-clause analysis of (b) is implausible at the word *examined*. Constraint-based accounts therefore predict that people will find it much easier to adopt the reduced relative analysis in (b) than (a). In accord with this, Trueswell *et al*. (1994) found that people were disrupted reading *by the lawyer* in (a) but not in (b). Early effects of 'referential' semantic processing have also been demonstrated, though alternative interpretations of these data are possible.

Constraint-based accounts also assume that the relative frequency of different analyses affects initial parsing preferences rather than (for example) minimal attachment. In other words, people initially prefer frequent analyses, not simple ones.

The sentence *The criminal confessed his sins harmed too many people* is locally ambiguous, in that confessed can either take a noun-phrase object (e.g. *his sins*) or a sentential complement (as turns out to be the case). If people experience difficulty reading *harmed*, this suggests that they initially interpreted *his sins* as the object, and then had to re-analyze. As the object analysis is simpler, garden-path theory predicts that it will always be adopted initially, and hence that re-analysis will always be necessary. While some recent work has supported this, other work has found that people re-analyze if the main verb more frequently takes an object than a sentential complement, but not if it more frequently takes a sentential complement.

Overall, there is good evidence that people use many relevant sources of information rapidly, but it is unclear precisely which model of comprehension is correct. Although it is by now unlikely that the garden-path model is correct, other autonomous parsing accounts may well be able to explain current data. Constraint-based accounts face challenges too (for instance to their claims that ambiguity resolution involves competition between alternatives and that lexical ambiguity resolution is a form of syntactic ambiguity resolution).

PARSING AND COMPREHENSION

The traditional focus on the nature of ambiguity resolution and its implications for the initial stages of parsing is, to some extent, being replaced by an interest in a series of broader questions about parsing and its relation to other aspects of language comprehension. One critical issue is what people do when they realize they have adopted the wrong analysis (or have preferred it, within a parallel architecture). Some recent evidence in this area suggests that some kinds of re-analysis are easier than others and that people adopt particular re-analysis strategies (e.g. when more than one alternative analysis is available). Another interesting question is whether people only re-analyze as a last resort or whether they sometimes 'bail out' of an analysis before being absolutely certain that it is incorrect.

Questions of re-analysis, however, still relate entirely to syntactic processing, that is how people adopt a syntactic analysis. However, the ultimate goal of parsing is, of course, to determine the appropriate interpretation that should be assigned to a string of words and to integrate that interpretation with discourse context and general knowledge. Thus, researchers have asked how people use context to decide on the appropriate interpretation for expressions – for example how people interpret elliptical phrases, how they should interpret a pronoun or other referring expression, and so on. It is clear that theories of parsing need to be fully integrated into more general accounts of language comprehension. This is likely to be a major focus of future research.

Performance and Competence

Introductory article

Lyn Frazier, University of Massachusetts, Amherst, Massachusetts, USA

There is an important distinction between knowledge of the general principles of grammar (competence) and the way that knowledge is applied in actual language production or comprehension (performance).

Knowing the rules of addition is one thing. Actually adding a column of numbers is another. Likewise, knowing the rules of grammar is one thing. Actually using that knowledge to assign a structure and interpretation to a sentence is quite another. A theory of a native speaker's implicit knowledge of language is what is known as a 'grammar' or, equivalently, a theory of language competence. A theory of how that knowledge is applied to produce sentences, or to comprehend sentences, is a theory of language performance.

If one were to collapse the theory of competence and the theory of performance, a variety of problems would emerge. First, one would need to choose: should the theory characterize language production, mapping from an intended 'message' to a set of motor instructions, or should it characterize language comprehension, mapping from a perceptual input to an intended meaning? Given a theory of language competence, the well-formedness rule of grammar (the subject precedes the verb in English, the object follows the verb, proper names aren't preceded by determiners, e.g. **the Mary*) can be stated once and for all, even though this may be used for purposes of speaking, writing, listening, or reading.

Further, the theory of grammar can abstract away from issues concerning step-by-step processing in real time. The subject of a sentence must precede the verb independent of the moment-by-moment processing operations required to utter an actual sentence token or to understand one. To return to our addition example, imagine that the rules of addition were stated only in a theory of mathematical performance. In this case, someone who was capable of adding a column of numbers from top to bottom might be unable to add from bottom to top, or in groups with the even numbers added first and the odd numbers later. The step-by-step performance mechanisms would be inextricably bound up with the characterization of the mathematical principles themselves.

The grammar of English or any other natural language will define the well-formed sentences of the language (syntax), how they are pronounced (phonology), and what they mean (semantics). To account for actual language behavior, it must be determined what computation is performed at each step of processing, what information is consulted, what options are pursued at choice points, and the like. Without a detailed theory of language performance, it would be difficult to explain why some sentences are 'unacceptable' even though they are grammatical. Consider the sentences in (1):

a. The woman died.
b. The woman the man loved died.
c. The woman the man the child liked loved died. (1)

Sentence (1a) is a simple clause. In (1b), the subject 'the woman' is modified by a relative clause, producing the intelligible phrase 'the woman the man loved'. In (1c) the phrase 'the man' is also modified by a relative clause, producing 'the man the child liked'. But (1c) is usually considered unacceptable by speakers when they first encounter it. The problem is that (1c) is difficult to process even though it abides by all the same rules as the acceptable (1b). Given the competence–performance distinction, the account of (1) is straightforward: all the sentences in (1) are grammatical, but only (1a) and (1b) are acceptable. The grammatical (1c) has a structure that is difficult for perceivers to recover.

Examples like (1) have been used to argue that it would be arbitrary to rule out sentences like (1c) using grammatical mechanisms. In fact this argument can be strengthened. Consider (2):

The vase the man you met bought broke. (2)

Sentence (2) has the same grammatical structure as (1c) but it seems acceptable. Perceivers can recover the correct structure for (2) because the initial noun phrases are dissimilar, discouraging any attempt at a conjoined noun phrase structure. Further, constraints from the meaning of 'met' and 'bought' aid the perceiver. What the acceptability of (2)

shows is that limiting the number of self-embedded relative clauses (say to two) would not only be arbitrary, but it would be empirically wrong. In (1c) two is too many, but in (2) it is not. What differs between (1c) and (2) are not the grammatical properties of the structure, but factors which make the structure easier or harder for the perceiver to recover.

Examples like (3), due to Tom Bever, make a similar point. When native speakers first encounter (3), they cannot correctly identify its structure:

The horse raced past the barn fell. (3)

Typically they take 'The horse raced past the barn' as a simple sentence and then don't know what to do with 'fell'. But (4) does not present a similar problem:

The horse ridden past the barn fell. (4)

The structure in (3) and in (4) is the same. The problem in (3) is simply the ambiguity of 'raced' which, unlike 'ridden', could be a simple past tense verb. Once perceivers have encountered (4) and they realize that (3) is equivalent to 'The horse (which was) raced past the barn fell' they usually accept the sentence. Their grammar (theory of competence) has not changed, they have simply managed to recover the structure of (3).

Performance mechanisms and actual language comprehension behavior may be influenced by numerous nongrammatical factors. For example, perceivers are less likely to accept a sentence as being grammatical/acceptable if they are asked to look into a mirror while they are making grammaticality judgments. Mirrors make people self-conscious which in turn makes judgments more conservative. But this is most likely not a fact about linguistic knowledge *per se*. It is probably best explained by a theory of social psychology, not grammar.

Distinguishing between competence and performance allows us to capture the fact that grammatical knowledge is atemporal and is the same whether it is exploited for purposes of production or comprehension. The theory of competence will characterize the grammatical sentences of the language. The performance theory will account for which of these structures is easy, difficult, or impossible to produce or to understand under various circumstances, relieving the grammar of the need to make arbitrary stipulations on self-embedding, as in (1) or (2), or *ad hoc* restrictions that would be needed to capture grammatically the effects of ambiguities in particular contexts such as the 'garden-path' sentence in (3). Realizing that grammaticality/acceptability judgments are themselves a type of linguistic and cognitive behavior also eliminates what would otherwise be inconsistencies in the data (judgments) that inform theories of grammar.

Phonetics

Introductory article

IM Roca, University of Essex, Colchester, UK

CONTENTS

Phonetics is the discipline concerned with the study of the articulation, acoustics, and perception of the sounds of speech.

INTRODUCTION

We all know from experience (unless we happen to be profoundly deaf) that language is manifested as sound: the speaker *speaks* (produces sound), and the hearer *hears* (receives and perceives sound). (The sign languages of the deaf have a visual manifestation, rather than a sonorous one, for obvious reasons; we will not be concerned with these languages here.) It is sound that allows us to differentiate, when we speak, 'cat' from 'kit' from 'cot' from 'cut' from 'coot', and 'lad' from 'dad' from 'mad' from 'sad' from 'pad' from 'cad' from 'fad', or, more dramatically, 'table' from 'anticonstitutionalism': we *hear* the differences between these words spontaneously, without any overt training, and we hear such differences because the speaker has *made* them in the first place. All speakers (that is, all of us when we speak) produce sound, and hearers (all of us when we hear) receive and perceive sound. It is in fact rather like music: some people play it, and others hear (and enjoy) it. *Phonetics* is the discipline that investigates speech sound in its three material stages: production by the speaker, transmission through the air, and reception by the hearer.

ARTICULATION OF SPEECH SOUND

Speech sound is invariably made in the mouth (also in the nasal and laryngeal spaces, concomitantly), not, for instance, with the fingers (unlike finger clicking). The reason for this is purely biological: we do not think about it or decide on it, nor does Parliament legislate on the matter. Indeed, babies show an irrepressible urge to use their vocal apparatus and make speech sounds, gradually shaping their output in the direction of the language of their surroundings. (Noam Chomsky has been arguing for close to half a century that language is a biological, not a cultural, phenomenon: more like laughter or hair growth than like car manufacturing.) The organs with which both babies and grown-ups make the sounds of language can be likened to the instruments with which musicians play music. Like a musical instrument, the vocal apparatus has its own physical characteristics, which can be studied. Also, the sound(s) produced by a musical instrument or by the vocal apparatus can be dissected and analyzed. With regard to language, matters like these fall within the remit of *phonetics*.

Among the principal organs of speech contained in the mouth, the tongue stands out as the chief active articulator (the articulator that moves). It produces a variety of consonantal sounds by approaching a passive articulator (an inert articulator) inside the mouth: *dental* consonants when it approaches the upper teeth, *alveolar* consonants when it approaches the ridge behind the upper teeth, *palatal* consonants when it approaches the hard palate (the bony section of the roof of the mouth, at the front), *velar* consonants when it approaches the soft palate (the fleshy section of the roof of the mouth, at the back), *uvular* consonants when it approaches the uvula (the appendage that dangles at the back of the soft palate), and *pharyngeal* consonants when it approaches the back wall of the pharynx (the very back part of the oral cavity, which connects it to the larynx, in the throat: see below). In addition, the lips can produce *bilabial* consonants (upper lip with lower lip) and *labiodental* consonants (lower lip with upper teeth). Examples of all these sounds are given below.

Not surprisingly, different parts of the tongue are involved: for any one sound, the tongue area

involved in its production faces the passive articulator. Three main tongue areas can be distinguished: the *blade* of the tongue at the front (involved in the production of dental and alveolar consonants), the *body* of the tongue in the middle (involved in the production of palatal, velar, and uvular consonants), and the *root* of the tongue bending down right at the back (involved in the production of pharyngeal consonants).

Figure 1 provides a visual representation of the vocal tract and the speech articulators.

CLASSIFICATION OF SPEECH SOUNDS

The first criterion for the classification of consonants concerns the place where the consonant is articulated: its *place of articulation*. According to this criterion, consonants are classified into bilabial, labiodental, dental, alveolar, palatal, velar, uvular, and pharyngeal, as defined above. Narrower criteria are possible: for instance, dentals can be divided into dental proper and interdental, palatals into prepalatal, palatal, and postpalatal, and so on. Notice that the labels derive from the Latin names of the corresponding (usually passive) articulators: 'dental', for instance, refers to the teeth, 'velar' to the soft palate.

So far we have been considering the action of the active articulator on the passive articulator as one of 'approaching'. We must now be more precise. There are two main ways in which the articulators can produce consonants. The first involves the active articulator making contact with the passive articulator and stopping the airflow from the lungs: the corresponding consonants are known as *stops* (e.g. '**b**ay'). The alternative manner of articulation involves the creation of a narrow channel between the two articulators (crucially, without stopping the air): such action results in the production of

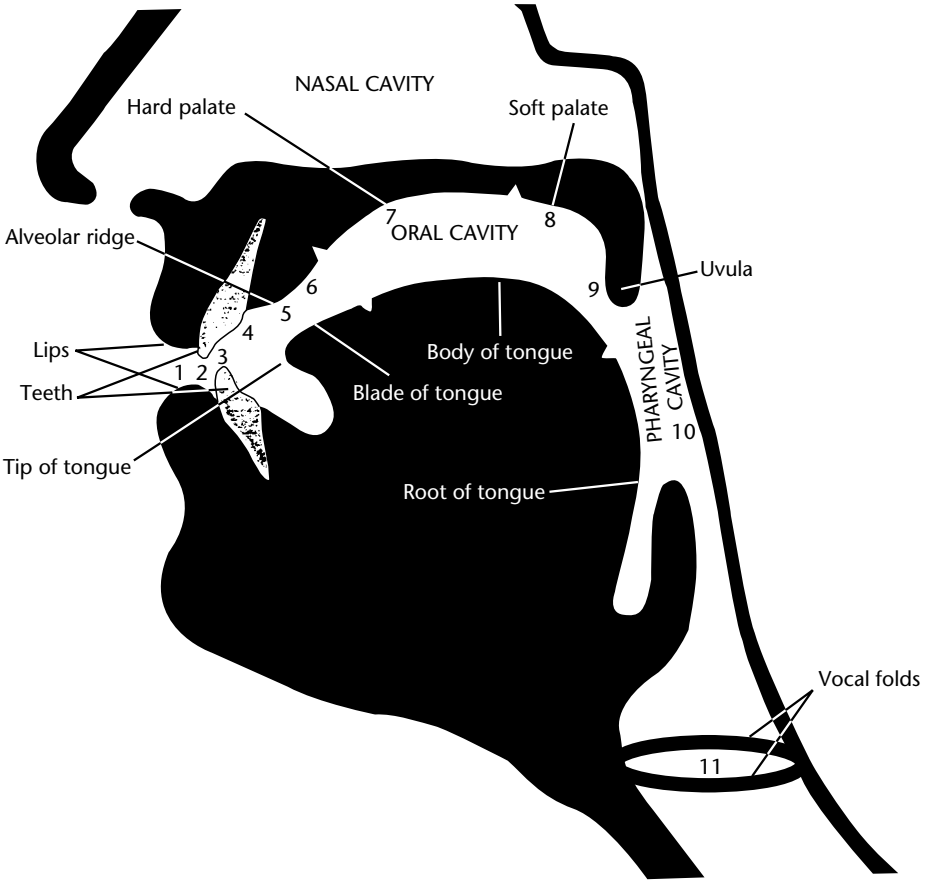

Figure 1. Outline of the vocal tract, with the speech articulators and the places of articulation: (1) bilabial, (2) labiodental, (3) interdental, (4) dental, (5) alveolar, (6) palatoalveolar, (7) palatal, (8) velar, (9) uvular, (10) pharyngeal, (11) glottal. Adapted from Roca and Johnson, *A Course in Phonology*, first reprint, 2000, p. 726, by kind permission of Blackwell Publishers.

fricative noise, and the corresponding consonants are known as *fricatives* (e.g. '**s**ay'). A handful of consonants, known as *affricates*, involve the production of both a stop and a fricative in rapid succession, in this order ('**ch**air'). The term *approximant* is sometimes applied to sounds with a wider channel than fricatives and therefore no fricative noise ('**w**ay'). These sounds resemble vowels, and may indeed be simple instances of them. *Manner of articulation* is the second criterion for the classification of consonants.

The tongue is, of course, also involved in the production of vowels. The difference between vowels and consonants is in essence one of manner of articulation: while, as we have seen, the production of consonants involves the two articulators either blocking the air (for stops) or restricting it (for fricatives), the production of vowels involves neither action. In particular, while vowels are also produced by the movement of an active articulator (more specifically, a section of the tongue) towards a passive articulator, the distance between the articulators remains sizeable, such that no noise is generated. From this perspective, vowels can be construed as 'sounds' with a wider articulatory channel than consonants (width of articulatory channel is what the traditional label 'manner of articulation' essentially refers to), in particular a channel wide enough to prevent the production of noise. According to degree of channel opening, vowels are classified into *close* (or *high*) with the narrowest channel, *open* (or *low*) with the widest channel, and *mid* with intermediate channel width.

The nose and the larynx can also participate in the production of speech sounds. A raised soft palate (or velum) keeps the nasal cavity shut off from the oral cavity. If the velum is lowered, however, the air coming out of the lungs will also flow through the nasal cavity, where it will resonate and add a particular nasal quality to the sound: it will make it a *nasal* sound. Nasality (or its converse, *orality*) constitutes the third criterion for the classification of consonants, and can also be a component in the classification of vowels.

The last criterion for the classification of speech sounds involves the state of the vocal folds, in the larynx. The larynx is the voice box housed in the throat (it can protrude as the Adam's apple, particularly in males). It constitutes the upper section of the trachea (the windpipe by which the mouth cavity connects to the lungs). Across the larynx lies a membrane with a slit-shaped back-to-front opening in the middle controlled by two small lips, known as the vocal folds (or vocal cords): they close up automatically to prevent food falling into the trachea and causing death by choking, among other physiological functions. When the vocal folds are relaxed and held relatively close to each other, a fast airflow will cause them to open and close in rapid succession, in an action reminiscent of a flag flapping in the wind. The effect of this vibration is known as 'voice' (in effect, a form of humming). Consonants can be *voiced* (i.e. have voice superimposed on their articulation) or *voiceless* (with no voice). Vowels are usually voiced, but can also be voiceless (in that case they sound as if they were whispered).

The criteria we need to classify speech sounds from the viewpoint of their articulation are summarized in Table 1.

PHONETIC TRANSCRIPTION

So far, we have looked at examples in ordinary spelling, which (particularly in English) is a very poor index of the actual sound produced by a speaker. The following anonymous rhyme provides a convenient illustration of the problem:

Hints on Pronunciation for Foreigners

I take it you already know
Of tough and bough and cough and dough?
Others may stumble, but not you,
On hiccough, thorough, lough and through?
Well done! And now you wish, perhaps,
To learn of less familiar traps?

Beware of heard, a dreadful word
That looks like beard and sounds like bird,
And dead: it's said like bed, not bead –
For goodness sake don't call it 'deed'!
Watch out for meat and great and threat
(They rhyme with suite and straight and debt).

A moth is not a moth in mother,
Nor both in bother, broth in brother,
And here is not a match for there
Nor dear and fear for bear and pear;
And then there's dose and rose and lose –
Just look them up – and goose and choose,

And cork and work and card and ward,
And font and front and word and sword,
And do and go and thwart and cart –
Come, come, I've hardly made a start!
A dreadful language? Man alive!
I'd mastered it when I was five!

It is clear that if we are to keep an accurate written record of sound we must avail ourselves of a different system.

Table 1. Main classification criteria for the sounds of speech

Place of articulation							
Bilabials **p**ea	Labiodentals **f**ee	Dentals **th**ee	Alveolars **t**ea	Palatals **h**ue, **y**es	Velars **c**ow	Uvulars **r**iz 'rice' (French)	Pharyngeals ħuut 'whale' (Arabic)
Manner of articulation							
Stop consonants **p**ea	Fricative cons. **f**ee		Close/high vowels k**ey**			Mid vowels c**au**ght = c**our**t	Open/low vowels c**a**r
Nasal activity							
Nasals **m**e	Orals **b**ee						
Laryngeal activity							
Voiced **z**oo	Voiceless **S**ue						

The most widely used system is known as the alphabet of the International Phonetic Association (IPA). It is similar to conventional English spelling in as much as it is made up of letters (not, for example, ideographic symbols, along the lines of traditional Chinese writing: ideographic symbols correspond to ideas, rather than to sounds). Moreover, the symbols of the IPA alphabet are mostly taken from the Roman alphabet (like the letters used in English spelling), although some are taken from the Greek alphabet, and some have been made up specifically for the purpose. The advantage of the IPA alphabet (like any other phonetic alphabet) is that each symbol corresponds by definition to only one sound, and, conversely, each sound is represented by only one symbol. So, for instance, every time we see the symbol [h] (phonetic symbols are conventionally enclosed in square brackets) we know that we are referring to the first sound in words like '**h**ot', '**h**eat', or '**h**at' in standard English accents (not in accents that characteristically drop this sound, like London Cockney or Yorkshire, which are accordingly described as *h*-dropping). Therefore, the phonetic representation [ph] will correspond to the sequence [p] (as in 's**p**ace' or 'sus**p**ect') + [h] (as in '**h**ot' or '**h**at'): crucially, it does not correspond to the sound sometimes represented as *ph* in English spelling, which is in fact usually [f] (cf. '**ph**iloso**ph**y' or '**ph**onetics'; but [v] in Ste**ph**en!). Indeed, the phonetic sequence [ph] corresponds to the sound represented by the first letter in words like '**p**ie', '**p**et', or '**P**eter', an aspirated *p*; i.e. a [p] followed by an [h] (as against the plain [p] of 'sus**p**ect').

By way of illustration, consider the phonetic transcription in 'Received Pronunciation' (RP, the Southern English prestige accent of Britain) of some of the words with spelling–sound mismatches contained in the rhyme reproduced above (':' represents lengthening of the preceding sound, and the underscript '̥' devoicing of the sound represented by the symbol above it):

tough : [thɐf] bough : [b̥a͡ʊ̯]
cough : [khɒf] dough : [d̥ə͡ʊ̯]
hiccough : [hɪkɐp] thorough : [θɐɹə]
lough : [lɒx] through : [θɹuː]

We are now in a position to tabulate the main phonetic symbols, exemplified for English sounds in conventional spelling to facilitate recognition (Tables 2 and 3). The spelling correspondent is shown in bold when the sound it represents is sufficiently close in quality (in RP or some other main accent) to the sound the phonetic symbol is meant to stand for, and underlined when they only exhibit some resemblance.

UNIVERSAL INVENTORY OF SOUNDS

The sounds of English obviously do not exhaust the inventory of the sounds found in the world's languages. Indeed, some speech sounds are strikingly exotic to the ear of the English speaker. For instance, some languages spoken in Southern Africa contain clicks in their consonant inventories; that is, sounds similar to the ones we use to gee up horses (*tlk-tlk*, impressionistically) or to express

Table 2. Phonetic symbols for some common consonants[a]

	Bilabial	*Labiodental*	*Dental*	*Alveolar*	*Post-alveolar*	*Palatal*	*Velar*	*Uvular*	*Pharyngeal*	*Glottal*
Stop	p: s**p**y b: ab**b**ey			t: s**t**y d: ad**d**er		c ɟ	k: s**k**y g: ea**g**er	q ɢ		ʔ: pi**t**y[b]

Trill				r: **r**ay[d]						
Tap				ɾ: pi**t**y[e]						
Approximant	w: **w**ell			ɹ: **r**ay		j: **y**es	w: **w**ell			

[a]Where the box has two lines, the consonant in the top line is voiceless, and that in the bottom line voiced; where the box only has one line, the consonant is voiced.
[b]In London Cockney, for instance.
[c]In fast, unguarded speech, in some accents.
[d]In traditional Scottish pronunciation.
[e]Typically in American English.

Table 3. Main phonetic symbols for vowels[a]

	Front	*Central*	*Back*
High/close	i: b**ea**d y	ɨ ʉ	ɯ u: b**oo**m
	ɪ: b**i**d ʏ		 ʊ: p**u**t
Mid-close/high	e: b**a**de ø	ɘ ɵ	ɤ o: b**o**de[b]
		ə: **a**bout	
Mid-open/low	ɛ: b**e**d œ	ɜ: b**i**rd ɞ	ʌ ɔ: p**o**rt
	æ: b**a**d[c]	ɐ: b**u**d[d]	
Low/open	a: b**a**d[c] Œ	(a: b**i**te)[e]	ɑ: p**a**rt ɒ: p**o**t

[a]Where the box has two lines the vowel in the top line is unrounded, and that in the bottom line rounded; where the box only has one line, the vowel is unrounded.
[b]In American English, rather than RP.
[c]Older RP [æ] now tends to be pronounced [a].
[d]Current RP English [ɐ] in words like 'bud' is often (mis) transcribed [ʌ].
[e]The IPA alphabet does not include a special symbol for the low central vowel, inconveniently (this is probably the most common vowel in the world's languages); in its absence, the symbol for the low front vowel, [a], is often made to do double work, and sometimes marked diacritically as [ä] when meant as central.

disapproval to children or even grown-ups (*tut-tut*). Some languages contain what is known as *implosive* consonants; that is, stop consonants made with air going *into* the mouth, rather than out, as is the case in English and generally. Some languages have *ejective* consonants; that is, consonants which incorporate a glottal stop, a stop sound made with the vocal folds (glottal stops are a common pronunciation of intervocalic (between-vowel) *t* in several accents of English, London Cockney, for instance: *pity* = [phɪʔi]). French has nasal vowels (vowels pronounced with a lowered velum), as in *main* 'hand' [mɛ̃] (making up a minimally contrasting pair with *mai* 'May' [mɛ]), and also front vowels with rounded lips, as in *vue* 'sight' [vy] (contrasting with *vie* 'life' [vi]), rendered [vi̯uː] by English speakers in a name like 'Bellevue'. And so on.

ACOUSTIC AND AUDITORY PHONETICS

Our focus so far has been on articulatory phonetics for at least two reasons. First, the articulation of sounds is accessible to plain observation (particularly self-observation, but to some extent also observation in others). Second, articulation is usually thought to provide the bridge with the sister discipline of phonology. There are, however, two other areas of phonetics which must be mentioned here, if only cursorily. (*See* **Phonology**)

The first is *acoustic phonetics*, which deals with the intrinsic physical properties of sound. In particular, what we call 'sound' in general corresponds to the

vibration of molecules (their to-and-fro movement) in the surrounding air. In turn, each speech sound corresponds to a specific pattern of such vibration, brought about by the corresponding articulatory gestures. The patterns of air movement can be captured instrumentally and displayed visually, a technique that greatly facilitates investigation into acoustic phonetics.

The other branch of phonetics, *auditory phonetics*, deals with the mechanisms responsible for the perception of sound in the hearer's brain. First, the soundwave hits the ear-drum, a membrane stretching across the inner entrance of the ear. Second, the vibration moves on through a chain of three tiny ear bones. Third, this mechanical vibration is converted into pressure differentials in a special fluid that fills the cochlea, a snailshell-like structure connected on the outside to the last of the three ear bones and divided lengthways inside by the basilar membrane, from which stem a number of 'hair cells' set in motion by the pressure differentials. Finally, the movement of the hair cells converts to electrochemical signals which are perceived by the brain. (*See* **Phonology and Phonetics, Acquisition of**)

SPELLING AND SOUND

Before ending, we must return to the relationship between sound and spelling, to dispose of any remaining misconception. Indeed, some may think that words like 'cat' and 'cot', or 'pad' and 'fad', are different, not so much because they *sound* different, but because they are *spelled* differently: their difference in sound would simply be a consequence of their difference in spelling. That is not correct.

First, each word of a given language usually has a constant spelling (the differences in spelling between America and the UK are absolutely minimal, and in any event unconnected with the pronunciation): 'cat' is always spelled *cat* in English, and 'tonsillitis' *tonsillitis*. And yet, when each of these or other words is spoken there are obvious differences in the way it sounds, not just subtle voice-related differences from one individual to the next (and, more systematically, from a child to a grown-up, from a woman to a man, from someone with a cold to someone without, etc.), but rather gross differences related to accent. For instance, the *t* of the English word 'writing' can sound similar (if not identical) to the *t* of 'tingle', or be weakened and sound very similar to a *d* (in a typical North American accent, among others), or be realized as a glottal stop (in a London Cockney accent, for instance). And besides the usual weak sound for English *r*, there is a stronger one in Scottish English, and one similar to *w* in the pronunciation of some individuals (most commonly children). Next, the sequence *ng* in *-ing* can sound as a velar *n* [ŋ] (remember, an *n* pronounced with the body of the tongue on the soft palate), or as an alveolar *n* [n] (the *n* of words like 'tin', or, for that matter, 'knit'), or as a sequence *n* + *g* [ŋg] (this would be the typical Birmingham or Liverpool pronunciation, for instance). Finally, the first *i* of 'writing' typically sounds like 'eye', but can be less open (in Scottish or Canadian English, for instance), or sound more like the *a* of 'spa' (e.g. in the proverbial Southern US states pronunciation). So, the only letter in 'writing' that seems to have a more or less uniform phonetic correspondent throughout the English-speaking world is the *i* of *-ing* (the *w*, of course, is silent everywhere).

What these simple examples confirm is that the spelling is not really a mirror of the pronunciation, or conversely. Rather, the spelling of a word is a conventional symbolic representation that we associate with the pronunciations of the word (notice the plural!), similar to the way we associate the letter 'tee' with its multiple materializations on paper: small roman 't', capital roman 'T', small italic '*t*', capital italic '*T*', courier 'ｔ', monotype corsiva *t*, century gothic 't', and so on, not to mention its multiple individually based implementations in longhand writing.

There are many other facts that incontrovertibly show that pronunciation and spelling are not just two sides of one coin. Many English words that sound the same (at least in most accents) have a different spelling ('homophones'): 'road' versus 'rode', 'flour' versus 'flower', 'peer' versus 'pier', 'tail' versus 'tale', 'earn' versus 'urn', 'course' versus 'coarse', 'loan' versus 'lone', etc. Conversely, some words with the same spelling sound different ('homographs'): 'row' (a line or a quarrel), 'bass' (a fish or a singer), 'wind' (air in motion or to bend). Some words are spelled the same in English and in other languages, but the sound is substantially different, and conversely: 'sublime', 'admirable', and 'suave' are [səblá͡im, syblím, sublíme], [ædmɪɹəbl, admɪʁábl, admiɾáble], [suάːv, syáv, suábe], in English, French, and Spanish, respectively, while [bo͡i] and [dan] are spelled *voy* 'I go' and *dan* 'they give' in Spanish, but 'boy' and 'done' in English (on a broad phonetic interpretation: a more rigorous English transcription would be [b̥ɔ͡ɪ] and [d̥ʊn]), and [kʰiː] can correspond to English 'key' or 'quay', or to French *qui* 'who' (again, broadly interpreted). Some languages, like Chinese, do not use letters to represent their words,

but, rather, stylized pictures which originally bore a (more or less abstract) relation to the meaning, rather than to the sound. Last, and decisively, speech invariably precedes writing in both children and mankind as a whole. Indeed, some people remain illiterate for the whole of their lives: how could such individuals pronounce anything (and therefore speak) if sound were only a manifestation of spelling? The conclusion we must draw is that, interesting and important as it is for cultural and educational reasons, spelling ultimately need not have much to do with the sound of language.

Phonological Encoding of Words

Intermediate article

Antje S Meyer, University of Birmingham, Birmingham, UK
Linda R Wheeldon, University of Birmingham, Birmingham, UK

CONTENTS

During phonological encoding of a word the speaker retrieves the word's sound form. It consists of two representational tiers: an ordered set of segments and a metrical representation capturing the word's syllable structure and stress pattern.

INTRODUCTION

In this article, we will first explain how phonological encoding is related to other processes involved in the production of words (for details see Levelt *et al*., 1999). We then turn to the description of the two main layers of representation generated during phonological encoding – the segmental representation, which consists of phonological segments, and the metrical representation, which captures the word's syllable structure and stress pattern.

WORD PRODUCTION: AN OVERVIEW

In order to produce a word, a speaker must decide what to say, retrieve the appropriate word from the mental lexicon, and pronounce the word. The retrieval of a word from the mental lexicon is often thought to involve two steps: the selection of a lemma, which specifies the syntactic properties of the word (e.g. whether it is a noun or a verb), and the retrieval of the phonological form. An important argument for the distinction between lemma and word-form retrieval is the occurrence of tip-of-the-tongue states, in which speakers can retrieve grammatical information about a word but not the corresponding word form (e.g. Vigliocco *et al*., 1997). Some models assume that lemma and word-form retrieval are serial processing stages, which implies that first one lemma is selected and then the corresponding phonological form is retrieved. Other models assume cascading processing, which implies that several lemmas can be simultaneously activated and can retrieve their word forms in parallel. Some cascading models assume feedback from lower to higher processing levels. In such models, the availability of word-form information can affect the selection of lemmas. The available experimental evidence concerning the flow of information between lemmas and word forms is inconclusive (for a comparison of the models see Rapp and Goldrick, 2000).

Word-form retrieval consists of two steps: the retrieval of morphological and of phonological information. For many words (e.g. 'hand', 'umbrella', 'generate') only one morpheme is to be retrieved, but for others (e.g. 'handbag', 'generated') two or more morphemes are to be retrieved and combined. Reaction time experiments have revealed two important facts about morpheme retrieval. First, it is frequency sensitive, that is, speakers can retrieve frequently occurring morphemes faster than less frequently occurring ones. Second, it is sequential, that is, speakers retrieve morphemes in sequence, as they appear in the utterance (for a review of the evidence see Levelt *et al*., 1999).

The second step during word-form retrieval is the generation of the phonological code of the word. During this process segmental and metrical information are retrieved and combined. The output of phonological encoding is an abstract representation of the sound form of the word. This representation is the input for the next set of processes, phonetic encoding. They generate a more detailed context-specific representation that governs the articulatory movements carried out during speaking. Below we consider the process of phonological encoding in some detail. It is important to keep in mind that most of the available empirical work stems from studies of Indo-European languages. Further research will have to show whether the conclusions that seem warranted for these languages will generalize to languages with fundamentally different phonological systems (e.g. tone languages or languages with less variable syllable structures).

THE SEGMENTAL REPRESENTATION

The retrieval of a morpheme is followed by a process often called segmental spell-out. During this process, the morpheme is decomposed into individual phonological segments and perhaps certain clusters (e.g. /st/, /sp/). The most compelling evidence for phonological decomposition stems from analyses of speech errors (for further discussion of the speech error evidence described here see Fromkin, 1971; Shattuck-Hufnagel, 1983). Speakers often make sound errors, such as (1) and (2) below, in which the intended word and the word that is actually produced differ by a single segment. These errors show that at some point morphemes are decomposed into segments – if they were treated as units throughout the word-planning process, segmental errors could not arise.

it's a real mystery → ... a meal mystery (1)

gone to seed → god to seen (2)

the heater switch → the sweeter hitch (3)

big and fat → pig and vat (4)

infantry men → intry men (5)

at an early period → at a pearly period (6)

(all errors from Fromkin, 1971)

To understand the significance of segmental errors, two other results of speech error analyses must be considered. First, about 90 per cent of all sublexical errors involve single segments or clusters of two adjacent segments, usually syllable onsets, as in (3) above. Errors like (4) involving single features (such as voicing or place of articulation) or complete syllables (like (5), where a syllable has been deleted) do arise, but, compared to segmental errors, they are extremely rare. Thus, the most important processing units at the phonological level appear to be segments, not syllables or features. It should be noted, however, that phonological features must be represented in some way. This is because the segments interacting in errors tend to be phonologically very similar. In most cases, they differ by only one feature. In addition, syllabification (to be discussed below) and some phonological rules refer to phonological features. If features were not represented, these processes could not apply.

The second important result of speech error analyses is that the error outcomes are usually phonotactically well formed, that is, they rarely result in sound sequences that are pronounceable but are not permitted in the language. Moreover, sometimes the preceding context is changed after an error. This is illustrated in (6) above, where the error consists of the addition of the onset consonant, and the preceding determiner is changed from 'an' to 'a', as appropriate for the new consonantal onset. The well-formedness of sound errors is important because it shows that the errors do not arise during phonetic encoding or articulation, but must arise earlier, during phonological encoding, such that phonetic rules still have a chance to apply after the error has occurred. Thus, the errors can be taken as evidence for decomposition during phonological processing rather than during later processes.

Further evidence for the decomposition of morphemes into segments stems from reaction time experiments. These experiments have also shown that the segments of a morpheme are likely to be activated simultaneously. However, their association to metrical frames (to be discussed below) is a sequential process, proceeding from the beginning of the word to the end (e.g. O'Seaghdha and Marin, 2000).

THE METRICAL REPRESENTATION

Word forms are not just strings of segments. Instead segments are grouped into syllables, which are stressed or unstressed. In line with current linguistic theory, most theories of word production represent the syllabic structure and stress pattern of words on a separate tier from the segmental information. Syllables are often viewed as frames with slots, corresponding to syllable constituents. The main constituents of a syllable are the consonants preceding the vowel, which form the onset (e.g. /b/ in 'bin', /sp/ in 'spin'), and the rhyme. The rhyme can be further divided into a vocalic nucleus (/I/ in the examples) and a postvocalic coda (/n/ in the examples). During word-form encoding, segments and syllable frames are independently retrieved and then the segments are associated to positions in the syllable frames. This view is supported by another important result of speech error analyses, often called the syllable position constraint. This is the observation that misplaced segments almost always move from their target positions to corresponding positions in other syllables. Most commonly, consonants that were intended to be onset consonants assume new onset positions (as in (1) and (3) above). They rarely move to a coda position as in (7):

fish → shiff (7)

Theories of word-form retrieval differ in the types of frames they postulate. The options include frames with the syllable positions onset and rhyme, or the positions onset, nucleus, and coda (Dell, 1986), and so-called CV-frames with separate positions for each consonant and vowel (Stemberger, 1990). It is difficult to discriminate between these options on the basis of results of speech error analyses because most errors involve word onset consonants, which move to new word onset positions. To determine the nature of the frames one would have to inspect word-internal and syllable-internal errors, which are very rare. The available experimental evidence on the nature of the frames is likewise inconclusive (see Levelt *et al*., 1999, for further discussion).

According to many models, metrical information is stored in the mental lexicon for all lexical entries. However, Levelt *et al*. (1999) argued that the syllable structure of all words can be derived by rule from segmental information. (Essentially, each vowel or diphthong is assigned to a different syllable, and consonants are treated as syllable onsets whenever permitted by the phonotactic rules of the language.) In addition, many words are stressed according to simple default rules. For example, there is only one way to stress monosyllabic words, and most disyllabic English words are stressed on the first syllable with a full vowel. Thus, Levelt *et al*. proposed that the lexical entries for most words consist only of ordered sets of segments. During phonological encoding, the segments are syllabified and assigned stress according to the rules of the language. Only for words with exceptional stress patterns, metrical information is stored and combined with segmental information during phonological encoding. As Levelt *et al*. pointed out, the syllable position constraint on sound errors can easily be accounted for without assuming stored syllable frames. It could arise because segmental errors usually involve word onsets and because misplaced segments tend to replace phonetically similar rather than dissimilar segments.

In sum, all models of phonological encoding assume that morphemes are decomposed into segments, and that the string of segments is syllabified and assigned stress. The result of phonological encoding is an abstract phonological representation consisting of stressed and unstressed syllables. This representation is likely to be the representation speakers attend to in inner speech and when they monitor their planned speech for errors. It is the input to the next set of processes, phonetic encoding, which compute the articulatory gestures to be carried out. For frequent syllables there may exist pre-assembled packages of articulatory gestures (e.g. Levelt and Wheeldon, 1994).

One may ask why morphemes are first decomposed into segments and subsequently reassembled into syllables. The likely reason is that morphemes can be pronounced in many different ways, depending on the context in which they appear. For instance, 'hand' may lose its final consonant in 'put your hand down', and it may be pronounced with a final /m/ in 'handbag'. The word 'hand' corresponds to a syllable in 'I will hand Kate the book', but not in 'I am handing you the book'. More generally, when words are produced in context, phonological information is retrieved from the mental lexicon as described above. But the retrieved word forms are not just concatenated but are combined into new phonological units. The smallest unit is the syllable, already discussed above. The next larger unit is the phonological word. Phonological words often correspond to lexical words, that is, the forms stored in the speaker's mental lexicon. However, morphologically complex words (such as 'handbag') may comprise several phonological words, and unstressed closed class items (e.g. conjunctions such as 'and', pronouns such as 'it', and bound morphemes such as '-s' in 'shoes' or '-ed' in 'played') combine with a neighboring content word (i.e. a noun, verb, or adjective) into a single phonological word. Importantly, phonological, rather than lexical, words are the domain of syllabification and of the application of many phonological rules. Thus, when a speaker says 'find it', two morphemes are retrieved and combined to form one phonological word. The string of segments stemming from both morphemes is syllabified, yielding [fein] [dit]. Thus, syllables can, and often do, straddle the boundaries of lexical words. In many cases, the decomposition of morphemes and the re-assembly into phonological forms are not vacuous processes but yield phonological forms that differ from those stored in the mental lexicon. A likely reason why these 'connected speech forms' are generated is that they are easier to articulate than concatenations of stored phonological forms would be.

This article concerned phonological encoding in speech production. Phonological representations are, of course, also generated during spoken language comprehension and they play an important role in reading. The structural properties of the phonological representations involved in these different tasks are likely to be similar, but the representations are generated in fundamentally different ways. In speaking, the immediate input to phonological encoding is a morphological representation,

which in turn is generated on the basis of syntactic and semantic information. By contrast, in reading, phonological representations are derived on the basis of the orthographic input, and during auditory speech processing, they are accessed on the basis of the continuous speech signal. Phonological Processes

Advanced article

Diana Archangeli, University of Arizona, Tucson, Arizona, USA

CONTENTS

Phonological processes are the patterns that are found in the sound sequences that occur in individual human languages. Languages limit which sounds are used; they also limit the permissible sequences of these sounds. These phonological processes, or regular restrictions on sound sequences, generalize both within and across languages.

INTRODUCTION

Phonological processes are the patterns that the sounds of our languages form. Broadly speaking, languages manipulate both the syllable structure and other prosodic properties of words as well as the detailed properties of individual sounds. This article is limited to a discussion of those phonological processes that affect characteristics of individual sounds, that is, the featural processes. Prosodic phenomena such as epenthesis, syncope, and stress assignment are not addressed.

This discussion assumes some familiarity with the terms 'segment', 'feature', and 'lexical representation', and with the contrasts between 'autosegmental' and 'linear' representation of features, as well as a nodding acquaintance with certain features. For those readers who find these terms unfamiliar, they are explained briefly here. Others are invited to skip ahead to the section on harmony.

Lexical representation. A discussion of phonological processes presupposes that such processes do, indeed, exist. Phonologists view these processes as the link between the abstract representation in the speaker's head, called the 'lexical representation', and the 'surface representation', the form that connects to the phonetic interpretation, that is, the sounds coming out of the speaker's mouth.

Segment refers to individual sounds within a word. For example in the English word 'late', there are three sounds, a 'l' sound, a 'long-A', and a 't' sound. Note that the number of sounds does not necessarily correspond to the number of letters. Alphabets such as the International Phonetic Alphabet have been created to provide a one-to-one mapping between sound and symbol. Such symbols are used here, inside square brackets: *late* [leit].

Feature refers to individual properties of sounds. These features are manipulated phonologically, but they are not purely abstract: they roughly correlate to certain acoustic and/or articulatory properties. For example, the sounds [m] and [n] share a feature [nasal], for both have air passing through the nose. The sounds [o], [u] share the feature [round] because both involve rounding of the lips. Any sound involving constriction of the lips is viewed as having the feature [labial]: in addition to [o], [u], this would include [m, p, b, f, v]. Some features are less easily sensed: one dimension that some languages use widely is the position of the root of the tongue. Vowels with advanced tongue root (ATR) sound more or less like the English 'long' vowels, i.e. those in *seed* [i], *staid* [e], *soup* [u], and *soap* [o]. Those with retracted tongue root sound more like the English 'short' vowels, such as *sip* [ɪ], *set* [ɛ], *soot* [ʊ], and *sought* [ɔ].

Segments, then, are characterized as composites of features: a [nasal, labial] consonant is [m] while a [round, labial, advanced] vowel is [u].

The *autosegmental/linear distinction* refers to how these features are represented with respect to the segment. In the linear model, all features for a given segment are bundled into a single unit (a *matrix*). Lexical representations consist of sounds lined up like beads on a string. Manipulation affects the features of each sound individually. The autosegmental representation separates features from the segment, so that a single feature may be a property of several segments simultaneously, as in harmony, and multiple features may be properties of a single segment, as in one type of apparent metathesis.

With this brief introduction as background, the next topic is a description of a number of different phonological processes. The goal here is to identify

the clusters of phenomena typically associated with each of the types of process under discussion. It is important to remember, however, that these terms have been used by numerous different individuals in a variety of different ways. The descriptions here are intended to provide a generic overview, not to account for every variant that has occurred in the literature.

HARMONY

The term 'harmony' refers to a pattern in which some feature(s) inherent to one sound in a word propagate across a domain larger than the one sound. For example, in Chukchee, vowels lower if there is even one low vowel in the word: the [e] vowels of *jeɣvel* 'orphan' are lowered to [a] under the influence of the [aa] of *aacek* 'youth': *jajvaɣ-aacek* 'orphaned youth'.

The variations on this one theme reveal much about the ways in which humans organize the sounds of their languages. Languages with harmony differ in how they identify the harmonic feature(s), the source of that feature (the 'trigger'), the elements undergoing harmony (the 'targets'), which elements are irrelevant to the harmony ('transparency'), which elements prevent harmony from propagating ('opacity'), the direction of harmony, and the morphological domain of harmony.

The Harmonic Feature(s)

Many harmonies involve only a single harmonic feature (e.g. tongue root harmonies such as Yoruba ATR harmony); others involve a complex of features propagating in a single pattern (e.g. Yokuts round/back harmony); still others involve complexes of features, each of which propagates in its own fashion, for example in Barra Gaelic.

A second consideration is the provenance of the harmonic feature(s). In some cases, these are necessarily a part of the lexical representation; nonlexical features do not harmonize. In other cases, both lexical and nonlexical instances of the feature harmonize (e.g. [−ATR] in Yoruba tongue root harmony).

A very entertaining type of harmony is one in which the harmonic feature is introduced as a morpheme in and of itself. One such instance is found in Coatzospan Mixtec: the feature [+nasal] marks the difference between a verb (oral) and verb with a familiar second-person subject (nasal): *kaʔu* 'write' versus *kãʔũ* 'you (fam.) will write', *βiðe* 'wet' versus *βĩðẽ* 'you (fam.) are wet'.

Triggers

In some cases, to trigger a harmonic pattern, a segment need only have the relevant feature. In other cases, triggers are defined as a subset of those segments bearing the feature. In Menomini, for example, although both high and nonhigh vowels may have the feature advanced tongue root, [+ATR], only the high vowels serve as triggers for the harmony process. The retracted [ɪ] in the first syllable of *sɪ̱ːpɪ̱ːw* 'river' raises to [i] when followed by a suffix with the advanced [i], as in *siːpiah* 'river-locative'. By contrast, when the suffix contains an advanced nonhigh vowel, no harmony takes place: *maskʊ̱ːtə̱w* 'prairie' with a retracted [ʊ:] despite the advanced [ə] versus *maskʊ̱ːtiah* 'prairie-locative' with an advanced [u:] due to the advanced high [i]. Only the high advanced vowels trigger harmony.

Targets

Targets are identified in a number of ways. In some cases, any segment that might bear the harmonic feature is a potential target. In other cases, targets are restricted. Common restrictions are 'only vowels', or 'only some vowels'. For instance, in Menomini, long high vowels are targeted; in Standard Yoruba, only nonhigh vowels are targets; in Akan, nonlow vowels are always targets while low vowels are not: advanced *o-fiti-i* 'he/she pierced (it)', retracted *ɔ-cɪrɛ-ɪ* 'he/she showed (it)', versus the disharmonic *o-bisa-ɪ* 'he/she asked for (it)' – the advanced [i] does not affect the low [a].

In other types of harmony, the target may be consonants rather than vowels, for example laryngeal harmony in Salish and in Indo-European, and place harmony of Chumash, Navajo, and other languages. In Chumash, for example, [s/š] alternate to match the rightmost sibilant: *k-s̱unon-us̱* 'I obey him' versus *k-šunon-š* 'I am obedient'.

Finally, some harmony processes affect both vowels and consonants, for instance nasal harmony (e.g. Orejon) and emphasis spread in Arabic.

Transparency and Opacity

Although there are cases in which essentially all segments are targets, such as the Arabic emphasis harmony, there are also cases in which only some segments are acceptable targets. The unacceptable targets may exhibit either transparency or opacity.

Transparency

Typically some segments do not undergo harmony, nor do they hinder harmony. In a sense, they behave as if they are not present at all. These are the transparent segments. For instance, when a feature such as [round] passes from vowel to vowel in Turkish, the consonants remain unaffected by the harmony. In the Menomini examples above, long vowels advanced to [i:] and [u:] despite being separated from the triggering vowel by several segments, including other vowels: [nɪsu̲:pɒma:hki̲m] 'sugar-maker' (compare this to the retracted high long vowels in [su̲:pɒma:hkʊw] 'he makes sugar').

Opacity

In many cases, there are segments which neither undergo harmony nor do they trigger harmony, nor do they permit harmony to pass them. These are opaque segments. For instance, in Yoruba tongue root harmony, high vowels are ineligible targets; at the same time, they also prevent further propagation of the tongue root feature.

A particularly striking example illustrating both transparency and opacity is found in translaryngeal harmony (Steriade, 1987). In translaryngeal harmony, all vowel features spread across only the laryngeal consonants ([h] and [ʔ]). For example, in Yapese, the suffixes *-o* and *-i* cause a root vowel to harmonize when the final consonant is a laryngeal. Note the alternation between *boh-* and *bih-* in the root *bah-* 'go' in *ma bo̲h-o̲* 'he is not going out' versus *ma bi̲h-i̲* 'he did not go out'.

Direction

Harmonies orient either towards the left edge of the word or towards the right edge of the word. A left-edge harmony is one in which the targets are to the left of the trigger; a right-edge harmony is one in which the targets are to the right of the trigger. Some languages orient their harmonies in both directions, but restrict the two directions in different ways. For instance, in Maasai, the left-edge harmony targets nonlow vowels but low vowels are opaque: note complete harmony in *kidotuñe* 'we shall pull it out with something' versus the opaque effect of *ta* in *kɪta̲dotuñe* 'we pulled it out with something'. By contrast, in Maasai, right-edge harmony targets all vowels, turning the final retracted *-ta* into advanced *-to*: *atɛpɛ̲ta̲* 'I kept close to it' versus *atapɐ̲to̲* 'I smeared it'.

Morphological Domains

The distance that the harmonic feature propagates varies from harmony pattern to harmony pattern. Harmony may be limited to a single morpheme, as in the case of Tiv verbs. Harmonies may also be limited phonologically within a particular morphological domain, for example within the foot. Harmony may occur both within morphemes and across morpheme boundaries, as in the Chukchee example above. Harmony may even jump across word boundaries, as in Kinande: the retracted vowels in *è-mí:-tì* 'trees' are advanced in a phrasal context: *è-mí:-tí míkù:hì* 'short trees'.

Analysis of Harmony

Within the generative tradition, there have been two general representational strategies to analyzing harmony, linear and autosegmental. Whichever method is adopted, it is necessary to account for all of the general types of phenomena noted above.

The linear approach changes feature values depending on the context; it requires recursive application of rules in order to force feature-changing across the entire domain (feature propagation). The autosegmental approach involves feature-spreading and/or feature copy, subject to limitations on trigger, target, and domain. (See Clements, 1981; Archangeli and Pulleyblank, 1994.)

There are analyses of both types within Optimality Theory (Prince and Smolensky, 1993; McCarthy and Prince, 1993a). The Alignment view (McCarthy and Prince, 1993b) assumes an autosegmental representation while the Optimal Domains approach (Cole and Kisseberth, 1994) adopts a more linear segmental representation.

ASSIMILATION AND DISSIMILATION

Assimilation refers to two segments becoming more like each other. A familiar example of assimilation is that of nasals assimilating in place to a following consonant. For example, in English, the negative prefix *in-* appears in such words as 'inopportune' and 'inapplicable' as well as 'intolerable' and 'indecisive'. However, when added to a word such as 'balance' or 'possible', we find a labial nasal, not a coronal nasal: 'imbalance', 'impossible'. The nasal has assimilated place features from the following consonant, thereby becoming more like that consonant.

Assimilation is a fairly common process. There is also evidence suggesting that there are phonetic

processes of harmony and assimilation, and again there is a high degree of similarity. Phonetic harmony is also termed a *cline* effect and assimilation is termed *co-articulation*.

Dissimilation refers to two segments becoming less like each other. For example, certain Latin suffixes (such as *-alis/-aris*) alternate between a form with [l] and a form with [r], the latter surfacing when the affix is attached to a root already containing an [l]: *naval̲is* 'naval' but *sol̲ar̲is* 'solar'. The [l] of the suffix has become an [r], and therefore less like the [l] of the root. Dissimilation is not rare, but it does seem to be less common than assimilation.

Assimilation is not restricted to place features alone. For example, in Malayalam, a nasal–stop sequence may surface as a geminate nasal in colloquial speech: formal *can̲d̲ʾanam* 'sandalwood' is colloquially *can̲n̲anam*. Note also that in this example, it is the stop that assimilates to the nasal, rather than the nasal assimilating to the stop.

Vowels assimilate to neighboring vowels, even vowels separated by a consonant. For instance, in Basque, vowels raise when following a high vowel. The 'professional' suffix alternates between *-ari* and *-eri* depending on the vowel that precedes: *eskel̲ar̲i* 'beggar' but *trat̲ul̲eri* 'dealer'. (This type of effect of one vowel on another is also termed *umlaut*.)

Finally, there are cases of consonants assimilating to neighboring vowels and vowels assimilating to neighboring consonants, for example the palatalization of coronal consonants [t, n, l] following the vowel [i] in Barrow Inupiaq: this is illustrated with [n/ñ] in *sisu-n̲iaq* 'will slide' versus *niRi-ñ̲iaq* 'will eat'. Labialization, pharyngealization, and spirantization are other effects that may result from the influence of a vowel on a neighboring consonant.

When comparing characteristics of harmony described above and those of assimilation given here, we see great similarities. In both cases, only some feature(s) may harmonize/assimilate. Only some segments are potential targets; there may be transparent and/or opaque elements. Direction varies: in an AB sequence, one of the two is the target and the other is the trigger. Finally, each type of process may be sensitive to certain types of morphological boundaries.

These many phenomenological similarities suggest that assimilation and harmony are formally extremely similar phonological processes, and that the formal devices necessary to account for one set of patterns will also account for the other set. The primary difference is that assimilation is local, involving only adjacent or almost adjacent segments, while harmony is long-distance, involving segments that might be separated from each other by several other segments.

There is a second and more subtle difference, however, in the use of these terms. Typically, 'harmony' is used for the assimilation (long-distance or local) of any feature(s) that may be involved in a long-distance process, while 'assimilation' is used for the assimilation of any feature(s) that typically are involved only in local processes. Thus, we speak of place assimilation, since place features typically have only a local effect. And we speak of tongue root harmony, even in a language like Lango in which tongue root features affect only vowels in adjacent syllables, because tongue root features frequently have a long-distance effect.

An important area for investigation is to understand which features typically (or necessarily) pair with local effects and which with long-distance effects, and then to understand why this is so. Once the role of the features is understood, we will be in a better position to determine whether these two effects must be characterized in formally distinct manners.

The term *dissimilation* suggests in some sense the antithesis of assimilation. Broadly speaking, this is true in descriptive terms, for dissimilation refers to two sounds becoming less similar.

Dissimilation typically identifies some feature(s) that cannot occur too close to each other. Thus, in the Latin example above, two instances of the [lateral] feature cannot occur in close proximity.

In some cases, it is necessary to define the nature of the trigger more specifically than simply any segment bearing the dissimilatory feature. For example, in Akkadian, a prefixal [m] alternates with [n] when attached to a root containing a labial consonant: *m̲a-zuukt* 'mortar' versus *n̲a-raam̲u-m* 'favorite'. Labial vowels do not cause this effect (*m̲a-zu̲u̲kt*, not **n̲a-zu̲u̲kt*). Similarly, suffix [m] has no effect (*m̲a-śʔanu-m̲* 'place'). Thus the trigger must be identified as [+ labial] borne by a root consonant – both phonological and morphological restrictions.

Targets of dissimilation may be restricted as well. A particularly interesting case of restricted targets is found in Woleaian. The low vowel [a] dissimilates to a mid [e] when the next syllable contains another low vowel, long or short [a, aa, ɔɔ]: *g̲a-b̲o̲sǫ̊* 'causative-him to show off' versus *g̲e-m̲aarǫ̊* 'causative-make him starve'. However, this occurs only if the target vowel is short: *f̲aar̲ag̲i̥* 'to walk', not **f̲eer̲ag̲i̥*. Thus, the element targeted for [low] dissimilation is restricted to unround, short vowels.

As with harmony, both transparency and opacity play a role in dissimilation too. Transparent

elements are ignored by the dissimilatory effect. In the Latin example already cited, for instance, consonants and vowels other than [l] are irrelevant: dissimilation occurs in both *lun-aris* 'lunar' and *sol-aris* 'solar', despite the greater distance between trigger and target in *lunaris*. Latin also gives evidence of opaque elements: an [r] intervening between the two [l]s prevents dissimilation: *flor-arlis* 'floral', not **flor-aris*.

Latin exhibits a further important point, that the domain is critical. Latin lateral dissimilation takes place only across morpheme boundaries, not within morphemes: *calculus* 'pebble, stone', not **calcurus*.

Dissimilatory effects also have a left or right orientation. In Latin, for instance, it is the righthand [l] which must change. In Russian, it is the leftmost of two nonhigh vowels which must change, not the rightmost: *d'is'átka* 'tenfold' versus **d'es'átki*.

Finally, the key point that distinguishes 'harmony' from 'assimilation' is the potential distance of trigger from target. In the cases considered thus far, the dissimilatory trigger–target pair can be quite distant from each other. However, this is not always the case. In Kera, for instance, two [a] vowels are separated by no more than one consonant in order for the leftmost [a] to dissimilate to [ə]: *bəla* 'want me' (not **bala*) but *balla* 'you must want', not **bəlla*.

Intriguingly, then, although the basic effect is quite different (segments becoming less like each other rather than more like each other), the specific properties which define a particular instance of dissimilation find clear counterparts with the properties defining both harmony and assimilation.

METATHESIS

The classic definition of metathesis is that two adjacent segments trade places, as in the difference between the Old English root *acs* (and the current colloquial pronunciation *aks*) and present day *ask*. Metathesis also occurs in language acquisition, for example the child's *aminal* for *animal*. Metathesis is perhaps more familiar from studies of language change than it is from synchronic processes. Another class of diachronic cases of metathesis is sketched in Sagey (1986), in which cognates in related languages reveal the [AB] versus [BA] ordering. For example, two mutually intelligible dialects of Yatye reverse the order of place:

Alifokpa dialect	Ijiegu dialect	
icwɛndɛ	ipyɛndɛ	'pot'
ecwu	epyu	'head'
jwu	byu	'drink'

Sagey suggests that in fact there is no reordering of segments, but rather that the labial and palatal features are both properties of a single consonant segment, but the order in which they are phonetically realized varies. That is, in both dialects, there are palatal-labial stops; in Alifokpa, the palatality is timed to begin before the labialization while in Ijiegu, the timing is the opposite. Thus, the formal account involves no reversal of the order of segments.

There are a few cases where the analysis does suggest the reversal of features. In Rotuman, words have two versions, one which is vowel-final and another which tends to be consonant-final: *tokiri* versus *tokir* 'to roll', *rako* versus *rak* 'to imitate'. Depending on the qualities of the two vowels, other effects may occur, such as umlaut: *mose* versus *mös* 'to sleep'. McCarthy (1995) argues that the shorter form is prosodically reduced; in particular the position for the final vowel is lost. The features of that vowel, however, do their best to surface. Further support for this general analysis is that words ending with two vowels, such as *keu* 'to push', alternate with a form ending with a short diphthong, *ke͡u*, that is, the final vowel position is lost, but the features survive by crowding into the position for the preceding vowel. In certain cases, where umlaut and diphthongization are impossible, there is apparent metathesis: *pure* versus *puer* 'to rule'. Again, this can be viewed as the final vowel (here *e*) losing its position, yet finding a place for the features to survive by crowding into the remaining vowel position.

Metathesis seems to be relatively uncommon. Many of the known cases are amenable to a single-segment analysis along the lines of Sagey (1986). Others are similar to the McCarthy (1995) analysis of Rotuman, wherein dislodged features seek an anchor so that they may surface.

However, not all examples argued to show metathesis obviously resolve themselves in one of these fashions. For example, an analysis of Kasem claiming metathesis is presented in Chomsky and Halle (1968), yet there are no simple cases of input /AB/ being realized as [BA]. Metathesis here is argued to reorder two vowels when followed by a third vowel (there are further restrictions). However, other aspects of the analysis include the merger of two vowels into one and the deletion of one vowel next to another. Consequently, trivocalic inputs, such as /pia-i/ 'sheep-plural', are realized as monovocalic, e.g. [pæ], with no obvious surface reflex of the metathesis. Unfortunately, in many cases of apparent metathesis, including Kasem,

the data are incomplete, making it difficult to be confident of any analysis.

WEAKENING AND STRENGTHENING

Weakening and strengthening (also termed *lenition* and *fortition*, respectively) are another pair of descriptive terms that do not necessarily make a smooth transition to analysis. Descriptively, the phenomena are relatively simple: weakening refers to any change that makes a sound weaker while strengthening refers to any change that makes a sound stronger. Yet these definitions are circular, since 'weaker' and 'stronger' are not defined.

Weakening includes phenomena such as word-final devoicing (e.g. in Woleaian) or high vowel devoicing (e.g. in Japanese); it also includes intervocalic voicing of obstruents (e.g. in some dialects of Japanese) and intervocalic spirantization. Gosiute Shoshone provides a case in which obstruents undergo both voicing and spirantization when intervocalic, becoming doubly weakened. Voiced fricatives only occur between vowels while voiceless stops only occur initially (or in a strengthened form as geminates, [moppo] 'mosquito'): there are words such as [tɨβa] 'pine nut' and [(peðɨ)] 'daughter, niece', but no words such as *[βɨta] or *[ðepɨ].

Strengthening includes intervocalic gemination (which occurs in certain morphological environments in Gosiute). Strengthening might also be viewed as including lengthening or stressing phenomena.

At this point, weakening and strengthening are useful to suggest particular types of phenomenon. However, in many cases, such as the Gosiute examples, it is not clear whether the phenomena are phonetic (as in the weakening example of voicing and spirantization cases) or morphological (as in the strengthening gemination example). There are also cases where weakening and strengthening are complementary. For example, Spanish voiced obstruents are 'strong' stops when following a homorganic sonorant, but otherwise are 'weak' fricatives between sonorants. Thus, as with metathesis, there is currently a poor understanding of the dimensions along which variation can be found with these types of processes.

CONCLUSION

A large class of phonological processes involving features vary along a small set of dimensions: which features are critical, which segments undergo the process, which cause the process, the relevant domain, and the leftward or rightward orientation. A fine-tuning of the process comes in identifying transparent elements – those which are ignored by the process – and opaque elements – those which end a domain which otherwise would not end at that point. There remains a residue of ill-understood processes which may lead us to enlarge this set of dimensions but which may, under closer examination, fall neatly within this set.

CONTENTS

During their first year infants discover the elementary sound units that are used to form words in their native language. During their second year they begin to produce these sound units and acquire the structure of their native language.

INTRODUCTION

Much like the way that letters are the building blocks of written words, phonetic segments are the elements out of which spoken words are built. There is a finite set of such elements that are used in creating words in any natural language. However, any particular language, such as English, uses only a subset of the set of phonetic segments that are available for forming words. For example, English does not make use of click sounds that are used in some African languages, such as Zulu. By the same token, some sounds used in English, such as the initial sounds in the words 'then' and 'thick', are not found in French. So, one of the problems facing language learners is to discover which elementary sounds are used in forming words in the language they are trying to acquire. In addition to learning which elementary sounds are used, learners also have to understand the ways in which the elementary units can be combined to form words in their language. For instance, someone learning Polish will find that it is permissible to begin words with consonant sequences, such as 'kt' and 'db'. By comparison, someone learning English will never encounter these particular consonant sequences at the beginning of words.

ACQUISITION OF PERCEPTUAL CATEGORIES IN INFANCY

When do infants begin to learn about the elementary sound units of their language? For many years, researchers could not begin to investigate this issue until infants actually began to produce speech sounds themselves. This is because they lacked suitable methods for studying whether infants could perceive differences in speech sounds, even before they are capable of producing these distinctions in their own utterances. However, during the 1960s a number of different methods were developed to study the visual and auditory capacities of young infants.

One method that became widely adopted for studying the speech perception capacities of infants was called the high-amplitude sucking procedure (often abbreviated as HAS). In this procedure, infants are given a pacifier to suck on. The pacifier is connected to a pressure transducer, which allows an experimenter to record the frequency and intensity of infants' sucking responses. After obtaining an estimate of how often an infant sucks on the pacifier in the absence of any auditory stimulation, the experimenter makes the presentation of an auditory stimulus, such as the syllable 'ba', contingent on the infant's sucking. The more often the infant sucks on the pacifier, the more often the syllable 'ba' is played. Even one-month-olds take only a few minutes to learn the contingency between their sucking responses and the presentation of the speech sound. Consequently, they increase their sucking rates considerably over their baseline rates. After listening to the same sound for several minutes, infants lose interest in it (i.e. they habituate to the stimulus) and their sucking rates begin to decline. At this point, if a new sound, such as the syllable 'pa', is substituted for the original one, and the infant is able to perceive the change, then their sucking rates will typically increase in response to the novel sound. By observing whether infants react to a change from one speech sound to another, investigators can determine which types of phonetic contrasts infants can perceive.

Investigations using methods such as HAS showed that even one-month-olds are able to perceive a distinction, such as the one between 'ba' and 'pa'. This is remarkable considering that the sounds are alike in all respects, except for one that linguists refer to as *voicing*. For a voiced sound like 'ba', the vocal cords begin vibrating when air is released from the lips, but for a voiceless sound like 'pa', air is released from the lips about 50 milliseconds (ms) before the vocal cords begin vibrating. Whenever two sounds are alike in all respects except for one phonetic dimension, such as voicing, linguists refer to them as *minimal pairs*. In addition to the voicing distinction used in the first investigation of infants' speech discrimination abilities, infants in the first few months of life have been shown to discriminate a number of different kinds of minimal pairs, such as the stop consonants [b] versus [d] which differ in place of articulation, [b] versus [w] which contrast between a stop consonant and a glide, the liquids [r] versus [l], the nasals [m] versus [n], etc.

What role does experience play in infants' abilities to discriminate minimal pairs? Do infants have to have some period of prior exposure to these different speech sounds before they are able to discriminate them? The available evidence suggests that such experience is not required. First, even infants only a few days old have been shown to discriminate phonetic contrasts involving minimal pairs. Second, studies show that during the first six months of life, infants are able to perceive contrasts between phonetic segments not present in the native language that they are exposed to. For example, Kikuyu (a language spoken in Kenya) does not have a distinction between [b] and [p], yet infants from Kikuyu-speaking homes are able to perceive this distinction. The picture that emerges from these studies is that infants are born with the ability to discriminate any kind of phonetic contrast that occurs in the world's languages. However, this does not necessarily mean that they respond to any acoustic difference that they can detect between two different speech sounds. For example, even infants a few days old display some ability to distinguish one speaking voice from another. Yet six-month-olds can ignore such talker differences in performing a task that relies on their ability to distinguish [a] from [i]; they are able to do so, even when listening to many different talkers' productions of these vowels. The latter ability is important because in order to learn which phonetic segments are used to form words in their language, infants must be able to ignore individual differences in how different talkers produce these segments.

These findings indicate that, in the first months of life, infants possess the perceptual capacities that would allow them to learn the phonetic segments in any native language. However, infants still have to identify which segments are present in their own native language. There are some indications that they learn about these segments during the second half of their first year. During this period of time, infants appear to become much more focused on the particulars of the sound organization of their native language.

One indication that infants are becoming more focused on their native language comes from studies of their speech discrimination abilities. Between six and eight months, infants still display an ability to discriminate non-native language speech contrasts. Thus, English learners are able to discriminate contrasts from Hindi (the retroflex versus dental distinction that varies the precise positioning of the tongue behind the teeth) that do not appear in English. By eight to 10 months, though, their abilities to discriminate these contrasts begin to decline, and by 10 to 12 months, they no longer show any ability to discriminate them. Interestingly enough, it is during this same period in which a similar decline has been noted in Japanese infants' ability to discriminate [r] from [l], which is a distinction that is not used in Japanese.

Why does a decline occur in the ability to discriminate many non-native speech contrasts towards the end of the first year, such as the Hindi /ṭa/–/ta/ and the English /r/–/l/? One theory was that lack of exposure to the relevant speech sounds was the cause of the decline. However, it has been shown that at least some non-native contrasts continue to be perceived well, even into adulthood. An alternative view is that towards the end of the first year, infants learn about the organization of the elementary sound categories of their native language. An important part of this process involves learning when two apparently different sounds are actually variants (or allophones) of a particular phoneme of the language. For example, the English phoneme /t/ is realized as any one of a number of different phonetic segments, depending on the context in which it occurs. When /t/ occurs at the beginning of a word, it is produced with a large puff of air (i.e. it is aspirated), yet when /t/ occurs as the last segment of a word, it is usually unaspirated. When /t/ occurs immediately before /r/ as in 'intricate', it is produced as a retroflexed segment (i.e. the tongue is curled when it contacts the roof of the mouth). In a language such as Hindi, the distinction between a retroflexed *t* and an unaspirated *t* might convey a

meaningful distinction between words. In English it does not, so the English-learner has to learn that both are variants of the same English segment. Learning which kinds of distinctions that occur in speech input are meaningful and which are to be ignored appears to contribute to the decline in discriminating non-native contrasts.

Other findings indicate that infants are learning about other aspects of the sound organization of their language during the latter half of the first year. For instance, infants appear to learn about the permissible orderings of phonetic segments in words between six and nine months. This was shown in a study in which infants were played lists of unfamiliar English words and lists of unfamiliar Dutch words. Dutch and English words have the same rhythmic and pitch structure; they differ chiefly in which segments and segment sequences they use. The words used in the experiments from each of these languages contained phonetic sequences that were not permissible in words in the other language. At six months, English-learners are as content to listen to the lists of Dutch words, which violate English word structure, as they are to listen to the lists of English words. However, by nine months, English-learners listen longer to the English lists, whereas Dutch learners listen longer to the Dutch lists. The fact that nine-month-olds display these preferences, even when phonetic segments distinctive to each language were removed, suggests that they have learned about which kinds of phonetic sequences are permissible in words in their language. This phonetic sensitivity presumably arises from exposure to sounds in the infant's native language environment that vary in their relative frequency of occurrence.

In summary, the well-developed perceptual capacities that infants display in the first months of life enable them to make considerable progress in learning about the organization of the sound structure of their native language by the end of their first year. In the second year, infants further refine this sound structure as they begin to produce words.

EARLY SPEECH PRODUCTION

Although infants produce some vocalizations during the first four months of life, the characteristics of these differ considerably from the sounds that are typically used in producing words. At best, infants might produce some sounds that resemble drawn-out vowel sounds and occasional 'gooing' sounds. Only after four months do they begin to produce sounds that resemble some consonant–vowel sequences. These sounds are often produced in the contexts of other sounds, such as 'raspberries', growls, and squeals. Moreover, productions of sounds that resemble consonant–vowel sequences during this period lack the temporal characteristics of syllables used in speech production. At some point, around six or seven months of age, infants begin to produce syllables and strings of syllables with the temporal characteristics of ones used in language. This marks the onset of what linguists refer to as *canonical babbling*. Infants now produce well-formed syllables that exhibit the kind of vocal cord vibration, articulatory movements, resonance patterns, and temporal changes that are typical in language production. However, the syllables which infants produce during the first few months of the babbling period lack a clear segmental organization. Although these syllables may approximate consonant–vowel sequences, they do not show the range of permutations that would be expected if there were segments that could be freely recombined. Thus, the syllables that infants initially produce seem to be unanalyzed wholes, rather than combinations of individual phonetic segments.

Over the years, there has been considerable discussion about the relation that babbling bears to the development of linguistic production. One early view held that babbling is prelinguistic, and that a silent period intervened between babbling and true speech production. It was suggested that during the babbling period, much as young infants show the ability to discriminate phonetic contrasts from any of the world's languages, they also showed the ability to produce all the sounds of these languages. However, infants were thought to emit these sounds in a random fashion, rather than in any systematic attempt to achieve a targeted articulation. Moreover, a natural consequence of this view that babbling is a prelinguistic activity, not systematically controlled by the infant, was the claim that the babbling of deaf infants is the same as that of normally hearing infants. It was claimed that the chief difference between the two groups was a decrease in the amount of vocalizing that deaf infants do as they get older.

The view just described was based largely on anecdotal observations and diary descriptions of infants' babbling. More carefully documented analyses and recordings of babbling have largely refuted this view. For example, observers who have systematically recorded the babbling behavior of infants over many months have found no evidence of a silent period intervening between babbling and the production of words. In fact, the available evidence suggests that there is

considerable continuity between babbling and the production of infants' first words. For example, phonetic segments that occur frequently in later stages of canonical babbling are more likely to appear in the words that infants choose to produce. Similarly, although a range of different sounds does occur in babbling, there is no evidence that infants produce all the sounds of the world's languages. Indeed, the physical state of infants' developing vocal tracts during the first year precludes the production of certain types of speech sounds. Finally, the development of better clinical screening methods for detecting deafness in early infancy has allowed researchers to make more direct comparisons of babbling of deaf and hearing infants. Recent investigations reveal several abnormalities in the vocalizations of deaf infants. In particular, there is little evidence of canonical babbling in deaf infants during their first year, well after the onset of canonical babbling in normal infants.

The kinds of sounds that are likely to appear initially in canonical babbling are usually stop consonants such as [p], [b], [t], [d], and less frequently [g] and [k]. Nasal consonants such as [m] and [n] also appear early. These consonant sounds are most often produced with the vowels [a] (as in *hot*), [æ] (as in *bat*), and [ʌ] (as in *nut*). The production of these types of consonants and vowels early is a natural consequence of the opening and closing of the jaw. The consonants that appear are ones that result from completely closing the vocal tract at some point, whereas vowels such as [a] and [æ] result from a large opening of the mouth. Many of the repeated sequences of syllables that appear during canonical babbling (e.g. *dadada*, *mamama*) are a natural consequence of repeated openings and closings of the jaw.

For many years, it has been claimed that babbling drifts in the direction of the native language sound patterns, so that the babbling of English-learners comes to resemble English, whereas the babbling of Cantonese-learners comes to resemble Cantonese. Initially, these claims were based on the subjective judgments of adults listening to babbling produced by infants from different language-learning environments. One report suggested that influences of the native language on babbling are evident as early as eight months, in that French adults could distinguish the babbling of French-learners at this age from that of Arabic-learners. More recently, careful acoustic analyses of the vowel sounds produced by French, Arabic, English, and Cantonese 10-month-olds documented differences in infants' productions that reflect the vowels produced by native speakers of these languages. Changes reflecting the structure of the native language have also been noted in infants' production of consonants. For instance, a cross-linguistic study of English, Swedish, Japanese, and French infants revealed that the proportion of stop consonant sounds produced by 10-month-olds reflected the frequency and distribution of these sounds by adult speakers of these languages. Similarly, the intonation patterns and rhythmic patterns that occur in babbling have been shown, during the course of the latter half of the first year, to increasingly resemble those of the native language. Thus, just as influences of native language sound organization are evident in the perceptual capacities of infants towards the end of the first year, so too are they evident in the speech sounds that infants produce.

Infants' earliest productions of words are not usually accurate reproductions of words used by adults. Rather, they often involve some simplification of the segments present in the adult form of the word. For instance, a child attempting to say 'duck' may pronounce it as 'guck', so that the initial and final consonants have their vocal tract closure in the same place – namely, at the velum. Clusters of consonants may be reduced to a single consonant so that 'blue' may be produced as 'boo' and 'spoon' may be produced as 'poon'. Syllables of longer words are often dropped in a systematic fashion. Typically, unstressed syllables are more often omitted, especially word-initial ones: so, a child would be more likely to omit the first syllable of 'giraffe' than the second syllable of 'monkey'. The source of such differences between the child's productions and the adult word forms does not appear to be a failure of perception on the child's part. Rather, such differences appear to be governed more by difficulties that children have in planning, sequencing, and remembering the articulatory gestures required to produce the adult target word correctly. Children often appear to notice the discrepancy between their productions and the adult word forms, as evidenced by the fact that they often object when an adult reproduces the child's form rather than the correct form. Also, there is some evidence suggesting that children will avoid producing words that contain segments that they are unable to produce accurately.

OVERGENERALIZATION IN MORPHOPHONOLOGY

Linguists refer to the smallest unit of linguistic meaning as a *morpheme*. A word such as 'dog' is considered to be a morpheme, but so is the '-s' that

is added to make the plural of this word. Consequently, the word 'dogs' is considered to have two morphemes. Similarly, the '-ly' ending that we add to 'pretty' to make the adverbial form 'prettily' is another morpheme of English, as are the endings such as '-ing' and '-ed' that we add to the ends of verb forms.

One interesting property of some of the morphemes that we add to the ends of words in English is that these particular morphemes often have more than one phonetic realization. For example, consider the '-s' that is added to form the plural of nouns in English. In some cases, '-s' is pronounced as [s], such as when it is added to words such as 'cat, bike, rope'. However, in other cases, the '-s' is pronounced as [z] when added to the end of words such as 'dog, tab, pig', or even as [ɪz] when added to 'dress, bush, church'. Which phonetic realization of '-s' is used to form the plural is not arbitrary. Rather, it is governed by the nature of the phonetic segment at the end of the morpheme to which it is to be attached. With a few exceptions, words that end in voiced consonants or in vowels typically take the [z] form, whereas those that end in voiceless consonants take the [s] form. The exceptions are words that end in the fricatives [s], [ʃ] (the last sound in 'fish'), [ʒ] (the last sound in 'barrage'), and [z], or affricates (such as the final sounds in 'bench' and 'judge'). Similarly, it is the phonetic properties of the final segments of verbs that governs whether the past tense '-ed' will be phonetically realized as [d] (as in words such as 'fibbed'), [t] (as in words such as 'looked'), or [əd] (as in words such as 'fitted').

There has been a longstanding interest in when language learners master these apparently rule-governed alternations in the phonetic realization of these types of morphemes. A classic experiment in the study of language development presented pre-school-aged children with a picture of an object described as a 'wug'. The experimenter named the object, then pointed to a picture of two such objects and asked the child for the correct completion of the sentence, 'There are two ____'. In this case, the children correctly pronounced the plural ending as [z]. They also correctly pronounced the plural ending as [s] when shown comparable pictures of another object referred to as a 'bik'.

Although many nouns in English form plurals by adding '-s' and many verbs form their past tense by adding '-d', there are some exceptions. For example, the plural form of 'child' is 'children', the plural form of 'mouse' is 'mice', and the plural form of 'foot' is 'feet'. Similarly, the past tense form of 'is' is 'was', the past tense form of 'go' is 'went', and the past tense form of 'break' is 'broke'. These kinds of nouns and verbs are said to be irregular in that they do not form plurals or past tense in the way that most of the other words in the language do. Interestingly, many of these irregular nouns and verbs have a higher frequency of occurrence in the linguist input than do particular words that take regular forms. Moreover, children often produce the past tense of irregular verbs such as 'bring' and 'go', before producing the past tense of regular verbs such as 'kiss' and 'hug'. However, when they do begin to produce regular plural and past tense forms of words, they often overgeneralize these forms by applying them to irregular nouns and verbs. Thus, children who begin to pluralize 'ring' as 'rings' and 'cat' as 'cats' may also begin to say 'foots' and 'mouses' for the plural forms of 'foot' and 'mouse'. Similarly, children who correctly produce the regular past tense forms 'kissed' and 'hugged' may also begin to say 'goed' and 'breaked', even though they may never have heard any adults produce these forms. The existence of this kind of overgeneralization is an indication that children do not simply imitate what they hear adults say. Instead, these types of errors are an indication that children look for general kinds of patterns in the input and attempt to apply such patterns systematically in their productions. In time, children learn not to apply the rules for the regular forms to these irregular nouns and verbs.

CONTENTS

Various methods of computational modeling of phonological processing have been developed, especially in speech and language technology but also for cognitive models.

INTRODUCTION

Computer programs for various phonological tasks have been developed in several areas. Speech synthesis and recognition devices, for example, relate symbolic representations (e.g. phonetic transcriptions) to speech signals and to normal spelling. For speech synthesis, prosodic properties of a text must be computed, such as stress, intonation, and the division of words into syllables. All these computations can be performed by programs that employ phonological rules. These rules must be: (1) explicit (they must not need any human intervention to interpret them), (2) complete (they should deal with all inputs that they could ever be given), and (3) computable (a program that follows the rules must stop after a finite number of processing steps, not go into an endless loop). In real-world applications, they must also be computable in practice, i.e. reasonably quickly, given available hardware. In cognitive models of phonological processing, rule-based models are sometimes proposed, such as Coltheart's model of reading (Coltheart *et al*., 1993), which is similar to the grapheme-to-phoneme translation programs used in speech synthesis. But in cognitive science, connectionist methods now enjoy great popularity. (*See* **Prosody**; **Stress**; **Intonation**; **Reading, Psychology of**)

APPLICATIONS

A division can be drawn between applications intended to be useful tools for working linguists and 'pure' computational phonology, the development and evaluation of implementations of theoretical proposals. An example of the former is Lowe and Mazaudon's (1994) 'reconstruction engine', which helps linguists to compile a lexicon of reconstructed words in a proto-language, given lexicons of the daughter languages and a list of sound change rules. This helps researchers to manage their data and to explore the consequences of altering the proposed sound changes or the reconstructed words. An example of the latter is Williams's (1994) 'LexPhon' system, an implementation of the kind of phonological rule system proposed by theoretical phonologists. Computational implementations of most areas of theoretical phonology have been developed. But most research in 'pure' computational phonology is concerned with the development of new frameworks for phonological processing, such as two-level phonology, using finite-state transducers (Kaplan and Kay, 1994), constraint-based phonology (e.g. Bird and Klein, 1994), and probabilistic approaches. (*See* **Phonology**)

FINITE-STATE APPROACHES

The rules employed in traditional generative phonology are all of the form 'A → B/C — D', read as 'symbol A is rewritten as symbol B when it follows C and precedes D'. In many phonological analyses, B may be empty, meaning that A is to be deleted. It has been proved that such grammars are more powerful than is necessary for the definition of human languages: they are computationally expensive and psychologically implausible. Phonological analysis using such rules may be inefficient or even uncomputable (Bear, 1990). This processing problem can be ameliorated, to some degree (Maxwell, 1994). However, the most important advance in dealing with such rules was the proof by Johnson (1972) that if phonological rules are restricted in two ways, only regular languages can be generated. Such languages can be recognized, generated, and processed in other ways very efficiently. The two restrictions are (1) the distinctive features of the

symbols in the language must have a finite number of values (e.g. + and −, but not an open-ended set of integers); and (2) rules may not reapply to their own output. These restrictions are actually met in most phonological analyses. (*See* **Distinctive Feature Theory**)

FINITE-STATE AUTOMATA

The words or expressions of any regular language can be generated or recognized by a type of abstract computing device, a finite-state automaton. These have a mathematical specification, described in most formal language theory textbooks, and they can be implemented as working software. An automaton can be depicted as a network of nodes, each representing a state of the automaton, and arrows, representing changes from one state to the next. The arrows are labeled with sets of symbols, one of which must be read or written by the machine in order to move from one state to the next. Figure 1 shows an automaton which can be used to generate or recognize many of the syllables of English. (*See* **Finite State Processing**)

The automaton can be used to generate a syllable, as follows. Node 1, dashed, is the start state of the machine. From here we can move to state 2, 3, or 4, by following an arrow. In doing so, one of the phoneme symbols on the arrow should be written down. For example, to move from state 1 to 2, the letter 's' must be written. From state 2 moves to states 3 or 4 are permitted. To move to state 3, a 'p', 't' or 'k' must be written. A path can be followed from state 1 to state 8, 9, or 10, writing out a sequence of symbols as we proceed, for example, 's, t, r, a, j, f' (representing the pronunciation of *strife*), or 'p, j, u, w' (*pew*). States 8, 9, and 10 are end states, shown by a double-ringed circle. One way of traversing states 1, 2, 4, 5, and 8 writes out 's, m, a, r', a word that does not occur in English, though it is a possible word. Continuing to state 10 would generate the word *smart*.

A partial encoding of Figure 1 that is amenable to computational implementation is Table 1, a symbol–state table. Starting in state 1 (the second row), select any of the numbered cells in the row, write out the symbol at the top of the column, and move to one of the states (rows) given in the cell. Dashed cells show which symbols cannot be written in that state. Cells containing more than one number have several possible next states, making this automaton nondeterministic: a mechanism

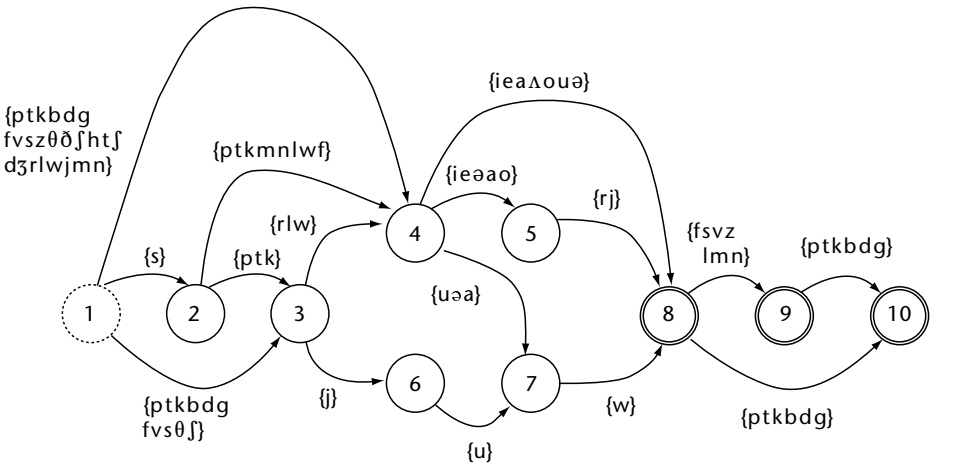

Figure 1. An automaton which defines many of the syllables of English.

Table 1. Symbol–state table encoding part of the automaton in Figure 1

Symbols	b	d	ð	ʤ	f	g	h	j	k	l	m	n	p	r	s	ʃ	t	tʃ	θ	v	w	z
States																						
1	3, 4	3, 4	4	4	3, 4	3, 4	4	4	3, 4	4	4	4	3, 4	4	2, 3, 4	3, 4	3, 4	4	3, 4	3, 4	4	4
2	–	–	–	–	4	–	–	–	3, 4	4	4	4	3, 4	–	–	–	3, 4	–	–	–	4	–
3	–	–	–	–	–	–	–	6	–	4	–	–	–	4	–	–	–	–	–	–	4	–
4	…	…																				
…																						

would have to guess at this point which state to go to next. Nondeterministic automata can be made deterministic, if necessary, but we might prefer to keep the nondeterminism: for example, we could associate probabilities with different state transitions.

Automata can also recognize strings, if the symbols on each arrow are read in and checked rather than written out. For instance, the string 'splajn' (*spline*) is acceptable: 's' takes the automaton from state 1 to 2, 'p' from 2 to 3, and so on. But 'sflajn' is unacceptable: 's, f' (as in *sphere*) takes the automaton from state 1 to state 4, but further moves are impossible as none of the transitions out of state 4 are labeled with 'l'. Thus, *sfline* is not a well-formed English word.

Finite-State Transducers

Most phonological computations involve relationships between two levels of representation; for example, converting English spelling to a phonemic transcription, or vice versa. We can modify Figure 1 accordingly: instead of single symbols, the arrows can be labeled with *pairs* of symbols. For instance, (th, /θ/) means that the pronunciation of 'th' can be /θ/, as in 'thin'. It can also be /ð/, as in 'this'. We could replace the label on the arrow from state 1 to 4 by a set of paired symbols, including {(c, /k/) (ph, /f/) (th, /θ/) (th, /ð/) (sh, /ʃ/) (ch, /tʃ/) (j, /ʤ/)}. Now transitions can be interpreted in four ways: (1) given the normal spelling, write out the corresponding phoneme; (2) given a phoneme, write out the spelling; (3) given a string in normal spelling and a transcription, check whether they correspond to one another; (4) given no inputs, generate paired spellings and transcriptions. Of these modes of use, the first might be used in speech synthesis, and the second in a speech recognition device (for spelling unknown words, perhaps). The fourth will generate a pronouncing dictionary of possible words. (*See* **Speech Recognition, Automatic**)

Similarly, paired phonemic and phonetic symbols enable us to generate or recognize the specific details of pronunciation at different positions in a word. Thus, some aspects of pronunciation variation according to context may be modeled. If instead of alphabetic phonetic symbols we use acoustic representations of slices of the speech signal, such as linear prediction coefficients, we can relate speech signals to their phonemic transcriptions. Because of the large number of distinct states of a signal, the construction of such a device has to be automatized. Hidden Markov Models (HMMs), in which a probability distribution is associated with each state transition, are an important extension of this approach. The probability distributions are determined empirically, by training the automaton on pairings of known signals with their transcription. Such devices are usually used for automatic speech recognition (Rabiner and Juang, 1993), though HMMs can also be used to generate a signal from a transcription (Donovan, 1996).

Finite-state techniques yield richer fruit which we do not have the space to savor here. Automata may be combined in various ways to yield more complex automata. Importantly, most phonological rules may be expressed as finite-state transducers. For example, the Japanese rule that /s/ is pronounced as [ʃ] when it occurs before /i/ is encoded as a transducer in Figure 2. An entire rule system can be translated into finite-state transducers and then automatically combined into a single, large automaton for efficient processing (Kaplan and Kay, 1994). Because of these discoveries, speech technology makes extensive use of finite-state transducers.

CONSTRAINT-BASED APPROACHES

Traditional phonological rules are applied in a certain order, rather like a simple program of the form 'first, change A into B; then, if C, change B into D, etc.' Computer science no longer relies on this *imperative* approach to programing. Techniques such as structured programing and object-oriented programing have broadened the repertoire of computational methods. In constraint-based approaches, the specification of languages is kept apart from questions of how computations such as generation, recognition, and translation are performed. Linguistic properties can be specified by declarative constraints, such as 'a word consists of one or more syllables', 'a syllable consists of an onset, a nucleus, and a coda', '/b/ can be a coda', '/a/ is a nucleus', or prohibitions such as '/b/ is not a nucleus'. Such constraints define a set of 'words', such as /bab/,

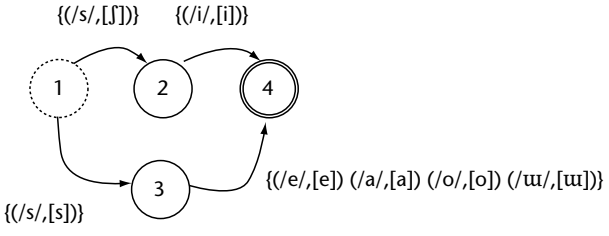

Figure 2. A finite-state transducer which encodes the phonological rule of Japanese that /s/ is pronounced as [ʃ] when it occurs before /i/, usually formalized as /s/ → [ʃ] / — /i/.

/babbab/, /babbabbab/, etc., and a set of nonwords, such as /bbbb/. If constraints are expressed as propositions of logic, questions such as 'Is /babbabab/ a word?' and 'What is the set of words that end with /k/?' may be determined using automated deduction. Because of the similarities between this approach to computation and current thinking in phonology, constraint-based methods are arguably the most popular approach to pure computational phonology (Bird and Klein, 1994). Most phonological rules can be expressed as constraints. For example, a feature-filling rule such as [+nasal] → [+voice] can be interpreted as the proposition: 'if x is [+nasal] then x is also [+voice]'. (*See* **Constraint-based Processing**; **Inference using Formal Logics**)

Constraints are usually required to be consistent, without contradictions. Theoretical phonologists have recently developed a constraint-based approach, optimality theory, in which constraints may conflict with one another. For instance, the constraints that 'a word consists of one or more syllables' and 'a syllable begins with a consonant' conflict with the statement that '*astronaut* is a word', because *astronaut* begins with a vowel. Optimality theory permits conflicts between constraints which express defaults or tendencies rather than exceptionless regularities. Where two constraints conflict, it is necessary to state which one has priority. Statements of prioritization define a ranking of the set of constraints, expressed 'A >> B >> C, D >> … X', meaning that constraint A has the highest priority and X the lowest; C and D have equal rank. A lower-ranked constraint does not need to be upheld if to do so would lead to the violation of a more highly ranked constraint. Various approaches to computation using this kind of system have been explored, usually employing finite-state methods yet again (e.g. Ellison, 1994). (*See* **Optimality Theory**)

CONNECTIONIST APPROACHES

Connectionist models are well-suited to the computation of relationships between distinct levels of representation, especially when the correspondence between the two levels is unclear or ill-formalized, because (like HMMs) they can be 'taught' correspondences between representations by presenting them with numerous examples of the relation in question. This makes it unnecessary to discover and debug a list of phonological rules, a task which often yields unforeseen errors. Faced with the difficulty of finding a complete and correct set of rules for e.g. grapheme to phoneme translation, training of a model is an appealing prospect. Connectionist models have been employed with some success for grapheme to phoneme translation (Sejnowski and Rosenberg, 1987), recognition of phonemes from speech acoustics (Waibel *et al*., 1989), learning syllabification and stress patterns (Larson, 1992; Gupta and Touretzky, 1994), predicting the next phoneme in a string of phonemes (Elman, 1990), and even acquiring phonological representations, given semantic, acoustic, and articulatory representations (Plaut and Kello, 1999). From the perspective of speech technology, connectionist approaches leave much to be desired, because of the degree of error in such models. However, from a cognitive science perspective, the similarities between the performance of these models and human behavior is most interesting.

Phonology

Introductory article

IM Roca, University of Essex, Colchester, UK

CONTENTS

Phonology is the branch of linguistics that studies the patternings of sound in language(s), and formalizes them by means of networks of distinctive features and higher abstract structure organized into levels of representation related by rules.

INTRODUCTION

The sounds musicians make are, typically, not random, but organized into tunes and melodies. Similarly, the sounds of language obey certain principles and are patterned in certain ways. Put differently, what hits our ear may be the blast of the trumpet or the beat of the drum, but what we perceive (and enjoy) is the melody of which this blast and this beat are a part. The melody (which can be written down as a score) is an abstract pattern: abstract if nothing else because we cannot hear it all at once, but must keep mental track of it as the music plays along. Without the score (written or mental) there would be no melody, and therefore no music to speak of, just random sound. Similarly in language, the sounds we produce follow an abstract score. It is the job of *phonology* to discover the substance of such a score and the properties that govern it (the entry on *phonetics* provides the necessary background on speech sound, and should be consulted first). (*See* **Phonetics**)

PHONEMES AND ALLOPHONES

The idea of the *phoneme* underpins the English spelling system (among others). Consider the sounds that correspond to the letters *p*, *t*, *c* in words like 'pie', 'tie', 'corn', and compare them with those in the words 'spy', 'sty', 'scorn': the sounds are different, even if they are represented with the same letter. In particular, in the first set of words, but not in the second, the sound corresponding to each of our letters is followed by a distinct puff of air ('aspiration') which, if exaggerated, would be powerful enough to blow out a candle. The sounds represented by *p* in 'pie' and 'spy' are therefore objectively different from each other. Does this mean that we are wrong in spelling them both with the same letter? Well, although different, the two sounds are still pretty close to each other: they both involve retention of air behind the lips, and its subsequent sudden release, with no vocal fold vibration (i.e. no concurrent humming, or 'voice'): technically, they are both voiceless oral labial stops. Moreover, were we to spell the *p* of 'pie' as, say, *ph*, with the *h* representing the aspiration (in conventional English spelling *ph* is of course usually equivalent to *f*, [f]), to keep it distinct from the *p* of 'spy', which has no aspiration, what exactly would we be gaining? Phonetic accuracy, to be sure: the phonetic symbol for the *p* of 'pie' is indeed [ph] (or [p^h]). But will such phonetic accuracy help us in any way? The answer is, clearly, no, at least for ordinary purposes (it would obviously help us if we were carrying out a phonetic investigation). The reason is that the presence of aspiration in English is totally predictable: it occurs, for instance, at the beginning of words, but not after *s*. Therefore, there is no point in writing in such information: it does not carry any functional load and therefore it is redundant. Conventional English spelling is, accordingly, quite right in representing the *p*s of 'pie' and 'spy' identically.

Compare now a language like Thai. Thai also has the two types of *p* that English has: with and without the aspiration. Consider such minimally contrasting Thai word pairs as *phet* 'spicy' versus *pet* 'duck', *phraang* 'to disguise' versus *praang* 'face', *phaw* 'to barbeque' versus *paw* 'to blow air', and many others, where the *h* following the *p* indeed stands for aspiration. What do these words show

us? They show us that aspiration does carry a functional load in Thai, since it keeps words apart: [ph]*et* from [p]*et*, etc. In English, by contrast, there simply cannot be a word *su*[ph]*er* distinct from *su*[p]*er*, for instance. This is where the 'phoneme' comes in: /ph/ and /p/ are distinct *phonemes* in Thai, but not in English, even though the two sounds [ph] and [p] also exist in English, as realizations, or *allophones*, of a single phoneme /p/ (phonemes are conventionally enclosed in slant bars /…/, and allophones in square brackets […]).

The advent of the phoneme marks the birth of modern phonology: besides the sounds we hear, we now have an abstract sound level underlying them (abstract because it is structural, not phonetic). Sometimes, the contents of the level of abstract sound and those of the level of concrete sound are nondistinct (cf. the Thai correspondences /ph/ ↔ [ph], /p/ ↔ [p]), but sometimes they are distinct (cf. the allophone [ph] of the phoneme /p/ in English). When the contents of the two levels are distinct, we can (somewhat anachronistically) relate them formally by means of context-sensitive rules, each connecting a phoneme to an allophone. For instance, we can 'derive' the English allophone [ph] from the phoneme /p/ by means of the rule 'p → ph /#__', where '→' relates input and output, '/' announces the context, '#' symbolizes the edge of the word, and '__' stands for the position where the conversion, or mapping, takes place. In the absence of one such allophonic rule, the identity mapping is assumed: simply, the phonemic form manifests itself unchanged phonetically.

At this juncture a question arises, why should we assume /p/, or /ph/, at all? (Obviously, if we assume /ph/ we will have to reverse our rule of allophony.) The point is that both [p] and [ph] are *surface* realizations: there is no *a priori* reason to think of either of them as basic. Instead, we could assume that the basic form is something in between [p] and [ph], which we will formalize as /P/. But what do we mean by something in between? In order to answer this question we must first work out what exactly we mean by [p], or [ph].

DISTINCTIVE FEATURES

By [p], of course, we mean the *p* of 'spy', and by [ph] the *p* of 'pie'. But what are these? If you think of it, the pronunciation of a *p* (whether it is the *p* of 'spy' or the *p* of 'pie'), or of any other sound, is rather like a tone an orchestra plays: the product of *several* instruments playing together in certain *ways*. What are the instruments for *p*? Well, mainly the lips, which 'play' the *p* by *stopping* the airflow on its way out of the mouth (if they were to *restrict* it, rather than stop it, we would get a sound similar to *f*; *f* is actually produced with the lower lip and the upper set of teeth). Other available instruments are: the vocal folds in the larynx, which are wide open during the production of *p* (not vibrating, as they are for the *b* of 'rubber'), and the nose cavity, which is shut off for both *p* and *b* (air would be going through if we were pronouncing *m*). The point, therefore, is that a sound like *p* is a composite of several gestures. It takes only a short step to designate these gestures, rather than the end product, as the primitive elements of linguistic sound, that is, the *phonological primes*. This step (foreshadowed at several points in history) was taken in the 1950s by Roman Jakobson, developing work by Nikolai Trubetzkoy. This means that, in some way, the layman is mistaken in thinking that 'pie' is made up of two sounds, respectively spelled out *p* and *ie*: the sound spelled *p* (and similarly for the sound spelled *ie*) is not a unitary entity, but a conglomeration of more basic elements, as we have just seen, rather like molecules are made up of atoms, or atoms of subatomic particles.

Such primitive elements of phonology are known as *distinctive features*. The original set of distinctive features set up by Jakobson (eventually in collaboration with Morris Halle) was deliberately rather small (12 features in all), and was orientated towards acoustics, the physics of sound. With the advent of 'Generative Phonology' in the 1960s, this stance underwent a radical shift, and in 1968 Chomsky and Halle declared the set an open one, actually listing over 20 features. Moreover, they based the description of the features on their articulatory, rather than acoustic, make-up, that is, on the mechanics of their production in the mouth and allied articulators. For example, they differentiated the vowels in words like 'bead', 'bed' and 'bad' by means of features named 'high' and 'low', which refer to the raising and lowering of the body of the tongue, respectively.

Whichever way we approach distinctive features, the strongest phonological justification for them lies in the fact that they define 'natural classes', that is, classes of sounds that behave similarly. We shall illustrate with data from English plural formation. Before doing so, however, we shall answer our pending question and state that indeed nothing prevents us in principle from postulating an *archiphoneme* /P/ as underlying the allophones [ph] and [p]. Assuming that the difference between [ph] and [p] lies in their opposing specification for a feature [±aspiration] (distinctive features are usually formalized as binary, that is, as

Table 1. Definitions of distinctive features[a]

+consonantal	obstruction to the airflow along the median plane of the mouth: [p, b, f, m, t, d, n, l, r, θ, s]
+sonorant	equal air pressure in the mouth and outside: [m, n, ɲ, ŋ, l, ʎ, r, ɹ; i, e, ɛ, a, ɔ, o, u, y, ø, œ]
+continuant	no airflow stoppage along the median plane of the mouth: [f, v, θ, ð, s, z, ʃ, ʒ, x, ɣ; i, e, ɛ, a, ɔ, o, u]
+strident	a hissing sound: [s, z, ʃ, ʒ, ɬ, ɮ]
+nasal	airflow through the nasal cavity: [m, n, ɲ, ŋ]
+lateral	unimpeded airflow over the sides of the tongue: [l, ʎ, ɬ, ɮ]
+voice	concomitant vocal fold vibration: [b, v, m, d, ð, z, n, l, ɹ, g, ŋ; i, e, ɛ, a, ɔ, o, u, y, ø, œ]
+aspiration	puff of air following release of blockage: [ph, th, kh]
labial	involving the lips: [p, b, f, v; u, ʊ, o, ɔ, ɒ, y, ø, œ]
+round	with rounding of the lips: [u, ʊ, o, ɔ, ɒ, y, ø, œ]
coronal	involving the blade of the tongue: [t, d, θ, ð, s, z, ʃ, ʒ, n, l, r, ɹ]
−anterior	coronal sound articulated behind alveolar ridge: [ʃ, ʒ, ɹ]
+distributed	coronal sound articulated with long constriction: [θ, ð, ʃ, ʒ]
dorsal	involving the body of the tongue: [c, ɟ, ɲ, k, g, ŋ; i, e, ɛ, a, ɔ, o, u, y, ø, œ]
+high	raising of the body of the tongue: [c, ɟ, ɲ, k, g, ŋ; i, ɪ, u, ʊ, y]
+low	lowering of the body of the tongue: [æ, ɑ, ɒ]
+back	retraction of the body of the tongue: [k, g, x, ɣ, ŋ; ɑ, ɒ, ɔ, o, u]
radical	involving the root of the tongue: [i, e, ɛ, a, ɔ, o, u, y, ø, œ]
+ATR	advancement of the root of the tongue: [e, i, u, o]

[a]Where a value (±) has been specified, the opposite value has the opposite definition; where there is no value specified, the feature is assumed to be monovalent, i.e. either present or absent.

carrying one of the two values + or −), i.e. [+aspiration] and [− aspiration], respectively, /P/ will be *underspecified* for this feature, which will accordingly be absent from its representation.

We make things more concrete in Table 1, with a succinct definition of each distinctive feature and a selection of sounds (drawn mainly from English) that contain the feature value defined in the table.

ENGLISH PLURAL ALLOMORPHY

We can now turn to the English plural. Orthographically, regular English plurals are formed by the addition of *-s* or *-es* to the singular: 'book**s**', from 'book', 'field**s**' from 'field', 'pie**s**' from 'pie', 'window**s**' from 'window', on the one hand, and 'ash**es**' from 'ash', 'church**es**' from 'church', or 'class**es**' from 'class', on the other (plurals like

'men' from 'man', or 'mice' from 'mouse', are of course irregular). English spelling is, however, a very poor reflection of actual sound. Indeed, there are three alternative realizations ('allomorphs') of the English regular plural: [z], [s], and [ɪz], as in *field*[z], *book*[s], and *ash*[ɪz], respectively ([ɪz] can be [əz] in some accents). The question is – why doesn't the English regular plural have a uniform manifestation?

Let us consider the *alternation* between [z] and [s] first: why does the plural show up as [z] in *field*[z], but as [s] in *book*[s]? The answer is that the plural suffix comes out voiced if the preceding sound is voiced, and voiceless if the preceding sound is voiceless: [d] is voiced, hence *fiel*[dz], but [k] is voiceless, hence *boo*[ks]. Now, how are we going to formalize this alternation between [z] and [s]? First, of course, we have to decide which is the underlying form of the suffix. An argument for an underlying form /z/ (rather than /s/) can be made on the basis that the surface manifestation of the plural suffix is [z] when the preceding segment is not a consonant, but a vowel (*spa*[z] from 'spa', *pea*[z] from 'pea', *zoo*[z] from 'zoo', etc.): it is unusual for a vowel to affect the voice status of the following consonant. Assuming thus /z/, we could formulate a rule to change it to [s] after /k/, to get *book*[s], as follows (the '+' in the environment stands for the boundary between two 'morphemes', that is, the lexical or grammatical elements that make up a word: here, the base morpheme and the plural morpheme, the latter a 'suffix' because it *follows* the base):

$$\mathrm{z} \rightarrow \mathrm{s} / \mathrm{k} + \_\_ \qquad (1)$$

This rule will obviously implement the change we are seeking, as can be seen in the corresponding *derivation* in (2) (for simplicity, we provide phonetic symbols only for the segments under examination):

underlying representation	*boo*/k + z/	
rule (1)	s	
surface representation	*boo*[ks]	(2)

Now, because rule (1) requires /k/ in the left environment, it will not apply in forms like *soaps*, *mats*, *cliffs*, etc. If the underlying representation is /z/ and the rule does not apply, the plural of these forms is predicted to be **soap*[z], **mat*[z], and **cliff*[z], contrary to fact (forms which do not correspond to fact are conventionally represented starred; the correct plurals are of course *soap*[s], *mat*[s], *cliff*[s]). How shall we proceed? One alternative would be to say that for these words the underlying representation of the plural morpheme is /s/, rather than /z/. This is only a pseudosolution, however, for at least two reasons. First, generative phonology is grounded in the assumption that each family of alternants derives from a single underlying form: this is indeed the way their relationship (the fact that they constitute a family) is formalized in this theory. Second, the solution we are exploring is totally *ad hoc*: it handles the facts, but it does not explain why singulars ending in /p/, /t/, /f/ should not combine with the same underlying plural form as those ending in /k/.

Let us accordingly try a different tack. A better solution would be to postulate a similar rule for each of the consonants in question. For example, we can account for *soap*[s] by means of the following rule:

$$\mathrm{z} \rightarrow \mathrm{s} / \mathrm{p} + \_\_ \qquad (3)$$

The effectiveness of this rule is demonstrated in the following derivation:

underlying representation	*soa*/p + z/	
rule (3)	s	
surface representation	*soa*[ps]	(4)

Likewise, of course, for *t*, *f*, etc. The problem with this solution, however, is that it requires a different rule for each different contextual consonant. Moreover, it is quite unexplanatory, because it does not tell us why it is the consonants in question (/p/, /t/, /k/, /f/, etc.) that trigger the change of /z/ into [s], let alone *why* they trigger it. Indeed, on this approach the fact that it is precisely these consonants that trigger precisely this change is quite arbitrary.

NATURAL CLASSES

We shall now bring distinctive features into the picture. Assuming features, the only difference between [z] and [s] concerns their respective value for [±voice]: [z] is [+voice], because it is voiced, whereas [s] is [−voice], because it is voiceless. Now, notice that *all* the consonants that trigger the change z → s are voiceless, i.e. [−voice]. If so, we can compress our rules above (and the remaining rules we have not formulated) into one simple rule:

$$\mathrm{z} \rightarrow \mathrm{s} / [-\mathrm{voice}] + \_\_ \qquad (5)$$

Rule (5) says that plural /z/ becomes [s] if the preceding sound is voiceless ([−voice]), as are all the consonants in question. If the sound that precedes the /z/ is voiced, the rule will not apply, because the contextual conditions it imposes are not met. This is indeed correct (cf. *fiel*[dz], *sp*[ɑz], etc.). Therefore, our approach (which makes crucial use of features) successfully passes the empirical

test. Moreover, we are now seeing that distinctive features define *natural classes* of sounds: in this case, a class of voiced sounds (formalized as [+voice]) and a class of voiceless sounds (formalized as [−voice]).

There is actually more to it. Why should the presence of a voiceless ([−voice]) consonant on the right edge of the base trigger the change from /z/ to [s] in the suffix? The answer becomes obvious when we remember that the only difference between these two consonants concerns the feature [±voice]: the value for [±voice] of the plural suffix therefore agrees with the value for [±voice] of the segment that precedes it. In particular, the underlying + value of this suffix changes to − when the preceding sound is [−voice]:

$$\text{z} \rightarrow [-\text{voice}] / [-\text{voice}] + \_\_ \qquad (6)$$

Agreement in the value of a feature in adjacent segments ('assimilation') is a common occurrence in the phonology of languages.

We now turn to the third alternant of the English plural suffix, [ɪz], illustrated in words like *ash*[ɪz], *massag*[ɪz], *atlas*[ɪz], *quizz*[ɪz], *finch*[ɪz], *cabbag*[ɪz]. Where does this alternant come from? Notice that the rule we have currently available is unable to derive it (e.g. for *ash*[ɪz]):

underlying representation	*a*/ʃ + z/	
rule (6)	s	
surface representation	**a*[ʃs]	(7)

We obviously need an additional rule to derive the correct output. On the basis of *ash*[ɪz], we can formulate this rule as follows:

$$\text{z} \rightarrow \text{ɪz} / \text{ʃ} \_\_ \qquad (8)$$

The incorporation of this rule has the desired effect on the derivation (we shall explain shortly why rule (6) fails to apply in this derivation):

underlying representation	*a*/ʃ + z/	
rule (8)	ɪz	
surface representation	*a*[ʃɪz]	(9)

Our success, however, is tempered by the fact that the approach does not work for forms which do not have a base ending in /ʃ/ and which nonetheless also select the plural allomorph [ɪz]: *massag*[ɪz], *atlas*[ɪz], *quizz*[ɪz], *finch*[ɪz], *cabbag*[ɪz]. The solution, once more, lies in the incorporation of distinctive features. In particular, the consonants that take [ɪz], viz. /ʃ/, /ʒ/, /s/, /z/, /ʧ/, and /ʤ/, share the specifications [+coronal, +strident], where [+coronal] designates a segment articulated with the blade of the tongue (the front part of the tongue, that we can stick out without discomfort), and [+strident] a fricative segment that sounds 'rough', like [ʃ] or [s], for instance (as against [ɵ], which sounds 'smooth'). We can accordingly give rule (8) a more general scope, as follows:

$$\text{z} \rightarrow \text{ɪz} / \begin{matrix}[+\text{coronal}] \\ [+\text{strident}]\end{matrix} + \_\_ \qquad (10)$$

All the plurals *ash*[ɪz], *massag*[ɪz], *atlas*[ɪz], *quizz*[ɪz], *finch*[ɪz], *cabbag*[ɪz] are taken care of by this rule.

As in the previous case, the question arises of why the process should occur at all. Also as in the previous case, the answer requires decomposing into distinctive features. In particular, /z/ is also specified as [+coronal, +strident]: evidently, thus, a sequence of two [+coronal, +strident] consonants is not allowed in English (nor in many other languages). In order to circumvent this prohibition, the phonology of the language provides a rule inserting ('epenthesizing') a vowel between the two [+coronal, +strident] consonants, rather as the umpire stands between the two boxers when they need to be separated. Strictly speaking, therefore, the rule must be formulated as follows ('∅' stands for the null symbol, or zero; 'z' informally stands for the remainder of the features that make up [z]):

$$\emptyset \rightarrow \text{ɪ} / \begin{matrix}[+\text{coronal}] \\ [+\text{strident}]\end{matrix} + \_\_ \begin{matrix}[+\text{coronal}] \\ [+\text{strident}]\end{matrix} \qquad \text{z} \qquad (11)$$

The motivation for the process is now transparent. The formal linchpins are, of course, the distinctive features which make possible direct reference to natural classes of sounds.

RULE ORDERING

We must now explain why the application of rule (11) excludes the application of its competitor, rule (6). If it did not, an incorrect output would, of course, be derived:

underlying representation	*a*/ʃ + z/	
rule (6)	s	
rule (11)	ɪ	
surface representation	**a*[ʃɪs]	(12)

The output **a*[ʃɪs] does not match the correct form *a*[ʃɪz].

The solution traditionally adopted consists in imposing on the sequence of rules the specific ordering that yields the targeted output. In the present case, all we have to do is invert the order of the two rules in derivation (12):

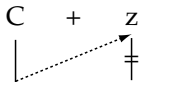
underlying representation	*a*/ʃ + z/
rule (11)	ɪ
rule (6)	not applicable
surface representation	*a*[ʃɪz] (13)

As can be seen, rule (6) is now inapplicable, for the simple reason that the environment it requires has been destroyed by the previous application of rule (11). In technical parlance, the order rule (11) > rule (6) that we are imposing on these two rules is a 'bleeding order', because the application of rule (11) removes (bleeds away) the environment required by rule (6), that follows it in the proposed ordering.

AUTOSEGMENTAL PHONOLOGY

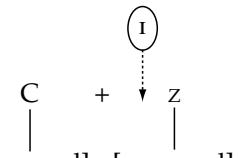
As a matter of fact, the formalization we have been using for our rules is now a little old-fashioned. In particular, our two rules of Voice Assimilation (6) and Epenthesis (11) would nowadays tend to be formalized as follows:

Voice Assimilation:



(14)

Epenthesis:



(15)

The new formalization is visually more transparent than the previous one. Consider the rule of voice assimilation (14) first. We can immediately see what is going on: given a sequence C (= any consonant), + (= morpheme boundary), and /z/, such that C is associated to the valued feature [−voice] (notice the continuous line linking the two), this minus-valued feature takes over the neighboring segment /z/ (notice the arrow-headed broken line), which concomitantly loses its previous association to [+voice] (notice the crossing out of the corresponding association line). The end result, of course, is the devoicing of /z/, which becomes [s] (implicit in the figure in the new association of /z/ to [−voice]). With regard to epenthesis (15), the ringed ɪ is shown being inserted between the two [+coronal, +strident] segments.

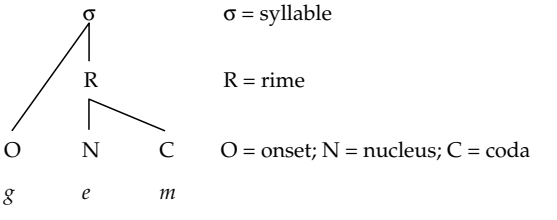
Visual clarity aside, the main advantage of the new formalization (commonly referred to as *autosegmental* phonology, perhaps not very transparently) is that it affords each feature true formal autonomy in a three-dimensional space. We do not have room to expand on the details of this autonomy here, nor to justify its superiority. Suffice it to say in the present context that there is practically unopposed consensus in the field that phonological representations indeed are autosegmental.

SYLLABLES

The autosegmental modeling of segments represented a significant step forward in our understanding of phonology. However, we will now see that it needs to be supplemented.

Consider the two very similar English words 'attractive' and 'atlantic' (similar in particular in their initial sequences *attrá*…, *atlá*…). Despite this similarity, the respective pronunciations are quite different. First, the first *a* of 'attractive' reduces to 'schwa' (it sounds [ə], like the article *a* in the phrase 'a tractor'), but not so the first *a* of 'atlantic', which sounds [æ], like the *a* in 'at (Lancaster)'. Second, the *t* of 'attractive' always comes out as a full *t*, indeed an aspirated *t*: [th]. By contrast, the *t* of 'atlantic' is weaker: definitely not aspirated, and possibly even reduced to a glottal stop [ʔ] again as in 'at Lancaster'. Last, the *l* of 'atlantic' is fully voiced, similarly to the *l* of 'land'. The *r* of 'attractive', by contrast, usually loses its voice, totally or partially: it does not quite sound like the *r* of 'rack'. These differences pose an obvious puzzle.

The solution involves recognizing that segments are not like carriages in trains, each linked to the next. Rather, segments cluster in ways comparable to planetary systems, each centered around a sun, surrounded by planets. In particular, segments organize themselves into *syllables*, typically with a vowel as the *nucleus*, and possibly with consonants on either side: in the *onset* when preceding the vowel, and/or in the *coda* when following the vowel. Such internally structured syllables can be graphically represented as in the following diagram, where the nucleus and the coda are grouped under a common node *rime*, responsible for rhyme in verse, among other things:



Each syllabic subconstituent onset, nucleus, and coda can either be simple, when it dominates only one segment, or complex, when it hosts more than one segment: compare 'pan', 'plan', 'land', 'planned', etc., all monosyllabic (= 1 syllable), 'planner', 'landing', 'landless', etc., bisyllabic (= 2 syllables), 'landlessness', etc., trisyllabic (= 3 syllables), and so on. Speakers usually have very clear intuitions about the number of syllables in the words of their language, and even about the boundaries between syllables, although in English the location of syllable boundaries may be somewhat blurred (would you syllabify 'planning' as *plann.ing* or as *pla.nning*, where the dot signals the syllable boundary?). Poets make privileged use of intuitions like these by applying them to poetic metre, which obviously involves syllable counting. In some languages (Spanish, for instance, although not English), a convention dictates that in ordinary writing lines can only be broken between syllables.

We can now return to the contrasts between 'attractive' and 'atlantic'. Suppose we syllabify the two sequences differently: *a.ttrac*… versus *at.lan*… Two questions ensue: first, what is the point of doing so, and second what is the empirical justification (we should not do things in an *ad hoc* manner just to suit our analytic convenience, but, rather, ground them in true fact). Let us answer these two questions in turn. The point of postulating these two different syllabifications is that they allow us to understand the differences in pronunciation we pointed at. In particular, *a* reduces to schwa in 'attractive' because it is not protected by a coda consonant (in 'atlantic' it is); on the other hand, *t* is always strong in 'attractive' because it occupies the syllable onset, whereas in 'atlantic' it occupies the syllable coda, and therefore it can undergo weakening; finally, the *r* of 'attractive' can lose its voicing because of the influence of the preceding *t*, with which it shares the onset (the [h] of [th] invades the *r*, so to speak): there is no such influence of the *t* of 'atlantic' on the *l* because the two segments belong in different constituents, and therefore do not interact (at least to a degree that makes devoicing possible). So, what seem to be three independent (and puzzling) phenomena are unified and made sense of when we refer them to syllable structure, the case for which is accordingly strengthened. Moreover, in the case at hand there is additional independent evidence for the different syllabic allocation of the *t* in the two words: while there are many English words beginning with the sequence *tr* ('tractor', 'try', 'troglodite', etc.), there is *none* beginning with *tl*. Crucially, this is not an accidental gap, but a principled one, probably attributable to the fact that *t* (and *d*) and *l* share their place of articulation: [l] is like [d] with the sides of the tongue lowered; in turn, [t] is like [d] without the voicing. Languages do tend to eschew similar adjacent elements within the same structural unit (a bit like close blood relations eschew marriage!).

SYLLABLE STRUCTURE AND STRESS

Syllables (and their internal structure) manifest themselves in many other ways. We shall mention just a couple of them here. In all English words, one of the syllables carries special prominence, or *stress*. For instance, we know whether 'torment' corresponds to a noun ('a horrible torment') or a verb ('I don't wish to torment you') because of the location of the stress (*tórment* and *tormént*, respectively). Native speakers know intuitively where to put the stress in each word, and phonologists have discovered the laws that govern such distribution in many languages, English among them. One reason syllables are relevant to stress is, therefore, that stress is carried by syllables (here *tor* and *ment*, respectively).

There is an additional, perhaps less obvious, aspect of the relevance of syllables to stress: in some languages, the location of stress is influenced by the structure of syllables. Consider English words like 'algebra', 'asparagus', 'hippopotamus', 'aluminium', 'aluminum', on the one hand, and 'agenda', 'amalgam', 'memento', 'asbestos', 'amanuensis', on the other, with the stress falling on different syllables: antepenultimate (*álgebra*) and penultimate (*agénda*), respectively. Assuming (abstracting away much complexity) that English nouns target antepenultimate stress, the question arises why stress is penultimate in *agénda*, rather than antepenultimate. One answer (on the right track, as we will see) is that it is drawn in, in some way, by the consonant cluster *nd*. The problem with this explanation is that *álgebra* also has a consonant cluster in the same position: *br*. However, reflection will reveal that the two clusters are syllabified differently: *n.d* and *.br*, respectively. In other words, the two consonants of the cluster belong in different syllables in *agen.da*, but in the same syllable in *alge.bra*. As a result of these syllabifications, the syllable *gen* in *agenda* includes a coda consonant (*n*), and is therefore 'closed', whereas the corresponding syllable *ge* in *algebra* does not, and is 'open'. If we now assume that closed syllables (as well as syllables containing a long nucleus) are 'heavy', and open syllables 'light', we can say that a heavy syllable in penultimate position stops the leftward journey of stress to the antepenultimate

syllable, the desired target in English nouns, as we said (final syllable heaviness is obviously irrelevant here). Syllable structure, correspondingly, has a direct effect on the positioning of stress.

SONORITY

We still have not explained the reason for the syllabifications *alge.bra*, *agen.da*, rather than *algeb.ra*, *age.nda*, which would yield the opposite results with regard to stress (**algébra*, **ágenda*). The reason is twofold. First, each syllable is a mountain-shaped cluster of sonority, where by sonority we mean the amount of actual sound carried by each segment. It is not difficult to see that vowels carry more sonority (i.e. project more sound) than consonants: for instance, we use vowels, rather than consonants, to call someone's attention (*oy*, or *eh*, rather than *ppp*, or even *fff* or *lll*). The point about syllables is that the nucleus must constitute the sonority peak, with the sonority of the onset and the coda sloping down to the respective syllable boundaries, a profile commonly known as *sonority sequencing*. A few sets of sonority relations are now provided, with examples in brackets ('>' = 'more than'):

a. vowels ([i]) > consonants ([s])
b. low vowels ([ɑ]) > mid vowels ([ɛ]) > high vowels ([i])
c. obstruent consonants ([b]) > sonorant consonants ([m])
d. stop obstruents ([b]) > fricative obstruents ([v])
e. voiced stops ([b]) > voiceless stops ([p])
f. voiced fricatives ([v]) > voiceless fricatives ([f])
g. liquid consonants ([l]) > nasal consonants ([n])
h. rhotic liquids ([r]) > lateral liquids ([l])

These partial sets can be combined into a global *sonority scale*, as follows:

low vowels > mid vowels > high vowels >
rhotics > laterals > nasals > voiced fricatives >
voiceless fricatives > voiced stops >
voiceless stops

The problem with a syllabification *age.nda* is that a syllable *nda* would not be mountain-shaped with regard to sonority: instead of the sonority of its segments sloping up to the nucleus (such that $S_1 < S_2 <$ Nucleus), it contains a sonority trough between the *n* and the *a* (*n* > *d* < *a*). The presence of this sonority trough rules out *nda* as a possible syllable, and the *n* and the *d* must instead be assigned to different syllables: *agen.da*.

A syllabification *algeb.ra* would not violate intrasyllabic sonority sequencing, since both *geb* and *ra* would be mountain-shaped with regard to sonority. However, such a syllabification would infringe another syllabification principle adhered to by many languages, English among them: the principle that onsets must be maximized, that is, made as large as is compatible with the other syllabification principles (the principle of sonority sequencing paramount among them). Therefore, on onset maximization 'algebra' is syllabified *alge.bra* (not **algeb.ra*), like 'attractive' is syllabified *a.ttractive* (not **att.ractive*), although 'atlantic' does need to be syllabified *at.lantic* (not **a.tlantic*), as we explained above.

The model of phonology we have developed up to this point contains strings of autosegmentalized clusters of distinctive features making up segments. In turn, segments are organized into syllables, each with an obligatory nucleus (usually a vowel) and with an optional onset and/or coda (typically made up of consonants). One of the word's syllables carries special prominence, or stress. The composition of the syllable can have an effect on the location of stress: heavy rimes arrest the train of stress in some languages, like English, as we saw.

OPTIMALITY THEORY

Before ending our presentation, we shall refer briefly to a recent approach ('Optimality Theory') which substitutes surface constraints for rules and derivations. Remember that we have accounted for the surface alternation of the English plural morpheme ([z], [s], [ɪz]) by postulating a common underlying representation /z/ and a set of two ordered rules (Epenthesis (15) > Voice Assimilation (14)) mapping this representation onto the appropriate surface allomorphs. Suppose instead that we allow a general, universal device (the 'generator', GEN) to generate (by means of a rather general universal set of rules) an indefinite number of surface forms, not just the correct ones, but any number of them. The phonological grammar of English would now have the task of *selecting* the correct form in each case, discarding the rest.

Let us see how this would be done in the case of plural allomorphy. Suppose that the phonology of English includes the two surface constraints in (16) and (17), conveniently streamlined to keep the presentation simple ('α', a 'Greek letter variable' = + or −):

NO VOICE CLASH (NVC): *[αvoice][−αvoice] (16)

NO STRIDENT CORONAL SEQUENCE (NSCS): *[+coronal][+coronal] [+strident][+strident] (17)

It is clear that NVC will rule out **boo*[kz], and NSCS **a*[ʃz] or **a*[ʃs] (**a*[ʃz] will also be ruled out by NVC, of course). This means that these forms will not be allowed to occur, exactly as sought.

It is not obvious yet how the *correct* forms are obtained, however. For instance, a form **boo*[z], from *boo*/kz/, would also comply with our two constraints, as would **boo*[k]. Similarly, **a*[ʃ], **a*[z] or **a*[s] would all be legitimate plurals of *ash* (also other possible forms, too numerous to be listed here). How can we ensure that the procedure selects precisely *boo*[ks] and *ash*[ɪz], respectively? The answer is that constraints (16) and (17) are not the only constraints that control the surface plural form (or, indeed, other surface forms). Of direct relevance here is a family of *faithfulness* constraints that aim at ensuring the identity of the surface form with the underlying form (its 'faithfulness' to it). Clearly, in the case at hand the faithfulness constraints will strive for the surface forms **boo*[kz] and **a*[ʃz]. How can we get the correct forms *boo*[ks] and *a*[ʃɪz], then?

The answer is that, in any given language, not all the constraints have the same *power*: some are more powerful than others. In English, NVC and NSCS overpower the relevant faithfulness constraints, whichever these are. These power relations are formalized by means of constraint 'ranking', here as follows (>> signifies 'ranked higher than'):

NVC, NSCS >> faithfulness

It is now clear why the plural surface forms cannot always replicate the underlying forms: faithfulness must give way to prevent violations of NVC or NSCS. The question is – why does it give way the way it does? That is, why do we get *boo*[ks], rather than, for example, **boo*[gz], or *a*[ʃɪz], rather than, for example, **a*[z]? The answer is implicit in our discussion: There must be some constraints ranked higher than the constraints discussed so far which therefore rule out these forms. In particular, the faithfulness constraints affecting the base are ranked higher than the faithfulness constraints affecting the suffix, and the constraints prohibiting deletion are ranked higher than the constraints prohibiting insertion, such that *a*[ʃɪz] is favored over **a*[ʃ], for instance:

some faithfulness constraints >> NVC,
NSCS >> other faithfulness constraints

For reasons of space we cannot go into further technical details here. However, we feel reasonably confident that the basic mechanics of Optimality Theory are satisfactorily summarized in the outline we have managed to offer.

COGNITIVE RELEVANCE

The cognitive relevance of phonology, as of linguistics in general, must be sought at the level of *competence*, the knowledge of the language its speakers need to have in order to engage in actual *performance* (this dichotomy originates in the work of Noam Chomsky). It is perhaps helpful to relate competence in language to programs in the world of computers: hidden from the user's view, but obviously a prerequisite to what we see on the screen. However, formal models of phonology are not supposed literally to represent actual operations in the mind, although a mental correlate of some kind is usually assumed, at least implicitly.

A central issue which arises out of formal models like the ones we have presented here concerns learnability: how can the learner of the language arrive at the specific analyses (underlying representations included) from the surface data? In particular, certain rule orderings render certain surface forms *opaque*, in as much as the generalizations embodied in some rules are irrecoverable directly from the surface. If so, how can the learner induce such rules and, *a fortiori*, the underlying representation? The problem obviously disappears if the power to order rules externally (i.e. by the analyst's fiat) is removed, and indeed such power is commonly, although not universally, disfavored by practitioners. Among the advantages claimed for Optimality Theory is precisely its flat structure, with no derivations: this architecture obviates rule ordering. Optimality theorists also postulate a procedure ('lexicon optimization') by which learners work their way up from the surface form to the underlying representations, making use of the same set of constraints and constraint rankings that are necessary for the selection of the winning candidates in the language. Notwithstanding these advances, opacity seemingly remains an irreducible empirical fact of the phonology of languages, and is motivating important modifications in the theoretical apparatus of Optimality Theory, in an attempt to empower it to overcome the challenge.

Various types of experiments aimed at establishing the psychological reality of the various formal constructs have been carried out through the years, often with mixed results, although clearly questioning the more abstract analyses. More recently, access to actual neural reality is being attempted through neuroimaging techniques that register activity in areas of the cerebrum. The main results obtained reveal that productive regular alternations (e.g. regular plurals of the 'book' to 'books' kind examined above) are associated with different

brain potentials and involve different brain areas than do irregular alternations (e.g. plurals like 'children' or 'mice'). The former, thus, parallel the neurological correlates of syntactic processing, while the latter are reminiscent of those associated with the handling of single words. A reasonable inference to draw from these equivalences is that productive regular processes are neurologically real, whereas irregular alternants are stored piecemeal.

Phrase Structure and X-bar Theory

Intermediate article

Geoffrey K Pullum, University of California, Santa Cruz, California, USA

CONTENTS

The phrase structure of an expression is its structure in terms of the subexpressions of which it is composed and the categories to which they belong. X-bar theory is a family of related theories of phrase structure.

INTRODUCTION

Most modern syntactic theories for natural languages are based on three fundamental insights. The first is that expressions are classified into a restricted range of types, traditionally called parts of speech and referred to here as syntactic categories: *enjoyed* is a verb, *movie* is a noun, and so on. (The categories may also have subcategories: *enjoy* is a transitive verb, for example. In some languages words belonging to some of the categories also have forms that belong to morphosyntactic (inflectional) subcategories; for example, *enjoyed* is a verb inflected in the preterite tense.) Every syntactic theory recognizes at least some distinct categories for different kinds of word.

The second insight is that there are phrases. Although some expressions (e.g. words) are syntactically atomic (i.e. have no subparts), there are other expressions that have subparts that are also expressions. Thus *enjoyed the movie* is a verb phrase that is made up of *enjoyed* and *the movie*. It is not a necessary assumption that some expressions have parts that are expressions; dependency grammar essentially denies this, treating syntax as a matter of relations of dependency holding between words. But it is fundamental to all American structural analysis, and to the transformational syntax that succeeded it, that expressions have this kind of structure, which is known as 'constituent structure' or 'phrase structure'.

The third insight is that the subparts of an expression have specific functions within the expressions they make up. For example, the two parts of the expression *enjoyed the movie* have different functions: *enjoyed* is the head of the expression *enjoyed the movie*, and *the movie* is a complement (specifically, a direct object) of the expression. Neither part could serve the function that the other serves (*the movie* could not be the head of a verb phrase, for example). In some theories of syntax such functions (or grammatical relations) are very important; in relational grammar they are the basis for nearly all the content of the theory, and in dependency grammar they completely replace phrase structure. Within transformational grammar since 1970 the function 'head' has become particularly important, and the notion of 'X-bar theory' described below is founded on it.

SYNTACTIC CATEGORIES

Traditionally there are eight to ten word-level categories in English. The most significant, seldom absent from any English grammar, are listed in Table 1.

Table 1. Major syntactic categories

Symbol	*Category name*	*English examples*
N	Noun	*tree*, *cat*, *spoon*, *absence*, *sugar*, *Michael*, *Japan*, *April*
V	Verb	*weep*, *eat*, *feel*, *escape*, *greet*, *give*, *furnish*, *be*, *have*, *do*
Adj	Adjective	*good*, *long*, *nice*, *heavy*, *wide*, *large*, *predatory*, *continual*
Adv	Adverb	*soon*, *quite*, *so*, *too*, *nicely*, *heavily*, *beautifully*, *continually*
P	Preposition	*at*, *by*, *from*, *of*, *in*, *out*, *into*, *between*, *throughout*, *despite*

N is universally the category containing the most basic words for naming persons, places, things, substances, natural kinds, and abstract notions referred to as if they were things or substances (*idea*, *knowledge*). It is an open category: new nouns are added constantly as names are invented or borrowed to name new entities and kinds of entity. V, the category of verbs, traditionally a class of labels for actions, events, and occasionally states, is also open to a very considerable extent: new verbs are added to the language frequently (often by conversion of nouns). The categories Adj and Adv are not always distinct from one another in all theories, and indeed, are not always present in every grammar (there are a few languages that appear to do without adjectives, and it is not entirely clear that adverbs can be identified in all of those languages either). In languages that have both, adverbs are often transparently formed from adjectives by derivation (this is very largely the case in English, where most adverbs are formed by suffixing *-ly* to adjective roots). Both kinds of word are often coined and borrowed, though perhaps not as frequently as new verbs.

The category P contrasts with the other categories in that it changes membership relatively little, though new members have been added frequently during the history of English (the chief sources are recategorization from verbs and adjectives, and occasional borrowing from languages like Latin and French). It also contains a number of items that have very specific grammatical functions and in many of their occurrences have little lexical meaning. P is listed here as a major category, however, because there can be little doubt that P can be the head of full internally complex phrases (Jackendoff, 1973; Huddleston and Pullum, 2002, Ch. 7).

In addition to these major categories there are minor ones on which there has been more divergence in nomenclature. Within earlier generative grammar many *ad hoc* categories were employed: 'T' for tense morphemes, 'M' for modal verbs, 'Aux' for a constituent containing various auxiliary verbal items, 'Q' for a class of determinatives known as quantifiers, 'Deg' for degree particles like *too*, and other minor categories that have been posited in recent generative grammar (these are discussed further below under 'functional categories').

For the major categories, it is accepted by most grammarians that there are corresponding phrase types. The standardly accepted ones are listed in Table 2. (See below for discussion of the current view that a phrase like *the tree* is not an NP, but has *the*, belonging to the category D of determinatives, as its head.)

GENERALIZATIONS ACROSS CATEGORIES: THE X-BAR THEORY

The correspondence between Table 1 and Table 2, and names like noun phrase (NP) and noun (N), might seem to suggest that noun phrases should be expected to contain nouns, verb phrases should be expected to contain verbs, and so on. It was noted by Lyons (1968, p. 330ff) that this does not follow from phrase structure rules saying things like 'VP → V NP' (a verb phrase may consist of a verb and a noun phrase), because 'VP → P NP' would have been just as simple a rule to write.

Another thing that is clear from inspection is that the five phrasal categories listed in Table 2 have a strikingly similar internal structure. The NP *his teacher's absence from class* contains an obligatory N (*absence*) optionally followed by a phrase of some category with an appropriate meaning (here, the PP *from class*) and preceded by some word or phrase adding specificatory detail (here, *his teacher's*). The obligatory item that gives the phrase its specific syntactic character is called the 'head' of the phrase; the phrase that may follow it if its meaning requires

Table 2. Phrasal categories

Symbol	*Category name*	*English examples*
NP	Noun phrase	*the tree*; *eight cats*; *this spoon*; *every trick I knew*; *her teacher's absence from class*; *many nice pictures of us*
VP	Verb phrase	*wept bitterly*; *eat lots of fresh vegetables*; *usually feel pretty dreadful*; *was able to see clearly yesterday*
AdjP	Adjective phrase	*very good*; *stronger than I had expected them to be*; *proud of the result*; *quite obviously better than the rest*
AdvP	Adverb phrase	*really soon*; *just then*; *so much more nicely than the others*; *quite separately from all the other species*
PP	Preposition phrase	*at home*; *by candlelight*; *right out over the edge*; *away from such temptations*; *because you have been so kind*

Table 3. Structural parallelism across phrasal categories

	Specifier	*Head*	*Complement*
NP	*her teacher's*	*absence*	*from class*
VP	*sometimes*	*acted*	*rather stupidly*
AdjP	*very obviously*	*better*	*than the rest*
AdvP	*quite*	*separately*	*from all the others*
PP	*right*	*out*	*of the picture*

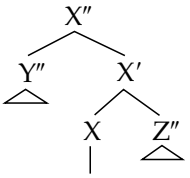
or permits it is called a 'complement'; and the item that precedes the head and adds specificatory detail is generally called the 'specifier'. The same structure is found in the case of all of the other phrasal categories, VP, AdjP, AdvP, and PP, as can be seen from the parallel examples in Table 3.

X-bar theory has its origins in attempts to express both of these generalizations – that the categories of phrases are related to the categories of their heads, and that phrases have similar internal structure across categories. The idea of defining successively more inclusive phrases of noun type as N, N^1, N^2, etc., is due to Harris (1951, Ch. 16). It was revived by Chomsky (1970, p. 210ff). (Chomsky writes N^k as N with *k* overbars, which gave rise to the term 'X-bar theory' and the term 'bar level'. Later works took to writing N^k as N with *k* primes: N, N′, N″, etc. Here we use either the prime notation or the numerical superscript notation, as appropriate.)

The idea was that phrase structure rules would be written in forms using variables X, Y, etc., over the lexical categories, and adding bar levels: $X^2 \rightarrow Y^2\ X^1$, $X^1 \rightarrow X\ Y^2$, etc., where X and Y are chosen from among N, V, P, etc. Chomsky employed this idea in an attempt to account for structural similarities between NPs and clauses which was not very successful: despite the semantic parallelism between a clause like *Microsoft dominates the software industry* and its nominalized correspondent, *Microsoft's domination of the software industry*, the internal structures of NPs and clauses differ in many ways (see McCawley, 1975, for criticism). The idea is much more successful in bringing out the similarities seen in Table 3.

The most thorough attempt to work out the implications of X-bar theory was that of Jackendoff (1977), which diverged considerably from Chomsky's initial presentation. Jackendoff allowed no nonhead-dependent grammatical items at all; he proposed that every word of the language, grammatically restricted in function or not, belonged to a category that projected a full phrase. Thus *the captain* for Jackendoff had not one projection (of the noun *captain*) but two: the first constituent was a nonhead Article Phrase (for him, Art^3), and the second was the phrasal head of NP (i.e. of an N^3), labeled N^2. For Jackendoff, clauses were V^3, their heads were V^2, the head of a V^2 was a V^1 (the traditional verb phrase), and the head of a V^1 was V^0(=V). (A similar proposal about clauses with 2 as the maximum bar level was proposed in Gazdar *et al*., 1985.)

Assuming 2 rather than Jackendoff's 3 as the maximum bar level, the structures of the phrases in Table 3 can now all be seen as instantiating the general pattern seen in the following tree, where Y″ is in what is known as 'specifier position' and Z″ is the complement of the head X:



Linear order is not relevant here; X-bar theory says nothing about it. In most current generative analyses the specifier position is the position for external arguments such as subjects. The 'VP-internal subject hypothesis' holds that the VP category contains subjects as well as objects at the pretransformational level: in the diagram above, X would be V, Y″ would be the subject position, and Z″ would be the direct object position.

Six principles of X-bar theory can be identified in the literature. Not all authors respect all of them, but all six are widely accepted as default assumptions, and are sometimes made explicit. Kornai and Pullum (1990) state the principles in fairly precise terms. They may be summarized informally as follows:

1. Lexicality: the only phrasal categories are those constructed from categories to which words belong.
2. Succession: each phrase has a unique constituent called its 'head' that has a bar level one lower than the phrase itself.
3. Uniformity: for every category X of bar level 0 there is a corresponding one-bar category (X′) and a two-bar category (X″).
4. Centrality: the root node label is X″ for some X. (Usually this is assumed to be C, so the root node label is C″ = CP.)
5. Maximality: nonhead constituents are X″ for some X.
6. Optionality: nonhead constituents are optional.

Lexicality expresses the fundamental principle that all phrasal categories are projections of some word class: there are no phrases that are not founded on categories to which words are assigned. Succession implements Zellig Harris's idea of labeling phrases

using numbers to indicate increasing levels of inclusiveness, i.e. increasing remoteness from the head. Uniformity claims that phrases have a maximum bar level that is the same for every lexical category (the adherence to this principle even in the face of little supporting argument is very clear in Jackendoff, 1977). Centrality guarantees that the label of root nodes (the category corresponding to 'sentence') is of maximum bar level, and maximality requires the same of all nonhead daughter categories.

The last principle, optionality, states that no nonhead is a strictly obligatory constituent. The plausibility of this condition can be appreciated by examining the results of omitting constituents from the examples in Table 3. In every case, either specifier, or complement, or both can be omitted, and the result is grammatical (while omission of the head does not lead to ungrammatical phrases of the relevant category in any case, as succession predicts). None the less, optionality is the principle that syntacticians have shown the least inclination to respect in descriptive practice. A key problem is that both constituents are obligatory in a simple clause like *You lied*, yet if heads are unique and obligatory, one of the two words has to be a nonhead. There are generally assumed to be additional principles, external to X-bar theory (for example, a principle stipulating that clauses must have subjects) that guarantee the necessary obligatoriness, in effect vacating the optionality claim.

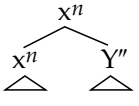
Various proposed revisions of X-bar theory have attempted to get rid of bar levels as such, or at least to eliminate bar levels intermediate between 0 and the maximum m. In a sense this is trivial: it was proved by Kornai (see Kornai and Pullum, 1990, for a proof) that for every language generated by an X-bar grammar with maximum bar level k, for any $k \geq 2$, there is also an X-bar grammar with maximum bar level 1. But Chomsky (1995) advances a theory of 'bare phrase structure' that sets out to revise the theory of phrase structure to get rid of bar levels completely, and even eliminates categories, nonterminal nodes being labeled with structured objects built up out of the lexical items that label terminal nodes. For an attempted clarification of the content of this theory using techniques from logic, see Kracht (1997).

HEADS, COMPLEMENTS, AND ADJUNCTS

The notion 'head of a phrase' is reconstructed by X-bar theory via the principle of succession: the head of an X^n is its only daughter labeled X^{n-1} (and also, according to optionality, its only obligatory daughter). A head labeled X (with bar level 0, therefore necessarily the head daughter of a node labeled X′ with bar level 1) is a lexical head. Lexical heads are divided up into subcategories according to which constituents must or may accompany them within their immediately containing X′. Verbs are thus spoken of as subcategorized into (i) intransitive verbs (which require nothing else in the V′), (ii) transitive verbs (which require a noun phrase in the V′), and so on – there are perhaps a dozen or more other types of verb. (The notion of subcategorization in this sense, sometimes known as 'strict subcategorization', is introduced in Chomsky, 1965.)

The phrases that occur in X′ are determined by the subcategory of the head X and are known as 'complements'. (Not all of the literature uses the term 'complement' in the same way; Huddleston and Pullum (2002) draw a distinction between internal complements such as objects and external complements such as the subject. In X-bar theory descriptions it is standard to call the subject an 'external argument', but not a complement; only nonhead constituents of X′ are called complements.) Some complements appear to be syntactically obligatory. For example, the verb *keep* must have a complement (either an NP, as in *I decided to keep the money*, or a clause, as in *They kept laughing at me*); likewise the preposition *at* must have a N″ complement. Such cases provide part of the evidence that the optionality condition cannot be interpreted as absolute: nonhead constituents are optional unless the subcategorization restriction of the head of their immediately containing X′ dictates their obligatory appearance.

Some constituents are not selected according to the subcategorization restrictions of lexical heads but instead function as optional modifiers of X′ or X″ phrases. These constituents are known as 'adjuncts'. Under strict versions of X-bar theory they must be daughters of X″ and thus sisters to X′, because phrases are not permitted to occur anywhere else. But many syntacticians assume a weaker X-bar theory in which adjunction (often called 'Chomsky-adjunction' after the tacit use made of it in early works of Chomsky's) is permitted; that is, configurations like the following (where the n stands for some specific bar level) are allowed:



(As noted above, linear order is not relevant; the Y″ could precede or follow the X^n.) Here the head of an X^n is another X^n, in contravention of succession. Jackendoff (1977) maintains a strict X-bar theory with succession and thus permits no configurations in which an X^n immediately dominates an X^n, but this is not compatible with a 'stacked' structure for adjuncts: e.g. the bracketed phrases of category P″ in *We met* [*on Tuesday*] [*in the board room*] [*in the presence of our lawyers*] or the bracketed relative clauses in *Anyone* [*who did not sign up*] [*who still wants to go on the trip*] *should see me*. Adjunction structures are commonly assumed by syntacticians to be permissible, and this means that they weaken the succession condition.

FUNCTIONAL CATEGORIES

In recent generative grammar (increasingly since the mid-1980s), full X-bar projections have been assumed for many categories beyond N, V, A (the category embracing the traditional Adj and Adv), and P.

The idea that 'complementizer' (C) is a zero-bar-level category that is the head of a subordinate clause (CP = C″) actually originates with Langendoen (1975, p. 540) but gained no currency until it was reinvented, apparently independently, in the 1980s (see e.g. Chomsky, 1986). After that it was rapidly adopted by almost all transformational grammarians.

The idea that the definite and indefinite articles of English belong to a category that is the basis of an X-bar projection is due to Jackendoff (1977), but for Jackendoff the 'article phrases' (ArtP) that the idea gives rise to were nonhead adjuncts in the structure of noun phrases (thus in *only these books* the phrase *only these* would be an ArtP). The idea re-emerged in a different form when Abney (1987) suggested that determinatives (D) were actually the heads of what had until then been called 'noun phrases', so that the phrase *those boxes of books* would be a DP with *those* (D) as its lexical head, *boxes of books* being a complement to D. The label NP now took on a new meaning as the label for this sort of complement, of which *boxes* (N) would be the head, *of books* (PP) being a complement to N.

Both CP and DP introduce problems relating to selection. Regarding CP, when verbs (or other lexical heads) select particular clause types, they select properties reflected in the internal structure of the clause (the IP) rather than in its complementizer: *know* takes a *that*-clause in which the clausal part is finite and indicative (*know that this was not done*), while *demand* takes a *that*-clause in which the clausal part is subjunctive (*demand that this not be done*). Instead of verbs selecting properties of the head of their complement constituent, we find here that a V is selecting the T head of a TP which is complement to the C head of its complement CP: selection is treating C as if it were not a head. This observation is taken by Huddleston and Pullum (2002) to justify rejection of the view that complementizers ('subordinators') are heads of subordinate clauses. Transformationalists generally take it as indicative of some kind of special syntactic relationship between C and its closest subordinate I or T.

And with regard to the DP analysis, there is no case of a lexical head syntactically or semantically selecting a complement with a particular type of D, such as a verb that demands a DP with definite determiner. The DP hypothesis predicts them, but none has ever been identified. Verbs that are only appropriate with certain types of complement PPs select the head preposition (*approve of it* but not **approve from it*; *rely on it* but not **rely to it*); but instead of selecting D in phrases like *the bishop* they select appropriate nouns: *frighten* needs a direct object with a noun denoting an animate entity, *merge* needs a direct object denoting a plurality. This is just what would be expected if (as in more traditional views) the noun were the head of a direct object phrase rather than the determinative. (Again, Huddleston and Pullum, 2002, accept this consequence.)

A development of the late 1980s was the hypothesis that clauses actually had as their heads instances of the tense/agreement inflectional element, generally called 'Infl', or simply 'I'. Clauses would therefore be labeled IP (I″, assuming a maximal bar level of 2). Pollock (1989) proposed revising this by breaking tense and agreement apart and treating each as an element founding a separate projection. He also treated the negation element as founding a projection. Given three bar levels (0, 1, and 2), this introduced nine new category labels: T, T′, T″, Agr, Agr′, etc., two of them present in every finite clause. In subsequent work many additional functional categories and functional projections have been posited.

STRUCTURAL RELATIONS DEFINED ON TREES

Constituent structure trees can be formalized as graphs. A graph is a set of elements (linguists call them 'nodes') on which is defined a relation (linguists call it 'dominance'). Diagrammatic representations indicate nodes by points and represent two

nodes as being in the edge relation by drawing a line between them. Constituent structure trees meet several conditions. First, the nodes are labeled with category names. Second, the edges are directed: a line from a to b (representing the fact that a dominates b) is not the same as a line from b to a (representing the reverse situation). Third, another basic relation is defined on certain node pairs, a strict partial ordering left-to-right relation called 'linear precedence': each pair of nodes is related either by dominance (in one direction or the other) or precedence (in one direction or the other), and never by both. Fourth, when a node precedes (or follows) another it is also required to precede (or follow) all of the nodes dominated thereby (i.e. precedence is recursively inherited by daughters). And fifth, there is a node called the 'root' that, uniquely, dominates every node in the tree (the single root condition). It is customary to show trees as diagrams with the root at the top and precedence represented by the left-to-right direction across the page, as is done above.

Additional derivative relations between nodes can be defined on trees in terms of dominance and/or precedence. Subjacency, for example, is definable in terms of these two relations and certain references to categories. Among the other relations that are commonly referred to in the syntactic literature are these:

- Linearly adjacent: x and y are linearly adjacent if and only if x precedes y and there is no intervening node i such that x precedes i and i precedes y.
- Immediately dominates (is the mother of): x immediately dominates y if and only if x dominates y and there is no intervening node i such that x dominates i and i dominates y.
- Daughter of: is the inverse of 'immediately dominates'.
- Sister of: x is the sister of y if and only if there is a node m that immediately dominates both x and y.
- Commands: x commands y if and only if every clausal node that dominates x also dominates y.
- C-command: x c-commands y if and only if every node with two or more daughters that dominates x also dominates y.
- M-command: x m-commands y if and only if every node labeled with a maximal bar-level category that dominates x also dominates y.

The definitions of the last three relations are clearly very similar. Abstracting their similarities, Barker and Pullum (1990) defined a more general notion of 'command relation': given any property of nodes ϕ, a node x is said to ϕ-command a node y if and only if every node with property ϕ that dominates x also dominates y. Barker and Pullum show that there is a minimal (smallest) command relation, which holds between a pair of nodes x and y if (and only if) any command relation holds between x and y. This relation is IDC-command, and it is generated by letting ϕ be a trivial property possessed by every node. That is, x IDC-commands y if and only if every node that dominates x also dominates y.

Kayne (1994) proposed that asymmetric c-command should be regarded as the fundamental relation in syntax, precedence being parasitic on it in the sense of being predictable from it (and proposed structures should be revised where this is not the case). In fact it appears that Kayne's intent is best captured if the relation appealed to is IDC-command rather than c-command under its classical definition.

CONCLUSION

Phrase structure (or constituent structure) analysis involves analyzing expressions into subparts that are themselves expressions. Subparts are of specific categories, and have specific functions such as 'head of'. X-bar theory is based on the idea that every phrase has a head subconstituent, and phrases can only be founded on specific lexical categories, i.e. categories that specific words belong to. Lexical categories have bar level 0, and project phrases of higher bar levels up to some specified maximum. A phrase X^m with the maximum bar level m is known as a maximal projection, and corresponds to a maximally inclusive phrase of the type founded on X. Most current theories of grammar maintain some version of X-bar theory (Chomsky's 'bare phrase structure' replacement for it cannot be said to have become standard). X-bar theory comes in differing versions (what is most typical is to set the maximum bar level at 2 and have X ranging over the whole vocabulary of lexical and functional categories), but the general framework is constant across a wide range of transformational-generative syntactic theories.

Phrase Structure Grammar, Head-driven

Intermediate article

Robert D Levine, Ohio State University, Columbus, Ohio, USA

CONTENTS

Head-driven phrase structure grammar is a monostratal theory of natural language grammar, based on richly specified lexical descriptions which combine according to a small set of abstract combinatory principles stated as formulae in a constraint logic regulating, for the most part, the satisfaction of valence and other properties of syntactic heads. These constraints, applying locally, determine the flow of information, encoded as feature specifications, through arbitrarily complex syntactic representations, and capture all syntactic dependencies – both local and non-local – in elegant and compact form requiring no derivational apparatus.

BASIC CONCEPTS

Generative theories of linguistic structure can be categorized in various ways, most fundamentally, into theories that license sentences by constructing a set of structures and then deriving further structures from these, until some point where no further structures are derivable; and theories that admit only a single structural object corresponding to each sentence (or a set of such objects, corresponding to syntactic ambiguity), where admission entails simultaneous satisfaction of a set of applicable constraints. The first approach, generally referred to as transformational grammar, typically uses the successive stages in the derivation of the sentence to establish appropriate linkages in information content among parts of the representation; while the second, often called monostratal, establishes such linkage by directly constraining information distribution, typically encoded as the values assigned to certain attributes, or 'grammatical features'.

Grammatical frameworks may also be divided into those whose admissible objects are characterized by phrase structure, and those in which no persistent configurational properties of representations are posited. Categorial grammars, for example, specify functor–argument possibilities for individual lexical items: such possibilities determine whether a given sequence of words can combine to give rise to an object corresponding to the type associated with a clause, but the order of combination does not impose structural configurations on the the string or its substrings which are subsequently available for stating rules or generalizations.

A third important division distinguishes theories that require a one-to-one match between syntactic form and propositional structure from those that do not. For example, in the sentence *Robin seemed to understand Dana's arguments*, it is evident that the individual named Robin has a semantic relation to the predicate denoted by the linguistic form *understand Dana's argument*, but has no semantic relation to the verb *seemed*. That this is generally true for the subject of such verbs (called 'raising' verbs) is made clear by a variety of syntactic diagnostics (preservation of idiomaticity, preservation of truth under passivization, and so on). Yet in the syntax of this sentence, *Robin* is the subject of *seemed*, with no evident local structural relationship to *understand Dana's arguments*. There is thus a mismatch between syntactic form and semantic interpretation in such examples. On one standard approach to this problem, the mismatch is the result of a derivational history in which a structure with *Robin* appearing in the subject position of *understand Dana's arguments* in some early structural representation is displaced to the subject position of *seemed*. On another approach, *Robin* is syntactically always and only a subject of *seemed*, but is linked through various constraints to the semantic content of *understand Dana's arguments*, without any comparable linkage to the semantics of *seemed*. The former approach will naturally be restricted to derivational theories, but not all derivational theories follow this approach (e.g. Brame, 1976; Culicover and Wilkins, 1984). On the other hand, nonderivational theories have no choice: they must take as

basic the syntax–semantic mismatch exemplified here and motivate the discrepancy in their own formal structure – via meaning postulates, lexical entailments, representational properties, or some other means.

Against this background, phrase structure grammar (PSG) theories can be concisely characterized as a family of theories which assume only a single level of representation, and take this level to consist in a set of hierarchically structured objects, in which syntactic and semantic properties need not mirror each other in any respect.

Within the family of PSG theories, there is considerable variety. In this article we will illustrate the possibilities of the overall PSG framework with reference to one particular version, head-driven phrase structure grammar (HPSG).

HPSG

Ontological Assumptions

HPSG was developed by Carl Pollard and Ivan Sag (Pollard and Sag, 1987, 1994), initially as a refinement and extension of generalized phrase structure grammar (Gazdar, 1981; Gazdar *et al*., 1985). It belongs to a family of phrase-structure-theoretic approaches in which a rich set of lexical specifications, coupled with a few very general combinatorial constraints and restrictions on information-sharing, interact monotonically to give rise to sets of complex objects called feature structures, which model the properties of linguistic signs (though certain recent developments of HPSG have abandoned strict monotonicity by allowing defeasible default characterizations of feature-sharing principle to interact with 'hard' lexical entries or type declarations). Each feature structure admitted by an HPS grammar for some language licenses an expression in that language. Considerable effort has been made to provide an explicit model theory for HPS grammars, and to formulate the constraint systems which HPS grammars themselves consist of as statements in certain formal logics. Such logics are comparable to familiar systems such as the first-order predicate calculus, with the crucial difference that constraint satisfaction takes the place of model-theoretic satisfaction of, for example, a set of conventional formulae by some interpretation given for the latter. This approach, which has its origin in the computational linguistics of the mid-1980s, greatly expedites implementation of HPS grammars, but from the theoretical perspective its main significance is that the denotation of particular analyses and claims stated in the framework is always mathematically explicit: a necessary but often neglected condition for generativity.

An HPS grammar is a description, i.e. a set of formulae in some feature logic (see, e.g. Richter *et al*. (1999) for an example of such a logic that is becoming widely employed in HPSG), where only feature structures that satisfy the formulae of the grammar are taken to be complete representations of the grammatical properties of some linguistic expression. Feature structures themselves are sorted unary partial subalgebras in which feature names are functions from the set of nodes to the set of nodes, with each node assigned a 'type' or 'sort' label. Each node corresponds to some object with certain properties, and the node a given feature maps this object to corresponds to the value of that object for the property named by the feature.

Consider, for example, auxiliary verbs in English. Such verbs select a certain class of subjects and appear either in canonically ordered sentences (*Robin has left*) or inverted sentences (*Has Robin left?*). In HPSG, such a linguistic expression will be modeled by a feature structure including a specification for the feature `CAT`, providing relevant syntactic information, including a specification of the `HEAD` properties of that expression – those which are invariably shared between mother and head daughter. The feature `HEAD` is thus taken to be a function which maps nodes labeled by the sort `cat` ('category') to nodes of sort `noun`, `verb` and so on; for verbs, this latter node itself is mapped by a function `VFORM` to a node labeled by one of a set of sorts (`fin` ('finite'), `inf` ('infinitive'), `bse` ('base'), etc.) by a function `AUX` to one of the sorts `plus` or `minus`, and so on. In the same way, the feature `SUBJ` is a function from nodes of sort `cat` to nodes whose type corresponds to a (singleton) list identifying the kind of subject the verb can combine with, and the feature `COMPS` is a function from `cat` nodes to a different node of the same sort, identifying the morphosyntactic properties of the complements that the verb selects.

More generally, various versions of HPSG model theory essentially converge on the characterization of the model universe for an HPS grammar along the following lines:

1. Each grammar specifies a 'signature': a set of feature names, a set of sort names, and an assignment function which pairs with each feature name a mapping from the set of sort names to the power set of sort names. The signature in effect defines what kinds of objects there are, and what kinds can be mapped to (i.e. specified for) what other kinds of objects under the operation denoted by some feature name.

2. An 'interpretation' for an HPS grammar is a set of partial algebras, each of which specifies a set of sorted nodes and a set of unary operations, corresponding to the feature names. Each unary operator takes some subset of nodes as its domain and some subset of nodes as its range. For all mappings from subset to subset, the sort labels of the domain and range elements must adhere to the constraints imposed by the assignment function.
3. Given the objects and functions so far defined, it is possible to construct a formal notion of pathway – sequences of nodes – in terms of successive applications of appropriate feature functions. Thus, the pathway `CAT|HEAD|VFORM` specifies a function which maps an input node of a certain sort to a node of a sort such as `fin`. Feature logics can be defined on such pathways, and an HPS grammar specifies a number of constraints, stated in terms of such pathways. Constraints are descriptions that are satisfied for just those sets of partial algebras in which all pathways specify the values that these descriptions require them to. The constraints, as noted earlier, in effect play the role of meaning postulates in traditional model theories of natural language semantics: they restrict the set of admissible interpretations of the grammar – in this case, sets of partial algebras – to just those which reflect the property of the natural language modeled by the grammar.

These components of the HPSG model theory express standard HPSG assumptions: respectively, that the object that is the value of any given feature belongs to a particular sort, that only objects of certain sorts can be the value of any given feature, and that objects of different sorts are specified for different sets of features. The interaction of these assumptions constitutes an overall constraint on the possible set of feature structures that the grammar admits, corresponding to just the set of linguistic expressions taken to be well-formed by speakers.

It should be noted that this algebraic characterization of feature structures is similar to the formalization of category specifications of generalized phrase structure grammar (e.g. Gazdar *et al*., 1985, 1988). Feature structures, however, are typically represented not as partial algebras, but graphically – specifically, as pointed directed graphs in which nodes, each annotated with a sort label, are linked by arcs labeled with the names of grammatical features, where for some linguistic expression *C*, each feature *f* is taken to correspond to a property of *C* whose value is identified as the subgraph originating at the node on which the arc labeled by *f* terminates. A graph corresponding to the example discussed above is given in Figure 1. While such graphical representations seem to be more accessible than the algebraic structures which essentially define feature structures, they are still rather cumbersome to manipulate and far from perspicuous. Furthermore, under the HPSG assumption that feature structures are complete objects – that is, total specifications of the grammatical properties of linguistic expressions – the object in Figure 1 is not a feature structure, but rather a

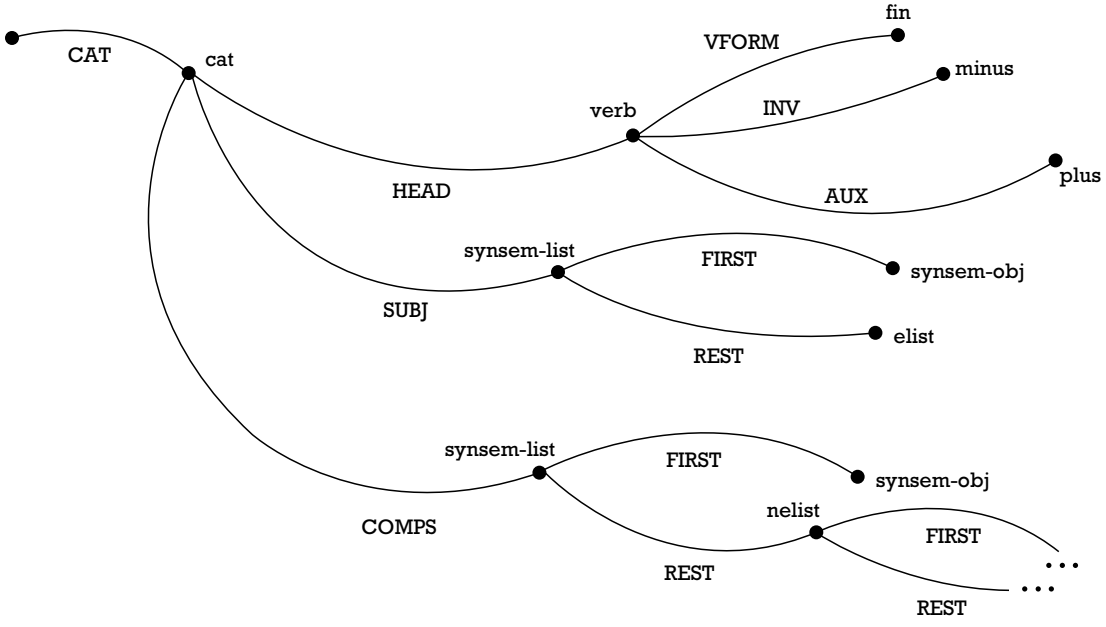

Figure 1.

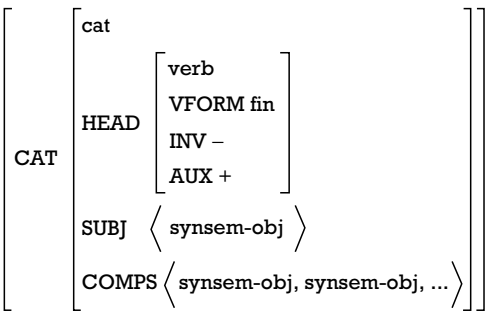

Figure 2.

small substructure; a full representation would involve an enormous number of nodes and arcs. Hence, a different and far more perspicuous format is used to describe feature structures. The feature substructure in Figure 1 satisfies the description given in Figure 2. Objects such as that in Figure 2 are called 'attribute–value matrices', and are used both to provide descriptions of feature structures and to state constraints on them.

It often proves convenient to assume that sorts themselves are organized hierarchically, into networks of subsort–supersort relations. Every object that the grammar licenses must satisfy the signature declarations on all the sorts of which that object is a subsort, in addition to whatever other constraints apply to it beyond those in the signature (e.g. the 'head feature principle' discussed below). Schematically, one can represent such relationships among sorts as a branching hierarchy. Each subsort is subject to a particular set of restrictions, imposed on it outside the signature properties themselves, in the constraint logic constituting the description language of the grammar. Elements lower (i.e. more specific) in the sort hierarchy inherit all restrictions imposed on the higher (i.e. more general) sorts dominating them. The objects in the HPSG model theory, the feature structures themselves, only contain maximally specific sort labels; but descriptions of (classes of) feature structures, including the constraints of the grammar, may refer to sorts of any level of inclusiveness.

For example, the very top of the sort hierarchy is, by convention, taken to be `object`, one of whose immediate subsorts is `sign`. Signs contain complete specifications for properties of classes of linguistic expressions. The signature will identify one of the immediate subsorts of `sign` as `word` and the other as `phrase`; a further constraint will restrict the feature 'daughters' (DTRS) to specification only for objects of the latter sort. The value of DTRS in turn must be of sort 'constituent structure' (`cons-struc`), which has two subsorts: `coordinate-structure` and `headed-structure` (`headed-struc`). The latter is subject to the restriction that it contain a specification for a feature 'HEAD DAUGHTER' (HEAD-DTR). The sort `headed-struc` has the further subsorts `head-subject-structure`, `head-adjunct-structure`, `head-filler-structure`, and so on. Each of these subsorts is of sort `headed-struc` and so necessarily contains a specification HEAD-DTR; in addition, each may be subject to idiosyncratic restrictions. All phrases, for example, of sort `head-filler-structure`, where a filler is linked to a gap site, require a specification FILLER-DTR which is related to the feature specifications on the HEAD-DTR category in a specific fashion allowing the filler and gap site to share relevant properties.

It is often suggested informally by researchers within HPSG that such type hierarchies are cognitively realistic, insofar as they are crucial to characterizing psycholinguistic processes such as language acquisition. The constraint inheritance property of the type hierarchy sketched above allows the lexicon itself to be relatively spartan, given a sufficiently rich hierarchy of sorts with associated constraints. This will be especially true if multiple lines of inheritance are permitted in the hierarchy. A given lexical item will have to bear only the feature information that is absolutely idiosyncratic; any information that can be predicted from the fact that it belongs to a certain class of lexical items can be built into a constraint on a sort to which those items belong, and if that class of items shares a certain property with a separate class of items, there will be a supersort under which the sorts of both classes appear, with the shared property identified as a constraint on the supersort. The sort hierarchy thus allows generalizations over the lexicon to be stated in a compact fashion, with fully specified lexical descriptions deducible in a straightforward monotonic fashion. It is not yet evident to what degree the type hierarchy captures significant properties of grammars that are otherwise unstatable. In other words, whether the type hierarchy has more than an abbreviatory status is still an open question. To answer this question, well-developed accounts of the interaction between formal grammar, on the one hand, and other linguistic phenomena, such as acquisition, processing, or language change, on the other, are needed.

The Architecture of Categories

The inventory of attributes or features in HPSG descriptions expressing properties of linguistic signs does not in itself determine the detailed structure of such signs. The latter is an empirical question, and since work in HPSG began, there has been continuous rethinking of the specific feature geometry required to capture grammatical properties of natural language in a sufficiently restrictive way. Currently, for example, there is general agreement among HPSG theorists that lexical signs require specification for phonology (PHON), syntax–semantics (SYNSEM), and morphology (MORPH), while phrasal signs require PHON, SYNSEM, and DTRS attributes. The general organization of phrasal signs is given in Figure 3. Such diagrams are to be understood as informal summaries of properties of the class of admitted feature structures. The value of SYNSEM is itself a set of specifications for 'local' (LOC) features, reflecting locally relevant properties of the sign, and for 'nonlocal' (NONLOC) features, encoding information that propagates over unbounded syntactic domains, such as information connecting fillers to gap sites, or information about *wh* formatives introducing information into relative or interrogative structures. LOC specifications identify syntactic properties of lexical or phrasal categories via the feature CAT, information relevant to logical aspects of interpretation via the feature CONT ('content'), and contextual information via the feature CONX. LOC is also specified for a feature QSTORE which plays a significant role in tracking the scope of quantifiers. For nominal categories, an INDEX feature is defined as part of the CONT specification, which (ignoring a very small class of exceptions) encodes reference to individuals or events. Values for CAT are particularly highly structured: this feature specifies valence information and also HEAD values, where the latter feature encodes properties of lexical items that are shared with all phrasal projections of those items, including part of speech, as well as other properties that depend on the part of speech of the item (case values for signs whose HEAD is of sort noun; auxiliary or non-auxiliary status for items of sort verb, and so on). Valence requirements are encoded in subspecifications of the feature VAL. The particular features that VAL is in turn specified for depend on the syntactic category of the head; thus, nominal lexical items select both complements (via a feature COMPS) and a specifier, identified by a feature SPR and manifest as a possessor, a determiner or nothing, while the VAL specification for verbs requires specification for a subject (encoded as a feature SUBJ) and COMPS, but not SPR.

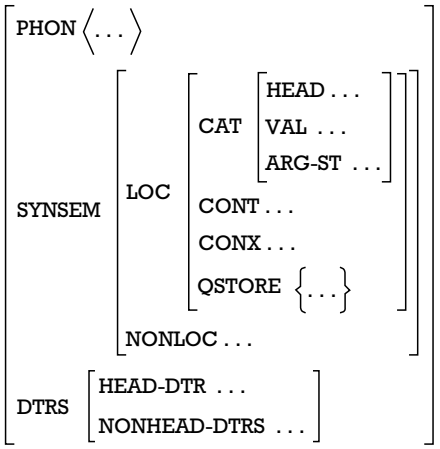

Figure 3.

In addition to the valence features SUBJ, COMPS, and SPR, HPSG posits a feature ARG-ST which typically takes the form of a list-append operation carried out on the valence lists. In the case of verbs, for example, the COMPS list is appended to the singleton SUBJ list, so that the ARG-ST list is identical to the COMPS list with one extra element corresponding to the subject added at the top of the list. The ordering of the elements on the ARG-ST list is the same as that on the valence list, and expresses the notion of 'relative obliqueness', discussed below. The ARG-ST list is not a valence list, but rather a record of the verb's argument structure; it plays a major role in the nonconfigurational HPSG theory of coreference, outlined below.

This organization of features expresses certain well-motivated assumptions about linguistic modularity. For example, the value of each of the valence features is required by appropriate sort declarations to be a list of synsem specifications, where the feature geometry of the framework packages syntactic and semantic information about categories, but not phonological or subconstituent information, within synsem objects. The result is the exclusion of access by a selecting head to information about either the phonological form or the syntactic subconstituency of its arguments.

Capturing Syntactic Dependencies

The critical task facing any grammar is capturing systematic linkages in form between (possibly quite distant) substructures of a larger syntactic structure. Were it not for the existence of such linkages,

or 'syntactic dependencies', natural language grammars would be far simpler than they actually are, since there would be little or no need to account for the sharing of often quite detailed information between different subcomponents of a sentence. Given the existence of such dependencies, a major goal of grammatical theory is the discovery of the optimal mechanism for expressing them.

The explicit specification of grammatical properties by means of highly structured descriptions, as sketched above, allows HPSG to capture syntactic dependencies economically. Agreement and case government are common examples of local dependencies, which typically hold between elements in a single clause, but other dependencies are more intricate, including several which have been taken as canonical demonstrations of the need for derivational relationships among syntactic objects. Such derivations typically serve to link the grammatical information shared among (possibly arbitrarily distant) structural positions. In HPSG, the linkage among the elements of the dependency is specified directly via the interaction of lexical properties with a small number of highly general declarative constraints, without the invocation of any mediating device such as movement.

Local dependencies

Local syntactic dependencies can in most cases be expressed by the correlation of properties of a selecting head with properties of a selected constituent, corresponding to some valence element. The simplest cases of this mechanism are syntactic selection and agreement. For example, the fact that the verb *give* must appear with an NP and a PP whose head is the preposition *to* is captured by identification of the verb's COMPS value as ⟨[1]NP, [2]PP[*to*]⟩, where [*to*] abbreviates [PFORM *to*], identifying the morphological form of the preposition via a feature PFORM, and where the angled brackets conventionally denote a list whose elements are ordered from left to right according to their relative obliqueness, corresponding to a traditional hierarchy of grammatical relations. Direct objects, for example, are the least oblique elements on a verb's COMPS list. At the same time, the CONT value of *give* specifies a particular relationship among an agent, a recipient and an object given. The HPSG approach to selection is illustrated in Figure 4.

Boxed alphanumeric symbols, called 'tags', are variables over nodes in the feature structures to which the descriptions containing those tags apply. Thus, when two features in a description appear with identical tags as their values, they have precisely the same node (and its associated subgraph) in the modeling object for those values. Sorts, where relevant, are indicated in lower case at the top of the description. The notation $X_{[n]}$ indicates that the INDEX value of X is n.

With these conventions, Figure 4 represents a partial lexical entry for *give*.

Two general principles of the grammar are assumed here. The 'valence principle' ensures that a phrase can be projected from a head just in case there is exactly one sister for that head corresponding to every synsem object on the head's COMPS list. The 'head feature principle' requires the HEAD specifications of a mother and its head daughter to be structure-shared (i.e. the arc from the mother category labeled HEAD and the arc from the head daughter category labeled HEAD terminate on the same node, in the graphic representation of admissible feature structures described above).

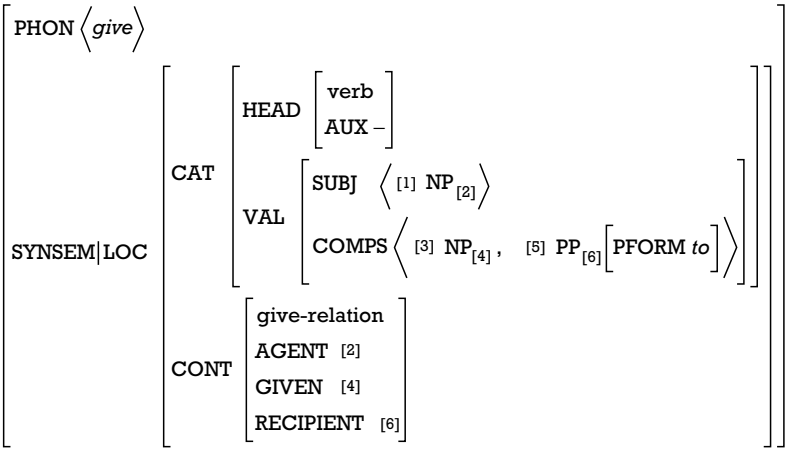

Figure 4.

The interaction of these principles with the lexical entry given in Figure 4 entails that the feature structures that will be admitted are just those in which the valence of the head is satisfied. Thus, if we represent the various DTRS feature values in terms of familiar branching tree structure, then the feature structure meeting the description in Figure 5(a) will be licensed, but those described by Figures 5(b), 5(c) and 5(d) will not be. All four descriptions in Figure 5 satisfy the head feature principle, but only Figure 5(a) the valence principle. Hence, only the VP depicted in Figure 5(a) is licensed by the grammar, yielding the relevant aspects of *give*'s subcategorization.

This same category selection mechanism can also enforce a correct match between the form of a verb and properties of its subject. Note, in the first place, that constraints on lexical types capture morphological generalizations; thus, it is unnecessary to separately stipulate that the third person singular form of *give* is *gives*, because a general constraint on the `third-sing` subsort of the `verb` sort automatically yields this form for a lexeme whose phonology is identified as [*g*ɪv*z*], and simultaneously imposes the specification [SUBJ ⟨NP[1][PERS 3, NUM sg]⟩] on all verbs of this subsort. It then follows from the valence principle that the only NPs that will be able to combine with VPs projected from *gives* and morphologically parallel verbs are third-person and singular.

Given the possibility of constraining the subject selection properties of classes of verbal heads with reference to some other grammatical property of those heads, the standard local dependencies of English can be captured simply along the following lines:

- Consider the consequence of positing a lexical relationship which guarantees that for every verb with a [SUBJ⟨ *S* ⟩, COMPS⟨ α_1, …, α_n ⟩] specification, there is a matching lexical entry with an identical phonology with the specification [SUBJ⟨NP$_{it}$⟩, COMPS⟨ α_1, …, α_n , S⟩], where `it` is a reserved INDEX specification uniquely associated with the dummy pronoun *it*. Nominals must in any case be subclassified to make expletives available for reference, so that, for example, ambient weather predicates such as *rain* take only *it* as subjects. But the lexical relationship just sketched will interact with the valence principle to ensure that for every clause projected from verbs such as *bother* or *astonish*, as in *That Robin would even consider spying for an unfriendly power astonished us* and *For Dana to act like that constantly would bother most people*, there is a matching clause with an *it* subject and an identical set of complement daughters, along with an additional clausal daughter (e.g. *It astonished us that Robin would even consider spying for an unfriendly power, It would bother most people for Dana to act like that constantly*). Thus, extraposition is accounted for without having to posit a derivational origin for this construction.
- The active–passive correspondence can be treated as a lexical relationship in which, either by a lexical rule or by a type constraint, an active verb is related to its passive counterpart in such a way that the COMPS list of the latter is that of the former minus the highest-ranking complement specification, where this 'lost' element reappears as the passive's SUBJ specification.
- The existential *there* construction can be captured by means of a partial lexical entry for the lexeme *be*, as in Figure 6, where the subscript `there` notates a separate `index` subsort like `it`, and both are distinct from the subsort `ref` ('referential'). Under this lexical analysis, *There are two lions in the closet* will denote exactly what the predicate *in the closet* applied to *two lions* denotes, while the verb morphology is (indirectly) correlated with the person and number specifications of the postcopular NP.
- Properties of raising constructions (e.g. *Robin seems to be having a difficult time*) can be straightforwardly captured by allowing raising verbs, such as *seem*, to bear specifications for the attribute SUBJ identical to those of their infinitival VP subjects; at the same time, the CONT specifications of raising verbs do not identify a semantic role for their subjects, only for their infinitival VP complements. This simple lexical property immediately ensures that raising verbs preserve the subject-selection properties of their complements. It also yields other familiar properties of raising verbs, such as their preservation of meaning invariance and idiomaticity under passivization. Similar observations follow for auxiliaries, if these are also taken to structure-share their subject values with their complements but not to associate these values with semantic roles.

Nonlocal dependencies

The selectional mechanism sketched above is not sufficient to guarantee the observed linkage between elements in the syntactic relationships usually referred to as unbounded dependencies. The difficulty can be illustrated in an example such as Figure 7. The examples in Figure 7 show that a significant amount of grammatical information is shared between the fronted constituent and the place from which some element is clearly missing, notated with an underscore. The apparently displaced material in brackets is an NP, and the reader can verify that replacing it with an AP or a PP, or indeed any other phrasal category, gives rise to an ill-formed result. Furthermore, it is not only the gross categorial description that is shared between this filler and the gap site: information about the number required for subject–verb agreement is also part of the linkage. Case information is also evidently preserved; e.g. the requirement that

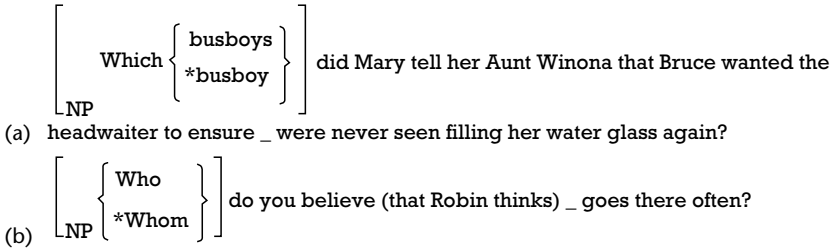

Figure 7.

subjects of a finite verb must be nominative is apparently imposed on arbitrarily distant fillers associated with the gap. Such data were for decades taken as the strongest possible evidence that derivational machinery – by allowing the filler to satisfy contextual requirements at a level of structure prior to its displacement in subsequent stages – is essential for an adequate account of syntactic phenomena.

It is evident that the local mechanisms introduced above cannot mediate such relationships. These mechanisms require the components of the dependency to be visible to a single lexical head, allowing properties of subjects and VPs to be correlated in appropriate fashion, giving rise to the dependencies observed, whereas in a nonlocal dependency, there is no single lexical head in whose VAL list specifications the properties of the filler and of the gap site may both be specified. Indeed, the filler in such constructions typically appears in a configurational relationship with a clause which, by definition, is saturated for all valence features, so that there is no way for information about the filler to be linked by means of such valence features. The solution, inherited in HPSG from work by Gazdar (1981) and Gazdar *et al*. (1985), is to introduce a separate feature SLASH, whose values are a set of LOC specifications – all the information contained in SYNSEM values except for information about nonlocal features, including SLASH itself – which is shared between a mother and at least one daughter. The propagation pathway for SLASH terminates in a gap under specific conditions ensuring that the crucial information about the filler is preserved at the gap site. In HPSG, following the approach in generalized phrase structure grammar, this is accomplished by defining a three-part mechanism for filler–gap linkages:

1. The 'top' of such linkages is licensed by identifying a clause whose DTRS value is of sort `head-filler-phrase`. This sort is constrained to specify a non-head daughter with a LOC value that is structure-shared with the SLASH value of the clausal head daughter. The effect is to guarantee the existence of structures of the form shown in Figure 8.

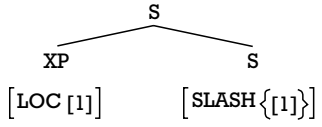

Figure 8.

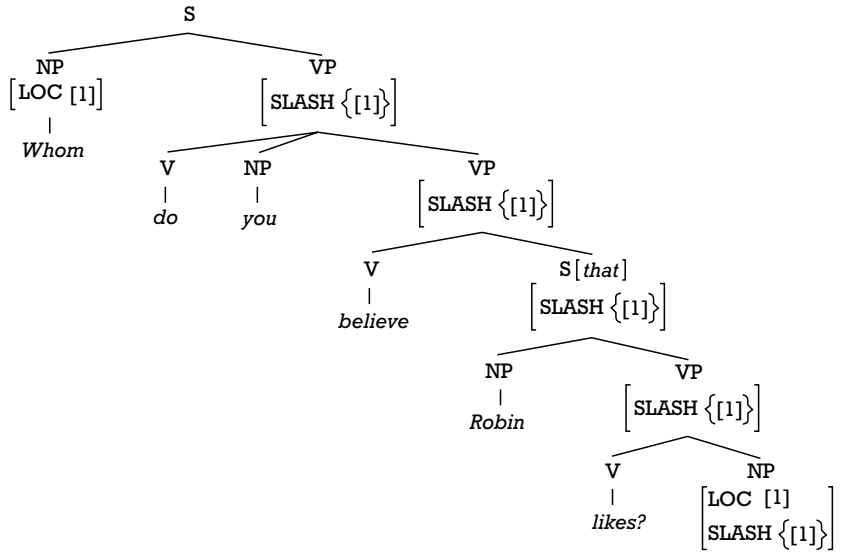

Figure 9.

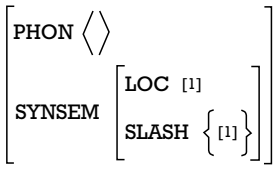

Figure 10.

2. The 'middle' of the linkage arises as the effect of a constraint, the 'nonlocal feature principle', which forces SLASH specifications on mothers to be shared with at least one daughter and vice versa, subject to conditions which ensure that the SLASH value at the top of the dependency is bound off at that point. Thus, once SLASH has been introduced into a structure, it must appear at every hierarchical level below the point of its introduction until it is terminated.
3. HPSG theorists are divided on how the SLASH pathway terminates. On one account, the SLASH specification is 'cashed out' by means of an empty category. An alternative account terminates the percolation of SLASH at the bottom of its path on a lexical head whose valence is reduced by an element corresponding exactly to the SLASH value of that head. Figure 9 illustrates the form of a filler–gap dependency using the first approach.

Given the existence of the lexical entry in Figure 10, the SLASH path will terminate in a phonologically null category which – since it has a LOC value identical to that of the SLASH (and of the filler) – preserves all the categorial and content information of the filler, and therefore must be compatible with any restriction imposed at the gap site.

Syntactic conditions on anaphora

The obliqueness ordering on valence elements provides an essential component in the HPSG account of syntactic factors that enter into the determination of whether two given constituents can be interpreted as denoting the same entity. A very concise set of principles – the so-called 'binding theory' – can provide an account of this relationship of coreference over a wide range of linguistic phenomena. The binding theory defines, for each of a small number of types of referring expression, the conditions under which it may be coreferential with some other component of the linguistic sign in which it appears. The HPSG framework is perhaps unique among phrase-structure-theoretic approaches in appealing to conditions on coreference that make no appeal to the configurational relationship between coreferring elements. Rather, the basis of the binding theory is the obliqueness relationship defined on the ARG−ST list, in which all the elements selected by some lexical head are displayed in order of ascending obliqueness, with subjects taken to be the least oblique elements on such lists.

An argument of a given head is said to 'locally o-command' any more oblique coargument. More generally, it 'o-commands' any more oblique coargument, the head of that coargument, any arguments of that head, and any other elements that the arguments of that head themselves o-command. For any lexical head, this recursive definition in effect picks out a path from some argument of that head through arbitrarily deep levels of structure linked by headship and selection. Its

application to the statement of coreference possibilities is illustrated below directly.

The HPSG binding theory can then be succinctly stated as follows:

1. Reflexive and reciprocal forms with referential local o-commanders must be coindexed by one such o-commander.
2. Pronouns that are not reflexive or reciprocal forms must not be coindexed with a local o-commander.
3. Non-pronominals cannot be coindexed with any other elements.

This theory of coreference provides a satisfactory account of a wide variety of coreference facts in English, illustrated in the sentences below:

Robin_i admires $\text{him}^*(\text{self})_i$. (1)

Pictures of $\text{him}(\text{self})_i$ intrigue Robin_i. (2)

$\text{It was only herself}_i$ that she_i had to blame for what happened. (3)

Robin_i believes that people_j admire $\text{her}(^*\text{self})_i$. (4)

*She_i believes that people_j admire Robin_i. (5)

*Who_i does she_i believe that people admire t_i? (6)

In sentence 1, the subject appears on the same ARG-ST list as the object, hence locally o-commands it. If the object is a reflexive, then by principle 1 above it must be coindexed with the local o-commanding NP, and by the same token, if the object is a personal pronoun, it must not be bound by a locally o-commanding antecedent. In sentence 2, on the other hand, there is no locally o-commanding antecedent, since the nominal head *pictures* has no other arguments; hence the example vacuously satisfies principle 1 and reference is syntactically free, though constrained by pragmatic factors. By the same token, the absence of any local o-commanding antecedent in this example allows the personal pronoun to appear. Thus, the often-noted failure of reflexives and personal pronouns to exhibit completely complementary distribution follows straightforwardly from the HPSG binding theory.

Sentence 3 again illustrates how reflexives can appear freely in the absence of a local coindexed o-commander; here, *it*, though it o-commands the reflexive, does not have an index of sort ref, hence, by principle 1 above, it does not require a coindexed local o-commander. In sentence 4, a local, referential o-commander is present with which a reflexive fails to be coindexed, yielding ill-formedness. By the same token, however, a pronoun contraindexed with the local o-commander can appear, in accordance with principle 2 above.

Sentences 5 and 6 illustrate the ill-formedness resulting when non-pronominals are coindexed. In both cases, *she* as matrix clause subject is less oblique than the clausal complement of the matrix verb, and therefore (locally) o-commands this clause. In view of the preceding discussion, it therefore o-commands the head of this clause, *admire*, and all the elements that *admire* itself selects, including *Robin* in sentence 5 and the trace of *who* (which is taken to be non-pronominal) in sentence 6. Hence these non-pronominal elements are o-commanded by, and coindexed with, *she*, in violation of principle 3 above, and sentences 5 and 6 are therefore ruled out as required.

Preliminaries to Semantic Interpretation

Every sign in an HPS grammar is specified for a CONT value which provides the input to semantic interpretation. Nominal content values, of type nom-obj, identify an index and a set of restrictions on that index; thus, the noun *gift* optionally combines with two PPs, *of* $\text{NP}_{[2]}$ and *to* $\text{NP}_{[3]}$, whose own CONT values are identified with those of their complement daughters, yielding nominals such as *gift of a book to Robin*, whose CONT has the form shown in Figure 11. This partially saturated nominal will then combine with some determiner, such as *the* or *every*, whose own content identifies its quantificational properties, and whose lexical specifications allow it to take the content of a nominal head such as Figure 11 as the restriction on the relevant quantifier. The semantic content of the quantifier is identified as the NP's QSTORE value, an implementation in a feature-based framework of earlier proposals made by Robin Cooper (e.g. Cooper, 1983). QSTORE values of daughters are added to those of their mothers progressively up the tree, to the point where a quantifier is retrieved from the QSTORE of some category and

$$\begin{bmatrix} \text{INDEX} & [1] & \\ \text{RESTR} & \begin{bmatrix} \text{gift-relation} \\ \text{INSTANCE} & [1] \\ \text{GIVEN} & [2] \\ \text{RECIPIENT} & [3] \end{bmatrix} \end{bmatrix}$$

Figure 11.

added to the QUANTS value at that same node, thus fixing its scope. When the top of the tree is reached, all elements have been retrieved from QSTORE, with their left-to-right order identifying their relative scoping.

Thus, essentially two kinds of information must be tracked under this architecture: on the one hand, there is a kind of quantifier-free 'nuclear' content, and on the other the retrieval and ordering of scoping among quantifiers over structures of arbitrary depth. The former corresponds to the successive embedding of argument structures as parts of increasingly complex linguistic expressions, as required by the valence principle and other constraints of the grammar. The latter may be thought of as the gathering of quantifier contents into the QSTORE set at successively higher levels in phrasal structure and their removal at the point in the structure where they are required to take scope in order for a given reading to be represented. This dual percolation of information is regulated by the constraints already mentioned, and a separate condition, the 'semantics principle'. The retrieval of quantifiers from QSTORE is nondeterministic, so that all possible scopings are realized, subject to whatever empirically motivated restrictions prove necessary.

ADVANTAGES AND LIMITATIONS

Among the various competing grammatical frameworks currently under investigation, HPSG enjoys a number important strengths:

- Like other monostratal frameworks, HPSG can compactly express analyses of natural language phenomena, incorporating significant generalizations, without the assumption of derivational histories to encode the relevant properties of the phenomena described.
- The assumption of phrase structure configurations in natural language provides a straightforward basis for defining the percolation of information in syntactic objects. In particular, syntactic heads can serve as the locus of feature sharing between mother and daughter categories. This has been used in recent HPSG treatments of the distribution of nonlocal features and of QSTORE.
- The formal foundations of HPSG are mathematically explicit and well understood, taking the form of a logic of constraint satisfaction which ensures a complete interpretation for all posited constraints. This guarantees that any inconsistent components of an HPSG analysis are in principle detectable.
- The monotonicity of HPSG's mechanisms for regulating the distribution of grammatical information in syntactic structures, combined with the formal explicitness already noted, makes computational implementation of HPSG analyses particularly straightforward. Indeed, much of HPSG's theoretical apparatus has been developed in tandem with computational practice (e.g. the existence of efficient unification algorithms). Although defaults have sometimes been introduced, the nature of these defaults is essentially abbreviatory, in that every such grammar can be compiled out to one in which no defaults appear, using more restricted formulations of the relevant constraints. The essentially abbreviatory status of such defaults ensures that, from a computational point of view, all current HPSG implementations can be regarded as monotonic.
- The use of rich modeling objects such as typed feature structures allows the theory to combine a high degree of descriptive flexibility (conspicuous, for example, in its ability to model various kinds of unbounded dependency construction) with a feature-geometric organization that captures important modularity properties of natural language grammars.

The downside of HPSG's phrase structure basis emerges in contexts where it is less clear that the elements involved in the relevant constructions are definable in highly configurational terms. Coordination, for example, manifests in a number of phenomena in which it appears that string parallelism, rather than constituency, is the basis of a satisfactory account. HPSG currently lacks a detailed theory of coordination, and nonconstituent coordination, in particular, is problematic for phrase-structure approaches. The greater combinatorial flexibility of categorial grammar probably compares most favorably to phrase-structure approaches in this empirical domain. Currently, the lack of a well-developed approach to coordination is one of the most serious deficits in HPSG's theoretical coverage.

A second difficulty faced by current HPSG is a consequence of defining the relevant command relation for binding theory strictly in terms of valence. Since, under conventional assumptions about adjunct elements, adverbs and other modifiers are not lexically selected by heads, the binding theory sketched above should be inapplicable to elements within adjuncts. But it is not clear that this prediction is empirically warranted. Assuming that adjuncts are indeed lexically selected brings adjuncts into line with clearly selected elements, but again in a way that clashes with significant data. It is not clear, therefore, whether a strictly valence-based account of coreference possibilities is tenable, or if a configurational component must be reintroduced in order to bring the binding theory into line with the full range of relevant facts.

FUTURE PROSPECTS

Important discoveries tend to deflect established lines of research onto unforeseen pathways, but certain trends already evident in HPSG are very likely to become increasingly significant. In particular, future work in HPSG will almost certainly focus on a number of issues where the current theory is notably incomplete:

- New approaches to problems posed by word order, in particular cases of so-called 'discontinuous constituency', are likely be be developed based on what has been called the 'linearization framework' within HPSG, in which word order facts are associated with a descriptive domain related to, but formally separate from, that which defines constituency.
- The 'constructional' approach to syntactic phenomena (Sag, 1997), relying on elaboration of the phrasal sort hierarchy to capture both regular and idiosyncratic syntactic properties, will become increasingly prominent. Exceptional behavior, such as the fact that relative clause modifiers with neither *wh* nor *that* formatives cannot be attached to nominal heads corresponding to their subjects (*the guy Robin criticized is here* / **the guy criticized Robin is here*), or the fact that PPs containing *wh* can link infinitival relative clauses to nominal heads but *wh* NPs themselves cannot (*something about which to complain/*something which to complain about*) will increasingly be handled through sort declarations that encode them as construction-specific constraints. It must be stressed, however, that there is far from unanimous acceptance of this 'constructional turn'.
- The semantic component of HPSG is still seriously underdeveloped, following its dissociation from the situation-theoretic perspective which guided much earlier work. The CONT and QSTORE features provide information which constitutes a kind of logical form representation, but there is currently no generally accepted constraining relationship between such representations and empirically motivated formal models. A particularly stubborn obstacle to the formulation of such relationships is the difficulty posed by major outstanding empirical problems, such as the semantic nonequivalence in opaque contexts of intensionally equivalent objects. Research currently in progress in HPSG is aimed at eliminating this deficit of the theory, and will probably intensify.
- Finally, there has already been work on constraint-based phonology which extends the HPSG approach of using sorted feature structures to state mutually constraining representations to phonology, with the ultimate objective of providing a completely nonderivational theory. An overview of work along these lines, with pointers to relevant sources, is given in Bird and Klein (1994). The application of sorted feature structures and other aspects of the HPSG formalism will probably become increasingly important for foundational work in phonology.

Pragmatics, Formal

Intermediate article

Craige Roberts, Ohio State University, Columbus, Ohio, USA

CONTENTS

Formal pragmatics is a subfield of linguistics, with a focus on the influence of context on interpretation. It has close ties to the study of formal semantics, as well as to philosophy of language and to language processing in the field of artificial intelligence.

PRAGMATIC PHENOMENA

Within linguistics and the philosophy of language, the study of pragmatics over the past century has encompassed a number of phenomena pertaining to the way that context influences interpretation, including at least the following:

- what a given utterance may be taken to presuppose, especially via conventional presupposition triggers (conventional implicature);
- the various ways in which speakers may be taken to mean more than they say (conversational implicatures);
- how we understand indexical expressions (including first- and second-person pronouns, and expressions such as 'this' and 'that') and other context-sensitive expressions (e.g. adjectives such as 'local', 'former', 'relevant', 'good', among many others);
- sentence mood (e.g. when is 'you will like broccoli' an assertion, when a question, when a command?) and the relations between moods (what is an acceptable answer to a given question? – does it mean the same thing to reply to a question with 'yes', as to an assertion, or to a command?);
- speech acts (e.g. when is 'I will eat my broccoli' a prediction? a promise? a threat? – and how do we differentiate between these (and other) things we can do in uttering this sentence?);
- the ways in which speakers negotiate the construction of their dialogue, including conversational turn-taking;
- rhetorical structure, the ways in which different utterances, even by the same speaker, may be related to build an argument, make an explanation, etc.

More recently, there has been considerable interest in how contextual factors play a role in these facets of semantic interpretation, as well:

- anaphora resolution: how we find the intended antecedents for various anaphoric elements in discourse, including third-person pronouns, but also null arguments (as in Japanese or Spanish, where subjects are optional) and other forms of ellipsis, and non-nominal proforms (pro-VerbPhrases, pro-clauses, etc.);
- the semantic role(s) of intonation, and the related phenomena of Focus and Topic (which very often involve prosodic factors such as intonation, but may also involve word order, special syntactic constructions, or morphological markings);
- domain restriction: the ways in which the interpretation of quantificational operators is influenced by context (e.g. when we say 'Everyone seems cold today', we generally mean some relevant subset of the set of all people; when we use a modal auxiliary such as the deontic 'should' we generally assume that the assertion in question is true relative to certain background assumptions about what is right and reasonable; when we say 'John only likes BAGELS', we generally mean that the only relevant property John has is liking bagels, ruling out perhaps liking toast or sausage, but not breathing or liking dogs).

GOALS OF A FORMAL PRAGMATIC THEORY

Until the 1970s, most of the theories proposed to explain such pragmatic phenomena were informal. But since that time, more and more work on pragmatics has been carried out in the spirit of generative linguistics. In a generative theory, for example of the syntactic structure of a particular language, one attempts to characterize all and only those utterances which are grammatical in the language in question. We can say that a generative grammar predicts whether a given sentential structure is grammatical or ungrammatical (in the language). In order to be fully explicit and clear about these predictions, such theories are relatively formal, formulating hypotheses (or *rules* in the grammar) in such a way that they are both clear as to their conditions of application and unambiguous about the results. Formal linguistic theories hence provide more predictive power than

informal theories. Instead of *post hoc* explanations, we have clear predictions about what will be acceptable to native speakers of the language in question.

Where pragmatics is concerned, the notion of acceptability is not that of grammaticality, as in syntax, but of meaning and felicity in context. The data derive from the behavior of native speakers as this reflects their intuitions about whether a given utterance seems felicitous in a particular context, and, if so, about what they take the utterance to mean in that context. For example, in (1) and (2), the same sentence is uttered by a speaker B in two different contexts:

[Context: A and B are perfect strangers, standing at a bus stop. B turns to A and says:] 'I got splashed by a bus this morning, too.' (1)

[Context: A and B are perfect strangers, standing at a bus stop. A bus pulling up to the curb splashes A with water. B turns to A and says :] 'I got splashed by a bus this morning, too.' (2)

In neither context has there been prior dialogue. But in (2), the utterance seems perfectly natural, while in (1) it does not. We say that the utterance of this sentence is *felicitous* in the context given in (2), while it is *infelicitous* in (1); we often mark infelicity with a '#' at the beginning of the sentence, a pragmatic parallel to the use of '*' to mark ungrammaticality in syntax.

Just as context may determine felicity, it may license certain types of variation in understood meaning. B's utterance in (3) takes place in a different context from that of the same sentence in (4), and because of this difference in context of utterance, the two utterances are likely to convey different information:

A: Do you have any idea who might have three chairs they could loan me for the party tonight?
B: I'm pretty sure Mary has three chairs. (3)

A: I need to know how many chairs each of these people on the planning committee owns, so I know how many chairs we already have for the party.
B: I'm pretty sure Mary has three chairs. (4)

We are more likely to understand B in (3) to mean that Mary has three or more chairs, while in (4), we are more likely to understand B to mean that she has exactly three.

As illustrated by these examples, in explaining what determines felicity and meaning in pragmatic theory we cannot simply consider the linguistic structure(s) of the sentence uttered and the semantic rules for interpreting these structures. Rather, pragmatic phenomena generally involve interaction between the utterance (as characterized by its various linguistic structures – syntactic, prosodic, morphological, etc.) and some aspect or aspects of the context of utterance. So the fundamental requirements for a formal pragmatic theory are (1) a theory of the linguistic structures of an utterance, (2) a theory of linguistic context, and (3) a theory of how these interact to yield the attested felicity and interpretations. We look to the other subfields of linguistics – syntax, phonology, morphology – for (1). Then the development of (2) and (3) constitute the principal goals of formal pragmatic theory.

CONTEXT AND CONTEXT CHANGE

A theory of linguistic context should make clear the kinds of information to which interlocutors in a conversation typically have access that may bear on the interpretations they give to utterances in that conversation. And it should organize that information in such a way as to optimally facilitate the characterization of the dynamics of information change over the course of the conversation. One question about the information influencing interpretation is *whose* information this is. Stalnaker (1972) argued that the relevant information is that in the common ground of the interlocutors – that information which they commonly (purport to) hold true, characterized as a set of propositions (each proposition a set of possible worlds). Although many authors since have assumed that the common ground is the correct information set for pragmatic interpretation, others have argued that it is, instead, the speaker's assumptions about the hearer's information which are critical, while others argue for a more complex notion than the common ground, for example, including a number of alternative possible common grounds to reflect the fact that we are not always able to determine with confidence exactly what our interlocutors believe. As these different conceptions reflect, it seems clear that successful communication requires that a speaker attempt to keep track of the information shared by all the interlocutors. The question, then, is whether the theory should idealize to the case where this attempt is relatively successful, or instead attempt to capture directly

the fact that keeping track of shared information is fraught with difficulty in the actual case.

Early work in formal pragmatics came out of formal semantics. Context in the theories of semanticists who followed the general approach of Montague was captured as a set of indices, or contextual parameters. These were pointers to specified sorts of contextual information, utilized to feed the relevant information into the process of compositional interpretation which yielded the proposition expressed by the sentence in the specified context. This limited set of indices typically included the world and time of utterance (a way of capturing the facts about the utterance situation, as well as interpreting tenses and utterances of such words as 'now'), the speaker and sometimes the addressee (for 'I', 'we', 'you', etc.), the location of the utterance (e.g. for the interpretation of 'here' or 'local'), and a function assigning values to free variables (the logical form counterparts of pronouns and other proforms). Additional indices were sometimes posited for elements such as indicated objects (for deixis accompanying 'this' and 'that') or even the relative status of the interlocutors (e.g. for Japanese honorifics or French *tu* versus *vous*) and the level of formality of the discourse. However, it is not clear that one could in principle specify a finite set of indices of this type which would be adequate to all the types of information relevant for capturing pragmatic influences on interpretation. Moreover, the values given by these indices for a given sentence were arbitrarily selected, without any mechanism for keeping track across a given discourse of what was being talked about and how this might bear on the interpretation of that sentence in that discourse.

Following Stalnaker (1972), Gazdar (1979) worked with a rather different notion of the context of utterance, conceived of as a set of propositions, and treated the meaning of an utterance as a function from contexts into propositions. Gazdar used this notion to develop a formal theory of implicature and presupposition in which the felicity of an utterance depended on whether the context of utterance could be consistently updated with the (propositional) information presupposed or implicated.

Theories of dynamic interpretation like those in the pioneering work of Heim (1982) and Kamp (see Kamp and Reyle, 1993) take the notion of context-incrementation yet further, marking a turning point in the development of pragmatics. In this work the meaning of an utterance is neither a proposition nor a function into propositions, but a function from contexts (of utterance) to (updated) contexts; Heim called this the utterance's *context change potential*. This approach offers a new dimension to Bar-Hillel's earlier characterization of an *utterance* as a pair of a sentence and a context. On the dynamic view of interpretation, we might consider an utterance to be a pair of the sentence under a linguistic analysis, or its logical form, and an input context, the context just prior to utterance. Given that the logical form is conventionally (perhaps even compositionally) correlated with a context change potential, this implies as well an output context, that is, the value of the context change potential given the input context as argument. For example, utterance of (5) in the context suggested will result in the updated context indicated:

Input context, IC: Information characterized as a set of propositions, including the proposition that B is speaking.
B: I am hungry.
Output context: IC plus the proposition that B said *I am hungry* in IC and (assuming no one questions B's trustworthiness) the proposition that B is hungry. (5)

The dynamic theories cited take different views of what context is. Heim takes it to be an elaboration of Stalnaker's common ground to include not only the set of propositions that the interlocutors hold in common to be true, but also a set of *discourse referents*. A discourse referent is an abstract entity-under-discussion. Such an entity may or may not actually exist – we can talk about hypothetical entities, even nonexistent ones – but we keep track of the information about each such entity across discourse. Heim characterizes a discourse referent informally as a file card; technically, it is an index, corresponding to the referential index on the noun phrases (NPs) used to refer to this entity in the discourse. Keeping track of discourse referents permits a theory of definite NPs such as 'the sun' in which such an NP carries a presupposition of familiarity to the interlocutors; that is, its utterance presupposes that there is a corresponding discourse referent in the input context of interpretation. Indefinites such as 'a cloud' are said to carry novelty presuppositions, requiring that in an input context there be no pre-existing corresponding discourse referent. Heim's context, then, is an abstract notion, a set with two kinds of information.

Kamp's Discourse Representation Theory (DRT) is very similar in spirit to Heim's Context Change Semantics and obtains many of the same results (as well as encountering many of the same problems). For example, discourse representations contain elements which behave very much like Heim's

discourse referents, as well as formulae that play much the same role as Heim's propositional component of the common ground. But instead of Heim's sets of information, DRT offers instead a representational characterization of context, as a particular type of logical form. And Kamp seems to conceive of the context in more psychologistic terms than Heim, as a mental representation or mental model, a tendency continued in much of the subsequent work in DRT and its descendants. But differences aside, in both these theories as well as in other subsequent work on dynamic interpretation, most contextual information can be characterized, directly or indirectly, in propositional terms, with a proposition viewed as a set of possible worlds (or situations).

Dynamic theories offer a number of advantages over the earlier index-based theories of context. Since contextual information is basically propositional in the dynamic theories, it is no longer necessary to attempt to characterize that information as a set of indices, with all the awkwardness of attempting to determine just how many indices, and of what character, are required. With no loss of theoretical elegance, there may be any number of different types of propositions in the context, bearing on the interpretation of an utterance in as many different ways. Moreover, the context now contains information about prior discourse and the situation of discourse, and it is this information which plays a central role in constraining the interpretation of any anaphoric or deictic elements which may be used. Heim treats such elements as presuppositional, and in subsequent work proposes an important extension of Context Change Semantics to include a full theory of utterance presuppositions and of presuppositional felicity in context. In this extension, an utterance presupposition is taken to be a constraint on contexts of utterance; technically, the context change potential corresponding to the utterance's logical form is undefined for any context which does not satisfy the presupposition in question. For example, in (2) above, B's utterance presupposes that someone other than B has been splashed by a bus, a presupposition conventionally triggered by the adverbial 'too'. The utterance is felicitous in this context because the utterance's presupposition is satisfied by the context, which makes it clear to both interlocutors that A (someone other than B) has just been splashed by a bus. But nothing in the context of (1) gives us this type of information. Hence, the (same) utterance presupposition fails in (1), so that the utterance is infelicitous; that is, context update is undefined for utterance of this sentence in this particular context.

Thus, dynamic theories of interpretation avoid the arbitrariness and disconnectedness of the earlier, index-based theories; each utterance looks to the preceding context for presupposition satisfaction, and in turn updates it with the information it contains. Still, these theories are primarily designed to capture logical relations between utterances. And because of this, they offer insights into only a few of the types of pragmatic phenomena listed at the outset of this article, presupposition and (in part) anaphora resolution and indexicality. What of the other phenomena which a full-fledged theory of formal pragmatics ought to say something about?

TOWARDS A UNIFIED PRAGMATIC THEORY: QUESTIONS, INTENTIONS, RHETORICAL RELATIONS

Recently, several theorists have attempted to develop more ambitious, inclusive formal theories of pragmatics. There seem to be two main trends in this work, one focusing on speakers' intentions and the role of these intentions in organizing discourse, the other on the role of rhetorical structures in discourse. Some of the most interesting work in each of these directions builds on the successes of the dynamic theories by extending one of those theories to allow for other dimensions of the information shared in conversation.

The first trend, focusing on speakers' intentions and the plans which these intentions constitute, comes as much out of work in artificial intelligence as out of linguistics or philosophy. Grice's (1967) conversational principles acknowledged the central role of speakers' intentions, what he called 'the purposes of the exchange', in conveying conversational implicatures in discourse. For example, we can understand what someone means only if we understand the purposes of the conversation and assume that their utterance pertains to those purposes. In artificial intelligence, Grosz and Sidner (1986) argue that speakers' intentions are the central organizing features of discourse, determining what information in the discourse is salient at any given point. They develop a theory based on this intentional structure to help explain anaphora resolution, offering insight into facets of that problem not addressed by the dynamic theories, but do not consider the role of compositional semantics in determining interlocutors' plans. Carlson (1983) develops a theory of discourse as structured by questions, and the relationships between questions and between questions and answers, as an extension of the game-theoretic semantics of Hintikka.

However, the theory is couched in syntactic terms, offering a grammar for discourse without making reference to the interpretations of the structures in question, and so again, fails to connect with the literature in formal semantics.

The work of Roberts (1996) exemplifies the use of intentions and plans in the analysis of discourse pragmatics in such a way as to preserve the results of formal semantics, borrowing on earlier work on the semantics of questions and the (formal) pragmatics of answers due to Groenendijk and Stokhof (1984). In Roberts' theory, discourse is organized by questions and the relations among them. The basic idea is that discourse is essentially a game of intentional inquiry. In this game, questions establish the local goals in a discourse – answering these questions, and thereby constrain what a speaker may say at a given point. Interlocutors are required to address the immediate question under discussion; anything else would be irrelevant. Knowing this, and knowing the question under discussion, a hearer can make certain reasonable inferences about what information the speaker intended to convey with a particular utterance. For example, A's question in (3) makes it clear that she is only interested in knowing who has at least three chairs, since that's all that matters to her for being able to borrow three. But in (4), A's question is about determining the total number of chairs owned, so that she needs exact figures to the extent possible. Someone responding cooperatively to one of these questions will only give the type of information requested, leading to the quantity implicature in (4) ('exactly three chairs'), but not in (3). Welker (1994) argues that under this type of view, conversational implicatures like that in (4) become contextual entailments, and that so-called implicature cancellation really amounts to context revision. That is, if context is sufficiently well defined, one can predict which implicatures will arise as a consequence of a given utterance, and even offer minimal pairs of contexts which differ in which implicatures they trigger for a given utterance. This approach can be extended to yield the intended understanding of ellipses (see Ginzburg, 1996), and the intended domain restriction for any operators in an utterance.

In addition, Roberts argues that Focus can be adequately analyzed as a presupposition about the question which an utterance is intended to address, whether that question is explicit or merely implicit; this would represent a simplification of the ground-breaking formal work on Focus by Rooth (see Rooth, 1992), which posits multiple functions for Focus. Finally, as Grice had predicted, the conversational maxims (e.g. Relevance) may be seen as theorems which follow from the basic goals and structure of the language game, rather than independent axioms of the theory. For example, given interlocutors' commitment to the established discourse goals of the language game, the questions under discussion, an utterance is Relevant if and only if it addresses the immediate question under discussion. Roberts' work is couched as an extension of the dynamic semantics of Heim, in which the discourse context is treated as a tuple, including both the common ground, or propositional information, and a set of questions under discussion, as well as other types of information. Each utterance is interpreted as a context change potential, updating the complex tuple of the input context by adding either a new question for discussion (if the utterance is interrogative in mood) or a new proposition to the common ground (if the utterance is indicative in mood).

The second trend in contemporary work on formal pragmatics is exemplified by the work of Asher and Lascarides (1998), who borrow from an earlier tradition of rhetorical analysis to develop a set of primitive rhetorical relations between utterances in a discourse, including Explanation, Elaboration, and Narrative, among others. They use an extension of Kamp's DRT in which the discourse representations for various clauses, determined on the basis of syntactic structure, are 'glued' together with these rhetorical relations. They offer detailed hypotheses about how the particular rhetorical relation intended for a given pair of clauses is determined by the hearer, using a default logic, on the basis of the compositional semantic interpretation of the clauses involved, representations of the assumed cognitive states of different interlocutors, a set of pragmatic principles, and various default assumptions. They argue that sentence mood and the speech act which a speaker intends to perform can be inferred on the basis of this information.

However, besides arguing for rhetorical relations as primitives of their theory, Asher and Lascarides also consider the crucial role of speakers' plans and intentions, as represented by particular types of questions, in drawing pragmatic inferences. One issue which subsequent work must address is whether rhetorical relations should be taken as primitives in a theory of discourse, or whether they can instead be defined in terms of the interlocutors' independently inferred intentions and plans. In the meantime, it seems clear that plans, intentions, and the intended relations between utterances in discourse need to be captured by one's

theory of discourse, and hence by pragmatic theory. In order to do this, contexts must be more than simply a set of indices or propositions (possibly with discourse referents). They must also include the questions under discussion in the discourse at that point, the interlocutors' intentions, and information about the relationships between the propositions and questions proffered in the discourse. And eventually, of course, contexts must also take into account the third major type of mood, the imperative.

PRAGMATICS AND LINGUISTICS

Current work in formal pragmatics raises interesting questions about the place of pragmatics in linguistic theory. For one thing, we might wonder about the extent to which the pragmatic theories and principles considered appear to hold across different languages (and different cultures). We know, for example, that rules of politeness do differ from culture to culture, and hence that while some languages include certain types of honorifics, and even special sublanguages, for addressing interlocutors of particular status, other languages do not. How deeply do such differences go? The work discussed so briefly here seems to assume implicitly that the pragmatic principles posited are universal in the use of human language. If questions or rhetorical relations underlie the organization of discourse, they do so regardless of the language in use (and the culture of the people who use it). If this is true – and it is an empirical question – why would it be so? Both the philosophical underpinnings of pragmatics and the particular theories under development suggest an answer: pragmatic principles are not part of the grammar of a language. Rather, as Grice (1967) argued, they reflect essential features of what it is to communicate with human language, rational principles which guide its optimal use. Hence, exploring pragmatics cross-linguistically may help to make more precise what exactly the human language faculty does, and how it is related to other cognitive capacities, including reason.

Production–Comprehension Interface

Intermediate article

Victor S Ferreira, University of California, San Diego, California, USA

CONTENTS

Many features of spoken language, from the nature of child-directed speech to audience design effects, reflect a sensitivity in language production to the needs and strategies of language comprehension. These adjustments, sometimes deliberate, sometimes automatic, ensure successful communication.

INTRODUCTION

The primary reason that speakers speak is so that their listeners can understand them. It is therefore unsurprising that unlike many cognitive tasks (such as perceiving, remembering, or decision-making), the language production performance of an individual speaker must take into account the processing capabilities and the knowledge states of another, namely, that speaker's intended listener. Research into this topic of the nature of the production–comprehension interface generally explores how production accommodates its processing to the needs of comprehension.

This article discusses the production–comprehension interface by exploring two related issues. The first concerns how speakers cater specific details of their utterances to take into account the knowledge and the comprehension capabilities and strategies of their listeners. The second narrows in on how speakers use common ground in their utterances – information that the speaker and listener believe to be mutually known in their present conversation or discourse.

INCLUSION OF INFORMATION BASED ON LISTENER KNOWLEDGE

The ways that speakers and listeners try to accommodate one another in conversations was described by Grice (1975). A Gricean approach to language specifies that interlocutors tacitly agree to the cooperative principle when they participate in a conversation, namely, that they agree to be mutually productive and efficient participants in their conversation. The cooperative principle is instantiated by four specific maxims. The maxim of *quality* states that interlocutors mutually assume that contributions to a conversation are legitimately provided as statements of truth. Thus, if a speaker says, 'it's raining', she or he has some evidentiary basis upon which to make that statement, and she or he does not intend the listener to understand that it is snowing. The maxims of *relation* and of *quantity* are relevant to the issue of common ground discussed below. The maxim of relation states that interlocutors are assumed to make their current utterances relevant by ensuring that current references relate to already known information. The maxim of quantity states that interlocutors are assumed to contribute an appropriate amount of information with each utterance, providing neither too little nor too much information (which cannot be done unless the speaker knows what the listener already knows). Finally, the maxim of *manner* states that interlocutors should endeavor to make their utterances unambiguous, brief, orderly, and that they should avoid obscurity. The maxim of manner can thus be taken to claim that speakers should make the form of their utterances easy for a listener to understand. Note that these maxims apply both to speakers and to listeners, in that speakers use the principle to guide utterance formation, and listeners use the principle to guide utterance interpretation. Furthermore, the cooperative principle can be flouted, or seemingly violated for the sake of communication (creating an implicature). For example, when asked how a tennis match was, if

a speaker says 'well, it was a tennis match', she or he seems to violate the maxim of quantity (by providing too little information), but thereby communicates that not much is to be said about the tennis match.

Grice's maxims are of two importantly distinct types. The maxims of quantity, quality, and relation are about what a speaker chooses to mention, whereas the maxim of manner is about how a speaker describes what they have decided to mention. This latter issue is discussed next, describing how speakers modify the form of their utterances to make those utterances easy to understand. Then, the issue of what a speaker chooses to mention is described, leading to the issue of the use of common ground.

MODIFICATIONS OF THE FORM OF SPOKEN UTTERANCES

Speakers cater the form of their utterances to their listeners in two general ways. One way involves explicit recognition by the speaker that their listener may encounter comprehension difficulty, typically because the listener may have limited linguistic abilities. Here, speakers are consciously aware of the potential for communicative difficulty, and they thereby make general modifications to their speech to circumvent that difficulty. The second way involves implicit production strategies that speakers use to create easy-to-understand sentences. Here, speakers are typically unaware of the difficulty their listener may have, but nevertheless tacitly make very specific modifications of their speech to enhance comprehensibility. Each of these kinds of modifications are discussed in turn.

When a speaker addresses a listener, the general style or register of his or her speech will be partially based on the nature of the relationship between the speaker and listener. Thus, for example, a speaker generally adopts a different register when addressing parents or grandparents, compared to when speaking to siblings. Students say 'yes, professor' to a university professor, but talk about 'my prof' to their friends.

While many of the features of a speech style reflect or communicate something about the social relationship between speaker and listener, other register effects may reflect a speaker's estimation of the linguistic capabilities of his or her listener. This is most strongly revealed by analyses of speech directed to populations with limited linguistic capabilities, including speech directed to children (child-directed speech or 'motherese'), to foreign-language speakers (for the purpose of communication or for language instruction), and to cognitively impaired listeners (e.g. the mentally retarded). When addressing populations like these, speakers (intentionally) include a host of features in their utterances that (intentionally or unintentionally) serve two related purposes: speakers modify their utterances so that they are more easily understood, and so that they are more likely to capture and hold their listener's attention. The features of utterances that accomplish these goals are listed in Table 1.

In addition to these general modifications that occur in response to perceived characteristics of a speaker's current listener, speakers make other, more specific modifications that occur automatically. Unlike the register effects just described, these more specific changes do not depend on the characteristics of a speaker's listener, and indeed occur in the absence of any listener at all.

For example, one bit of information that is useful for a listener to know is whether a mentioned entity has previously been mentioned in a discourse, or whether that entity is new to a discourse (this is part of the information structure of a discourse). Languages have a number of devices to mark this difference between given information and new information, including lexical, syntactic, and acoustic devices. Lexically, speakers can refer to given

Table 1. Features of a speech register that make it easier to understand and more likely to capture and maintain listeners' attention

Features that make speech easier to understand	*Features that make speech more attention-getting*
Shorter utterances	Greater use of names
More repetition of words and phrases	More questions
More rephrasals	Higher and more modulated pitch
More common words	Longer vowels
Simpler and more transparent syntactic structures	Longer pauses
Hyperarticulation	Greater rhythm

information with pronouns ('she', 'he', etc.) and by using definite articles ('the', 'this', etc.). Syntactically, speakers mark the difference between given and new information typically by word order, where speakers tend to mention given entities in their utterances prior to new entities. For example, if the sentence 'I saw Bill yesterday' sets 'Bill' up as given information, it is more natural to say 'he was disappointed by the election', with the given information first, compared to 'the election disappointed him', with the given information second. Finally, acoustically, speakers tend to diminish the auditory characteristics of words that refer to given information (affecting the prosody of those words), by reducing the duration, the loudness, and the pitch of those words. These cues to the given versus new status of information are used redundantly, in that the use of one kind of cue does not preclude the use of another (e.g. given information might be produced early in a sentence and in reduced fashion).

Speakers use other subtle signals to communicate useful information to their listeners. Some of these signals arise when speakers anticipate upcoming or recognize past production difficulty. For example, speakers use the familiar fillers 'uh' and 'um' differently, in that 'uh' is used when speakers anticipate a relatively short disruption to their own speech, whereas 'um' is used when speakers anticipate a longer disruption. Similarly, speakers tend to use 'thee' instead of 'the' when they are about to have difficulty retrieving the following word (Fox Tree and Clark, 1997). When speakers repair an erroneously produced part of an utterance, they typically say 'er' or 'I mean' to mark that a repair is to follow, and they reproduce enough of the original utterance so that the utterance plus repair are easily understood. Other constraints (termed *perceptual constraints*; see Cutler, 1987) include a tendency to speak with a consistent rhythm (which assists listeners in finding word boundaries), and a tendency to use easily recognizable forms when creating novel words (e.g. speakers prefer to say 'ambiguize' over 'ambigwify', because the former sounds more similar to the root form, 'ambiguous').

It is important to recognize that these specific modifications occur unintentionally and automatically. For example, the tendency to manipulate word order so that given information occurs before new information occurs in the complete absence of any listener, in a manner that appears to be sensitive to how easily retrieved an entity is from the speaker's memory. The tendency to diminish the acoustic characteristics of words referring to given information has been found when speakers address 14-month-old children (who, at this largely preconversational stage of linguistic development, are unlikely to usefully distinguish given from new information), and when speakers produce the first and the second mention of a word to different listeners. This is different from what occurs with the register effects discussed above, which are generally dependent upon the presence of a linguistically challenged interlocutor for the appropriate register features to appear correctly.

Different mechanisms are used by the language production system to automatically modify the forms of utterances to ease comprehension. In some cases, variation emerges naturally from the manner in which production operates, and then comprehension processes learn to infer the validity of the systematic cue that production provides. For example, there is nothing about positioning a word early in a sentence that inherently marks it as referring to given information; this systematic variation is likely to be a consequence of normal production that comprehension processes become sensitive to. In other cases, an easily comprehended utterance comes from a pressure to create easily produced sentences. For example, speakers will tend to produce a more easily understood common word instead of a less easily understood uncommon word, not because of the difference in comprehension ease *per se*, but because production of the more common word is easier than production of the less common word. Interestingly, a different kind of mechanism seems to underlie the adjustments speakers make to the content of their utterances based on listener knowledge. This is described next.

MODIFICATIONS OF THE CONTENT OF SPOKEN UTTERANCES

Speakers cater the content of their utterances to the comprehension strategies and the knowledge states of their listeners. Interestingly, the role that the actual listener plays in the nature of these listener-sensitive modifications varies; sometimes, the modifications are quite independent of the actual knowledge states of listeners, whereas at other times, speakers specifically take into account what their listeners know. This variability in how listeners' knowledge is accounted for during production seems to reflect a general mechanism that people use when they estimate the knowledge states of others.

For example, many factors affect what kinds of labels speakers use for reference (e.g. referring to a tree outside as 'the tree on the left'). One factor is

that when possible, a speaker will collaborate with their listener to arrive at a suitable label for successful reference, by proposing a label that the listener can approve of, or suggest modifications to. Another important factor is the prior discourse history between a speaker and listener (Brennan and Clark, 1996). If, for example, a speaker has previously referred to 'the creepy tree' with a particular listener, they can use that label again with that listener without renegotiating from scratch. Interestingly, an egocentric bias arises when speakers use their prior discourse history. Whereas it is the case that with a new listener, speakers are relatively less likely to use a label that was used previously with a different listener, the labels that speakers do use with new listeners are nevertheless more similar to the labels that they've previously used (with different listeners), compared to labels that speakers use for the first time. The egocentric bias is revealed by the fact that a speaker's own discourse history, independent of his or her listener's history, influences the nature of the labels that speakers use.

Another example demonstrates how the egocentric bias operates. It has been shown that in story retellings, speakers are more likely to mention atypical instruments of actions (e.g. an icepick for a stabbing event) than typical instruments of actions (a knife for a stabbing event; see Dell and Brown, 1991). This tendency is an elegant reflection of Grice's maxim of quantity: if an idea to be conveyed includes an action that is performed with a highly typical instrument, then the instrument need not be explicitly described, as the listener is likely to infer that particular instrument if necessary. On the other hand, if the action is performed with an atypical instrument, the instrument should be explicitly described, because a listener cannot infer the existence of an atypical instrument. Interestingly, an egocentric bias still arises, in that it has been shown that under some circumstances, whether the speaker knows the listener to already possess knowledge of the instrument does not affect the tendency to especially mention atypical instruments. This is only true, however, with sentences that describe the action itself. So, for example, speakers are as likely to say 'The robber stabbed the victim with the icepick' whether or not their listeners know about the icepick. On the other hand, in subsequent sentences (after the action has been described), speakers are sensitive to listener knowledge. So, a speaker is less likely to say 'Oh, and there was an icepick' when a listener already knows about the icepick, compared to when the listener does not.

These observations hint at a mechanism that turns out to be common in social-cognitive functioning generally (see Nickerson, 1999), as well as in processing related to the production–comprehension interface specifically. The fact that speakers' initial references to an action include mention of atypical instruments equally often regardless of listener knowledge suggests that speakers' initial production decisions are based on egocentric information. That is, utterances are first formulated based on what the speaker knows, relatively independently of what listeners know. This can account for the general egocentric bias that arises in production. Then, the observation that subsequent references to the instrument are sensitive to listener knowledge suggests that after the initial production, speakers are better able to accommodate the differences between what the speaker knows and what their listeners know. Overall, it appears that speakers accommodate the content of their utterances to the knowledge states of listeners with a general two-stage strategy: speaker-centered, egocentric knowledge guides initial utterance formulation, and then listener-specific knowledge is taken into account in subsequent processing.

Why might the production system adopt such a two-stage strategy? For reasons of processing efficiency. In terms of processing resources, it is costly to keep track of the knowledge states of all listeners, with respect to all possible facts that a speaker could express. A reasonable heuristic is that if the speaker knows some fact, his or her listeners are also likely to know that fact. Based on this egocentric strategy, production processes can efficiently formulate an initial utterance that is likely to be good enough for successful communication. However, once the initial utterance is formulated, the specific information expressed in the utterance can more easily be evaluated with respect to listener knowledge. So, the initial formulation can be followed by elaborations and modifications that take into account listener knowledge. Interestingly, if production occurs with relatively little pressure, it is possible that this formulation-then-adjustment strategy could occur prior to articulation. Indeed, this kind of mechanism seems to reflect how common ground information is processed, which is described next.

COMMON GROUND EFFECTS

For a speaker to make definite reference – for example, as occurs with the use of a noun phrase with the definite determiner 'the' – she or he must assume the truth of a remarkable number of facts.

First, the speaker must know about the entity to which she or he wishes to refer. Second, the speaker must know that the listener knows about this entity. And third, the speaker must think that both the speaker him- or herself as well as the listener know about the other's knowledge of this entity. For example, Mary cannot say to Bill 'the guy you voted for is a clown' unless: (a) Bill knows who Bill voted for; (b) Mary knows who Bill voted for; and (c) Mary thinks that both of them know of the other's knowledge of who Bill voted for. Shared knowledge is not sufficient for definite reference, in that it cannot merely be the case that each independently knows of Bill's vote. There must be mutual knowledge, in that both knows of the other's knowledge. If Bill doesn't know that Mary knows of his voting choice, then Mary's statement can fairly be responded to with 'how do you know who I voted for?' It is this mutual knowledge that a set of interlocutors possesses that is termed *common ground*.

THE NATURE OF COMMON GROUND

Without some semblance of the common ground between speaker and listener already in place, a conversation can hardly get off the ground. Many a science fiction story portrays two members of mutually unknown species, struggling futilely to communicate without any shared basis of communication, until that shared basis is discovered, at which point the journey of information exchange begins. The same occurs any time two strangers meet, if less dramatically. In fact, 'current weather conditions' as the reliable kindling of any conversation can be understood in this light: the current weather conditions are encompassing enough that any co-present interlocutors can assume them as a shared basis of conversation (i.e. that it's likely to be common ground), though they are changing and important enough that they are (more or less) worth talking about (thus permitting speakers to respect Grice's maxim of quantity).

Though common ground begins as a necessary starting point for a conversation, it then continues to build across that conversation, and indeed across the continuing interactions between any given interlocutors. Common ground refers not only to what interlocutors can talk about, but how they can talk about it. For example, based on common ground, a speaker will decide whether to speak in English, French, or American Sign Language, and in those languages, what register to use. Research has identified two different bases that jointly contribute to these many different aspects of the common ground that is shared between interlocutors (Clark, 1996). Communal common ground refers to the abilities and knowledge that interlocutors can assume to be possessed by virtue of the community membership of the participating interlocutors. Thus, for example, if a speaker is aware that his or her interlocutor is a French Canadian, an accountant, a bridge player, or a parent, she or he will assume mutual knowledge of a set of facts that members of each of those communities will typically know. Personal common ground refers to the set of facts that interlocutors come to know as a consequence of their joint experiences, including things that happen within a conversation (the entities that speakers refer to) as well as those outside the conversation (events that interlocutors can be assumed to have noticed). All facts learned in past conversations or mutual experiences among a set of interlocutors become parts of those interlocutors' common ground.

PROCESSING CONSIDERATIONS

Speakers clearly recognize information that is in common ground when they speak. This is evident not only from the fact that speakers' definite references overwhelmingly succeed in conversation, but also by more subtle audience design effects (e.g. Krauss and Fussell, 1991), where speakers seem to cater their utterances to account for what their listeners are likely to know already (i.e. for what is in common ground). For example, speakers will refer to local landmarks or provide navigation directions differently if they think their listeners are local residents, compared to if they think the listeners are not local. Speakers will also produce utterances differently if they think their speech is for themselves (i.e. for the purpose of future reference) compared to if the speech is for others, or if speech is intended for a personal friend compared to if it is intended for a stranger. Furthermore, research has shown that communication is more successful when speakers correctly know who their intended audience is.

How speakers recognize common ground is not a trivial issue, however. Because language users do not have direct access to the cognitive states of others, each must infer whether a particular fact is mutually known. There are many specific strategies that interlocutors can use to infer whether a fact is in common ground. For example, if interlocutors notice that each has made eye contact with a particular object in the environment, they may assume that object to be in common ground. Or, if one interlocutor verbally refers to an entity, all

interlocutors who could reasonably be assumed to have heard the verbal reference can have that entity ascribed to their common ground. Interestingly, the egocentric bias described above arises too when speakers attempt to account for common ground. With respect to communal common ground, it has been found that while speakers can quite accurately estimate what other members of specified communities do and do not know, they still exhibit a systematic bias to overestimate the likelihood that others know things that they themselves know. This effect, a version of the 'false consensus effect' from social psychology, suggests that with respect to common ground, an interlocutor who idiosyncratically knows a fact is relatively likely to ascribe knowledge of that fact to others, and therefore assign that fact to common ground.

Research investigating the use of personal common ground has found evidence not only of an egocentric bias, but also for the two-stage model described above. If speakers formulate utterances freely, without any time pressure, they can easily provide enough information to refer successfully to an intended concept in its context (see Deutsch and Pechmann, 1982), and can distinguish information in common ground from privileged information (information that only the speaker knows about). However, if speakers formulate utterances under time pressure, the distinction between common ground and privileged information erodes, as speakers are more likely to make (infelicitous) references to privileged information in utterances that are directed to their listeners. Thus, initial formulations – ones that are used when time pressure does not permit subsequent revision – are based on egocentric information, until subsequent modifications of the initial formulation can correct for the different knowledge states that speakers and listeners might have (see Horton and Keysar, 1996).

Overall, then, for communication to succeed, speakers must take into account the linguistic capabilities and the knowledge states of their listeners. Grice's cooperative principle provides an ideal to which speakers and listeners can appeal with each contribution to a conversation. Given this ideal, the extent to which speakers follow the cooperative principle is impressive. Although speakers show some general deviations from producing language in an entirely cooperative manner, these can largely be understood as the result of speakers' use of fallible heuristics – heuristics that are necessary given the pressures involved in timely production, as well as the intractability of the demands involved in estimating mutual knowledge. Despite these difficulties, speakers modify the form and the content of their utterances so that their listeners can more easily understand those utterances. The listener-sensitive accommodations that speakers make during language production are a revealing compromise between what speakers know, and what they guess others know.

Prosody

Introductory article

Fernanda Ferreira, Michigan State University, East Lansing, Michigan, USA

CONTENTS

Every utterance is produced with variations in word duration, pitch, and stress. These features constitute the prosody of language and provide important information about meaning and structure.

INTRODUCTION

Any spoken utterance is produced with a particular sound pattern. For example, in English declarative sentences, pitch gradually falls, whereas pitch rises at the end of an interrogative or question. Words such as 'of' and 'the' tend to be short in duration, but words at the ends of clauses are usually stretched. In the default case, the word at the end of a clause also receives the greatest stress, but emphatic stress can be shifted to some other word, indicating that it is semantically prominent. These variations in pitch, duration, and stress provide an utterance with its prosody. Regardless of whether the utterance is a list of grocery items or a complex multiclause sentence uttered as part of a conversation, it will be assigned a prosodic pattern. This generalization holds for all human languages. Indeed, the prosodic patterns of a language are among the first linguistic abilities infants acquire. As anyone who has listened to the meaningless babble of a baby can appreciate, the utterances of even six-month-olds are gibberish but to a remarkable degree the prosody is similar to what would be appropriate for a real sentence of the child's language.

Prosody, then, is a general term that refers to the aspects of an utterance's sound that are not specific to the words themselves. For example, consider the sentences 'Bill likes to run' and 'Jane quit her job'. The two are made up of entirely different words, and so they are completely different at the level of their *phonemic content* (the individual sounds that make up words are called phonemes). And yet the sentences would be spoken with an almost identical prosody: pitch would gradually fall, giving both an intonational pattern that is sometimes called the 'declarative contour'; 'to' and 'her' would both be clipped, but 'run' and 'job' would be lengthened considerably; and the major stress of the sentence would fall at the end, on 'run' and 'job'. Prosody can be divided into three main aspects: intonation, which has to do with variations in pitch; timing, which concerns the durations of words and the locations and durations of any pauses between them; and stress, which roughly has to do with the loudness of the various words (more precisely, particular syllables within the words).

Prosody is an important tool that speakers use to define the informational structure of their utterances – the separation between information that links up with the ongoing discourse and information that is new and therefore being added to interlocutors' common ground. The latter is often referred to as the 'focus' of the utterance, and focused elements tend to be those that are prosodically prominent.

An important question in cognitive science is: how do speakers produce these prosodic patterns? That is a question about the creation of prosody during language production, a topic that will be discussed at the end of this article.

INTONATION

An 'intonational phrase' can be thought of as a series of words that fall into the same pitch group. For example, the sentence 'Bill wants to walk but Jane prefers to take a taxi' would typically be produced as two intonational phrases: [Bill wants to walk] and [but Jane prefers to take a taxi]. A single intonational phrase normally consists of one accented syllable ('Bill', for example) and a series of unaccented syllables ('wants to walk'). The accented word is said to receive a 'pitch accent', and the overall pitch movement of the phrase is

said to create its 'tune'. The tunes of the two phrases in the above example are not the same, however. The first one falls but ends with a rising tone that indicates that the utterance will continue; the second one ends with a falling tone, which is characteristic of pitch at the ends of complete utterances. The last syllable of an intonational phrase will tend to be stretched and might also be followed by a pause. In addition, the first syllable of the new intonational phrase will begin at a higher pitch. This pitch resetting allows the speaker to produce the gradually falling intonation pattern which is characteristic of declarative utterances without falling outside his or her pitch range.

Different tunes are associated with particular sentence meanings. The distinction between a statement and a question has already been mentioned. Even statements of various types may have distinct intonational patterns. If someone asks, 'Why are you going to Montreal?', one might reply 'My brother goes to McGill'. But if that person asked, 'Are you excited about visiting Concordia when you're in Montreal?', the same reply might be given but the tune would be different – pitch would be flatter until the word 'McGill', at which point pitch would rise quite sharply. The latter tune would signal that the speaker is negating the other conversational participant's presupposition about the university in Montreal with which she has an association.

The formal system that is used to characterize intonation is referred to as *ToBI*. This term stands for 'tones and break indices', and it is a formalism used to represent different tunes. The fundamental idea that underlies the system is that all tunes comprise just two basic tones: High (H) and Low (L). The most accented syllable in an intonational phrase – the syllable that receives a pitch accent – is symbolized as H*. The syllable that ends the intonational phrase is represented with a %, as in L%, and is referred to as the boundary tone. Figure 1 shows the pitch contour for a declarative sentence ('It was the terrorist that kidnapped the ambassador'), along with simplified ToBI transcription and corresponding waveform.

Intonation, then, concerns the tune or melody of an utterance and is the basis for its division into prosodic phrases. The next section describes another aspect of prosody: the durations of words and pauses, which make up an utterance's timing.

TIMING

Consider the utterance 'Bill wants to walk but Mary wants to drive' and compare it to 'Bill wants to walk to the store'. *Walk* would have a longer duration in the first example than in the second. This difference is based on the phrasal position of the word 'walk' in the two cases: when it occurs at the boundary of a phrase or clause, it tends to be

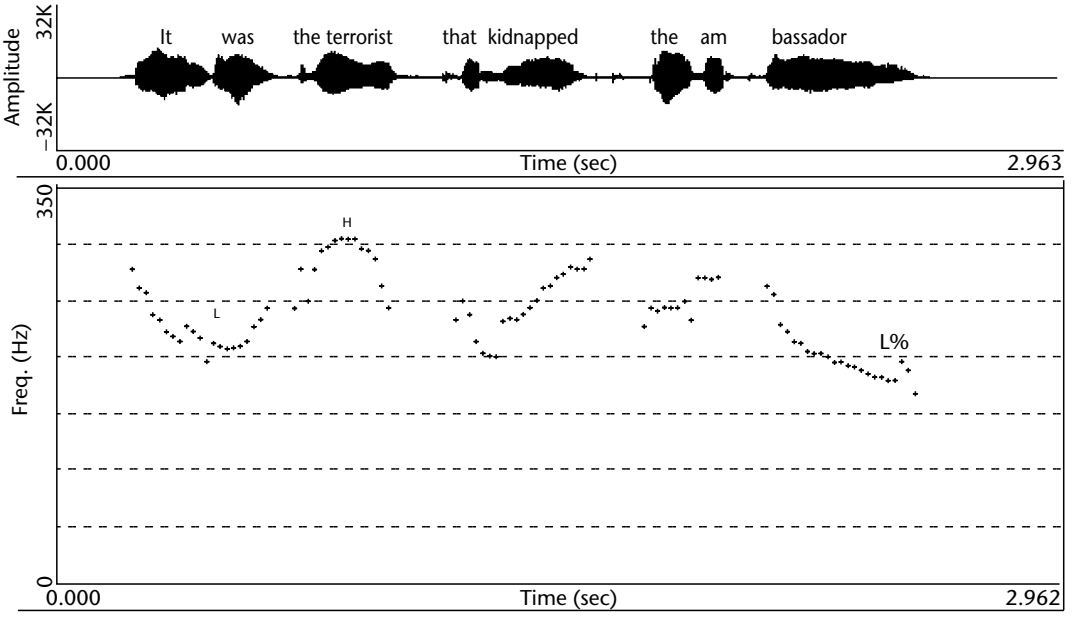

Figure 1. Acoustic representation of a spoken sentence. The top portion is a waveform, which displays amplitude variations as a function of time. The bottom portion is a representation of changes in fundamental frequency (pitch) as a function of time. The bottom portion also includes ToBI annotations.

lengthened to a greater extent. This phenomenon is known as 'phrase-final lengthening'.

An important consequence of phrase-final lengthening is that important syntactic boundaries will tend to be marked in normal speech. This cue might be used by young children as they learn about the grammatical properties of sentences. This cue is also useful for helping the listener resolve certain ambiguities in normal language. For instance, the sentence 'Mary saw the man with binoculars' could mean either that Mary used binoculars as a seeing instrument, or that the man she saw was in possession of binoculars and she saw that particular man. The spoken version of this sentence might distinguish between these two readings prosodically – if the speaker intends to convey that Mary has the binoculars, then 'man' will be at the end of a phrase (the object of the verb) and so the word would be lengthened. If the speaker intended the other meaning, then 'man' would not be lengthened, because in that case it does not occur at the end of a phrasal boundary. Lengthening, then, serves as a cue that can be used both by children acquiring language and by competent adults trying to understand utterances.

Another important feature of the timing of utterances is that so-called 'function words' are almost always short. Function words are grammatical words such as 'of', 'the', 'and', 'on', and so on. The term 'function word' is meant to highlight the fact that such words tend to be important for the grammatical properties of a sentence. In contrast, a 'content word' conveys most of the meaning of a sentence, and these overall tend to be longer than function words. For example, we can directly compare 'I want two leaves' and 'I want to leave'. The words 'two' and 'to' are homophones, but 'two' is a content word and 'to' is a function word. The latter has a noticeably shorter duration than the former in a normal sentential context, and that difference is directly attributable to the word's status as a function word.

Of course, function words *can* be made long under the right discourse circumstances. One factor that may cause a function word that would normally have a short duration to be lengthened is emphatic stress. For example, one would normally say 'Put the book on the table' so that the word 'on' was quite clipped. But if one were in a situation in which one wanted to emphasize that the book should go on and not under the table, then the word 'on' would be stressed and, consequently, also lengthened. A second factor that can cause a function word to be lengthened is its position within a phrase. Recall the phenomenon of phrase-final lengthening. In a sentence such as 'Who do you want to talk to?', the final word 'to' would be much longer than it would be in 'Do you want to talk to Tom?' To execute this lengthening, it is necessary to produce the word 'to' in its citation form; that is, the vowel in 'to' that would normally be reduced to a schwa (the default lax, unstressed vowel sound found, for example, in the second syllable of 'other') instead has its full, long pronunciation.

Pauses also support utterances' characteristic timing patterns. People often pause because they are having trouble formulating their utterances, but these are not the sorts of pauses that are relevant to timing. Consider that even in flawless renditions of text, it is normal to pause at phrase and especially at clause boundaries. These pauses that tend to cluster at syntactic boundaries are correlated with phrase-final lengthening; words that are lengthened often tend to be followed by a pause. The phenomenon is similar to that of a rest in music: in speech, people insert a brief pause in order to preserve the overall rhythm of the utterance's timing pattern, just as a musician uses a rest to maintain appropriate metre. These pauses are generally quite short – between a quarter-second and a half-second in duration.

STRESS

Words differ in the amount of stress (corresponding closely to loudness) that is normally assigned to their constituent syllables. Each of the syllables of a word such as 'chimpanzee' receives a different amount of stress: *-zee* gets the greatest stress, *-pan-* the smallest, and *chimp*-is assigned a stress level somewhere in between. In addition, when words occur in multiword contexts, their stress patterns are affected. For example, the word at the end of a phrase tends to be stressed the most, as in 'Mary wants a chimpanzee'.

One formalism for representing the different levels of stress that each syllable receives is to use a *metrical grid* that symbolizes the metre of the utterance. The sentence above would be represented as shown in Figure 2. A column of Xs occurs above each syllable, and the height of the column indicates the level of stress. The function word 'a', for example, gets only level 1 stress; the final syllable of 'chimpanzee', in contrast, goes all the way up to level 5, making it the most prominent syllable of the utterance (the most prominent syllable of the word is also the one that becomes the most prominent syllable of the utterance). This syllable's standing is a direct consequence of the placement

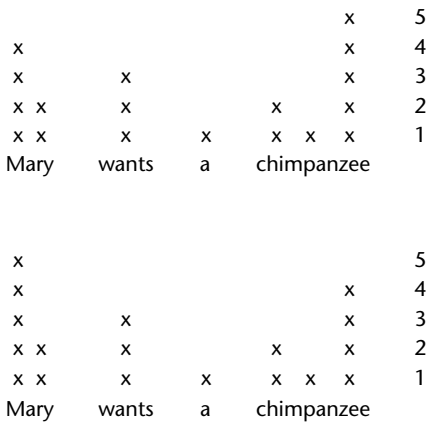

Figure 2. Metrical grids for two prosodic versions of the same utterance. The first would be a neutral rendition, and the second would be a rendition in which 'Mary' was focused.

of the word 'chimpanzee' as the last word of the utterance.

It is possible, of course, to make a different word in the utterance the most prominent – in our example, 'Mary' could be the informational focus. This rendition might be appropriate in a context in which someone mistakenly attributed the desire for a chimpanzee to Susan rather than Mary. The grid that would result for an utterance in which 'Mary' is most prominent is also shown in Figure 2. Notice that it is now 'Mary' that receives level 5 stress rather than 'chimpanzee'.

There is a tight link between stress and duration; the two features together create an utterance's timing pattern. Words that are stressed tend to be longer; words that receive little stress tend to be short. Indeed, notice that the default rule of utterance stress which reserves prominence for the last word operates on the same word that is usually the target of phrase-final lengthening. This correlation is not accidental; as mentioned earlier, stressed words are louder, and it is almost inevitable that a word which is produced so that it is louder will also tend to be made longer. This correlation can be verified through acoustic measurements. Any spoken sentence can be *digitized* so that, for example, amplitude values are sampled at various intervals. The result is a waveform – a representation that plots amplitude against time (see Figure 1). Waveform editors permit speech scientists to measure the durations of syllables exactly as well as their corresponding amplitude levels (the psychological experience of amplitude is loudness). If the word 'Mary' in 'Mary wants a chimpanzee' were the informational focus of the utterance, then it would not only be the site of higher amplitude values, but it would also tend to be longer than it would be in an utterance in which it was not the focus.

FOCUS

Up to now, the concept of focus has been invoked in various contexts but it has not been discussed in any detail. Focus is a somewhat complex concept, because it has both semantic and phonological aspects. Fundamentally, focus is a semantic notion; but the way focus is implemented in utterances often involves the manipulation of sound features such as stress, timing, and intonation.

To begin to appreciate what focus is, it is necessary to consider utterances in discourse contexts. One very common type of discourse is a conversation between two participants consisting of a question and corresponding answer. For example, consider the question 'Who does Mary admire?' In reply someone might say 'Mary admires the man who won the marathon'. The reply has a particular *information structure*. The presupposition that Mary admires someone is part of the background information shared by the speaker and hearer. The utterance then adds to the ongoing discourse the information that Mary admires the man who won the marathon. Another way to view this division is as follows: the question sets up the structure 'Mary admires x'; what the other participant in the conversation then does is to provide a value for x. The contents of x are the focus of the utterance.

So far we have established that sentences have information structures – they can be divided into background and focus. This issue pertains to the meaning or semantics of language. The next question that can be asked is how speakers signal this informational structure.

The example above makes clear that, in principle and for some types of discourses, nothing beyond the content of the question–answer pair is necessary, because a question may set up the background and the remainder would then be the focus. But often discourses do not have such a tidy organization. For example, person A might say 'Mary admires body-builders.' Person B might know this statement to be false, and furthermore, he might know that Mary actually admires endurance runners. Therefore, person B might reply, 'No, Mary admires MARATHONERS.' Following standard conventions, the focused element has been capitalized to indicate that the word is spoken with a pitch accent (recall that pitch-accented words receive heavy stress and tend to be lengthened).

Speakers also have other devices at their disposal for indicating focus; for instance, the speaker could have used a so-called 'cleft construction', a particular type of syntactic form, to focus the appropriate element. Thus, person A might say 'Mary admires body-builders,' and person B might reply 'No, it's marathoners that Mary admires.' Focus can be signaled by the use of a particular type of grammatical structure, or it can be indicated solely with sound, via a pitch accent. But interestingly, even when a syntactic device for focusing is used, pitch accenting seems to occur as well. This point can easily be appreciated by saying the cleft sentence above out loud: a speaker almost invariably ends up placing phonological emphasis on the word 'marathoners' in the structure 'It's marathoners that Mary admires.' Thus, it appears that even when a speaker in principle has already taken care of the need to signal the informational structure of her utterance by choosing a syntactic form tailor-made for that purpose, she still adds the apparently redundant phonological cues associated with pitch accents as well.

Why would speakers behave this way? Why would they signal focus with a pitch accent when the syntactic form of an utterance adequately conveys the information structure? Indeed, as was observed above, in some question–answer pairs simply the content of the question is sufficient to parse the utterance that follows into background and focus – neither a specialized syntactic form nor a pitch accent is necessary. Moreover, experimental studies of people's understanding of sentences have shown that the same sentence is perceived as having a different informational structure depending on the question that precedes it, even when the sentence itself is identical in the different contexts. Thus, if someone hears the question 'Who is wearing a blue hat?' they perceive the sentence 'The man on the corner is wearing a blue hat' as having the following focus–background structure: the background is 'X is wearing a blue hat', and the focus is X = the man on the corner. But when the exact same sentence spoken identically is preceded by the question 'What is the man on the corner wearing?' then the sentence is informationally parsed as follows: the background is 'The man on the corner is wearing X', and the focus is X = a blue hat.

But even though it has been shown that people understanding sentences *can* divide a sentence into background and focus without the aid of prosody, it is also clear that this task is easier if the focus is signaled with a pitch accent. It is possible, then, to design a psycholinguistic experiment to show that a sentence whose focus–background structure is not explicitly signaled is still understood as having one; but the reality of natural language production is that speakers tend to provide the phonological cues anyway, and listeners take advantage of those cues to locate the focus more efficiently. Recent research has even shown that focus can help to clear up ambiguity within sentences. For example, consider 'Everyone smiled at the son of the driver who had the beautiful, bushy moustache.' It is either the son or the driver who has a striking moustache; the syntactic structure of the sentence is not sufficient to specify unambiguously which one. But if the speaker places a pitch accent on the word 'son', then listeners tend to think he is the one with the moustache; if the pitch accent instead occurs on 'driver', then people interpret the sentence to mean that the driver has a moustache. These results demonstrate that not only is phonological signaling of focus helpful, it can even help the comprehender to resolve ambiguities in interpretation.

CREATION IN PRODUCTION

Most of the topics that have been discussed to this point concern linguistic representations having to do with prosody. Linguists have proposed various formal systems for symbolizing aspects of prosody, including intonation, timing, and stress. The issue that will be considered in this final section can be described as the psychological question: how do people give their utterances the prosodic features that have been detailed?

This question must be considered in the context of the entire enterprise in which the language production system is engaged. Briefly, to produce an utterance, the speaker must make a number of decisions. First, she must decide on the idea to be conveyed. This stage of 'message-level processing' requires the speaker to determine what it is she wishes to talk about and what she intends to say about the entity or entities. The speaker must choose words that appropriately express that meaning. The words must be organized into a grammatical form that places the words in an order that other speakers of the language will recognize as legitimate and that allow her semantic intention to be appreciated. For instance, if the speaker wishes to convey that it is raining outside at the moment, she could say 'It is raining.' The rules of English commit her to organizing the sentence in a particular manner; she could not express the same idea with the utterance 'Raining it is,' nor could she choose to omit the apparently

meaningless word 'it' (other languages, for example Romance languages, do allow such elements to be omitted). The sounds that make up the words must also be selected. Eventually, orders must be sent to the speech articulators to move the mouth, lips, tongue, and so on in the right ways so as to make the appropriate speech sounds.

One may ask, then, at what point in this general sequence does the prosodic form of a sentence get decided? Recent work has suggested that prosody is not spelled out in just a single stage during processing; instead, decisions about the prosodic features of sentences are made almost throughout the entire information-processing sequence, and then get implemented when the utterance is actually pronounced. The decision to focus a word or phrase is a high-level decision that typically is made during message-level processing. The speaker focuses a particular concept because semantically he takes certain information to be shared background between him and his interlocutor, and he wishes to add to their common ground – that is, he wishes to add new information. Decisions about intonation are also, to some extent, semantically based. For example, normally one would utter the sentence 'Billy slammed the ball' as a single intonational unit; but a sportscaster who wishes to convey something about the magnitude of the event might choose to divide the utterance into more than one intonational phrase as follows: '(Billy) (slammed) (the ball).' The effect the speaker wishes to create determines the choice, and so this decision too is largely based on semantic considerations.

The decisions that concern timing are not so much semantic as they are a function of the grammatical form of the sentence. If a speaker chooses to say 'Billy slammed the ball', then when a metrical grid for this utterance is set up, it will have to accept the words in those particular positions. As a result (in the simplest case), the sentence would be spoken as a single intonational phrase and the word 'ball' would be lengthened. In contrast, if the speaker had decided that the passive voice was required to convey his meaning properly, then the sentence would be 'The ball was slammed by Billy.' The processes that create the metrical grid would create a representation in which 'ball' had a much shorter duration, and 'Billy' would be the locus of phrase-final lengthening.

Another question related to the creation of prosody is what determines whether a speaker simply extends a word's duration or also chooses to insert a pause. The basis for this choice is largely not under a speaker's conscious control. A word's position in the metrical grid determines the amount of time that each word (more technically, each syllable of each word) should occupy in the utterance. If a word that is subject to phrase-final lengthening is made up of phonemes that are fairly stretchable, then a pause might not be necessary. But if the grid mandates an amount of time that cannot be filled out because the word is less stretchable, then a pause will be used to fill up the time that remains. Thus, consider the sentences 'The table that is black goes in the hall' versus 'The table that is green goes in the hall.' The words 'black' and 'green' both occur in a phrase-final position (each is the last word of the sentence's subject) and so they will be lengthened (compared to the durations they might have in 'The green table goes in the hall' and 'The black table goes in the hall'). The word 'green' is much more stretchable than is the word 'black', and so 'green' is much less likely to be followed by a pause. The logic is that if a word is not stretchable then the interval mandated by the grid cannot be filled with syllable lengthening. A pause must then be used to fill up the time that remains.

CONCLUSION

Prosody refers to the regular sound characteristics associated with spoken, multiword utterances. The primary components of prosody are variations in stress, duration, and pitch. The focus of a sentence is the new information that a speaker adds to an ongoing conversation with his or her linguistic contribution. When people speak, they make prosodic choices at virtually every stage of processing: semantic, syntactic, and word-level. These prosodic decisions then get implemented at the stage at which the speaker sends motor commands to the speech articulators.

Computational psycholinguistics seeks to build theories of human linguistic processes that take the form of working computational models. These models address processes ranging from word recognition to discourse comprehension, and produce behavior that constitutes predictions to be compared to human data.

INTRODUCTION

Computational psycholinguistics seeks to build theories of human linguistic processes that take the form of implemented computational models. These models are intended to explain how some psycholinguistic function is accomplished by a set of primitive computational processes. The models perform a psycholinguistic task and produce behavior that can be interpreted as a set of predictions to be compared to human data. As such, computational psycholinguistics is a paradigmatic example of cognitive modeling more generally. One problem with the label *computational psycholinguistics* is the implication that there is something that can be identified as *noncomputational* psycholinguistics. This is not presently the case: all psycholinguistic theories are, at some level, assertions about computational processes. Computational psycholinguistics is distinguished from other forms of cognitive modeling by its domain (not its techniques), and it is distinguished from other forms of psycholinguistic theorizing by its focus on producing functioning computational mechanisms that embody an explicit process model. The remainder of this article is devoted to reviewing the state of computational modeling in several of the major subfields of psycholinguistics.

MODELS OF LEXICAL PROCESSING

The most influential computational models in psycholinguistics have been those focused on word-level processes, in particular, spoken and visual word recognition. In fact, there are currently no major psycholinguistic theories of word recognition that do not take the form of a computational model. Competing theories are routinely tested by running the corresponding computational models to determine how well the models' behavior fits human data. At some level, there is significant theoretical convergence. All of the models of lexical processing are activation-based: lexical access is modeled as a dynamic process of modulating the activation of patterns of representation that encode information associated with specific lexical (or morphological) items. However, the models differ dramatically along many important architectural dimensions, such as the degree of top-down feedback and the nature of the computational principles determining the dynamic activation patterns.

Spoken Word Recognition

Models of spoken word recognition must satisfy a number of challenging functional and empirical constraints. These include: speech occurs in time, with no clear boundaries between words or phonemes, which may in fact overlap; there are effects of both left and right context on word recognition; lower-level phoneme identification may depend on higher-level lexical information; and there may be considerable noise in the environment (McClelland and Elman, 1986).

Current computational models of word recognition are extensions of ideas first put forward explicitly in the COHORT theory of speech perception (Marslen-Wilson and Tyler, 1980). The key principles in COHORT are that the initial sound of a word establishes a *cohort* or candidate set of possible words beginning with that sound, and this candidate set is incrementally narrowed down in real time as subsequent acoustic input arrives. Word recognition is achieved when the candidate set is narrowed to one, which may occur before the end of the word.

The TRACE model of McClelland and Elman (1986) provides an explicit computational realization of these basic ideas in COHORT, while addressing some of its most critical shortcomings. In particular, COHORT had no clear account of how word boundaries were identified in the continuous speech stream, and it assumed accurate bottom-up identification of phonemes. TRACE is an interactive-activation architecture with bidirectional excitatory connections between nodes representing acoustic features, phonemes, and words. Each time slice of input occupies a separate part of the input vector, and there are multiple copies of phoneme and word detectors centered over every three time slices. There are also inhibitory links within levels between mutually incompatible words or phonemes; thus, word and phoneme recognition is a competitive process. This competition and the distribution of multiple detectors across the network permits the model to recognize words without clear boundaries known in advance. The bidirectional nature of the within-level connections provides a way for the lexicon to directly influence the perception of lower-level phonemic and acoustic features.

TRACE has been used to account for a wide range of psycholinguistic data on word recognition, including the signature data originally used to motivate COHORT. Among these phenomena are: the effect of lexical context on phoneme recognition and its modulation by factors such as ambiguity; phonotactic rule effects on phoneme recognition, and their modulation by specific lexical items (phonotactic rules determine what sequences of phonemes are possible in a language); and the categorical nature of phoneme perception. TRACE was one of the prominent early successes of the PDP (parallel distributed processing) approach to modeling cognition and perception, and played a significant role in establishing the viability of the PDP paradigm.

TRACE has been challenged on both empirical and theoretical grounds, most notably by the Shortlist model of Norris (1994). A number of empirical studies have directly tested the assumption of top-down feedback in TRACE and yielded results more consistent with a purely bottom-up architecture in which phoneme recognition is autonomous and receives no feedback from lexical recognizers. For example, certain top-down lexical influences are dependent on using degraded stimuli, though TRACE should predict the effects in undegraded stimuli as well. Norris also argued that the TRACE architecture is implausible because it assumes the duplication of the entire network of lexical recognizers across multiple time slices. Shortlist is a purely bottom-up model that avoids the duplication of lexical recognizers by separating the process of generating candidate words (the 'shortlist') and the process of resolving identification via lexical competition.

Visual Word Recognition: Lexical Naming and Decision

Current prominent models of visual word recognition also take the form of computational models. One of the most influential of these models, the connectionist model of Seidenberg and McClelland (1989) (henceforth SM89), is a descendant of the McClelland and Rumelhart (1981) interactive activation model of word perception, which used localist word, letter, and feature units with hand-coded connections. SM89 builds on this earlier model but adopts distributed representations of both orthographic and phonological information. The model is a feedforward network with one hidden layer interposed between orthographic and phonological units. The connections between units were trained by back propagation on a word-naming task. The model accounts for several phenomena in word-naming, including differences among regular and exception words and differences in word-naming and lexical decision tasks. Because the model exhibits a gradual learning curve, it was also used to simulate the behavior of children acquiring word recognition skills.

One of the major debates in theories of word recognition is whether or not there is a single processing route from print to speech, or dual processing routes – separate lexical and nonlexical routes. The SM89 model is a clear example of a single-route architecture, and has come under sharp criticism from proponents of dual-route architectures. For example, Coltheart *et al*. (1993) note that the SM89 model actually performs more poorly on nonwords than humans do. Dual-route architectures are well suited to handing nonwords because the nonlexical route implements a general rule-based system that converts letter strings to strings of phonemes. Coltheart *et al*. also criticize the SM89 model for its inability to account for the dissociations evident in pure developmental surface dyslexia: normal nonword reading accuracy accompanied by gross impairments in reading exception words. Coltheart *et al*. offer a modular dual-route computational model, the Dual-Route Cascaded Model, which incorporates a learning algorithm for inducing the general pronunciation rules from examples (it was tested on the same letter-string/phone-string pairs

used by SM89). Although Coltheart *et al*. did not commit to the details of the lexical route, they suggest that something like the original McClelland and Rumelhart (1981) model may be an appropriate realization of that part of the word-naming system.

The debate surrounding dual-route and single-route architectures continues, with data from various forms of dyslexia playing an increasingly important role. The dual-route models have evolved to include explicit accounts of both reading aloud and lexical decision (Coltheart *et al*., 2001), and the connectionist models have evolved away from feedforward networks towards recurrent attractor networks that better handle generalization (Plaut *et al*., 1996).

Lexical Ambiguity Resolution: Processing Words in Context

One of the key lessons learned from several decades of attempting to program computers to process natural language is that massive local ambiguity is pervasive at all levels of linguistic representation. This is clearly evident in lexical processing, in which individual words are often associated with multiple syntactic and semantic senses, some mutually inconsistent, some partially inconsistent. Many of the theoretical themes noted above in word recognition are important in ambiguity resolution as well, in particular, the degree of autonomy or interaction present in initial lexical access. Differing positions on this issue distinguish the major theories of ambiguity resolution: *selective access models*, most closely associated with interactive theories, assume that contextual information provides direct top-down influence on initial sense activation; *ordered access models* assume that different senses are accessed in order of frequency of use; *exhaustive access* models, most closely associated with modular theories, assume that all senses are autonomously and exhaustively accessed in parallel; and *hybrid* models assume some combined effects of context and frequency.

In contrast to word recognition, the major theories of lexical ambiguity resolution are not strongly identified with specific implemented computational models (for reasons discussed below). However, there have been attempts to build detailed comprehensive computational models. One of the most successful is Kawamoto's (1993) recurrent connectionist model of ambiguity resolution. In this model, each lexical entry is represented by a pattern of activity over a 216-bit vector divided into separate subvectors representing a word's spelling, pronunciation, part of speech, and meaning. The network is trained with a simple error-correction algorithm by presenting it with the lexical patterns to be learned. The result is that these patterns become *attractors* in the 216-dimensional representational space. The network is tested by presenting it with just *part* of a lexical entry (e.g. its spelling pattern) and noting how long various parts of the network take to settle into a coherent pattern corresponding to a particular lexical entry. Kawomoto used these settling times to predict reading times, lexical decision times, and semantic access times. The model accounts for a wide range of phenomena, including frequency effects on processing of unambiguous and ambiguous words, context interactions with frequency, and the effect of task on the relative difficulty of processing ambiguous versus unambiguous words.

MODELS OF COMPREHENSION

Language comprehension involves more than the identification and disambiguation of words; the meanings of these parts must be pieced together in real time to yield the meanings of the sentences and the discourse. The state-of-the-art in computational linguistics and artificial intelligence places an upper bound on the field's ability to develop functional theories of comprehension processes. The best understood of these processes computationally and psychologically is syntactic parsing, the incremental assignment of grammatical structure to a string of words. Syntactic parsing is often assumed (though not universally) to be a necessary precursor to assigning a semantic interpretation.

Parsing

The major computational problem in parsing is how to handle local ambiguity. In fact, the prominent theories of sentence processing are actually theories of ambiguity resolution, and are distinguished by the positions they take on the key architectural questions surrounding ambiguity resolution. These include: are multiple structures computed and maintained in parallel at ambiguous points, or does the parser commit to a single structure immediately? What determines what structures the parser prefers when faced with ambiguity (e.g. referential discourse context, structural complexity, frequency of usage)? How do syntactic and lexical ambiguity resolution interact?

Two of the most influential models of sentence processing take opposing positions on most of these issues (though many of the issues are orthogonal).

Frazier's (1987) Garden Path Model asserts that the parser computes and pursues a single structure at ambiguous points, and that this initial structure is computed on the basis of general phrase structure rules without appeal to frequency, context, or detailed lexical information. Instead, structural simplicity is the principle that determines which structure is pursued in the case of local ambiguity. In contrast, the Constraint-based Lexicalist approach (MacDonald *et al*., 1994) claims that parsing is a constraint-satisfaction process that uses multiple information sources (or constraints), including context and detailed lexical information, without special architectural priority given to any particular constraint.

In sharp contrast to theories of word recognition, the dominant theories of sentence processing have not been strongly identified with specific computational models. (For example, the Garden Path Model was not implemented until 17 years after it was introduced (Spivey and Tanenhaus, 1998).) Among the earliest influential computational models were Marcus's (1980) wait-and-see parser, and the Wanner and Maratsos (1978) augmented transition network (ATN) grammar, which briefly contended with the Garden Path Model as a framework for understanding ambiguity resolution. Nevertheless, implemented computational models of sentence processing largely dropped from the scene in the 1980s.

Understanding why this happened will help place current parsing models in context. First, the early success of the Garden Path Model and the rise of modularity as a central theoretical theme in cognitive science jointly led the field to focus on modularity as the key architectural issue in sentence processing, and on ambiguity resolution as the key phenomenon providing insight into that issue. Second, Minimal Attachment is an extremely simple and practical theory – it can be stated in a few sentences and easily used to derive predictions cross-linguistically (once the underlying syntactic structures have been agreed upon). Computational models offered little advantage over such a theory, given this relatively narrow empirical and theoretical focus.

Two developments in the field are now leading researchers to develop more computational models. One is the need to provide more comprehensive, integrated accounts of sentence processing. Modularity is but one of several important architectural issues (Lewis, 2000), and computational modeling provides a way to develop and test interactions among components in a more functionally complete architecture. For example, computational models figure prominently among recent attempts to provide integrated accounts of both garden-path effects and working memory complexity effects in unambiguous constructions (Gibson, 1998; Lewis, 2000; Vosse and Kempen, 2000). Computational modeling also provides a way to import theoretical constraints from other areas of cognitive psychology, as in the Just and Carpenter (1992) working memory-constrained model.

A second development leading to more computational models is the rise of the constraint-based theories of sentence processing noted above. While these theories were initially proposed without associated computational models, it has become clear that the nature of these theories demands that they be formulated and tested as precise computational models. Several activation-based/connectionist models (e.g. Spivey and Tanenhaus, 1998) have been developed in the constraint-based framework.

Unlike computational models of word-level processes, which are almost exclusively the domain of connectionism, current computational theories of sentence processing are a mix of symbolic, connectionist, probabilistic, and hybrid models. As a class, the symbolic models tend to account for more complex cross-linguistic data, such as phenomena in head-final languages (e.g. Konieczny *et al*., 1997; Sturt and Crocker, 1996). However, recent models based on recurrent networks are attempting to push connectionist models in the direction of handling more complex syntactic structures, including difficult center-embeddings (Christiansen and Chater, 1999; Tabor *et al*., 1998). Several hybrid models are also under development, which have the promise of combining some of the strengths of both approaches (Jurafsky, 1996; Just and Carpenter, 1992; Lewis, forthcoming; Stevenson, 1994; Vosse and Kempen, 2000).

Discourse Processing

Processing running discourses of sentences in a text or verbal exchanges between interlocutors requires keeping track of multiple related levels of information (including, at least, the linguistic structure of the utterances, the goals and intentions of the participants, and the content of what is being discussed). Several major discourse processing theories have long been associated with implemented computational models. These include the Centering theory of Grosz and colleagues (Grosz *et al*., 1995), which provides an explicit algorithm for keeping track of attentional shifts among discourse entities and binding referring expressions to

these entities. The theory makes predictions about preferential patterns of pronominal reference that have been tested in reading time experiments (Gordon *et al*., 1993).

Another influential model is the Construction-Integration (CI) architecture of Kintsch and colleagues (Kintsch, 1998). Comprehension in the CI architecture is an activation-based process that proceeds in two phases. The *construction* phase produces local sentence-level propositions using simple, context-independent rules. The *integration* phase uses a constraint satisfaction process to integrate the possibly incoherent set of local propositions into a coherent whole organized by higher-level macropropositions. Many of the CI model's predictions about anaphora resolution, word identification, and the generation and retrieval of macropropositions have been empirically confirmed (Kintsch, 1998).

MODELS OF PRODUCTION

The dominant psycholinguistic theories of production are now associated with implemented computational models. Most psycholinguistic theories of production focus on the final stages of production: producing an ordered set of phonemes corresponding to some (given) intended utterance. (In contrast, much work on production in computational linguistics and artificial intelligence is focused on the functionally more difficult processes of higher-order discourse and speech act planning.) The theoretical landscape is quite similar to theories of lexical processing: all the models are activation-based, but differ in their assumptions about the nature of interaction between independent levels of representation. Among the best-known models are those of Dell (Dell *et al*., 1997) and Levelt (Levelt *et al*., 1999), which take opposing positions along this dimension. The Dell model is an interactive-activation-based theory that takes an ordered set of word units as input and generates a string of phonemes. Most of the important phenomena accounted for by the model are speech errors, including perseverations (e.g. *beef needle soup*) and anticipations (e.g. *cuff of coffee*). Dell's model consists of a network of word units (lemmas) and phoneme units and bidirectional links between word units and their constituent phonemes. The signature phenomenon accounted for by the feedback from phonemes to words is the statistical overrepresentation of mixed errors, such as saying *rat* when the intention is *cat*. When the word node for *cat* is active, the phoneme segments /k/, /æ/, and /t/ are activated. The latter two segments then feed activation to *rat*, which may already be above baseline due to a semantic association.

The WEAVER++ model (Levelt *et al*., 1999) is also activation-based, but eliminates bidirectional connections. Processing is staged in strictly feedforward fashion, starting with conceptual preparation (not implemented), and proceeding to lexical selection, morphological and phonological encoding, phonetic encoding, and finally articulation. Unlike most other production theories, the WEAVER++ model accounts primarily for reaction time (RT) data, and was developed exclusively on the basis of RT data from simple production paradigms such as picture naming. However, Levelt and colleagues have also shown that the model can account for some speech errors as well, including those used to motivate the bidirectional connectivity in the strongly interactionist models.

MODELS OF ACQUISITION

With one prominent exception noted below, computational models have only recently begun to play an important role in theorizing about language acquisition. A fundamental difficulty facing the development of serious computational models of acquisition is that the input to such models must generally be a large corpus of utterances *in context*. Although large computer databases of naturally occurring text and speech are now readily available, such databases currently lack a component that nearly all acquisition theories assume is necessary: some representation of the context in which the utterance occurs. For this reason, much computational modeling of grammar acquisition is currently done using small-scale, artificially created grammars or lexicons, in small-scale, artificial domains (Feldman *et al*., 1996).

However, current speech and text databases are well suited to exploring *distributional* theories of acquisition. For example, certain kinds of lexical and syntactic information can be determined from purely distributional analyses (Cartwright and Brent, 1997). One important example is specific verb subcategorization frames, which play a critical role in all modern syntactic theories and sentence comprehension theories. Computational models of speech segmentation have also been developed that learn to identify word boundaries from exposure to continuous speech (Christiansen *et al*., 1998).

By far the most controversial and influential computational acquisition model is the Rumelhart and McClelland (1986) (henceforth RM86) connectionist model of the acquisition of the past tense form of English verbs. Past tense inflection

acquisition has served as a kind of *Drosophila* for research on the mechanisms underlying apparently rule-governed linguistic behavior, and lies at the center of a much broader debate on connectionism and language. The RM86 model was proposed as an alternative account to the traditional view that the past tense form of English verbs is formed by dual routes: an abstract rule that handles all regular forms by adding *–ed* to a stem, and a memory that contains a list of irregular exception words (such as *ran*). The connectionist model instead proposed a single processing route, implemented as a feedforward network with a single hidden layer, and no explicit representation of a rule. The network was trained on 460 pairs of root and inflected forms. The network reproduced the well-known U-shaped performance curve often taken as prima facie evidence for the formation of a general *–ed* rule: children initially do not make overgeneralization errors (e.g. saying *runned* for *ran*), but then go through a period of apparently over-applying the general rule, and finally recover to adult levels of performance. Crucially, the network also generalized and transferred appropriately to novel low-frequency verbs (e.g. the network correctly produced *wept* as the past tense of *weep*), capturing subregularities among the irregular words in the corpus.

Every aspect of this work has come under sharp criticism, including the content of the artificial database on which RM86 trained their original network, the empirical robustness of the U-shaped curve itself, and the use of connectionist architectures more generally as accounts of human linguistic and cognitive performance (Marcus, 1996; Pinker and Prince, 1988). Some of these criticisms have been addressed in revisions to the model (MacWhinney and Leinbach, 1991), but new empirical evidence from adult processing has also accumulated in favor of the dual-route view (Marslen-Wilson and Tyler, 1998).

CURRENT DIRECTIONS

A number of short-term and long-term theoretical directions are evident in this review. One overarching trend is clear: computational modeling is playing an increasingly important role in theorizing in all subfields of psycholinguistics. There are several reasons for this, all related to theoretical trends in psycholinguistics more generally. There are four trends in particular that are likely to continue in the near term. First, there is a gradual move towards providing more *integrated accounts* of multiple components of linguistic processing. For example, several computational models now combine theories of lexical ambiguity resolution and sentence processing, or ambiguity resolution and working memory (e.g. Kintsch, 1998). Second, there is an increasing move towards developing theories that are *jointly constrained by processing and acquisition data* (e.g. Seidenberg and McClelland, 1989). Accompanying this trend is a growing reliance on large machine-readable corpora to test models that have some role for linguistic experience. Third, theories of normal linguistic performance are increasingly constrained by *neuropsychological data* from patients with linguistic deficits due to brain damage. Computational models of intact performance can be 'lesioned' and tested against both normal and patient data (e.g. Plaut *et al*., 1996). Fourth, there is increasing convergence in all subfields of psycholinguistics towards *continuous activation-based* models of processing. These include parallel distributed processing approaches, but also many activation-based symbolic models.

There are also some emerging trends that will most likely play out over the longer term. These include increasing attempts to integrate psycholinguistic models with other process theories in cognitive psychology, such as detailed models of memory and skill, and increasing convergence with efforts in computational linguistics as both fields attempt to tackle functionally difficult areas such as word sense disambiguation and robust parsing. These latter efforts will naturally result in greater contact with linguistic theory. In particular, linguistic theories which prove to be important in the development of scalable and robust speech and natural language systems will be incorporated in psycholinguistic models that place a premium on functionality and scalability.

Reading and Writing

Introductory article

Alexander Pollatsek, University of Massachusetts, Amherst, Massachusetts, USA
Brett Miller, University of Massachusetts, Amherst, Massachusetts, USA

CONTENTS

Reading and writing are two important human activities in which language transmission is carried out through skilled visual processing and motor acts. Evidence suggests that reading, even for skilled readers, is essentially a word-by-word process, involving accessing the spoken language.

INTRODUCTION

In a speech on discoveries and inventions, Abraham Lincoln characterized writing as the greatest invention of mankind, as it allowed people to communicate over great distances in space and time – and, as a result, he thought that civilization and institutions such as democracy were not possible without reading. The focus in this article is on the 'lower-level' issues in reading and writing: how the transmission of language, which is biologically programmed to be in the form of speaking and listening, has been transformed into skilled visual processing and motor acts. Indeed, it's remarkable that the average skilled reader can easily read text at about 300–350 words a minute, or about twice the speed at which language is normally spoken, even though we are genetically programmed to hear language rather than read it.

WRITING SYSTEMS

The production of writing systems has been a very recent development in human evolution. Of course, when 'writing' first occurred depends to some extent on one's definition of a writing system. According to the Merriam and Webster dictionary, writing is 'the act or art of forming visible letters or characters'. This definition is ambiguous, in that it's not clear what the characters are supposed to represent. If we demand that 'writing' not only has to convey the essence of a spoken utterance, but convey it word by word, then the first unambiguous examples of a writing system (found in Mesopotamia) are from about 7,000 years ago.

Written languages have usually developed in a systematic fashion: from a pictorial representation of words (logography), to a system in which the characters represent syllables, and then to an alphabetic representational system which represents even smaller units of speech. In a logographic system, a visual symbol is used to represent a word (e.g. a drawing of a duck might represent a 'duck'). There are several problems with such a system. First is the problem of representing abstract nouns, articles, prepositions, or pronouns. Second is the difficulty of drawing recognizable characters, even if the word is a concrete noun. In fact, although such systems started out with many fairly recognizable 'characters', in most modern logographic systems the majority of the characters are quite abstract. The most widely used logographic writing system today is Chinese, and most non-Chinese readers would be quite unlikely to guess the meaning of all but a few characters. Actually, the characters in Chinese represent the smallest units of meaning (*morphemes*) rather than words. In English, words with affixes and compounds have two or more morphemes (e.g. de/code, ring/ing, re/view/er, cow/boy). A character in Chinese also reliably represents a spoken syllable. Japanese also employs logographic characters (*kanji*), that are derived from the Chinese system, but also has phonologically based characters (*kana*) as well.

Most modern writing systems are alphabetic, and have evolved from the Phoenician and Hebrew writing systems, which in turn evolved from systems that were logographic and syllabic. In alphabetic systems, an individual character does not convey meaning; instead it is a code that ideally represents the smallest unit of sound, the *phoneme.* In some languages, such as Spanish, the alphabetic code is quite regular (i.e. there are rules allowing

one to convert the letters to phonemes): once one knows the rules any written word can be correctly pronounced. English has probably the most irregular alphabetic writing system, having both strangely spelled words like 'island' and letter combinations that have no rules governing how they are pronounced (e.g. 'bough, dough, rough, through'). However, the relation between letters and phonemes is not a simple one even in regular alphabetic systems, because a letter doesn't always represent a single phoneme. For example, in Spanish, *ch* or *qu* represents a single consonant phoneme, and in English, *x* usually represents two phonemes (a 'ks' sound). Moreover, a letter can represent different phonemes depending on the context (e.g. in Latin American Spanish *c* has an 's' sound when it is before either *e* or *i*, but has a 'k' sound before the other letters). It is worth noting that in most Near Eastern languages that use some variant of the ancient Hebrew orthography (e.g. Hebrew and Arabic), most vowels are not represented at all. One has to figure most of them out from context. However, there is a 'training' form of the orthography in which the vowels are represented by little marks above the letters.

The direction of text and relevance of spacing and punctuation varies across languages. In all European languages, words (and sentences) are written from left to right. In contrast, most Near Eastern languages (e.g. Hebrew and Arabic) go from right to left on the page. Chinese, historically, has used several orders. The current order that is most prevalent is that the script is organized in columns that go from the top of the page to the bottom, and the columns are read from the right to the left of the page. The use of spacing also varies by language. In most alphabetic languages spacing indicates a word boundary, whereas there is no spacing in Chinese to represent words.

THE PROCESS OF EXTRACTING VISUAL INFORMATION FROM WRITTEN LANGUAGE

Obviously, a major component of reading is moving one's eyes through the text. Perhaps a bit less obvious is the fact that these eye movements are not continuous. In general, unless one's eyes are following a moving target, they move in discrete and very rapid movements (*saccades*) and then stay still for relatively long periods (*fixations*). Saccades in reading take on the order of 15–30 milliseconds (ms) (depending only on the length of the saccade) and fixations in reading are usually about 150–400 ms, although they can be shorter or longer than that. No meaningful information is picked up during the saccades in reading (or any normal viewing situation), so that reading is essentially a 'slide show' with the slides (fixations) coming four to five times a second. This pattern is similar to what the eyes do when one is viewing a photograph or a static scene. About 10–15 percent of all eye movements in typical reading situations are *regressions* (i.e. going back in the text). Many are short (just going back a word or two). (See Figure 1 for an illustration of a typical eye-movement pattern in reading a sentence.) As the text becomes more difficult, this difficulty is reflected in many eye-movement measures: the average duration of fixations increases, the average size of a forward saccade gets smaller, and the number of regressions increases.

Why are the eyes moving so continually during reading? The answer is that in order for the reader to be able to identify the words, they have to keep on moving across the text. As Figure 1 illustrates, not all words are fixated, but the field of vision in which detail can be extracted is fairly small, so that one has to be quite near a word in order to be able to read it. We know that the field of vision in reading is small from several perspectives. First, the density of photoreceptors in the retina of the eye gets dramatically sparser as one gets further away from the center of vision (the *fovea*) making it hard to see detail away from the center of vision. Second, a series of studies have shown conclusively that the area of the page in which readers extract useful information from the text is quite limited, extending at most two words from the word being fixated. This means that claims that there are 'speedreaders' – people who can read whole sentences or paragraphs in a single glance – are false.

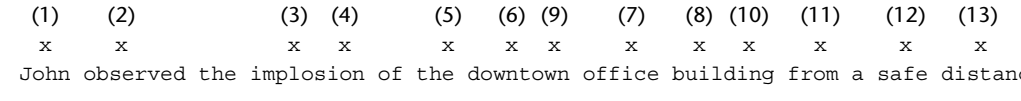

Figure 1. A typical eye-movement pattern when reading a sentence. Each *x* above the line indicates the location of a fixation on the line of text directly below the *x*, and the numbers in parentheses represent the order in which the fixations occurred. Note that although most words were fixated, not all were, and that some words were fixated twice. Also note that fixation 9 on 'downtown' was a *regression*, as the prior fixation had been on 'building'.

These studies used the *moving window* technique. Although we will mainly discuss studies in English, similar studies done with other writing systems indicate that the results are similar for all writing systems and languages. In these studies, people view text on a computer monitor while their eye movements are monitored by a precise system that knows what letter they are fixating (i.e. what letter their eyes are pointing to) and can measure the eye position with about 1 millisecond accuracy, so that the text can be changed very rapidly during each saccade. The reader sees normal text in a certain region around the fixation point (the *window*), but all the text outside the window is changed to something like random letters or 'x's. Regardless of whether the eyes move forward or backward through the text, the window will follow them and there will be normal text only in a restricted region around the fixation point. (See Figure 2 for an illustration of a moving window experiment.)

The major finding is that the window only has to extend from four letters to the left of fixation to 14 characters to the right of fixation in order for reading to be perfectly normal (i.e. both normal comprehension and normal speed). Conversely, if one presents random letters in a region that extends 14 characters to either side of fixation and normal text outside that region, reading is virtually impossible. Thus, not only do readers normally extract information in a relatively narrow window around where they are fixating, they have to. Moreover, cutting the window of normal text down somewhat from 14 letters doesn't prevent skilled reading. If it contains only the fixated word, reading speed is roughly 60 percent of normal reading speed for skilled readers, and if it contains the fixated word and the word to the right, reading speed is 90 percent of normal!

In summary, the acuity of the eyes limits the region of text from which meaningful information can be extracted to 14 characters, or about three words. Attentional patterns limit the region even more: virtually no information is extracted from the left of the fixated word or from other lines of text. There's nothing magic about right versus left, however. For Hebrew readers (Hebrew is read right to left) the asymmetry of the window is reversed, as their window went from 14 characters to the left of fixation to four characters to the right of fixation. (As Hebrew–English bilingual readers, when reading English, had windows that looked like those of other readers of English, the asymmetry of the window is clearly due to attentional factors.)

The data thus indicate that readers are moving their eyes through the text to read individual words. However, the agenda on each fixation is often a bit more than reading a single word:

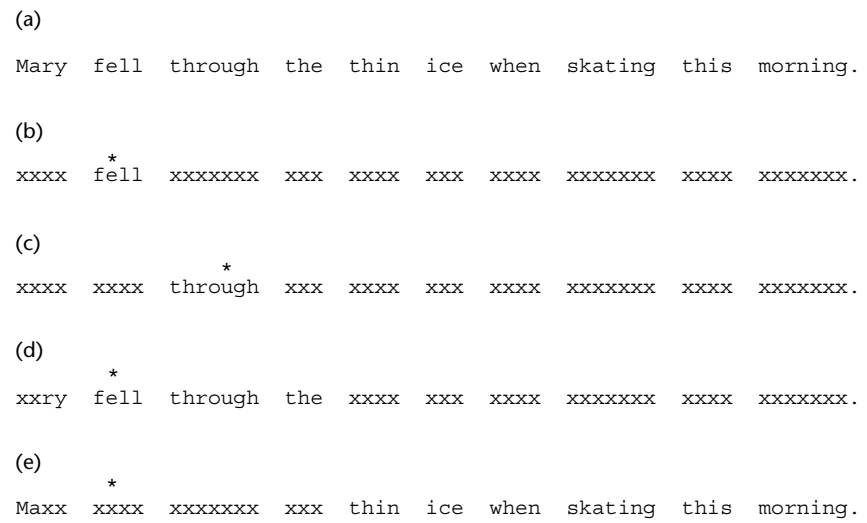

Figure 2. Illustration of the moving window technique. (a) Shows how a sentence would appear under normal viewing conditions. In (b) and (c), two successive fixations (indicated by the asterisks) of a *one-word* window condition are illustrated. (d) Illustrates a single fixation in a different window condition, where the reader sees four characters to the left of fixation and 14 characters to the right. (Here, reading is normal.) (e) Illustrates a single fixation in a condition where the area around the fovea is occluded (and reading is virtually impossible). The usual measure of the effect of the window is reading rate (comprehension is usually near perfect) along with finer measures such as average fixation time and number of fixations.

sometimes two words, and perhaps rarely three short words, can be read. The statistics in reading bear this out: *content words* (nouns, verbs, and adjectives) are fixated about 90 percent of the time and *function words* (articles, prepositions, and conjunctions) are fixated about 30 percent of the time in normal text. However, the processing on each fixation is even more complex than this. On many fixations, partial information about a word seen to the right of fixation is processed and used to help identify that word on the next fixation.

This use of partial information has been uncovered using the *boundary* paradigm, where only a single word in the text is changed as the eyes move. (See Figure 3 for an illustration of the boundary paradigm.) As in the figure, if 'steak' is the *target* word that belongs in the sentence, one of a number of possible *previews* (e.g. 'stone', 'stald', 'roast', 'rozcd', 'clasp', or 'dncbo') might appear in the target word location before that location is fixated. By the time the target location is fixated, the preview is replaced by the target and the target remains visible for the rest of the time. (Readers are totally unaware of the existence of the preview and are unaware that there are any text changes in these experiments.) A major finding is that when the preview (either a word or a nonword) shares

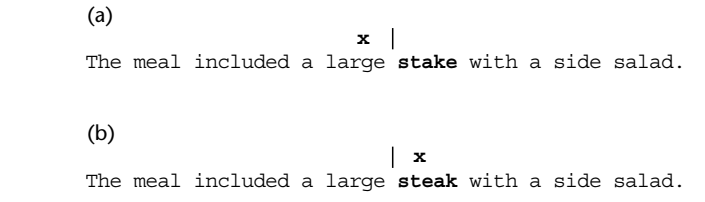

Figure 3. Illustration of the boundary technique. The critical word that is changed is marked in bold in the figure for illustrative purposes, but it is not so marked during the experiments. Before the reader's eyes cross the imaginary boundary (the boundary is represented here by a '|' and the fixation point by an **'x'**), a preview – another word or a nonword – appears in the target word location (see (a)). After the imaginary boundary has been crossed, the preview changes to the target word and remains as the target word for the rest of the time that the reader spends reading the sentence (see (b)). Other possible preview stimuli could be totally different words (e.g. 'clasp'), a visually similar word or nonword (e.g. 'stone', 'stald'), or a semantically similar word (e.g. 'roast'). Note that the preview and target always have the same number of letters. The usual measure of the effect of the preview is fixation time on the target word (and possibly fixation time on the following word or two as well). Also note that people are virtually never aware of the preview or the change.

several letters with the target, such as 'stone' or 'stald', the fixation time on the target word 'steak' is less than if the preview were something like 'round' or 'rozcd'. This suggests that people are extracting visual features from words before they fixate them. Yet other studies indicate that the features aren't really 'visual': one gets just as big a benefit from 'STONE' as a preview for 'steak' as when 'stone' is a preview for 'steak'. Thus, it appears that abstract information about letters (especially beginning letters) is extracted on one fixation that helps identify the word on the next fixation.

This raises the question of what other partial information about words is extracted from one fixation to help identify the word on the following fixation. One of the most surprising findings is that the meaning of the preview word is irrelevant. In the above example, a preview of 'roast' for 'steak' provides no benefit. In fact, for English–Spanish bilinguals, a preview that was a translation of the word fixated provided no benefit beyond what could be explained by letter overlap. Moreover, components of meaning (morphemes) are also largely irrelevant; 'cowxxx' is no better a preview for 'cowboy' than 'corxxx' is for 'corner'. However, the sound of the preview is relevant: a homophone (word that sounds the same) is a better preview for a target word than a word that is just as visually similar to the target but is not a homophone of it (e.g. 'stake' is a better preview of 'steak' than is 'stoke').

To summarize, although skilled readers read quite fast (over 300 words per minute), they do so by moving through the text fairly methodically. Reading isn't quite 'word by word' as not every word is fixated; some words are identified before they are fixated and are skipped. Moreover, the phenomenon of preview benefit indicates that words are often partially identified before they are fixated. However, the data indicate that people extract the information from virtually all words. Almost no words are merely 'guessed'.

The above discussion of previews indicates that the fixation time on a word is sensitive to the type of preview. In addition, the fixation time on a word is quite sensitive to many aspects of the text. Long words are fixated longer than shorter words, and less common words are fixated longer than more common words (even when they are equal in length). Moreover, when a word is highly predictable from the prior sentence or discourse context, it is both more likely to be skipped and will be fixated for a shorter period of time. As a result of these findings and others, it appears that the forward

movement of the eyes through the text is largely governed by identifying words. The signal to move the eyes forward is likely to be a decision that the fixated word has been identified sufficiently to be able to move on.

As indicated earlier, however, many eye movements in text are *regressions* or movements backwards to earlier parts of the text. These often signal processing difficulty. Regressions can appear because a word is misidentified, and as a result, the text becomes nonsensical. They have also been shown to occur in many situations where processing the sentence or discourse becomes difficult. They occur, for example, when the syntax is difficult or ambiguous (especially when one chooses the wrong syntactic interpretation of an ambiguous construction), or when it is unclear what concept a pronoun is referring to. Consider the sentence 'While the manager ate the man robbed the store.' This sentence is difficult because the reader may initially think the 'man' is the object that the manager ate, realize that this is implausible, and have to reanalyze the sentence. In fact, readers often make regressions to reread the earlier parts of such sentences. Although many of these regression effects are quite rapid (occurring half a second or so after the text that produces the difficulty has been read), they rarely occur immediately, in contrast to word frequency effects. It thus appears that most discourse processing lags a little behind word identification, and that the primary 'engine' driving the eyes forward is the identification of individual words. This makes sense: if we always kept fixating on a word until we were sure it made sense in context, it would slow reading down appreciably. Instead, a better strategy appears to be to move ahead throught the text by successfully identifying individual words (with the sentence processing lagging behind a little) and then regress when something doesn't make sense at the sentence or discourse level, especially because most such errors are caught quickly (after a word or two). Thus fixing them doesn't incur a high cost.

USE OF PHONOLOGICAL INFORMATION DURING READING

Perhaps the most contentious issue in silent reading is how the spoken language enters into the process. Many people believe that this happens only for beginning readers, and that skilled readers go directly from print to meaning. However, there is now a large body of literature that indicates that this is not the case and that even skilled readers rely quite a bit on getting to a *phonological* or sound-based code. It's important to realize that phonological coding (i.e. having an auditory image) and *subvocalizing* (actually using the speech apparatus to form the sounds very quietly) are different. It's easy to say the digits 1 to 9 aloud at a rapid rate while thinking of the sound of a word. (Try it.)

The above illustration makes plausible that sounds can be accessed without subvocalization, but is there evidence that people do so? There are several lines of evidence that indicate that sound coding is important. First are experiments with accessing individual words, which ask people to make a decision about whether a word is in a particular semantic category. For example, people will first see a category label, such as FOOD, followed by a word, such as MEAT, that they have to judge as being a member of the category or not. The finding is that skilled readers are not only slower at responding *no* to homophones of category members (e.g. MEET) than to visually similar controls (e.g. MELT), they also make 10–15 percent more errors on them! A smaller, but similar, effect has also been observed with words that could be homophones but are not. For example, people have difficulty in rejecting PILLOW–BEAD as being unrelated (where 'bead' could be a homophone of 'bed' if it were pronounced analogously to 'head'). The evidence for sound coding comes not only from such experiments with individual words, but in silent reading experiments as well. As indicated earlier, in a boundary experiment (see Figure 3), a homophone of the target word served as a better preview than a visually similar word. Thus, phonological coding enters into reading even before a word is fixated.

Moreover, there is little evidence, developmentally, that reading becomes less dependent on sound coding as readers become more proficient at reading. It has been argued that less skilled readers are more dependent on phonological coding because they tend to show bigger effects produced by sound coding. For example, when asked to judge whether two words are synonyms, people are slower in responding *no* to homonyms than to unrelated words, and furthermore, this interference effect is bigger, in absolute terms, for beginning readers. However, from another perspective, the size of the interference effect doesn't change developmentally, as the size of the interference effect is proportional to the absolute times in the task. This latter observation (and some related experiments) suggest that as readers become more skilled, the process becomes more automated and less accessible to consciousness rather than changing qualitatively.

Another indication of the importance of sound coding is that poor performance on two different kinds of tasks that tap phonological coding are quite reliable predictors of *dyslexia* (i.e. substantial difficulty in reading). One reliable predictor of reading difficulty is being slow in naming things. People who have difficulty are not only slow at naming 'verbal materials', such as numbers and letters, but they are also slow at naming nonverbal materials, such as line drawings of common objects or color patches. A second predictor of reading difficulty is difficulty in analyzing a word for its constituent *phonemes*. One example is that people having trouble reading will have difficulty with the phoneme deletion task (e.g. responding /at/ after hearing /bat/). Young children, who are pre-readers, or people who have no experience with an alphabetic language also have severe problems doing this task. However, the children who have difficulty with this task usually have no difficulty deleting syllables in an analogous 'language game'. Thus, their problem in the phoneme deletion task is not being able to 'hear' the units that the letters represent rather than some general inability to play 'linguistic games'. (Incidentally, it is largely a myth that dyslexics are people who see upside-down or backwards and confuse 'dog' with 'god'. Only a few people with reading difficulty seem to have these kinds of problems.)

STUDIES OF WRITING

Writing research has proven much more difficult to conduct than reading research. The major reason is probably that, in writing, the text is produced by the participant, whereas in reading, the researcher can generate the materials and thus can more easily manipulate the variables of interest. Although the sheer amount of research conducted in reading may be larger than for writing, there have been some interesting findings from the research on writing.

Similar to reading difficulties (*dyslexia*), there are people who have writing and/or spelling difficulties (*dysgraphia*). Dysgraphia can either occur developmentally or be the result of later brain injury. There are a tremendous variety of symptoms that dysgraphic individuals display. These symptoms frequently co-occur with other language-processing difficulties such as dyslexia and aphasia. Some of the problems displayed by dysgraphic individuals include, but are not limited to: misspelling text; slow, painstaking writing; and producing illegible text despite formal writing training. Individuals may also show lexical intrusions (using inappropriate words) when writing (e.g. spelling 'quell' as *kwell*). It is important to note that not all individuals display the same pattern of deficits; however, there are patterns of deficits that tend to occur together, yielding different classifications under the umbrella of dysgraphia.

One interesting type of dysgraphia is phonological dysgraphia. Individuals with this impairment do not have much difficulty writing words that they know, but when asked to spell nonwords or novel words, these individuals are unable to do so correctly. For example, if a teacher said *agog* in class, someone with phonological dysgraphia would often either spell it incorrectly or be completely 'stumped' and not write anything. The normal writer would have the sound code available for the word he or she had just heard, and should be able to generate a plausible spelling. However, individuals with phonological dysgraphia often either have difficulty in breaking this word into phonemes or in translating known phonemes into appropriate letters or letter combinations. This syndrome indicates that phonological processing is important for writing as well as for reading.

There is also interesting evidence from dysgraphia about the involvement of abstract (i.e. case- and font-independent) letter representations in writing as well as reading. On some level, it is obvious that such a level exists in normal writers – otherwise, it would be impossible to copy strings of random letters where one has to change them all from upper to lower case, or vice versa. However, the work with dysgraphia indicates that there is structure to this level of representation. In general, patients who have writing problems as a result of strokes or other brain injuries do not make random errors when they attempt to write from dictation. For example, these patients make many substitution errors (e.g. writing *bord* instead of *bird*), but these errors are far from random. They typically substitute a vowel for a vowel and a consonant for a consonant over 80 percent of the time, which is clearly well above chance. Thus, it seems clear that their abstract letter level of representation includes the vowel–consonant distinction, and is likely to include other letter properties as well, but falls short of an adequate representation for generating 'correct' (i.e. possible) spellings for the words.

SUMMARY

To conclude, we've learned a lot about reading and writing throughout the last century or so. Reading is not a magical process. Contrary to some popular beliefs, we have to encode words, more or less one

at a time, by looking quite close to them, if not directly at them. Moreover, even though it is often believed that skilled readers go directly from print to meaning, this is not so. Even skilled readers use internal sound codes when they read and people who find it difficult to access the sounds of words have difficulty reading. To some extent, this may partly explain why alphabetic systems are so common. That is, they code for the sounds of words in an efficient way, which makes them a natural coding system.

Second Language Acquisition

Introductory article

Alan Juffs, University of Pittsburgh, Pittsburgh, Pennsylvania, USA
Robert M DeKeyser, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

CONTENTS

Second language acquisition (SLA) involves the development of the knowledge of a complex system of sound, word, sentence structure, and meaning of any non-native language by children as well as adults; it also involves the acquisition of the ability to use that system appropriately in different social settings.

THE RELATION OF SECOND LANGUAGE ACQUISITION TO FIRST LANGUAGE ACQUISITION

The acquisition of first language (L1) phonology (sound structure) and morphosyntax (the rules of word formation and sentence formation) normally occurs rapidly, effortlessly, and without explicit instruction. By about age five, research suggests that acquisition of the basic linguistic system is largely complete. Many studies that are based on abstract theories of language structure have also shown that children possess knowledge of subtle properties of their first language that they could not have acquired by simply listening to the speech of their care-givers or by repeating only what they hear. Although children are sometimes told when they make mistakes with vocabulary, they rarely receive useful corrections about mistakes in word order and morphology.

These facts about L1 acquisition have led to a widely accepted theory that children's acquisition of their mother tongue is guided by innate principles, which linguists have called Universal Grammar (UG). It remains a matter of debate whether these innate principles are specific only to humans' capacity for language or whether they are related to more general learning mechanisms. In either case, UG can be thought of as a blueprint of – or a set of constraints on – what a possible human language is; in other words, UG is a theory of properties that all human languages share and which vary only slightly from one language to another. The task that children face in acquiring their native language is to match the language spoken around them (the 'input' in acquisition) with the blueprint they have been born with. Using this blueprint to filter and understand the input, they construct the grammar of the specific language they are acquiring without conscious reflection.

Other views of first language acquisition downplay the role of innate mechanisms and seek to account for acquisition by studying the nature of the input that children receive, as well as their abilities to derive generalizations from this input. Hence, while UG is widely accepted within the field of linguistics, in the wider field of cognitive science the existence of a UG separate from general cognition remains highly disputed.

Many researchers believe that the acquisition of a second language by adults involves some of the same abilities that are involved in L1 acquisition. Even those researchers who question whether UG is still available after puberty (i.e. researchers who believe in a critical period for UG) accept that some knowledge of universal constraints on human languages may be accessible through knowledge of the first language. However, second language acquisition (SLA) is also thought to involve many other factors and processes that are not evident in the acquisition of a mother tongue.

One of the most important of these factors is that most adults have some classroom instruction or at least some opportunity to reflect on the process of learning a second language (L2). (Some adults may acquire a second language simply by contact with speakers of another language, but even in this case it is unlikely that they never think about their learning experiences at all.) Second, the role of affect, attitude to learning in general, and to the culture of L2 speakers can have an influence on learning outcomes. Third, the role of language aptitude and general intelligence may play a more important role in SLA than in first language acquisition.

Finally, one of the most important differences between L1 and L2 acquisition is that the learners already have a complete linguistic system in place when they begin learning a second language.

THE ROLE OF FIRST LANGUAGE KNOWLEDGE

Background

The effects of the phonology and morphosyntax of the first language (L1) in SLA is known as 'transfer'. Transfer can both help and hinder second language development. Positive transfer occurs when principles that apply to the L1 can be readily applied to the second language, whereas negative transfer occurs when a structure or principle that applies in the L1 is incorrectly used as part of the L2 grammar. Transfer can affect all levels of the linguistic system from basic sound patterns to morphology, syntax, semantics, and social conventions of language use. Here we will focus on morphosyntax, the lexicon, and phonology.

Morphosyntax and the Lexicon

Researchers disagree substantially on the role of transfer in the acquisition of morphosyntax and the lexicon; two major positions will be briefly discussed.

The first position is that the L1 plays only a limited role in SLA. The basis for this claim is that speakers of different L1s sometimes show the same developmental patterns when they are learning a second language; in addition, it has been claimed that these patterns show some similarities to stages that are found in first language acquisition. For example, during the early stages of acquisition children learning English, whether as a first or a second language, omit the subjects of sentences, they acquire verbal agreement morphology later than other morphemes, and they learn how to ask questions and negate sentences in somewhat similar developmental stages.

Furthermore, learners make some errors that cannot be traced back to the first language influence at all, but to other kinds of learning 'strategies'. These strategies include deliberate avoidance of a difficult structure or the use of a simple L2 structure to communicate an idea that is correctly expressed with a more complex structure. Finally, some learners do not use L1 forms to express certain meanings because they believe they are unlikely to have the same meaning or use in the L2. One example is the transfer of idiomatic meanings of words from L1 to L2. For instance, in addition to its basic meaning, the word 'eye' can also refer to the hole at the top of a needle or the sprout on a potato in both English and Dutch. Nevertheless, it has been reported that Dutch-speaking learners of English are reluctant to use the word 'eye' to refer to these non-basic concepts when speaking English.

In contrast, other researchers have claimed that L1 transfer has a very important role to play in SLA. Some researchers claim that the beginning point of second language acquisition is in fact the whole of first language grammar, minus the sound representation of vocabulary items. The evidence for this claim is that at the very early stages, learners appear to attach words from the second language (L2) to what seem to be L1 sentence patterns. Only later do they begin to adopt the syntactic patterns of the L2.

In addition, when learners fail to learn a property of the second language the cause can often be traced to the fact that the L1 allows consistently more options than the L2 where that property is concerned. For example, in English one can say 'John gave a book to Mary' or 'John gave Mary a book'; in French, the second word order is not possible, and so one can say that French is a subset of English in this case. As a result of this wider range of structures, English-speaking learners of French have difficulty in learning that French does not allow the equivalent of 'John gave Mary a book'. This relationship between languages has implications for instruction that are discussed below.

Phonology

A 'foreign accent' is perhaps the most easily identifiable characteristic of the adult second language learner; indeed, it is sometimes possible to identify the first language of the learner based on his or her accent. It is therefore clear that the sound system of the first language has an effect on that of the developing second language system. L1 influence can be detected in the pronunciation of individual sounds, in syllable structure, and in intonation. However, L1 phonology does not transfer wholesale and the severity of phonological transfer may be predicted on the basis of subtle differences in the underlying sound systems, not just on the basis of whether the first language has the same sounds as the second language.

For example, it is well known that Japanese-speaking learners of English as a second language have difficulty in distinguishing between the sounds [l] and [r] in English, as in the words

'lock' and 'rock'. It was thought that the source of this problem is that Japanese lacks the sounds /l/ and /r/, but instead has one single sound which is close to both, but not the same as either one.

While this explanation may be a simple one, it may not in fact be the best or correct one. Modern theories of phonology propose that sounds can be broken down into subparts that represent the separate, but coordinated and simultaneous, movements of the vocal cords, tongue, and other parts of the mouth. Research suggests that the source of difficulty is the construction of the abstract sound system based on these articulatory movements, rather than the presence or absence of individual sounds in different languages. For example, English only has lip-rounding with vowels that are produced at the back of the mouth; in contrast, French allows lip-rounding to occur with front, central, and back vowels. English-speaking learners of French must therefore learn to produce and distinguish vowels that have lip-rounding in more environments than English does. It is important for acquirers to incorporate the feature of 'lip-rounding' as a general distinguishing feature of *the whole vowel system* in French, not just individual sounds.

Second language learners also show influence from their L1 when they combine individual speech sounds into words and sentences. For example, some languages do not allow more than one consonant at the beginning of a word. In English the words 'plate' and 'floor' both begin with a sequence of two consonants ([p] and [f] followed by [l]), but the Korean language does not allow such sequences. As a result, Korean-speaking learners of English make syllabification errors in words with word-initial consonant sequences; they insert a weak vowel [ə] between the consonants, creating two syllables. Hence, they pronounce 'floor' as 'feloor' [fəlOr], and plate as 'pelate' [pəlejt]).

Summary

In general, the L1 grammar can be shown to influence the development of the L2 grammar, but it is clear that a direct relationship between a sound or syntactic structure in the L1 and the sound or syntactic structure in the L2 does not always exist.

PSYCHOLINGUISTIC ISSUES

Input Processing, Comprehension, and Acquisition

In order to understand a sentence when we read or listen to language, it is necessary to put the words into the structure of a sentence. This structure does not only reflect a strict word-by-word order, but it has a hierarchical as well as a linear organization. For example, in the sentence 'The man who was running tripped over', the verb 'tripped' is more important to the whole clause than the verb 'running'. This importance is represented in an abstract syntactic representation of the sentence. The process of putting words into a hierarchical structure is called *parsing*.

It is important to understand parsing because it may be an essential part of the acquisition mechanism and it may help develop better ways of helping students understand the L2. Unfortunately, we still have a poor grasp of how learners process the form and meaning of input in real time and how they use the results of that processing in constructing the developing grammar.

Methods used in first language sentence-processing research have only just begun to inform the issue of input processing in second language development. Computers and eye-tracking devices are being used to measure where learners pause in reading; from these pauses researchers can infer what the process of comprehension might be, or at what point in the sentence the learners are having problems. From results of studies like these we can gain insights into second language processing.

Results of preliminary L2 research suggest that second language learners, like native speakers, construct the sentence structure of a sentence that they are reading one word at a time, revising the structure they are building as they go along. They do not read seven or eight words and then decide on a possible structure for the group of words. It is becoming clear that the influence from first language parsing mechanisms, as well as the structure of the first language, can explain why even some advanced learners fail to process the second language efficiently.

Language Production in SLA

Speech production is a highly complex process that begins with conceptualization and ends with actually making the muscular movements to pronounce words in a sentence. Research suggests that conceptualization is not specific to a given language, but that all other components of the production process have some elements unique to that language. For instance, our conceptualization of properties of objects, such as 'wetness' and knowledge of the world (e.g. rain is wet, the sun is hot) may be separate from the individual words in each

language that represent concepts and properties. Evidence for the independence of concepts from language derives from at least two sources. Where nouns are concerned it seems that humans classify things into natural kinds, which have conceptual 'prototypes' for membership. For example, when asked whether *a penguin*, *a robin*, or *an ostrich* are good examples of 'BIRD', participants in studies tend to choose *robin*, even though penguins, robins, and ostriches all have wings. Hence, the word 'bird' appears to be a collection of properties rather than a list of discrete definitions which can be analyzed in a purely linguistic way. With verbs, all humans can presumably conceptualize the placement of things on a flat surface or the placement of something tightly over another item, for example a thimble on a finger, or a top on a pen. However, individual languages tend to encode these two concepts of placement in verbs in quite specific ways that are different from one another. Hence, linguistic systems are separate from conceptual systems, but they may of course influence one another.

It has been proposed that language learners are subject to processing constraints in their second language production and that these processing constraints dictate different stages in the acquisition of second language syntax. In this theory, language structures are available, but limited processing capacity constrains production. At the initial stages, the claim is that learners have a basic word order strategy and that they are unable to reorder words during the production process. Subsequently, they are able to add material to the beginning or end of a sentence, and later are able to insert material into the basic sentence patterns of their second language. Current revisions of this theory propose that processing constraints limit the ability to match the syntactic properties of one part of a sentence with another part of the sentence. Sentences that require minimal matching of parts, with only a small number of words between the parts, will be easiest to produce. For example, the agreement between a subject and a verb is easiest when the subject is right next to the verb. As language develops, learners acquire abstract properties of words (e.g. grammatical gender, tense) and become capable of matching these abstract properties with those of another word at increasing 'distances'. These distances are defined as the boundaries between phrases and clauses in a sentence.

Summary

Second language processing and production research is still very much in its infancy. A great deal more work remains to be carried out on the interaction of memory constraints, processing, and developing grammars.

IMPLICIT AND EXPLICIT LEARNING

Psychological Background

It was noted above that second language learners may still have access to some principles that guide first language acquisition, but that they also use conscious strategies. This distinction is relevant to the difference between implicit and explicit learning. While many definitions of implicit learning (IL) exist, the one that is used most commonly in the field of SLA and in related work in cognitive psychology is the following: a process whereby complex information about a set of stimuli is acquired independently of the learner's awareness of either the acquisition process or the resulting knowledge. Explicit learning is the opposite: learning with awareness of the learning that is taking place and of the resulting knowledge. This distinction is the focus of a large, complex, and controversial body of research in cognitive psychology. It is also central to much contemporary thinking about SLA, because one's views on this distinction determine in large part both how one understands the psychology of SLA and how one thinks second/foreign languages should be learned and taught.

The psychological research on IL that is most directly relevant to SLA deals with artificial grammars. In such experiments people are shown large numbers of strings of letters; these strings follow certain patterns ('rules') that constitute a system ('grammar'). The participants in these experiments are never told that there is a system of rules underlying the strings they see, yet they are able, to some extent, to classify new strings into two groups: those that follow the pattern of the previous strings and those that do not. This seems to be evidence of implicit learning: even though people have not thought about the patterns, and even though they cannot say what the patterns are, their classification of new strings shows that, at some level, they have knowledge of the underlying patterns. It is controversial, however, to what extent learning can be both implicit and abstract at the same time. Many researchers claim that learning in adults can be implicit, but that it will then be limited to fairly concrete patterns. They also believe that learning can be abstract, but that it will then be explicit, involving awareness/consciousness of what is learned.

Empirical Research on SLA

While young children clearly learn virtually all of their native language implicitly, the situation in adults is less obvious. Clearly, many adult immigrants eventually learn to communicate well in the language of their new country, without taking classes in the language or even reflecting much on its structure. On the other hand, many people have acquired much explicit knowledge about an L2 in school (in the sense that they can tell you how verbs are conjugated, or how gender agreement between nouns and adjectives or articles work), but they cannot speak the language fluently at all. These two facts together clearly illustrate the big difference between implicit and explicit knowledge. Some educators have concluded from these facts that successful learning of a language, even in adults, *requires* implicit rather than explicit learning. Recent research of various kinds, however, casts doubt on that reasoning.

First, research on naturalistic language acquisition (outside a school context) has shown that untutored adult immigrants, while learning to communicate well, often do so through an extremely rudimentary grammatical system, even after many years in their new country, and that even those who seem to speak perfectly grammatically have intuitions about grammaticality that rarely if ever match those of native speakers.

Second, research in L2 classrooms has shown that, at least for certain elements of grammar, students need explicit teaching of grammar and error correction. This is especially the case when the second language offers fewer options than the first language (e.g. about where in the sentence to put an adverb or about how to form a question). While it is easy to notice that the second language has forms or structures that do not exist in the L1, it is impossible to notice the absence in the L2 of one of the possibilities that exist in the L1. Thus explicit teaching is required to make students aware that certain L1 options do not exist in the L2.

Third, research under laboratory conditions (with miniature linguistic systems or very restricted parts of an existing language), often through computerized instruction, has shown that explicit teaching and practising of rules is far superior to mere exposure to relevant examples without explanation of structure, even when that exposure is very extensive (thousands of examples per rule). Only when the rules are very complex or fuzzy are the rules of no help; there might even be a slight advantage for IL in such a case.

In summary, while IL of many elements of an L2 by adults is possible, and while many adults can learn the whole set of abstract grammar rules of an L2 well, it is very doubtful that any adult can successfully learn the whole set of L2 grammar rules implicitly. This conclusion is very reminiscent, of course, of the research in cognitive psychology which suggests that adults can learn implicitly and can learn abstract patterns, but not both at the same time. It also explains the traces of nonnativeness in the syntax of untutored immigrants, even those who are able to get their ideas across perfectly.

Implications for Learning and Teaching of an L2

The history of L2 teaching has shown a repeated pendulum movement between emphasis on implicit and on explicit learning. Even over the last century alone, various teaching methods have embodied one extreme or the other.

Many people remember foreign language classes from their high school or college days in which they spent substantial amounts of time learning grammar rules and vocabulary items, and translating sentences, without ever practising the language for communication (the grammar-translation method), let alone learning anything implicitly through exposure to spoken or written text in the language. On the other hand, in more recent decades, some language teachers have tried to largely leave out grammar teaching and error correction, and to make their students absorb the structure of the L2 from large amounts of exposure to (usually adapted) input (the natural approach).

Most teaching practice, however, is somewhere in between. Audiolingual methodology, especially popular in the 1950s and 1960s, while emphasizing implicit absorption through endless drills, certainly did provide a highly systematic presentation of structures for practice, and not just adapted input. In many cases, in fact, grammar rules were explicitly presented before the extensive practice. Communicative language teaching, probably the most widespread methodology world-wide from the 1970s onwards, stresses communicative practice in comprehension and production, and varies in the extent to which rules are taught explicitly and practised systematically.

Variants of all these methods are still widely used in educational settings throughout the world. To some extent this variation reflects continuing debate in the language teaching profession

about the roles of implicit and explicit knowledge, but other, and often more important, factors are the training that the teacher received (sometimes decades earlier), the methodology endorsed by widely available textbooks, time constraints, and individual characteristics of the students. The last two factors deserve some further explanation. Time constraints often work against teaching methodologies that make sense from the point of view of research on second language acquisition because these methodologies are only efficient in the long run. Even those educators who are strong advocates of explicit grammar teaching and systematic practice will admit that this approach cannot lead to full proficiency after just a couple of years of study in high school or college, and that a less rigid approach with more time for authentic materials and fun communicative activities can seem more attractive under such conditions. Individual characteristics play a role in the sense that only students with a certain level of language learning aptitude (strongly related to verbal intelligence) can be expected to benefit maximally from a method that requires them to learn and use explicit rules. Therefore, in cases where all students of a certain age (are required to) take L2 classes, a teaching approach focused on the absorption of vocabulary and common phrases through extensive communicative use may be more efficient than an approach based on the systematic learning of explicitly taught rules. One should keep in mind, however, that while the more implicit methodologies may be the most *efficient* under those circumstances, they can by no means be maximally *effective* in bringing about high levels of both fluency and accuracy in spontaneous communication. Adults do need explicit learning to reach high levels of grammatical accuracy, as was argued above.

The need for explicit learning does not automatically entail the need for explicit teaching. Besides taking classes, adult learners have two other options for explicit learning: formal self-study by means of textbooks, phrasebooks, grammars, and dictionaries, and informal self-study by figuring out structural patterns in the input available from interaction with native speakers, recordings, or texts. From a psycholinguistic point of view, this institutional versus naturalistic distinction does not matter; in all these cases the learning process is explicit, because the learner is aware of both the learning process and the resulting knowledge of L2 structure.

Also, explicit learning does not require the use of extensive grammatical terminology or a traditional syllabus organized structure by structure. The crucial factor is whether the learner somehow pays attention to the structure of the language; in current professional literature this is often called 'focus on form'.

AUTOMATIZATION

Psychological Background

A behavior is said to be automatic when it requires little effort or attention, is carried out with high speed and a low error rate, and is hard to suppress consciously. In many areas of everyday life we engage in behaviors that have become automatic as a result of extensive practice: driving a car, typing a text, using our favorite piece of software. In all these cases our initial behavior may have been slow, effortful, prone to error, and very attention-demanding, but as a result of years of practice these behaviors have become 'second nature'. This gradual process of making a behavior more automatic through extensive practice is called automatization.

Some psychologists conceive of this process as the creation and fine-tuning of highly specialized rules for behavior. These are called production rules; they take the form 'if X and Y is the case, then do Z', and are created when people repeatedly engage in the relevant behavior while all the relevant knowledge is easily accessible in long-term memory. This stage of rule creation (often called proceduralization or production compilation) is followed by a long period of automatization in a more narrow sense. The latter involves the gradual decrease in reaction time and error rate that follows from extensive practice of these production rules. The reason why automatic behavior is so efficient is that these highly specific behavioral rules do not require interaction with elements stored in various parts of long-term memory; they are ready-made 'chunks' of conditions and commands, which can be retrieved and carried out in a single step. Other psychologists see automatic behavior as the retrieval from long-term memory of complex instances of past experience, which serve as the perfect model for action in the present. They all agree, however, that the gradual process of automatization follows a specific learning curve, which is often referred to as 'the power law of practise', and which has been shown to apply to the acquisition of a wide variety of cognitive skills, from making cigars to writing computer programs.

Automatization in SLA

There is little detailed empirical research on automatization processes in SLA, but the available

research suggests that automatization of second language grammar rules follows the same patterns as in other cognitive domains and that this process must, at least in part, involve the increasingly efficient use of specialized production rules. There is also evidence from reaction time measurements that even highly proficient bilinguals tend to be somewhat faster at vocabulary retrieval in one language than in the other, which reflects the current view of psychologists that automatization always remains a matter of degree.

Even though limited in size and scope, this SLA research and the related work in cognitive psychology have two implications for language teaching. When practising an individual grammar point, learners should be repeatedly engaged in a communicative behavior that draws on that grammar point, while the relevant grammatical knowledge is easily accessible in their minds. This is a precondition for the formation of production rules, which can then be gradually automatized through further practice. From the point of view of the curriculum as a whole, the challenge for language teaching is to integrate systematic practice of linguistic structures with a gradual sequencing of communicative tasks that will ensure increased accuracy, fluency, and complexity of expression.

Second Language Learning and Instruction

Advanced article

Barbara Graves, University of Ottawa, Ottawa, Ontario, Canada

CONTENTS

Our understanding of language development and second-language learning has been narrowly conceived and has underestimated the interrelated and dialectical processes involved.

INTRODUCTION

Despite general agreement that reading, writing and speaking a second language involve much more than the mastery of vocabulary and syntax, little attention has been directed towards understanding the sociocultural contexts of learning and the discursive practices that occur in classrooms and communities. In particular researchers have neglected the agency, identity, and voice of second-language learners. In part, this has been the result of a research tradition that adheres to cognitively oriented theories to explain second-language learning. In order to investigate the engagement with a second language as contextual, and to explore connections among knowledge, agency and identity construction from the perspectives of the learners themselves, researchers have argued for a reformulation of theory to investigate what it means to become literate in a second language (Cummins, 1996; Hall, 1997; Rampton, 1997; Lantolf, 2000).

While research in second-language acquisition has been informed from many disciplinary traditions including linguistics, psychology, anthropology, sociology and education, it has also experienced several distinct research phases, each of which can be linked to a specific psychological learning theory. These theoretical orientations can be characterized as behavioral, cognitive and (most recently) sociocultural. Each has had specific consequences for the research and teaching of second languages.

THREE THEORETICAL ORIENTATIONS

The Behavioral Orientation

Beginning in the 1950s, the dominant learning model informing second-language research was based on behavioral learning theory, which understood learning as a series of stimulus–response associations. An important tenet of this approach was that stimulus–response connections that are repeated become strengthened, and so learning became the formation of learned habits. The teaching method associated with this perspective for second language was the audiolingual method which, in adherence to the theory, focused on drill, practice and rote memorization of grammar and syntactic structures. Theories of learning framed by behavioral perspectives supported a teaching model based on the transmission of information from the more knowledgeable person (the teacher) to the less knowledgeable (the learner). Under this model knowledge was acquired incrementally from the simple to the complex.

Although influential, the behavioral approach was challenged by cognitive theorists who argued that such approaches could not account for the generative properties of human learning. In linguistics, Chomsky successfully argued that repetition and imitation could not account for the generative and problem-solving capabilities of language learning in particular.

The Cognitive Orientation

Cognitive psychologists sought to understand cognitive functioning and to that end focused on the mind and mental processes, not simply on observable behaviors. Concepts of importance within this

approach relate to learning as information processing. In the 1960s cognitive research began to reveal the mind as an information processing device actively engaged in the generation, storage and retrieval of knowledge. With the focus on knowledge, its acquisition and use, much attention was paid to how knowledge was organized in memory. One of the most robust findings from this research pertains to the role of prior knowledge in the learning process. Repeatedly it was found that learning was more effective when it could be meaningfully associated by the learner with information previously learned. The mental processes studied included perception, attention, memory, reasoning and problem-solving. These processes were studied without considering context, and the goal was to uncover universal principles of human performance. Instructional applications associated with cognitive research provided learning materials and activities with which learners could actively construct their understanding through exploration and problem-solving.

The cognitive approach conceptualizes learning a second language as an individual, psychological process, in which the means to produce and understand a second language are to be found in the learner. Thus much of the research investigated psychological properties such as motivation, ability, attitude, and cognitive learning style in relation to language learning. Measures of language proficiency were correlated with identified learner traits, as successful language learners were compared with those less successful in order to identify the qualities that would account for their success. From this perspective language learners were often seen as 'deficient' in relation to their second-language knowledge. Language itself was viewed as a formal system organized as a hierarchy of processing levels including the phonological, lexicomorphological, syntactic, and pragmatic.

While the contribution from cognitive science research has been substantial, this approach is wanting since it does not account for the context of mental activities. In addition, much of the cognitive research agenda rested on assumptions entrenched in binary oppositions such as mind–body, cognition–emotion, individual–social, and recognition–interpretation, which restricted an examination of the dynamic interactions in human activities.

The Sociocultural Orientation

In order to investigate how second-language learners make meaning, build knowledge through discursive interactions, and develop identities in the process, researchers are turning increasingly to theoretical perspectives located within a constructivist, sociocultural framework. The sociocultural orientation challenges traditional assumptions about cognition and human nature, and replaces the binary oppositions that have structured our thinking and activities for so long with a theory of cognition that emphasizes the mutual constitutions of persons and the experienced world. The sociocultural orientation which embraces the concept of the mind mediated by language and the role of discourse in knowledge-building and identity construction, draws on the theoretical contributions of Vygotsky's sociocultural theory of human development (Vygotsky, 1978, 1986), Halliday's view of language as social semiotic (Halliday, 1993), and Bakhtin's theory of discourse and the self (Bakhtin, 1986). Within the cognitive science tradition, researchers interested in exploring the situated nature of cognitive activities have developed a theory of situated cognition that integrates aspects of cognitive science with anthropological and cultural traditions.

Sociocultural theory views learning as a situated activity acquired from meaningful participation in specific communities. From this perspective, learners construct knowledge in relational networks which emerge from the interactions of people and activity contexts. Knowledge and inquiry processes are thus considered to be social activities, and learning of all kinds is mediated by cultural artifacts and resources, both symbolic (e.g. language, and numeracy systems) and material (e.g. computers). This shifts the traditional view of learning from the acquisition of something to a formulation of learning as participatory. In this way, learning in classrooms is viewed as a set of social practices which are learned by participants and understood through participation in language and multiple activities in specific contexts. This has led to classroom practices that provide learners with more opportunities for communicative interaction and discussion.

While Vygotsky writes of mediational means including both material and symbolic resources (Vygotsky, 1986), he focused much of his empirical research specifically on the examination of the role of language as a central mechanism of learning. Similarly to Vygotsky Bakhtin (1986) wrote about the individual's appropriation of language experienced in a world mediated by social texts, and his theory – which examines how the self is formed in dialogic response to a social world – bridges the divide between the individual and the social self.

Bakhtin maintained that all spoken or written language is dialogical since it is always addressed to someone. In addition, it is always delivered from a particular viewpoint. Taken together, these theoretical perspectives create a valuable explanatory framework for examining how learning takes place, how learners make meaning, what counts as knowledge, and whose knowledge and voices are recognized and valued.

DEVELOPMENT AND LEARNING

Traditionally, development and learning have been treated as occurring independently of one another, but sociocultural theorists see them as integral parts of a dynamic process. In particular, Vygotsky's theory of human development maintains that complex psychological actions such as reasoning and memory develop first in social interaction with others and only later become part of an individual's psychology. Learning and development both occur as a function of participating in meaningful activities. The sources of knowledge are from other participants as well as the mediational means which are part of the activities. Vygotsky formulated these views in terms of the zone of proximal development (ZPD), which he understood as

> the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers (Vygotsky, 1978, p. 86).

Simply stated, what a learner can do today with the help of another, a learner may do tomorrow independently. Because the individual and the social worlds are mutually constitutive of each other, transformation of the learner also involves transformation of the communities and of the joint activities. Activities situated in time and place may share features, but each activity remains unique owing to the participation of particular individuals with their own lived experiences and values. Consequently, outcomes of an activity cannot be completely specified in advance, nor can we predict with any certainty the the extent of the knowing as this ultimately depends on the characteristics of the learner as well as on the characteristics of the interaction.

NEW DIRECTIONS FOR SECOND-LANGUAGE RESEARCH

Since the 1980s there has been a substantial increase in second-language research focusing on pedagogical questions and the situated contexts in which they occur. Many learners first encounter a second language in the classroom, and it is important to understand the ways in which the discursive practices of teachers and learners create a view of what it means to learn a second language. The sociocultural perspective creates a valuable explanatory framework for examining the activities, voices, and multiple discourses in second-language classroom practice, as well as investigating how this community of practice is understood and valued by teachers and learners.

Agency and Biliteracy

A 3-year ethnographic research study of multilingual children as they learned English in a culturally diverse primary school in urban Montreal examined children's writing from an emic perspective (Maguire and Graves, 2002). This research challenged the epistemologies and research practices underlying many classroom-based studies which have ignored the possibility that bilingual children can be agents of cultural knowledge and self-monitoring in discursive activities. Beginning with pupils in the first grade, the researchers collected the journal writing entries of the children along with interview data. In the analysis of these data collected over 3 years, the children revealed competencies far beyond those normally assessed in many second-language classrooms. The children in these classrooms were given ample opportunity to express their views and to connect school to home, and the contribution that they brought to the classroom was highly valued. By grade three these multilingual writers were able to express their opinions, give reasons, explain, joke, and adopt a fictitious persona while writing in a third language. It appears that we have a great deal to learn about how much young learners are capable of when given this type of learning opportunity and validation.

The Good Language Learner

A qualitative study investigating the concept of the 'good' language learner from a sociocultural perspective (Norton and Toohey, 2000) concluded that the learners' successful second-language performance was not simply the result of personal abilities and strategies, but was related to the way they successfully negotiated access to the social networks in their respective learning communities and how this access transformed their identities as second-language learners. This research

suggests that it is necessary to understand what possibilities communities offer participants and how learners are able to partake in those activities. The researchers conclude that to understand what can be learned by whom, we need to understand what discursive practices and values are present in the culture and to explore how these interact with the lived experiences of the learners.

Creating Communities of Learners

A sociocultural investigation of two first-year high-school Spanish language classrooms (Hall, 1997) presents a comparative analysis of the communicative practices of the two classrooms. While the researcher found apparently similar resources in both contexts, the way in which these resources were understood and deployed created substantially different communities of learners. On one level the practices of 'reviewing homework' and 'practicing vocabulary' looked the same, but after detailed analysis of the turn-taking patterns and the ways in which students paid attention in the two settings, it became apparent that a different learner emerged in the two contexts. In addition, this was accompanied by a different understanding of what constitutes the appropriate use of Spanish in the classroom.

The findings from these studies in combination with the theoretical assumptions of sociocultural perspectives suggest that our understanding of language, development and second-language learning has been narrowly conceived and has seriously underestimated the interrelated and dialectical processes that connect many of these dimensions.

Semantics and Cognition

Intermediate article

Cliff Goddard, University of New England, Armidale, New South Wales, Australia
Anna Wierzbicka, Australian National University, Canberra, Australia

CONTENTS

The words and grammar of any language encode a vast array of prepackaged concepts, most of them complex and culture-related. Since language plays an important role in normal human cognition, the nature and extent of semantic variation across languages is a key research question for cognitive science.

INTRODUCTION

There are, broadly speaking, two traditions of semantics: the linguistic or conceptual tradition, which sees meaning as a cognitive phenomenon, and the logical or formal tradition, which sees meaning in terms of correspondences (truth-conditions) with an objective reality. This article adopts the linguistic or conceptual perspective.

Many aspects of human cognition, such as basic perception, attention, and visual processing, are substantially shared with other primates. Language is primarily relevant to higher-order cognitive processes which are largely, if not entirely, species-unique. Importantly, human cognition not only includes reasoning and information processing about physical reality, it also includes so-called social cognition (Tomasello, 1999), that is, assessing and reasoning about intentions, mental states, and social situations, and it is in this arena that language has some of its clearest cognitive effects. (*See* **Categorial Grammar and Formal Semantics**; **Social Cognition**)

The words and grammar of any language express 'prepackaged' concepts – concepts which are largely acquired in infancy and which are intersubjectively shared among members of the speech community. While higher-order thinking need not be conducted exclusively in terms of linguistic concepts, there can be no doubt that language plays a substantial role in normal cognition (including in categorization, planning, problem-solving, and memory). It is, therefore, a crucial fact that languages differ considerably in their conceptual semantics, in both lexicon and grammar. Of equal interest to cognitive science is the possibility that there may be language-universal conceptual categories embedded in human languages.

The relationship between semantics, culture, and cognition, often discussed under the rubric of 'linguistic relativity', has a long history in Western thought. Beginning in classical times it proceeds through John Locke, Johann Gottfried Herder, and Wilhelm von Humboldt into the early twentieth century, in which period Franz Boas, Edward Sapir, and Benjamin Lee Whorf are key names. The topic experienced a malaise from the 1950s until a revival of interest in the 1990s, coinciding with advances in contrastive psycholinguistics, cognitive linguistics, and cultural psychology. (*See* **Linguistic Relativity**)

MEANING AND MENTAL REPRESENTATION

Issues

The basic arguments for the involvement of language-specific semantics in cognitive processes are simple and compelling. In order to speak using the lexical categories and observing the grammatical distinctions of any language, speakers must attend to and manipulate a large number of language-specific conceptual distinctions. Thus, at the very least there must be a mode of cognitive processing (Dan Slobin's 'thinking for speaking'), which dovetails with linguistic concepts (Slobin, 1996). Viewed from another angle, any language can be thought of as a 'tool for thinking', inasmuch as its lexical and grammatical categories provide speakers with a vast array of ready-made concepts. The packaging of complex concepts into words enables intricate manipulations to be undertaken which would be impossible without conceptual 'chunking'. From the developmental perspective,

there is mounting evidence that language acquisition does not merely reflect conceptual development but contributes to it in complex ways. As a shared system of cultural representations, language is one of the main instruments by which children are socialized into the values, beliefs, and practices – including thinking practices – of their culture. (*See* **Semantics, Acquisition of**; **Language and Cognition**)

The intimate connection between language and cognition poses special conceptual and methodological problems. If one takes the view that language and cognition are in principle separable, then it seems obvious that linguistic and cognitive processes must be studied independently if one is to explore the relationship between them. Whorf's failure to observe this requirement is a standard critique of his celebrated work on the conceptual semantics of the Hopi language. An alternative, and perhaps ascendant, view rejects the assumption that higher-order cognition can be separated from language and studied independently, maintaining that language is both partially constitutive of higher-order cognition and epistemologically essential to any inquiry into it (Enfield, 2000). In any case, in order to describe and compare language-specific conceptual systems, no matter how divergent they may be, one needs a common measure, a *tertium comparationis*. The nature of any such conceptual *tertium comparationis* is a fundamental methodological issue.

Leading Current Approaches

Current approaches to semantic representation differ on several dimensions. At a theoretical level, one may distinguish propositional systems, whose fundamental units are discrete and word-like, from systems with scalar or image-like representations. Degree of abstraction is another theoretically interesting characteristic. One may also distinguish between systems which are partial or domain-specific, as opposed to those which are intended to be comprehensive, and between systems which have been devised from and tested only on English, as opposed to those which have been subject to significant cross-linguistic testing.

One point of agreement is that new models of mental representation are called for, beyond the binary feature analysis of traditional structural semantics and cognitive anthropology. There is wide agreement that many concepts incorporate 'script-like' structures which include stages arranged in a temporal sequence, and prototypical scenarios or schemas, also known as idealized cognitive models. Some approaches see metaphor and metonymy as fundamental to normal linguistic thinking. (*See* **Distinctive Feature Theory**; **Metaphor**)

Key features of two leading approaches can be summarized as follows. Both are propositional systems. From the point of view of their relevance to cognition, it is useful to highlight different conceptions about the fundamental semantic units – for these embody claims about fundamental elements of cognition. (*See* **Lexical Semantics**; **Cognitive Linguistics**)

The *Natural Semantic Metalanguage* (NSM) model has been developed over several decades by Anna Wierzbicka and colleagues (Wierzbicka, 1996; Goddard and Wierzbicka, 2002). It is based on the Leibnizian idea that a set of universal and indefinable concepts (semantic primes) can be discovered by intensive analysis of natural language. After numerous descriptive and analytical studies across a wide range of languages, the current NSM model includes about 60 concepts (see Table 1) which, it is claimed, constitute the semantic bedrock of human cognition and communication. Along with certain combinatorial properties, also held to be universal, semantic primes constitute a kind of mini-language of simple concepts in terms of which all other linguistic concepts can be explicated. A further key claim is that all languages can be expected to have concrete exponents – words, bound morphemes, or fixed expressions – for expressing the precise meanings of all the proposed semantic primes.

The NSM primes represent a rich set of hypotheses about many areas of conceptual representation. Although the NSM theory remains controversial, it has the longest and strongest track record in cross-linguistic semantics on the contemporary scene.

Conceptual Semantics (CS) has been developed primarily by Ray Jackendoff (1990), the major semantic theorist in Chomskyan generative grammar. Conceptual Semantics sees all possible word meanings (lexical concepts) as built up from a finite set of conceptual primitives and principles of combination, but unlike the NSM system, these elements and principles are held to be highly abstract. Doubting that any conceptual primitive could correspond to the meaning of an ordinary word, Jackendoff's system necessarily consists of an extensive formalism.

It is not feasible to list exhaustively CS semantic functions, but some impression of its character can be gained from example (1) below. This is intended to represent a rule of inference governing people's

thinking about rights and obligations (Jackendoff, 1999), namely, that if one person (X) has an obligation to another person (Z) and fails to fulfil it in a reasonable time, then Z has an 'existential right' to impose a roughly proportionate punishment. The primitive operators RT and OB are roughly equivalent to the English modals 'may' and 'must'. ACT stands for Action. VALUE maps two arguments, a Stimulus and an Experiencer, onto a Value – either positive or negative. The EXCH operator says that the action is in exchange for X's nonperformance.

$$\begin{aligned}&\text{HAVE } (X\alpha, \text{OB } (\text{ACT}_1\ (\alpha), \text{TO } Z)) \text{ at } t_1 \text{ and}\\&\text{NOT } \text{ACT}_1\ (X) \text{ in period from at } t_1 \text{ to } t_2\\&\quad \text{entails}\\&\text{HAVE}\\&\left(Z\beta, \text{RT}_{\text{Ex}}\left(\left[\begin{array}{l}\text{ACT}_2\ (\beta)\\ \lambda a\ (\text{VALUE } (a, X) = -)\\ \text{EXCH } (\text{NOT } \text{ACT}_1(X))\end{array}\right]\right)\right) \text{at } t_2\end{aligned} \tag{1}$$

CS has shown a tendency to evolve in the direction of increasing abstractness. For example, Jackendoff's (1990) treatment of motion employed conceptual functions such as [$_{\text{Path}}$TO (PLACE)], but within a few years the TO-function was further decomposed into a more abstract representation of features and functions. Relatively little cross-linguistic work has so far been conducted within the CS framework.

CONCEPTUAL CATEGORIES IN THE LEXICON

The cognitive influence of the lexicon is sometimes downplayed on the grounds that speakers may exercise a conscious choice over a range of lexical options. It is also said that although many lexical items, for example terms for kinship, material culture, and social institutions, designate culture-specific concepts, this fact is obvious and unlikely to influence sophisticated thinking. In reality, however, many culture-specific words are nonobvious, including words for emotions and sensations, for virtues and vices, for speech acts, and for social categories. Examples will be given shortly, but before that it is useful to review some other lexical matters of relevance to cognition.

Lexical elaboration designates the situation of a language having an impressively large number of words within a particular semantic domain, thereby providing the terminological scaffolding for fine conceptual discrimination within the domain. Lexical elaboration is often reflective of sociocultural facts. For example, compared with most indigenous cultures, European languages have a large stock of expressions to do with measuring and reckoning time (words such as *clock*, *calendar*, *date*, *second*, *minute*, *hour*, *week*, *Monday*, *Tuesday*, etc., *January*, *February*, etc.). Australian Aboriginal languages are celebrated for their profusion of kinship terms, amounting to a so-called algebra or calculus of kinship. Lexical elaboration is not necessarily apparent to native speakers.

Lexicalization pattern refers to a characteristic pattern of semantic packaging within an area of the lexicon. A well-known example concerns verbs of motion. Typically, English lexically encodes manner-of-motion (*run*, *walk*, *creep*, *crawl*, *limp*, *jump*, *fly*, *dash*, *climb*, *clamber*, etc.), but to further encode the path (direction, etc.) one needs to add

Table 1. Proposed NSM semantic primes

Substantives and relational substantives	I, YOU, SOMEONE, PEOPLE, SOMETHING(THING), BODY
	KIND OF, PART OF
Determiners	THIS, THE SAME, OTHER
Quantifiers	ONE, TWO, SOME, ALL, MANY/MUCH
Attributes	GOOD, BAD, BIG, SMALL
Intensifier	VERY
Mental predicates	THINK, KNOW, WANT, FEEL, SEE, HEAR
Speech	SAY, WORD, TRUE
Actions and events	DO, HAPPEN, MOVE
Existence and possession	THERE IS, HAVE
Life and death	LIVE, DIE
Logical concepts	NOT, MAYBE, BECAUSE, CAN, IF
Time	WHEN(TIME), NOW, BEFORE, AFTER, A LONG TIME, A SHORT TIME, FOR SOME TIME
Space	WHERE(PLACE), HERE, ABOVE, BELOW, FAR, NEAR, SIDE, INSIDE, TOUCH(CONTACT)
Augmentor	MORE
Similarity	LIKE

Source: after Goddard and Wierzbicka (2002).

an additional adverb (*away*, *out*, etc.) or prepositional phrase (*into the room*, etc.). Many languages follow the English pattern while many others – including Japanese, Turkish, Hebrew, and most of the Romance languages of Europe – follow the converse pattern. They have many verbs coding a path specification (akin to English words such as *enter*, *exit*, *ascend*, which have been borrowed from Romance languages), but to further express manner-of-motion one needs to add additional description. Evidence from a variety of measures – description tasks, composition, recall with visualization – suggests that preferred lexicalization pattern predisposes speakers to conceptualize differently motion events (Slobin, 2000). (*See* **Spatial Language**)

Cultural key words designate salient concepts which serve as conceptual focal points for an entire complex of culture-specific values, attitudes, and beliefs. Such terms are usually resistant to translation, but under close semantic study they can be extremely revealing. Two examples will suffice. The Russian word *sud'ba* (roughly 'fate', 'destiny') is used very widely, in very different registers, from colloquial speech to scholarly discourse to literary works. Corpus counts show that it is far more frequent than words such as 'fate' and 'destiny' are in English, being involved in numerous collocations, set phrases, and proverbs. It can be argued that the *sud'ba* concept encapsulates a characteristically Russian way of looking at human life – as an incomprehensible experience which, in the words of one classic source (Vladimir Solov'ev), is at the mercy of 'some overwhelming necessity to which we must submit'.

Scholars of Japan agree that *wa*, usually translated as 'social harmony', 'concord', 'peace', or 'unity', is one of the key Japanese social ideals. As one authority (Rohlen, 1974) has written: 'To achieve *wa* is certainly a major goal for any Japanese group, and it also is an essential ingredient in the attainment of other goals. In this regard, it is something like "love" in American popular culture, for it is both a major means to social improvement and an end in itself.' Thus, *wa* has clear implications of the value placed in Japanese culture on 'groupism' and, conversely, on something like 'anti-individualism'. Forged by collective effort, *wa* offers not only the comforting feeling of group unity and absence of conflict, but also the promise of group achievement.

Culture-specific concepts like *sud'ba* and *wa*, which are everyday 'common-sense' concepts in their home cultures, enable and promote patterns of thinking which would be otherwise impossible to carry out in a routine fashion.

Ethnopsychological categories hold particular interest for cognitive science, both because of their role within indigenous folk psychologies and because of their possible relevance to the agenda of cognitive science itself. This can be demonstrated with the aid of a thumbnail study in contrastive semantics – English *mind* versus Russian *duša*. The English word *mind* lacks precise equivalents in most of the world's languages, even European languages such as French and German. When Descartes argued for 'mind–body' dualism, for example, he was opposing the word *corps* 'body' to *âme*, a word with a significantly richer meaning than modern English *mind*. Similarly, Freud's primary concept was *die Seele* (roughly, 'soul') and to translate *Seele* as 'mind' is significantly to distort Freud's thinking. Arguably, the modern English concept of *mind* can be analyzed as in (2a) below (Wierzbicka, 1992). This explication reflects, firstly, the bifurcation of the person into two parts, the *mind* being the invisible and immaterial part, and secondly, the fact that *mind* is focused on thinking and knowing, rather than on feeling, wanting, or any other non-bodily processes. (To say that someone has 'a good mind' suggests that a person can *think* well, rather than, say, the emotional and moral qualities suggested by the phrase 'a good heart'.) (*See* **Cultural Psychology**)

Russian *duša*, variously rendered in English as 'soul', 'heart', and 'spirit', is a much broader concept. It is one of the leitmotifs of Russian literature and of everyday Russian conversation. Whereas *mind* is linked with rational functions, *duša* is linked, above all, with feelings, and especially those with a certain profundity or spiritual quality: the *duša* endows a person with moral capabilities. The *duša*, furthermore, is viewed as a kind of internal spiritual theater – a place where events happen which are in principle unknowable to outsiders. But though, as the proverb says, *čužaja duša potëmki* 'another person's *duša* is unfathomable', in Russian culture readiness to open and to 'pour out' one's *duša* is seen as important and good. Cognitive functions are not altogether excluded: one can know or say things *v duše* 'in one's heart' so long as these things are linked with values and feelings. The human will, too, is included in the domain of *duša*, as can be seen in the expression *duševnaja sila* 'spiritual strength, strength of character'. These and other considerations suggest a semantic structure as in (2b).

a. *mind* =
one of two parts of a person
people cannot see it, people cannot touch it
because of this part, a person can think
because of this part, a person can know things

b. *duša* (Russian) =
one of two parts of a person
people cannot see it, people cannot touch it
because of this part, many things can happen inside a person
these things can be good, these things can be bad
because of this part, a person can feel many things
other people cannot know what these things are if the person does not say it
it is good if a person wants someone else to know what these things are
because of this part, a person can be a good person (2)

A complex ethnopsychological concept such as *mind* or *duša* embodies an 'ethnotheory of the person'. Both ethnotheories are basically dualistic, but whereas the Russian lexicon opposes the body to a psychological entity which is unpredictable, emotional, spiritual, expressive, and moral, in English the basic dualism is focused on intellectual and rational aspects.

An important body of cross-linguistic semantic research (e.g. Harkins and Wierzbicka, 2001) concerns emotion terminology. One major finding is that despite the existence of cross-culturally recurrent themes, emotion lexemes differ significantly in their semantic structure across languages. Even salient basic-level categories of the English emotion lexicon, such as 'anger' and 'sadness', lack precise equivalents in many languages. For example, Yankunytjatjara (Central Australia) has three main translation equivalents for English *angry*, none of which is sufficiently general to serve as a precise equivalent: *pikaringanyi* is associated with active hostility, *mirpa<u>n</u>arinyi* with a sense of grievance, and *kuyaringanyi* with resentfulness. Another language, Malay, has a single basic word – *marah* – that is usually translated as 'angry' but really designates a more specific concept, closer in some ways to English 'offended'. It can be shown, furthermore, that many aspects of emotion terminology are significantly culture-related.

Clearly it would be invalid to assume that English lexical categories (be they ethnopsychological entities such as 'mind', or emotion categories such as 'anger' and 'sadness') transparently reflect psychological reality whereas those of other languages are misleading. One technique for minimizing the danger of such terminological ethnocentrism is to frame hypotheses about mental states and processes in terms of semantically prime meanings such as 'think', 'know', 'want', and 'feel', which do appear to have precise equivalents in all or most languages.

CONCEPTUAL CATEGORIES IN GRAMMAR

Theoretical linguistics in the second half of the twentieth century was largely preoccupied with the pursuit of abstract, innate universals of syntactic structure. Semantic aspects of grammar were of marginal interest until the last 15 years or so of the century when interest revived, largely on account of increasing evidence that lexical semantics plays an important explanatory role in syntax. Only a relatively few scholars in psycholinguistics and contrastive semantics have concentrated on investigating the conceptual content of grammar in a cross-linguistic and cultural perspective. Psycholinguistic research into correlations between grammar and cognitive processing has concentrated on domains which lend themselves to objective reference-based testing, such as categorization of objects and spatial orientation. Contrastive semantic analysis has concentrated on social and interpersonal domains. Some highly abbreviated examples follow.

Categorization in Yucatec Maya

John Lucy (1992) found significant differences in the way in which adult speakers of English and of Yucatec (a Mayan language of southeastern Mexico) process information about concrete objects, on a variety of sorting, similarity judgment, memory, and grouping tasks. English speakers show greater attention to number than Yucatec speakers and tend to classify by shape, while Yucatec speakers tend to classify by material composition. These differences correspond to what could be predicted on the basis of grammatical differences between the two languages. In English, number marking (via singular versus plural suffixes) is obligatory for most nouns, whereas in Yucatec it is often optional (*yàan pèek' té'elo'* 'there-is dog over-there' can be used regardless of the number of dogs). On the other hand, numeral classifier constructions, for example *ká'a-túul 'úulum* 'two-classifier turkey', are obligatory whenever a noun referent is quantified and force attention to referential categories.

English Interpersonal Causatives

Compared even with other European languages, English has a wealth of analytic causatives, that is, grammatical constructions which encode causative scenarios by means of an auxiliary verb. In many languages, the subtle differences between 'She had him do it', 'She made him do it', 'She got him to do it', and 'She let him do it' cannot be expressed in a compact grammatical form but would require several sentences of explanation. The *have*-causative, for example, implies some kind of hierarchical relationship such that the causee's readiness to take directions can be assumed; these directions, furthermore, do not have to be expressed directly but can be conveyed via another person. The *make*-causative implies that the causee does something unwillingly, in response to some kind of pressure (threats, parental authority, nagging, etc.). The causee's will is not completely overridden (compare 'She made him do it' and 'She forced him to do it'); rather, the implicit scenario is that the causee comes to realize that he or she has no choice but to act as the causer wants. The *get*-causative implies that the causee carries out the desired action willingly but only because the causer has done something to bring this about. Though these constructions are sometimes given labels such as 'coercive', 'manipulative', and so on, detailed analysis shows that the scenarios they express are too subtle to be accurately summed up in a single word.

'Fatalism' in Russian Grammar

The Russian language has a large family of impersonal dative-infinitive constructions which refer to inexplicable things that happen to people against their will or irrespective of their will (Wierzbicka, 1992). For example, the sentence *Ne budet tebe pasporta* 'There'll be no passport for you', which involves a dative pronoun, a negated existential verb, and a noun in the genitive case, conveys a subtle message that is not fully evident in the English translation. Essentially, a construction of this kind rules out the possibility of someone being able to obtain something beneficial and desired, implying at the same time that this is due to the fact that someone in a superior position does not want it to happen.

A second construction combines a human noun in dative case with a mental verb in the third person singular reflexive form; for example, *Segodnja mne vspomnilas' Praga – sady* 'Today I was reminded of Prague – of its gardens'. This depicts a mental event simply happening inside a person inexplicably, and, in a sense, irresistibly. The most important Russian expression of this sort is *xočetsja* lit. 'it wants itself to me', which suggests a spontaneous and involuntary desire. Also worthy of mention are impersonal modal predicates with dative subjects – extremely common in colloquial Russian – such as *neobxodimo* 'it is indispensable', *nel'zja* 'one may not', *nado* 'it is necessary', *nužno* 'it is necessary/required', *sleduet* 'one ought to', and *dolžno* 'one has to'; and the sundry infinitive and reflexive constructions conveying meanings related to helplessness, obligation, and necessity. Russian furnishes an excellent example of the grammatical elaboration of a semantic theme; in this case, the theme of *sud'ba* 'fate' (mentioned above) – of not being in control, of living in a world which is unknowable and which cannot be rationally controlled. Taken together, these constructions give the Russian language a cognitive profile which enables and facilitates habitual thinking in these terms.

CONCLUSION

This article has summarized evidence and arguments in support of the view that language-specific lexical and grammatical semantics significantly influences higher-order cognition. The issues remain controversial, however, largely due to lack of consensus about appropriate methodology for linguistic semantics, a field which remains underdeveloped in comparison with formal syntax. There are also differences of opinion as to what counts as acceptable evidence in conceptual analysis: intuition and appeal to usage, corpus studies of texts, controlled experiments. There is a pressing need for many more cross-linguistic studies, especially combining methods from linguistics and psycholinguistics, but a relative shortage of scholars with appropriately broad training who can carry these through. With the revival of interest in cognitive aspects of language and promising findings emerging from a number of research groups, it seems reasonable to expect significant progress in the near future.

Semantics and Pragmatics: Formal Approaches

Advanced article

Allan Ramsay, University of Manchester Institute of Science and Technology, Manchester, UK

CONTENTS

Formal languages can be used to throw light on how natural language relates to the world.

FORMAL APPROACHES

Language is used for getting other people to do things for you. You tell them what you believe and what your goals are, and if they are feeling helpful they do what they think you want. If it did not have this key function, it would be no more (and no less) than a highly complex set of rituals aimed at establishing social relationships – rather like the courtship displays of various bird species, or the cues that indicate dominance relationships within groups of primates. It would still be interesting, but it would hardly be the crucial facet of human behavior that it is. Just how interested would we be in the relationship between the active and passive voice, or in the effect of moving a phrase from its canonical position in a sentence to the left or right boundary, if these structural relationships did not convey *ideas*?

The fact that language can convey ideas (that utterances have meanings), then, is one of its most important properties. It is also one of the slipperiest to capture. Structural properties such as the syntactic and morphological characteristics of a language can be observed and described more or less objectively, by looking at corpora to see the patterns that occur and to explore hypotheses about patterns that might occur and don't, and by asking for native speaker judgments about what is and is not acceptable. Social consequences of particular linguistic behaviors can be judged, at least partly, by observing the correlation between linguistic choice and social interaction. But there is very little to *see* when someone assimilates an utterance: if I say '*I think Darwin's claim that people are descended from apes is nonsense*' and you say '*I've been saying that for years*', no observer can actually see what is going on in each of our heads.

To make matters worse, the only tool you have for describing meanings is language itself. There seems to be an unacceptable degree of circularity in Tarski's attempt to describe meaning by saying that the meaning of '*Snow is white*' is that snow is white. Saying that '*Snow is white*' means that the crystalline form of water uniformly reflects all wavelengths of visible light seems a bit better, as does saying that '*La neige est blanche*' means that snow is white. Nonetheless, it seems rather unsatisfactory to rely on natural language as the means by which we describe natural language meanings.

One way out of this impasse is to use a language for which we do have a clear independent notion of meaning. Giving the meaning of an English sentence by translating it into English seems rather unsatisfactory, whereas giving the meaning of a French sentence by translating it into English does appear to be helpful, at least for someone who understands English but not French. So perhaps translating into some other *kind* of language will enable us to make even further progress.

What other kinds of language are there? One family of languages that we might use is the family of mathematical languages, and especially the languages of formal logic. These are languages for which a tight relationship between the *form* of a sentence and the states of affairs that make it true has been very carefully mapped out. It is this relationship between form and content that earns these languages the title 'formal'. A formal logic specifies a relationship between what a sentence looks like, how it relates to the world, and what you can do with it.

There are many varieties of formal logic. In some cases this relationship between what a sentence

looks like, how it relates to the world (its semantics) and what you can do with it (its proof theory) is rather complex or unintuitive. So be it. Natural language is a remarkably expressive medium, allowing us to capture the most delicate nuances of human thought in very concise and elegant ways. A formal language with the same expressive power is therefore likely to be a complex object, since it will include devices for expressing the same nuances as the original natural language. The current article will consider some of these complexities, and will sketch the most prominent approaches to them.

SEMANTICS

A distinction is often drawn between sentence meaning and utterance meaning. Consider the sentence

The door is open. (1)

The meaning of this *as a sentence* is that some door that the speaker and hearer are familiar with is in a particular geometrical relation to the wall in which it is mounted. Its meaning as an utterance might be that the speaker wants the hearer to come into the room, it might be that the speaker wants the hearer to shut the door, it might be a warning that the tiger in the next room is about to come in and eat the hearer, it might be … The study of sentence meaning – semantics – deals with the relationship between the sequence of words the speaker chose and possible ways for the world to be. The study of utterance meaning – pragmatics – deals with the speaker's reasons for evoking a particular view of the world. The two are clearly interwoven, but it is generally assumed that any very detailed analysis of pragmatics will depend on a prior understanding of semantics. To put it bluntly, I will have difficulty understanding how '*The door's open*' can function as a request to close it if I don't understand the geometry of the situation that it conveys. The first task, then, is to extract an expression in some appropriate formal language which 'means the same as' the target natural language sentence.

Logical form

Such a paraphrase is often referred to as a logical form. If we can paraphrase natural language sentences into logical forms that have the same meaning, then we are in a position to see how they can be used to change other people's beliefs and affect their behavior. There are, however, two problems. The first is that we have to agree that the logical form does mean the same as the original, and the second is that we have to find some systematic way of finding logical forms.

The first of these seems to be the same circular problem as the one we had before. How can I be sure that $\forall X(man(X) \rightarrow mortal(X))$ means the same as '*All men are mortal*' when I don't know how to specify the meaning of '*All men are mortal*'?

Fortunately the languages of formal logic do provide a test which will at least tell us when our descriptions are *wrong*, namely we can see whether our logical forms enter into the right entailment relations. If someone says that all men are mortal and that Socrates is a man then they are committed to the claim that Socrates is mortal, and if they also say that no men are elephants then they are further committed to the claim that Socrates is not an elephant. Words and sentences enter into a web of entailment relationships: any theory of meaning must support the right entailments. A theory of meaning that allows me to say that Socrates is a man and that no men are elephants without committing me to the claim that Socrates is not an elephant is a poor theory of meaning. We can therefore exploit the fact that the languages of formal logic are designed to support entailment relations, so that if you produce a formal paraphrase in some logic you can see whether it supports the entailments that you believe the original natural language utterance supports. Different logics embody different notions of entailment, and it may well be that some of these are more appropriate when you are thinking about natural language semantics than others. But all of them support some such notion, and hence all of them make it possible to test semantic theories.

It seems, then, that it may be worth trying to obtain formal paraphrases of natural language sentences. The next task is to show how this can be done in a systematic way. The key to this lies in the principle of compositionality:

> The meaning of the whole is a function of the meaning of the parts and their mode of combination (Dowty *et al.*, 1981)

This principle underpins the entire tradition of formal semantics, from Frege's pioneering work through the crucial work of Montague to the current range of theories such as situation semantics (Barwise and Perry, 1983), discourse representation theory (Kamp, 1984; Kamp and Reyle, 1993), dynamic predicate logic (Groenendijk and Stokhof, 1991) and so on. The aim is to develop a *systematic* way of obtaining logical forms from natural

language sentences by assigning meanings to words and assigning rules for combining meanings to syntactic rules. If we can do this then we have an account of how sentences come to carry meanings, and we can test our account by seeing whether the formal paraphrases of related sentences have the same entailment relations as the original natural language forms.

The first substantial attempt to develop a compositional semantics of this kind was carried out by Richard Montague (1974), in a widely referenced (but seldom read) paper entitled *The proper treatment of quantification in ordinary English*, or PTQ for short. This paper, and the description of it given by Dowty *et al*. (1981), led to an explosion of interest, since it showed that for at least some parts of at least one language it was possible to obtain testable logical forms directly and systematically from the natural language text.

The key to Montague's work, and to most of what followed, was that if you have a hypothesis about what *might* be a good logical form for a given sentence, you can take it apart and identify those parts of the logical form that arise from the various syntactic constituents of the sentence. The notion of abstraction is crucial here. Consider sentences (2)–(4) and the corresponding (very simple) logical forms.

John loves Mary: *love*(*john*, *mary*) (2)

Bill loves Mary: *love*(*bill*, *mary*) (3)

Peter loves Mary: *love*(*peter*, *mary*) (4)

The English sentences share the property that they are each made up of a subject (which varies from case to case – '*John, Bill, Peter*') and a common VP – '*loves Mary*'. The logical forms share the property that they all fit the pattern *love* (-, *mary*), with the 'hole' being filled in by different individuals in each case. So if we knew how to 'fill holes' and we knew how to get '*loves Mary*' to mean *love* (-, *mary*) then we would be able to obtain *love* (*John, mary*) from '*John loves Mary*' and *love* (*ronald, mary*) from '*Ronald loves Mary*' and …

How can we make '*loves Mary*' mean *love* (-, *mary*)? Consider the VPs in (5)–(7), where each of them has a paraphrase which is analogous to the one for '*loves Mary*'.

loves Mary: *love*(-, *mary*) (5)

loves Susan: *love*(-, *susan*) (6)

loves Jane: *love*(-, *jane*) (7)

Again the English forms have something in common, namely that they are each made of an object, which varies from case to case, and a common verb: and the logical forms have something in common, namely that they fit the pattern *love* (-, -) with the *second* hole being filled by different items.

So what we have to do is to give lexical items meanings that may have holes in them, and then specify how we will fill in those holes. There are two standard approaches to this task, using function application or unification.

Function application

Montague suggested that the λ-calculus, which is a logic that was designed for talking about sets and properties, would provide a suitable framework for assembling meaning fragments into well-formed semantic expressions. The particular version of the λ-calculus that he used was carefully formulated to avoid the paradoxes of self-reference, such as the Liar Paradox – '*What I am now saying is untrue*', or '*I am lying*', which is true if it is false and false if it is true – and Russell's 'set of all sets that are not members of themselves', which is a member of itself if it isn't, and isn't a member of itself if it is. A number of alternative formulations have been developed and may also be used for this task (Turner, 1987; Bealer, 1982; Ramsay, 2001).

The λ-calculus provides a notation for talking about 'holes' and for specifying the order in which they will be filled. To take the example given previously, we could use the expression $\lambda A \lambda B love(B, A)$ to say that the word '*love*' denotes the relationship between two individuals where one loves the other, and that we are going to supply those individuals by supplying the person who is loved first and the person doing the loving second. The λ-variables indicate the holes that are to be filled. Since A is the outermost such variable, its hole is the one that will be filled first; that is, we are expecting to be told about the object before we get the subject (which is the order in which most grammars of English incorporate the arguments of the verb '*love*').

The process of supplying fillers for holes is then done by function application. If you have a λ-expression of the form $\lambda x P(x)$ and you apply it to some term t, written $(\lambda x\ P(x)).t$, then you can turn it into $P(t)$. The rule that licenses this, namely $(\lambda x P(x)).t \equiv P(t)$, is known as the Tarski biconditional (TB). You have to be careful how you use it when confronted with things like the Liar Paradox, but it does just what is needed for composing small fragments of meanings into larger ones. You just annotate your grammatical rules with appropriate expressions and apply the simplifications allowed

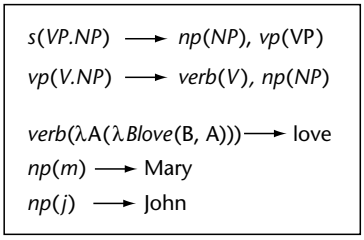

Figure 1. Simple grammar annotated with λ-calculus expressions.

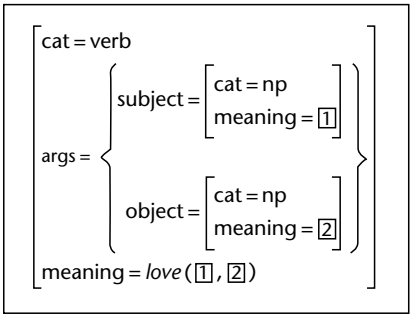

Figure 2. Lexical entry for '*love*'.

by TB. Figure 1 shows a tiny annotated grammar. If you apply this grammar to the sentence '*John loves Mary*' you will obtain the logical form $(\lambda A(\lambda Blove(B, A)).m).j$. The subformula $\lambda A(\lambda Blove(B, A)).m$ simplifies to $\lambda Blove(B, m)$, so the original simplifies to $\lambda Blove(B, m).j$, which in turn becomes $love(j, m)$ as required.

This works fine for very simple examples of the kind shown in Figure 1. It gets considerably more complicated as you try to cover more substantial fragments of the language, but it has remained popular because the rigorous work by logicians on the properties of the λ-calculus means that the interpretations that emerge are well-formed and well-understood, with even fragments and incomplete phrases being given sound interpretations.

Unification

An alternative way of filling in holes is to use unification for copying the meaning of one constituent into a hole in the meaning of another (Fenstad *et al*., 1987). Unification provides a way of saying that two items should be the same – if you refer to them using the same name they must be identical. It is widely used in grammar for imposing constraints such as number agreement between subject and verb, but it can also be used for specifying that the meaning of some fragment of an utterance plays a specified role in the meaning of the whole thing. This technique is often used with highly lexical grammars such as HPSG, (Pollard and Sag, 1994; Sag and Wasow, 1999), where a lexical entry will contain a complete description of its arguments and the way their semantics contributes to the meaning of the whole. Figure 2, for instance, contains a description of the word '*love*', showing that it requires a subject and an object and indicating how their meanings are utilized in the meaning of any sentence built around this word.

Using unification as the way you build meanings of larger units from the meanings of their constituents is well suited to highly lexical grammars, and provides a slightly easier starting position. It is less flexible than using the λ-calculus, and less well-suited to providing interpretations of fragmentary items. Recent work on glue languages attempts to provide some of the advantages of both (van Genabith and Crouch, 1997; Dalrymple *et al*., 1996), but it remains the case that building large scale semantic descriptions remains almost as hard as it is important.

Dynamic semantics

Montague's original work concentrated on a fragment of English which contained names, indefinite NPs, and universal NPs – sentences like (8)–(10).

All men are mortal. (8)

Some lecturer owns a red car. (9)

John wants a new bike. (10)

It's hard to get satisfactory logical forms for sentences like these, particularly when you realise that (10) has an unexpected ambiguity, since there may be some specific bike that John wants – '*John wants a new bike. He's put down a deposit on it, but he has to find the remainder by Saturday*' or it might just be that he wants to be in a situation where he owns a bike that is better than his current one – '*John wants a new bike. He hasn't chosen one yet, but he needs something with 18 gears*'. It quickly became apparent that none of the available logics could cope with definite NPs or pronouns. Attempts by philosophers such as Russell, Strawson, and Kripke to capture the meaning of sentences with definite descriptions using the tools of ordinary predicate logic all ran into problems. The tools for turning natural language sentences into logical forms existed, but it seemed that the available logical languages were somehow inadequate.

The development of a suitable logic for dealing with such expressions, and with other

'presupposition inducing' forms, became a priority, and a number of dynamic logics were developed (Barwise and Perry, 1983; Kamp, 1984; Groenendijk and Stokhof, 1991; Heim, 1983), with some, at least, of these growing out of work in dynamic logic as a foundation for computer science (Pratt, 1974). Other researchers in the area such as Gazdar (1979) and Karttunen (1973) tried to draw on non-monotonic logics and epistemic logics for the same purposes. The goal was to find some formal language which could specify a relationship between the situation in which an utterance was produced and the effect it was intended to evoke. The assumption was that natural language sentences were objects that *changed* the situation in which they were uttered, and that the way a sentence changes a situation depends on what that situation is like. In other words, natural language is dynamic – it has effects, and those effects depend on the context.

The range of logics that were developed or adapted for this task gives some indication of the complexities and subtleties that emerge when you try to give a concrete account of the various phenomena. What they all have in common, however, is that there is a two-stage process of relating the utterance to the current situation – of 'anchoring' it, in Barwise and Perry's terminology – and then using the resulting expression to 'update' the situation. What situations are like, how you do anchoring, how you update a situation, varies from theory to theory, but the key steps are pretty constant. So for a sentence like (11) you would get something like the logical form in Figure 3.

Mary saw the boy who she fancied. (11)

The conditions in Figure 3 have to be satisfiable in the current situation for this sentence to make any sense. In other words, you can only interpret (11) in a situation where there is some X called Mary, and some Y who is a female, and some Z who is a boy who Y fancies. Verifying that these conditions hold is likely to give you a handle on the identities of these individuals (with Mary and the female person probably being the same individual), though there are cases where you can verify the conditions without actually being able to identify the individuals in question. Once you have identified X, Y, and Z you can determine the 'content', namely that X saw Z, and use this to change your view of the world.

conditions: *name* (X, Mary), *female* (Y), *boy* (Z) & *fancy* (Y, Z)
content: *saw* (X, Z)

Figure 3. Logical form for (11).

This basic notion that natural language sentences express conditions that have to be verified by the hearer, with the process of verification fleshing out the content, is shared by a number of theories. The details can get rather complex, not least because people will often produce utterances in situations where they know that the hearer has no chance of verifying the conditions. I can say (12) to someone who has no idea how I get to work and confidently expect that although they cannot verify the condition introduced by the NP '*my train to work this morning*' they will be prepared to 'accommodate' it. But if conditions don't actually have to hold for a sentence to make sense, just what status *do* they have?

My train to work this morning was late. (12)

There are plenty of other problems associated with the general notion. Sometimes, for instance, conditions can be hypothetically satisfied, as in 'donkey sentences' such as (13) (Geach, 1962) and in certain opaque contexts, as in (14) (Karttunen, 1973).

If a former owns a donkey he beats it. (13)

John believes that the king of Ruritania is in the kitchen. (14)

In (13) the referents for '*he*' and '*it*' are only present in the *hypothetical* situation described by the antecedent '*a farmer owns a donkey*', so it is clear that the conditions do not have to be verified with respect to the *actual* situation. Similarly neither the speaker nor the hearer has to believe in the existence of a king of Ruritania (or even a country called Ruritania!) for (14) to make sense. Statement (14) is, in fact, open to at least two readings, one where the speaker believes that there is someone who is the king of Ruritania and that John believes that that person is in the kitchen (on this reading John need *not* believe that there is such a king) and one where the speaker doesn't believe there is a king of Ruritania but she does think that John believes there is.

There are plenty of other such problems, with different theories providing good solutions to some and not to others. The key to all such dynamic theories of semantics, however, is that something like the context, or the speaker's view of the context, or the speaker and hearer's mutual knowledge plays an important role.

PRAGMATICS

Even theories which emphasize the role of the context for instantiating the content of an utterance generally fail to explain why people say things or why they say them the way they do. Thinking about dynamic properties of language does raise some of these questions – why, for instance, would someone force their hearer to accommodate a presupposition, as in (12) above, rather than spelling out all the details as in (15) – but semantic theories tend to restrict themselves to considering the content of an utterance rather than its function.

I came to work on a train this morning. It was late. (15)

If it is true, as I suggested earlier on, that the most important role for language is as a means of influencing other people's behavior then we have to move on from the idea that language is used for describing the way the world is. We have to move on from semantics – what does this utterance say about the world? – to pragmatics – what does it say about me and my goals?

Speech acts

The form of an utterance gives the hearer some hint about what they are expected to do. Consider (16)–(18):

You are going to London tomorrow. (16)

Are you going to London tomorrow? (17)

Go to London tomorrow. (18)

The form of (16) marks it as being a statement – the kind of thing that you might say to someone who is known to be absent-minded and is likely to have lost their diary. The form of (17) marks it as a query. You would say (17) if you didn't know the plans of the person you were talking to. The form of (18) marks it as a command or an instruction, as something that the speaker wants or advises the hearer to do.

We could therefore wrap the content of the sentence up inside some operator that told us what to do. If I tell you something I want you to add it to your model of the world; if I ask you something then I must want you to tell me whether it is true; if I command you to do something then I must want you to do it. So we could try to map the form of the utterance onto something which is recognisable as some kind of action specification or state change description, obtaining logical forms like that in Figure 4 (which says that anyone who hears (16) is expected to accept it). The problem here is that what the speaker wants the hearer to do is often only indirectly related to the form of their utterance. Consider (1) again:

accept (∃*C agent* (*C*, *ref* (λ*Dhearer* (*D*))))
&*go*(*C*)
&*C is event*
&*to* (*C*, *ref* (λ*F* (*name* (*F*, *London*))))
&*tomorrrow* (*C*)

Figure 4. Logical form for (16).

The door is open. (1)

This sentence looks like a statement. Indeed it *is* a statement. But what the speaker wants when he utters it will vary greatly from situation to situation – he may want the hearers to note this new fact, he may want them to note it and take advantage of it by entering the room, he may want them to note it and make it untrue, …

Austin (1962) and Searle (1969) addressed this problem by introducing the notion of speech acts. A speech act is something that a speaker can do by uttering a sentence in an appropriate context. To take a simple example, I can successfully inform you that I am going out by uttering the words '*I am going out*' in a situation where I correctly believe that you are not already aware of my plans; and I can successfully *remind* you of this fact by uttering the same words in a situation where I correctly believe that you *are* already aware of them. I can perform different acts by uttering the same words in different contexts, with part of Austin and Searle's goal being to describe the effects that a given form of words will have in a range of contexts.

In some cases, however, there seems to be a considerable gap between the form of words and the intended effect. Although (1) has the form of a statement, it can clearly function as a command, and with a rising intonation it can function as a query, but since the intonation is part of the form this seems less problematic. Although '*Do you know the time?*' has the form of a yes/no query, it often has the same function as the WH-query '*What's the time?*'. The intended effect of an utterance, then, is often at odds with its apparent form.

Searle characterizes speech acts by describing the conditions under which it is possible to perform the act in question (so you can *assert* some proposition *P* only if you have grounds for believing *P* and it is not obvious that your hearer already knows *P*), and by specifying their intended effects (though he only

discusses the effects in any detail for the rather unusual act of promising). The idea that speech acts can be analyzed in terms of preconditions and effects maps very neatly onto work in artificial intelligence (AI) on planning (Fikes and Nilsson, 1971), and there is a large body of work showing how to explain the 'indirect' effects of utterances like (1) by linking AI planning theory and epistemic reasoning (Cohen and Perrault, 1979; Cohen *et al*., 1990; Bunt and Black, 2000). It is clear that the form of an utterance underspecifies its intended effects, and that some mechanism for connecting the consequences of the literal meaning to the speaker's and hearer's beliefs and goals is required. Whether this can be achieved by producing a table of speech acts, delineated by their preconditions and effects, remains open to question.

Discourse structure

Sentences have structure, which is used for encoding meanings. Extended discourses also have structure. Compare (19) and (20):

> Beach regarded him solicitously, but did not develop the theme. He had a nice sense of the proprieties. Between himself and this young man there had existed for eighteen years a warm friendship.
> *Heavy Weather*, P.G. Wodehouse (19)

> Beach regarded him solicitously, but did not develop the theme. Between himself and this young man there had existed for eighteen years a warm friendship. He had a nice sense of the proprieties. (20)

(19) makes far more sense than (20) even though the sentences in the two passages are identical. Part of the problem with (20) lies in the difficulty of dereferencing the pronoun '*he*', which clearly points to Beach in (19) but which might just as well pick out the young man in (20). Part of it lies in the *implicit* relationships between the propositions encoded in the three sentences. In (19) the second sentence explains why Beach did not develop the theme, and the third is the start of an extended description of the social positions of these two people. It is much harder to give a similar account of (20). It would be possible to link the first and second sentences, with their long-standing warm relationship explaining Beach's reluctance to discuss a difficult subject, but then it is very hard to see where the third sentence might fit in.

Extended discourses are used for conveying complex ideas – for telling stories, for providing explanations, for specifying courses of action. Complex ideas generally have a natural structure. A story is usually worth telling only if it concerns some individuals who are placed in a situation where one sequence of events would normally be expected to occur but some other sequence actually takes place. To tell a story, then, you have to introduce the individuals and the situation, describe how the actual course of events differs from what might have been expected, and then say what the individuals did in response to this deviation: a story has to have a beginning, a middle, and an end (Schank and Abelson, 1977; Rumelhart, 1975). A description, on the other hand, might proceed by introducing some entity which is quite like the thing you are trying to describe and then enumerating the differences (McKeown, 1985). Whatever a discourse is about, the subject matter is likely to be decomposable into smaller parts, and it is a good idea to make the structure of the discourse match this decomposition.

Language provides numerous devices for organizing extended discourses. There are lexical items that explicitly express connections between sentences – '*therefore*', '*however*', '*before that*', '*anyway*', … There are textual conventions such as the breaks that occur before paragraphs, and the chapter and section headings that are used to indicate the structure of very large texts such as books and articles: and there are a number of sentence-internal clues that indicate the speaker's attitude to what they are saying, and hence help to impose a structure.

The first of these sentence-internal clues relates to the fact that, in English, the first phrasal constituent of a sentence seems to carry more weight than the remainder. Halliday (1985) talks about the *theme* and *rheme* where the theme is the thing the sentence is *about* and the rheme is what is being said about it. Other authors use slightly different terminology – Hajicova and Sgall (1984), for instance, talk of the *topic* and *comment*, and the terms *given* and *new* are often used – and the syntactic device that marks the theme may vary from language to language, but the basic idea is clear: in a sentence like (2) I am telling you something about John, namely that he loves Mary, whereas in (21) I am telling you something about Mary, namely that John loves her.

> John loves Mary. (2)

> Mary is loved by John. (21)

The problem is that although the basic idea is clear at an intuitive level, it is exceptionally difficult to

pin it down. What does it mean to say that a sentence is 'about' John?

If we want to carry out our program of obtaining logical forms that mean the same as natural language sentences, we have first of all to find some way of including the division of this sentence into two parts in our logical form. To do this we have to decide what the parts are, which is quite easy in English since the theme is just the leftmost phrasal constituent; and then note that the meaning of one of these parts is 'about' the other – something like the logical form given in Figure 5, which was obtained as described by Seville (1999). Note that using the λ-calculus as the language in which we produce logical forms makes it possible to produce a logical form in which parts of the overall meaning appear independently.

Once we have such a logical form, however, it immediately becomes apparent that we have to say what *about* means. Intuitively it is fairly clear, but the motivation behind producing formal models is to make them precise and testable – to go beyond intuition. This turns out to be extremely hard. We need to know what follows from the fact that someone said (2) that would not have followed if they had said (21) and vice versa, and this is really very unclear.

Similar remarks apply to other local indicators of discourse structure, for instance to (22)–(24).

I married *Rosie*. (22)

I *married* Rosie. (23)

I married Rosie. (24)

As with (2) and (21), the state of affairs being reported is the same in each case. (2) and (21) both describe a state of affairs where John loves Mary, and (22)–(24) all say that the speaker married Rosie. The difference between them is that (22) would be uttered in a context where it had been assumed that the speaker married someone else, (23) in a context where it had been assumed that the speaker did something else to Rosie, and (24) in one where it had been assumed that someone else married Rosie. As with the theme:rheme distinction, it is possible to obtain logical forms which indicate that some part of the meaning is in *focus* (Ramsay, 1994; Pulman, 1993), but drawing out the consequences of choosing one of (22)–(24) rather than another remains extremely difficult.

Marking things as being interesting, or contrastive, or thematic, or … does, however, help to constrain the discourse structure. The tighter the connection between the themes of two consecutive sentences, the more closely those sentences are likely to be linked (so if S1 and S2 have the same theme, then S2 is probably a continuation of S1, if the theme of S2 was mentioned in S1 then S2 is likely to be some kind of explanation or elaboration of S1, and if S2's theme wasn't even mentioned in S1 then it may be that S2 is actually connected to some earlier sentence). Unfortunately, trying to pin down what is meant by saying that S2 is an explanation of S1, or an elaboration, or a justification is as hard as trying to formalize the claim that (2) is 'about' John. Mann and Thompson (1988) and Mann (1999) try to provide a systematic attempt to enumerate and describe the range of possible discourse relations, but there is certainly no consensus about how the components of a discourse relate to one another, even when explicit lexical cues such as '*anyway*' and '*moreover*' are present.

Nonetheless, although it is hard to be clear about how to relate elements of a discourse, the fact that they *are* related does seem worth pursuing. Centering theory (Grosz *et al*., 1995; Brennan *et al*., 1987; Joshi and Weinstein, 1998) extracts the structure of a discourse by following the way the theme changes. The devices used for spotting which item is the center are slightly different from Halliday's very simple decision to use the first phrasal daughter, but the ideas are very similar. Centering theory has been widely exploited for helping with pronoun dereferencing, partly to help pick out where the referent was likely to be introduced (e.g. in the last sentence which mentioned the theme of the current one (Hitzeman and Poesio, 1998; Seville, 1999)) and partly to control the order in which potential referents are tried (roughly speaking, you can't use a pronoun to refer to some item that was mentioned in the previous sentence if you have referred to its theme with a full NP). We may not quite know everything about how the form of an extended utterance encodes the message, but we do know that it plays an important role in making that message manageable, and that a system of mutual

$$about(ref(\lambda F(name(F, John))),\ \lambda G \exists D(agent(D,G)) \& love(D) \& object(D, ref(\lambda H(name(H, Mary)))))$$

Figure 5. Logical form for (2).

constraints between nominal form, especially the choice of whether or not to use a pronoun, and discourse structure plays an important role in specifying this structure.

Semantics, Acquisition of

Introductory article

Robin Clark, University of Pennsylvania, Philadelphia, Pennsylvania, USA
Laura Wagner, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

Semantic acquisition concerns the problems of learning word meanings, of learning how language marks time and temporal relations, and of learning the interpretation of quantified expressions.

INTRODUCTION

A fundamental part of learning a language is learning how to mean things with that language. The most straightforward approach to the problem of meaning in natural language has been to adopt some form of the principle of compositionality:

> *Compositionality*: The meaning of a syntactically complex expression is a function of the meanings of its parts.

For example, the meaning of a complex expression like 'John walked to the store' would be computed by combining the meaning of the subject, 'John', with the meaning of the predicate, 'walked to the store'. The meaning of the latter expressions would ultimately be a function of the meanings of the words that make them up. On this view, words (or their constituent morphemes – that is, the stems and affixes that combine together to form words) would constitute the atomic elements of meaning. An alternative view would be that words (or morphemes) only have meanings in the context of sentences. Although this view is internally consistent, it would require an abandonment of compositionality in the sense outlined here, with the result that acquisition of semantics could not be done on the basis of acquisition of word (or morpheme) meanings.

A reasonable first approach to a theory of semantic acquisition would use the principle of compositionality to work backwards to the meanings of lexical items. The problem for the learner would be to recover meaning from the pairing of the observed situation in the nonlinguistic environment along with the linguistic behavior of a fluent speaker, presumably an adult care-giver. There have been two broad approaches to the problem of semantic acquisition so construed. The empiricist approach assumes that the learner has access only to this 'utterance–world' pairing. The nativist approach assumes that the learner inherits a particular structure that biases its learning in certain predetermined ways. Both approaches have certain advantages and disadvantages.

According to the empiricist approach, learners apply some simple general inductive rule to utterance–world pairings to arrive at the meanings of the component elements. While the empiricist approach is appealing in its simplicity, it is subject to a number of difficulties. First, the utterance–world pairings massively underdetermine the generalizations that the learner can make. Second, even if the utterance–world pairing is unambiguous, the meanings of the atomic elements cannot be uniquely determined from the meaning of the utterance. To illustrate the first point, we take the famous example introduced by the philosopher W. V. O. Quine; given a speaker's utterance of 'Gavagai!' in the presence of a rabbit, a hearer cannot infer from the utterance–world pairing whether the speaker meant to refer to the rabbit or to a collection of undetached rabbit parts. Both possibilities are compatible both with the speaker's linguistic behavior and with the state of the world. The second point, the impossibility of inferring the atomic elements of meaning from the meaning of the entire utterance, follows immediately from the previous point. We will examine the problem of lexical meaning in the next section.

Quine's example uses the reference of a simple concrete noun to pose the basic problem that faces a theory of semantic acquisition. The problem is worse if we observe that linguistic meanings include such esoterica as the relationship between events and time. The following sentences all involve different mappings between the basic event

referred to in the sentence and time:

a. John has walked to the store.
b. John is walking to the store.
c. John will walk to the store. (1)

We will return to this problem below in the section on tense and aspect.

Finally, the elements of a sentence may combine in ways that differ from their surface word order. The following sentence, for example, is ambiguous with respect to how the quantified expressions 'every student' and 'some language' should be interpreted with respect to each other:

Every student in the class speaks some language. (2)

This is the problem of scope; learners must somehow discover that a single word order can sometimes encode different scoping relations between the quantified expressions in it. We will turn to this problem in the last section.

Nativist approaches have taken the problems that confront empiricism as evidence that learners have an innate structure that eases the learning problem by constraining the learner to make certain kinds of generalizations. Thus, learners have definite expectations about possible word meanings and can use linguistic evidence to sort words into semantic classes. Equally, learners may simply assume that certain elements can enter into scope ambiguities without needing direct perceptual evidence that they do so. Nativist theories have the problems that they are more complex than empiricist theories and they are more difficult to falsify.

LEXICAL ACQUISITION

Word-learning happens very rapidly in development. Children begin acquiring words around their first birthday, and know thousands of them by the time they are three years old. This happens despite the fact, noted above, that the world grossly underdetermines the possible referents for any given word. One part of the solution to this problem is cross-situational observation. Children must keep track of what's going on in the world when they hear a new word, and then compare across the situations in which the word was used to find out what they have in common. The common-sense idea here is simply that the word 'dog' (or French *chien*, or Japanese *inu*) is uttered more frequently in the presence of dogs than the word *cat* (or French *chat*, or Japanese *neko*) is; the regularity between the word's referent in the world and the word's use is information the child can use. This technique is useful, but it cannot be the whole story: it cannot solve the 'Gavagai' problem, since every time a rabbit is observed, so too are temporal stages of the rabbit. How then can the child learn the meanings of so many words so fast, when the world does not provide unambiguous evidence?

Empiricist approaches stress the importance of general cognition and social cognition in solving the word-learning problem. For example, it has been shown that children are sensitive to their interlocuter's intent during labeling. In a study by Dare Baldwin, children as young as 16 months old learned that a new label is the name for a novel object only if the labeler made eye contact with the object during the labeling. If the labeler was looking away (e.g. into a bucket), the child would not match the label with the novel object, even if the child herself had been looking at the object.

Nativists believe that word-learning also requires more language-specific constraints. For example, researchers have shown that children expect a new noun to refer to a whole object and to a taxonomic category; and they expect new words to contrast in meaning with other words in their vocabulary. When a child is shown an object whose name they know (e.g. a spoon) and a novel object (e.g. a honey-dipper), and given a novel name (e.g. *dax*), they assume that the new word labels the new object. In this way, the more children know, the easier the word-learning process is.

An additional language-specific cue that children might use to help them learn words is syntax. Since words are used as parts of sentences, the learner can use the structure of the sentence and morphological elements in the sentence to help them narrow down the meaning of the word. This process has been called *syntactic bootstrapping*, since children are using their syntactic knowledge to help them learn the meanings of words. For example, only verbs of cognition, perception, and saying can appear with a sentence complement structure, as can be seen in the examples below (the asterisk denotes an unacceptable form):

a. Suzy thought/saw/said that the world was round.
b. *Suzy ran/built/slept that the world was round. (3)

When a child hears a novel verb in a sentence complement structure, she can assume that its meaning has something to do with cognition, perception, or saying. In this way she can narrow

down the hypothesis space offered by the world and alleviate the 'Gavagai' problem. Research has shown that children are sensitive to this sort of information and can use it to help establish a novel verb's referent. For example, Naigles and colleagues showed that by the age of two years, children can correctly match a transitive sentence ('Bigbird is gorping Cookie Monster') to a causative scene in which Bigbird is pushing down on Cookie Monster and making him squat, and also match an intransitive sentence ('Bigbird and Cookie Monster are gorping') to the noncausative version of the scene in which both Bigbird and Cookie Monster squat beside each other.

TENSE, MOOD, AND ASPECT

Tense, mood, and aspect (TMA) are central features of grammar that serve to situate the meaning of a sentence. Tense situates an event in time (principally, past versus present), Mood with respect to reality (principally, realis versus irrealis), and Aspect with respect to a particular interval (principally, perfective versus imperfective). The acquisition of TMA poses problems for the learner on two main fronts. The first difficulty concerns the mapping of the TMA concepts onto the right morphology in the target language. Languages vary widely in how to mark TMA information. At the extremes, Mandarin doesn't mark tense grammatically at all, while Modern Hebrew doesn't mark aspect grammatically. The missing category can be expressed explicitly (e.g. *yesterday* [past tense], *right now* [present tense], *finished* [perfective], *in the middle of* [imperfective]) but typically it is conveyed only as a matter of conversational implicature: for example, events marked as perfective are probably in the past and events marked as present tense are probably also imperfective. Between these two extremes, languages also vary in how they combine TMA information into individual morphemes. For example, French combines the past tense and imperfective aspect into the imparfait form, while English combines the past tense and perfective aspect in the simple past form. Thus, even once children can correctly identify TMA reference, they must still determine which elements their language marks explicitly and how it does so, which it pairs together in a single morpheme, and which it conveys only through implication.

The second difficulty concerns how children identify TMA reference in the first place. TMA features refer to abstract properties of an event which are not readily observable. For example, both past tense and irrealis modality are only true of events that are not currently happening at the time of utterance – but they are true of different kinds of non-occurring events. Moreover, there is a natural tendency for some TMA dimensions to group together; for example, all things being equal, events happening in the present time are usually ongoing and hence warrant both present tense and imperfective marking. These natural groupings, however, pose a learning problem: how is the child to know whether the speaker intended to mark present tense or imperfective aspect, or even whether the two concepts can be expressed separately in the language? In their own speech, children appear to take a very conservative strategy, maintaining not only these natural groupings of tense and aspect, but extending them to inherent properties of lexical predicates. Thus, in their early production of TMA morphology, children tend to restrict past tense and perfective aspect marking to telic predicates (i.e. predicates describing result-oriented events such as 'find' and 'break') and they restrict present tense and imperfective aspect marking to atelic predicates (i.e. predicates describing general activities such as 'ride' and 'laugh').

In the course of development, children generally acquire the modality distinction (realis–irrealis) first, followed by aspect (perfective–imperfective) and finally tense (past–present). It is unclear, however, whether this pattern of acquisition is the result of language-specific biases children have (as predicted by the nativist approach) or is simply the result of the kind of evidence available for identifying each category (more in line with the empiricist approach).

QUANTIFIERS AND SCOPE AMBIGUITIES

Quantified noun phrases, like those underlined in (4), pose a particular problem for learners on two counts. First, they do not denote objects straightforwardly in the way 'Mary' denotes an individual, Mary. Second, they seem to be a counterexample to the simple approach to compositionality given in the introduction:

a. Every student studies.
b. Some girl eats apples.
c. At least two politicians accept bribes. (4)

Let us turn, first, to the problem of the denotation of quantified noun phrases. It is widely accepted that quantified expressions like 'every student' do not refer to an abstract individual but, rather, to a

function. A similar analysis can be given to any of the quantified expressions in (4); the problem for the learner is to discover the function that any given quantified expression refers to. For example, the learner must discover that 'every' denotes a function that returns true if the set of individuals with the property described by the subject is contained in the set of individuals with the property described by the predicate. Any individual pairing of the world with an utterance will be insufficient to determine the function that a quantified expression denotes. Instead, the learner must be presented with a sufficiently broad sample of such pairings in order to infer the correct meaning. This problem remains very much open, with some work done in artificial intelligence on the formal problem of inferring quantifier denotations but, as yet, little work on the problem in developmental psychology.

Turning to the second problem, compositionality, recall sentence (2) presented in the introduction. It contains two quantified noun phrases, 'every student' and 'some language' and is ambiguous, meaning that it can have two very different interpretations:

a. Each student in the class speaks at least one language, although the students may differ as to which language they speak.
b. There is a language which has the property that every student in the class speaks it. (5)

If (5a) is the intended interpretation, then 'every student' is said to have wide scope over 'some language'; if (5b) is the intended interpretation, then 'some language' has wide scope over 'every student'.

The ambiguity here should be contrasted with a case of lexical ambiguity, as in (6a), and with a case of structural ambiguity, as in (6b):

a. John went to the bank.
b. John saw the man with the telescope. (6)

The examples in (6a) and (6b) do not pose a particular problem for the principle of compositionality. In (6a), the word 'bank' is simply lexically ambiguous. Example (6b) is structurally ambiguous because the syntax of English allows the prepositional phrase 'with the telescope' to combine either with the noun phrase 'the man' or with the verb phrase 'saw the man', resulting in two distinct interpretations from normal composition.

The sentence in (2) is neither lexically ambiguous as was (6a), nor do the phrases appear to have the option of combining in distinct ways to generate the ambiguity, as was the case with (6b). In this sense, sentences like (2) seem to defy the simplest interpretation of compositionality. Instead, the learner must discover that quantified expressions can be given a variable scope within a sentence, resulting in the interpretations noted in (5b) and (5a). It has been well documented in the literature, by Crain among many others, that young children prefer to assign scope to quantified expressions in the order in which they appear in the sentence. That is, the leftmost quantified expression is given widest scope. In the earliest stage, children, when presented with an example like 'some horse jumped over every dog', interpret the sentence as unambiguous, with a single horse jumping over all the dogs. Indeed, this seems to be the most readily accessible reading for adults. Adults, unlike children, admit that the sentence can also be true when different horses jump over each dog. Children before the age of about four years will deny that this reading is possible. As they acquire more experience with the language, children appear to be less tied to the surface syntactic interpretation of such sentences and admit that the quantified expressions can take a variety of different scopes. While the stages that children go through in discovering how to interpret sentences containing several quantified expressions have been thoroughly documented, it is as yet mysterious how children discover that these alternative scopings are possible; that is, it is still unknown what it is about the child and her linguistic experience that forces the child to accept the adult interpretation of such sentences.

Language stands in a complex relationship to the world. The problems that the learner faces during the course of semantic acquisition are surely daunting at first glance. Word meanings cannot be fixed just by looking at the world, and some elements, TMA elements in particular, involve dynamic interpretations that involve highly abstract computations. The learner must untangle lexical and structural ambiguities. Structural ambiguities highlight the fact that linguistic interpretation involves computation. That children are able to fix the semantic atoms of their target languages with such apparent ease is, without doubt, a wonder of the natural world, one that presents a variety of interesting and subtle scientific problems.

Semantics, Dynamic

Intermediate article

Carl Vogel, University of Dublin, Dublin, Ireland

CONTENTS

Dynamic semantics is concerned with modeling the processes that change the information held by participants in a discourse or dialogue where those changes are brought about by the sentences contained in the discussion.

INTRODUCTION

The term 'dynamic semantics' refers both to a set of tools for analyzing the semantics of sentences in natural language and to ways of relating those tools to other areas of logic and computation. Muskens *et al.* (1997) provide a comprehensive survey of research along both of these lines (see also van Benthem, 1986, 1996). This article concentrates on the analysis of meaning of natural-language expressions as processes, using formal models of those processes that are logic-based dynamical systems.

Early work on natural-language processing began with processing models of syntax, with the aim of verifying the cognitive viability of process models (Winograd, 1983), but even identifying input–output correspondence between computational and cognitive models proved to be very difficult. Exact cognitive-processing mechanisms have still not been established. Nonetheless, current formal work is setting the stage for this program, both from the perspective of the syntax–semantics interface (e.g., Kempson *et al.*, 2000), and from the perspective of semantics alone.

This article describes varieties of dynamical formal systems for analyzing the semantics of natural language. This work is grounded in an understanding of how static systems work. Then various ways of achieving dynamics are described. In all cases, the basic intuition being modeled is that interpreting an utterance can lead to a change in the information state of the interpreter. Initially, this is modeled in systems in which propositions are Boolean combinations of propositional atoms, and subsequently in systems that admit more representational expressivity, with predicate–argument structure and truth depending on what names and pronouns refer to. The basic contrast between static and dynamical systems among models of formal semantics is a contrast between the meaning of a sentence being characterized by the conditions in which it is true (i.e., truth-conditional semantics) and the meaning of a sentence being given by the change of state induced by interpreting it in some context.

STATIC SEMANTICS

In formal semantics, there are two complementary traditions: the model-theoretic approach, and the use of intervening representation languages. Models can be viewed as representations, but in the model-theoretic paradigm, semantic phenomena are analyzed in terms of the constraints they impose on models into which sentences are directly interpreted. When indirect interpretation into an intervening representation language is adopted, formal semanticists typically rely on a logic. Many logics, with varying degrees of expressivity, exist: propositional logic, first-order (predicate) logic, and higher-order logics, with modal variations of each. Semanticists who use logics as representation languages are concerned with the translation of natural-language utterances into (as natural as possible) formal representations, while logicians clarify the mathematical properties of the corresponding languages. The advantages of logics include the fact that at least their semantics are well understood, even if the object language of study, natural language, is not. Thus, identifying alternative candidate translations from natural-language expressions into formal logics clarifies what semantic properties the natural expressions have. A logic is a formal language with a clear syntax and a clear semantics, as well as a deduction relation, which expresses what sentences must be true given the truth of a base set of sentences.

Certain forms of dynamic semantics follow from assuming that the initial base set of sentences is only partial (i.e. a sentence may be neither true nor false, but undefined), and that dynamics ensue from maintaining consistent sets of sentences following from the deduction relation while augmenting the base set. Other models of dynamics are insensitive to whether the base set is partial or not, because they effectively allow updating (i.e. addition of new sentences) as well as 'downdating' (i.e. deletion of old sentences), still maintaining deductive consistency everywhere else. The theory of mental models (e.g. Johnson-Laird, 2001) is an example of an approach based on fleshing out partiality in a system that is fitted to actual cognitive behavior.

To place the relatively large space of dynamical systems on comparable terms, it is helpful to consider a standard static semantics for a basic logical language, and to then indicate the various parameters under which the system might be dynamized.

A Propositional Language

An infinite propositional language can be constructed from a basic set of atomic propositions $\{p^0,\ldots,p^n\}$ and the following syntax rules for composite sentences:

- If p^i is a well-formed sentence, so is $\neg p^i$.
- If p^i and p^j are well-formed sentences, so are:
  - $p^i \wedge p^j$
  - $p^i \vee p^j$
  - $p^i \rightarrow p^j$

These syntax rules are more than are necessary under the standard interpretation of the connectives, but they illustrate how finite means can be used to provide an infinite number of sentences. While the rules indicate the sentences that must be grammatical, they do not stipulate what sentences must be true. That is the role of the semantics for a system, and the semantics is always relative to possible valuations. One way to consider the semantics is to say that relative to a particular valuation function, certain atomic propositions are true, and others false (and composite propositions' truth or falsity is determined compositionally). Another way of thinking about the meaning of sentences in the language is to say that the sentences all denote the space of valuation functions that make them true. These two possibilities are illustrated below. A great deal of work in dynamic semantics takes the latter view; but it is really just an abstraction from the former view.

When providing a semantics for a propositional language, it is common to outline a valuation function v which tells whether each atomic proposition is true or false. Another function $[\![\cdot]\!]$ is defined to deterministically identify the meaning of a complex expression from the meanings of its components, relative to the choice of valuation function for the basic expressions. Thus, at the outset v is used to map each p^i unambiguously into the set {1, 0}, where 1 represents truth and 0 represents falsity. The meaning function for arbitrary sentences is commonly defined as follows:

- $[\![p^i]\!]^v = v(p^i)$ iff p^i is atomic.
- $[\![\neg p^i]\!]^v = 1$ iff $[\![p^i]\!]^v = 0$.
- $[\![p^i \wedge p^j]\!]^v = 1$ iff $[\![p^i]\!]^v = 1$ and $[\![p^j]\!]^v = 1$.
- $[\![p^i \vee p^j]\!]^v = 1$ iff $[\![p^i]\!]^v = 1$ or $[\![p^j]\!]^v = 1$.
- $[\![p^i \rightarrow p^j]\!]^v = 1$ iff $[\![p^i]\!]^v = 0$ or $[\![p^i]\!]^v = 1$.

Consider the meaning of the proposition $p^1 \vee p^2$. Given a complex sentence made up from n distinct atomic propositions, there are 2^n distinct valuation functions to consider – in this example, four possible valuation functions. The value of $[\![p^1 \vee p^2]\!]$ depends on the particular valuation function chosen (see Table 1). Using v^1 it is false, but using v^2, v^3, or v^4 it is true.

The generalization of this view is to let $[\![p^i]\!]$ denote, not a truth value, but the set of valuation functions that make the proposition true. We write v below for the class of possible valuation functions:

- $[\![p^i]\!] = \{v^j | v^j(p^i) = 1\}$
- $[\![\neg p^i]\!] = v - [\![p^i]\!]$
- $[\![p^i \wedge p^j]\!] = [\![p^i]\!] \cap [\![p^j]\!]$
- $[\![p^i \vee p^j]\!] = [\![p^i]\!] \cup [\![p^j]\!]$
- $[\![p^i \rightarrow p^j]\!] = (v - [\![p^i]\!]) \cup [\![p^j]\!]$

Using the example above, $[\![p^2]\!] = \{v^2, v^4\}$ and $[\![p^1 \vee p^2]\!] = \{v^2, v^3, v^4\}$.

A few immediate observations are relevant to subsequent dynamic reinterpretations. A contradiction denotes the empty set: no valuation will make it true. A tautology denotes v: it is true no matter what valuation function is selected. A

Table 1. How $[\![p^1 \vee p^2]\!]^v$ depends on the valuation function v.

v	$v(p^1)$	$v(p^2)$	$[\![p^1 \vee p^2]\!]^v$
v^1	0	0	0
v^2	0	1	1
v^3	1	0	1
v^4	1	1	1

conjunction denotes an intersection: a subset of the set of valuations denoted by either conjunct individually. If each valuation provides a truth-value for each atomic proposition, then each valuation represents a total specification of how things might be: a possibility. A conjunction then involves an intersection of sets of possibilities. Therefore, a conjunction involves eliminating those possibilities not in the intersection. Intuitively, if a proposition represents the meaning of a sentence, then a conjunction of propositions represents a discourse, and interpreting the discourse as true eliminates possible ways the world might be.

A First-order Language

Generalizations to first-order languages are necessary because propositional languages do not capture the predicate–argument structure inherent in natural-language syntax. Arguments (apart from those of attitude verbs like 'knows') are typically individual entities syntactically marked as nominals, and predicates are typically relations, often marked as verbs. In addition to predicate–argument structure, it is desirable to have variables to capture anaphoric relations among sentences. Along with variables come possibilities for binding them, such as with existential or universal quantification. Here we will ignore issues associated with dynamics and generalized quantifiers such as 'most' and 'few'; however, see Kanazawa (1994). In dealing with a predicate logic, it is necessary to augment the syntax of the language with a set of variables (Var) and a set of individual constants (Cons); these represent the arguments of predicates. Additionally, propositions are regarded as predicates with no arguments (zero-arity) and predicate–argument structures are well formed only if an n-ary predicate combines with a sequence of exactly n constants or variables.

In the semantics, the valuation functions require more structure. In addition to the notion of truth and falsity, a domain of individuals is required, for variables and individual constants to refer to. Each $v^i \in v$ will be defined in terms of three parts: a function N that maps each constant to an element of the domain D, a function g that maps variables in an expression into D (on analogy with pronouns, which don't always refer to the same individual in discourse), and an interpretation function I for relation names that takes over the propositional role of v and generalizes it to predicates of arbitrary arity. Each of these relations is defined solely for its intended sort (i.e., N for names of individuals, I for predicate names, and g for pronouns (variables)); and for each v^i, N is injective (onto) and I and g are bijective (one-to-one and onto).

$$v^i(t) = \begin{cases} N(t) \in D & \text{iff } t \text{ is a constant} \\ g(t) \in D & \text{iff } t \text{ is a variable} \\ I(t) \subseteq (\overset{n}{\text{x}}D) & \text{iff } t \text{ is a predicate and} \\ & \overset{n}{\text{x}}D \text{ is the } n\text{-place} \\ & \text{cartesian product over} \\ & \text{the domain } D \end{cases} \tag{1}$$

Thus, many v^i agree in their specification of what names (N) denote and what relations are indicated by predicates (I), but differ on variable assignments (g), as many assignments will agree on all of N, all of I, and all but one variable specified by g. Moreover, variation is possible on each of the other parameters as well. Let $v^i \overset{N}{=} v^j$ indicate that the two valuations v^i and v^j have identical denotations for constants, and similarly let $v^i \overset{I}{=} v^j$ mean that the two valuations have identical interpretations of predicates. With such an arrangement, there are only three clauses to add to the propositional semantics (changing the semantics for atomic propositions, but retaining the clauses for composite sentences):

- $[\![p^i_n(t^1,\ldots,t^n)]\!] = \{v^j | \langle v^j(t^1),\ldots,v^j(t^n)\rangle \in v^j(p^i_n)\}$. A predicate of arity n denotes the set of valuations that make it true, allowing for the possibility of variance in the interpretation of constants, predicates, and variable assignments, where a valuation makes it true just if the sequence of elements denoted by the arguments (according to the valuation) is an element of the interpretation of the predicate name (according to the same valuation).
- $[\![\exists x P]\!] =$

$$\left\{ v^i \;\middle|\; \left(\begin{array}{ll} \{v^j | v^i \overset{I}{=} v^j\} & \cap \\ \{v^j | v^i \overset{N}{=} v^j\} & \cap \\ \{v^j | [\![P]\!] \neq \emptyset\} & \cap \\ \{v^j | v^i(y) = v^j(y) \text{for all } y \in \text{VAR except possibly } x\} & \cap \\ \{v^j | \text{for some } d \in D \text{ there is a } v^j{:}x^j(x) = d\} & \end{array} \right) \neq \emptyset \right\}$$

  An existentially quantified formula denotes the set of valuations in which the matrix formula (P) is true, where also the interpretation of all but the quantified variable (x) is held constant, and such that the quantified variable can point to some entity (randomly chosen) that makes the predication true, holding the interpretations of other variables, names and predicates constant.
  The formal representation above separates these issues ($\{y|q(y)\}$ refers to the set of things that have the property q). The property that each v^j in the denotation of $[\![\exists x P]\!]$ has when interpreted relative to a particular valuation v^i is that the intersection of a number of properties associated with the v^j are nonempty: the

valuations all agree on interpretations of basic predicates with v^i; the valuations all agree on the interpretations of constants; the valuations make the matrix formula P true; the valuations agree on the assignment of all variables except for possibly x, the quantified variable; the valuations make x point to some element of the domain such that the intersection with the set of valuations that make P true is nonempty (along with the intersections of the other properties).

- $[\![\forall x P]\!] =$

$$\left\{ v^j \;\middle|\; \left(\begin{array}{cc} \{v^j | v^i \stackrel{I}{=} v^j\} & \cap \\ \{v^j | v^i \stackrel{N}{=} v^j\} & \cap \\ \{v^i | [\![P]\!] \neq \emptyset\} & \cap \\ \{v^j | v^i(y) = v^j(y) \text{for all } y \in \text{VAR except possibly } x\} & \cap \\ \{v^j | \text{for all } d \in D \text{ there is a } v^i{:}v^j(x) = d\} & \end{array} \right) \neq \emptyset \right\}$$

A universally quantified formula denotes the subset of all those valuations in which the matrix formula (P) is true, where also the interpretation of all but the quantified variable (x) is held constant, and such that the quantified variable can point to every entity in the domain, making the predication true while still holding the interpretations of names and predicates constant.

It is common in the presentation of first-order languages to separate out the relativization of interpretation to the domain, the assignment of interpretations to terms and predicate names, and variable assignments, just as in the initial presentation of the semantics for a propositional language above (e.g., Gamut, 1991; Chierchia and McConnell-Ginet, 1992). In the preceding presentation the choice of domain is a background parameter, and the other three components are all taken as part of the basic valuation functions, so that sentences may uniformly denote sets of valuations containing the parameters most likely for dynamic analysis to attend to. Presentation using somewhat monolithic valuation functions is equivalent to the alternatives, but facilitates discussion of dynamics.

DISCOURSE DYNAMICS

In the static semantics presented so far, a formula denotes the set of valuation functions that make the formula true. The essential idea of dynamic semantics, whether in the propositional or first-order setting, is to associate with a formula two sets of valuation functions: the set of valuation functions that made all preceding formulae true, and the related set of valuation functions that make the current formula true. Thus, there is an input and an output set of valuation functions. A natural parameter for a dynamic theory to stipulate is the set of constraints that must hold between input and output valuations (e.g., one candidate is that the output valuations should be a subset of the input valuations).

As before for propositional systems, formulae may be evaluated as true or false relative to input valuations against which subsequent formulae are evaluated, or expressions may simply denote pairs of sets of input and output evaluations. In an irreducibly dynamic system, this can mean that the intepretation of some connectives is no longer commutative. Conjunction, for example, is in traditional systems taken to be commutative: if $p^1 \wedge p^2$ is true, then so is $p^2 \wedge p^1$. However, under a dynamic analysis, even if the two composite formulae have the same input and output valuations, within the formulae the situation is different – in the first expression p^2 is interpreted relative to the meaning of p^1, and in the second one it is not. Thus, internally the formula p^2 has a different meaning depending on where it is interpreted and what has been interpreted before it.

Recalling that valuation functions essentially encode possibilities, noncommutativity based on input and output valuations has been used in update semantics to explain the contrast in the pairs of discourses below (Veltman, 1991):

(a) It might be cold. It isn't cold.
(b) It isn't cold. It might be cold.
(c) It isn't cold. It might have been cold. (2)

Discourse 2(b) is usually perceived to be rather more odd than 2(a). The explanation is that in 2(b), the possibility of its being cold is eliminated before it is asserted to exist. Discourse 2(c) provides a paraphrase of a possible exegesis of 2(b) that makes it less strange; notice that it introduces an additional parameter of varying tense. In a propositional setting, when all that exists are truth values and valuations of proposition names, all that can be dynamized is which proposition names are true or false. Schütze (1996) provides a useful discussion of the foibles associated with grammaticality and acceptability judgments. Statements about ill-formedness made in this article are given with his caveats in mind.

In a first-order system, the domain is richer, and so are the valuations. As presented so far, the first-order system is intended to capture the spirit of 'discourse representation theory' (DRT) (Kamp, 1981); Kamp and Reyle, 1993) or 'file change semantics' (Heim, 1982), formalizing constraints on anaphoric relations across discourse, based on the 'dynamic predicate logic' of Groenendijk and Stokhof (1991). The basic ideas include the notions

that indefinite noun phrases introduce entities that may be referred to again, subject to accessibility constraints, that proper noun phrases are universally accessible, and that pronouns and definite noun phrases are anaphoric to accessible antecedents.

(Cataphora (e.g. *He$_i$ asked for a martini. Bond$_i$ further specified, 'stirred, not shaken'*) and generic noun phrases (e.g. *the dodo is extinct*) are not outside the scope of DRT, but are outside the scope of this article. Generiticy has received much important attention in a range of semantic frameworks, for example from Carlson and Pelletier (1995).)

Dynamics associated with anaphora is intertwined with Accessibility, correlates with the syntactic constructions (logical connectives) in which a discourse referent is introduced. These are all tied to the variable-binding components of the valuations (g), as the difference between a new and old discourse referent is in the existence of assignments for the variable corresponding to the discourse referent.

A variable introduced inside the scope of a basic sentence is accessible to a subsequent discourse-level conjunct. A variable introduced inside the scope of a negation is inaccessible to a conjunct of that negated sentence. For conditionals, a variable introduced in the antecedent is accessible to the consequent, but not outside the conditional as a whole. Data motivating these constraints include the following:

(a) A person is walking. The person is smiling.
(b) The person is walking. A person is smiling.
(c) The person is smiling. A person is walking. (3)

Neither 3(b) nor 3(c) induces coreference between the walker and the smiler: the antecedent to anaphoric requirements of the definite noun phrase is in both of these cases inaccessible. However, in 3(a) the variable is accessible to subsequent discourse.

(The notion of a 'basic sentence' is difficult. Keenan (1975) provides an operational definition as a sentence that doesn't require the understanding of other sentences for its interpretability for the purposes of identifying a family of properties cross-linguistically associated with subjects. For example, a sentence containing a verb that embeds a sentence is not basic. In contrast, in this literature, if a sentence is not marked by peculiar constraints on accessibility related to embedding, then it can be taken as basic.)

The following examples demonstrate constraints imposed by negation:

(a) Jan owns a bike.
A bike is in the stairwell.
The bike is rusty.
(b) Jan owns a bike.
A bike isn't in the stairwell.
The bike is rusty. (4)

While 4(a) allows the rusty bike to be identical with Jan's bike or the bike in the stairwell (or both), there is a strong preference for the discourse in 4(b) to disallow identity of reference among the three mentions of 'bike'.

The following examples show that conditionals also influence the information available for the interpretation of subsequent sentences:

(a) If Lee owns a bike it is rusty and it is in the stairwell.
(b) If Lee owns a bike it is rusty.
It is in the stairwell. (5)

In both cases an indefinite is introduced inside the antecedent of the conditional, the 'if' part. In 5(a) two pronominal references are made back to the entity introduced, both in the consequent of the conditional, the 'then' part. There is a contrast in 5(b): a pronoun in the consequent of the conditional may refer back to the entity introduced in the antecedent, but an entity introduced inside the conditional is not accessible to pronouns in separate sentences. While interpreters regularly accommodate discourses, finding antecedents where none explicitly exists (for a DRT treatment of presupposition accommodation, see van der Sandt, 1992), there is a difference in ready interpretability between 5(b) and 5(a). Structurally, the difference is in whether the anaphor occurs in the consequent of a conditional whose antecedent introduces the referent or whether the anaphor occurs outside the conditional in a discourse sister.

Dynamics, applied here, are tied to the way in which valuations are passed among constituents in various clause types and among discourse connectives. Importantly, the DRT tradition is aimed at stating which referents are accessible, not in resolving anaphora. Other dynamic frameworks have been developed to provide theories of which accessible antecedents are most likely to be anchors to anaphors. A well-known approach uses the notion of 'focus' within the discourse to explain the changes through the discourse in what anaphors may refer back to (Grosz and Sidner, 1986). Essentially these are theories that interface syntax, semantics, and pragmatics in suggesting what constrains the accessible referents for definites and

pronouns. Grosz (1977) emphasizes the importance of a mechanism for defining the relevance of the various things that might be referred to for the reference resolution at hand. Another parameter is an encoding of world knowledge that allows explicit mention in discourse of some entity or event to give access to other relevant entities, such as relevant parts of a complex object or sub-events of heterogeneous activities. The final parameter is a mechanism for changing the focus on potential referents through the course of dialogue. One mechanism is to model potential referents as existing in focus sets determined by relevance at their introduction in a stack of available focus sets until, for example, a discourse relation (e.g., 'on a new topic …') allows their accessibility to be eliminated.

In general, dynamics can apply to more than variable assignments – they can apply also to names of constants and interpretations of predicates, the other two components of valuations as set out above. The domain parameter can also be dynamized, as well as the formulae themselves (van Benthem, 1986). Vogel (2001), for example, analyzes first uses of metaphors, the introductions of new senses for terms and predicate names, via a dynamic view on the N and I components of valuations.

DIALOGUE DYNAMICS

The discussion so far has been strongly influenced by a discourse view of the phenomenological domain of semantics: that is, sequences of sentences in monologues. Chiefly, this results in eliminations of possibilities (successively smaller sets of valuations) across sentences conjoined in discourses. Of course, dialectic discourses exist, but these have more in common with dialogue than with narrative monologue. In dialogue settings, more than narrowing of possibilities is required, and even more than propositions are necessary as sentential contents: also necessary as potential contents are questions as bona fide semantic objects (e.g. that which is embedded by 'wonder' and 'know', but not by 'believe' (Ginzburg, 1995a, b)), acceptances of informational contributions (e.g., 'OK', 'yeah') and rejections (e.g. 'no way', 'you're wrong'). To the extent that negotiation enters and individuals revise beliefs, it is necessary for dynamic semantics to attend to the flow of information and beliefs among interloctuors. This area has been explored extensively at the propositional level (e.g., Alchourrón *et al*., 1985; Gärdenfors, 1986) and at the first-order level (Lemon, 1998). While much work in dynamics has been followed in discourse settings, some of the original motivations actually follow from dialogue situations.

Presuppositions of an utterance are the background assumptions that must be true (or accepted as true by speaker and hearer) in order for an utterance to make sense, independently of whether the utterance itself is true. Beaver (1997) provides a comprehensive review of both static and dynamic approaches to presuppositions; the literature is enormous. A brief overview of the sort of problems involved follows.

Consider the following utterances:

(a) The train is late.
(b) The train is not late.
(c) If there is a train, the train is late.
(d) There is a train. (6)

Both 6(a) and 6(b) presuppose that there is a train (6(d)). However, 6(c) does not have this presupposition. The difference in presuppositions between 6(a) uttered in an empty context (empty apart from background information about the meanings of words, etc.) and 6(c) uttered in an empty context is that 6(c) makes sense, but 6(a) does not. The utterance of 6(a) requires at least 6(d) in the context prior to interpreting the same sequence of words, 'the train is late' that also occurs in 6(c). Thus, the presuppositions of an utterance depend on the utterances that precede it. Such phenomena include a great deal more than just definite noun phrases (e.g., questions presuppose that answers exist). It is typical to model these phenomena by taking contexts as sets of valuations, and requiring that the contexts also make true the material presupposed by a sentence. Context must be sensitive to common knowledge. In a dialogue setting, it makes sense to use a definite noun phrase like 'the train' only if there is a unique entity that is salient to speaker and hearer as a train. Thus, the speaker must have a model of what the hearer knows, even if that model is not accurate. In practice, it has been demonstrated that speakers are not always sensitive to hearer's perspectives: Schober (1993) found that speakers with interactive partners were more egocentric in making references than speakers who spoke to imaginary partners, effectively in monologues. Nonetheless, in dialogue semantics it is clear that each speaker must maintain some sort of model of information that is shared, and that the course of dialogue induces updates to those models.

As indicated above, dialogue involves semantic contributions in addition to declarations of

propositions. There are also acceptances of propositional content (and acceptances or denials of presuppositional content) and questions. There are also other things, like exclamations, that have received more attention in pragmatics than in dynamic semantics. Obviously, the flow of information included in questions, responses, and the acceptance of answers is a dynamic process. This is perhaps less obvious in human–machine dialogue systems, in which one interlocutor (the machine) is supposed to be effectively omniscient about its domain and able to answer questions for the user about the domain. However, even in these systems the machine must have a model of dialogue interactions if it is to be easily used, even if only so that the human can make use of pronouns rather than making fully explicit all of the intended background restrictions that identify a noun phrase for each intended referent. Models of the syntax and semantics of dialogue contributions are very active areas of research (e.g. Ginzburg and Sag, 2000). The model of dialogue explored by Ginzburg and Sag involves tracking the 'resolvedness' of questions under discussion with stack-based mechanisms like those for resolving nominal references in the focus-tracking system of Grosz and Sidner (1986) mentioned earlier.

OPEN QUESTIONS

Dynamic semantics, in all its manifestations in formal semantics, involves data structures that model basic sorts of information, and processes that increment or decrement those information stores in accordance with the flow of sentences interpreted. Some representations of information are more expressive than others, and some uses of language require more sorts of semantic objects than others. Many models of dynamic semantics exist, differing in the ontology modeled, the technical details of the modeling, and the phenomena addressed. Primary open questions concern the unification of dynamical approaches to ranges of phenomena in comprehensive systems, and evaluation of their predictions with respect to the robustness of actual human behavior, and not simply introspectively circumscribed subsets of the phenomena.

Sentence Comprehension, Linguistic Complexity in

Introductory article

Edward Gibson, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

CONTENTS

The process of comprehending a sentence involves the moment-by-moment evaluation of a variety of informational and computational constraints. The combination of these constraints makes a sentence easy or difficult to process.

INTRODUCTION

Most sentences that we encounter in everyday life are easy to understand. But occasionally a sentence can be confusing or complex. For example, consider sentence (1):

The dog walked to the park had been chewing the bone. (1)

While reading (1), people generally get confused when the words 'had been chewing …' are encountered. People experience difficulty like this (a so-called 'garden-path effect') when there is an ambiguity earlier in the sentence for which they follow a likely interpretation, but which turns out to be incorrect. The temporary ambiguity in (1) is initiated at the word 'walked', which is ambiguous between a past tense verb and a passive participle verb. The past tense reading – the reading that is initially preferred – results in a main clause interpretation, in which 'the dog' is the actor (i.e. the agent carrying out the action) in a past-tense walking event. This interpretation is no longer viable when the words 'had been …' are input. The passive participle reading – the reading that is not usually noticed initially – involves 'the dog' as a patient (i.e. to whom the action is done) of a walking event, in which an unmentioned individual walked the dog.

Now consider sentence (2), which presents its readers with a second kind of processing difficulty:

The reporter that the senator that John met at the party attacked admitted the error. (2)

Sentence (2) consists of a main clause 'the reporter admitted the error', whose subject is modified by a relative clause (RC) 'that the senator … attacked'. The subject of the RC is then itself modified by another RC, 'that John met at the party'. This sentence is extremely difficult to understand, independent of any temporary ambiguities that it contains. In particular, sentence (2) is difficult to understand even when reading it for the second or third time. This is not so for (1): once it is known that the passive participle interpretation is the target structure, (1) becomes understandable.

Complicated sentences like (1) and (2) can be highly informative for telling us how the process of sentence comprehension occurs. In ambiguous sentences like (1), the combination of a variety of factors results in preferences for some structures over others, because not all structures can be pursued in parallel. In sentences like (2), without confusing temporary ambiguities, the combination of the same factors results in easier or harder processing, depending on the difficulty of the target interpretation. The analysis of a wide range of sentence comprehension studies involving many different structures across languages suggests that a variety of information sources are used in constructing an interpretation for a sentence, and that the process of building the target representation is constrained by the available computational resources. Some of the informational and resource factors are discussed below.

MEASURING LINGUISTIC COMPLEXITY EXPERIMENTALLY

Studies of sentence comprehension involve comparisons between target sentences and appropriate control sentences. For example, a control for sentence (1) above is a disambiguated version, as in (3):

The dog that was walked to the park had been chewing the bone. (3)

This sentence has the same structure as (1), but is disambiguated by the words 'that was' towards the passive participle interpretation of 'walked'. This sentence is correspondingly easier to understand than (1). A control sentence structure for sentence (2) is given in (4):

At the party, John met the senator that attacked the reporter that admitted the error. (4)

Sentence (4) contains all the same words as (2), with the same thematic relations among them, but (4) is much easier to understand. Thus, it is something about the structure of (2) that makes it difficult to understand.

A single individual's reactions to sentences like (1) and (2) on the one hand and their controls in (3) and (4) are not very informative by themselves. Because of individual variation, it is necessary to test hypotheses regarding sentence comprehension on a range of experimental participants and items. Perhaps the simplest method for gathering data on sentence comprehension is by means of acceptability (or grammaticality) judgments. This method consists of having experimental participants answer a questionnaire in which sentences are rated for their understandability, according to the participants' intuitions. A more objective method involves measuring reaction times to full sentences (presented either visually or auditorily) and accuracy to questions about the content of the presented sentences.

Often we want to know about the time course of processing load in a sentence: where in the sentence does the difficulty begin and end? End-of-sentence (offline) measures do not address such questions. Online measurements are necessary. In reading, measuring participants' eye movements to visually presented sentences is one online technique. At points of high complexity, participants slow down and/or regress to previous regions. A commonly used online alternative to tracking eye movements is self-paced reading with a moving window display. In this method, a sentence is initially presented on a computer screen as a series of dashes marking the length and position of the words in the sentence. Participants press a key (usually the spacebar) to reveal each region of the sentence, often one word at a time. As each new region appears, the preceding region disappears. The amount of time the participant spends reading each region is recorded as the time between key-presses. As in eye-tracking, participants tend to slow down at points of high complexity. Unlike eye-tracking, however, there is no way in self-paced reading for a participant to back up and re-read a region that was confusing.

It is more difficult in auditory language presentation to obtain an online dependent measure such as reading time. One way to obtain an online measure of difficulty in auditory presentation of language is via cross-modal priming. In a cross-modal priming paradigm, participants listen to sentences over headphones, and then perform a different task – such as deciding whether a string of letters is a word – at predetermined locations in the target sentences. People are faster at the interrupting task at points of lower complexity, such as when a word in the linguistic context is semantically related to the target stimulus (e.g. 'doctor' is related to 'nurse'). A second online auditory method involves tracking participants' eye movements with respect to a visually presented scene while the participants listen to instructions about the scene. This method is particularly informative with respect to the question of how the context of the presented scene influences sentence understanding. A third method involves monitoring the scalp with electrodes in order to measure event-related potentials (ERPs): minute voltage changes due to differences in neural activity while participants listen to sentences. This method, which is also used in reading research, requires an understanding of what the voltage changes mean. Some plausible interpretations are currently being proposed in this area.

RESOURCE CONSTRAINTS THAT AFFECT PROCESSING LOAD

In the process of understanding a sentence, it is necessary to integrate structures for incoming words into the structure(s) that have been built thus far, such that the potential integrations for an incoming word are determined by the syntactic rules for the language. According to one current theory – the dependency locality theory (DLT) – the processing cost of integrating a new word w is proportional to the distance between w and the syntactic item with which w is being integrated. Structural integration cost has been shown to be an important factor in accounting for online processing load. For example, consider the RC structures in (5) and (6):

The reporter that attacked the senator admitted the error. (5)

The reporter that the senator attacked admitted the error. (6)

In (5), the RC pronoun 'that' is interpreted as the subject of the verb 'attacked', whereas in (6), the same pronoun is interpreted as the object of the verb 'attacked'. People read the verb 'attacked' more slowly in a sentence like (6) than in a sentence like (5). This difference can be explained by integration distances. In (5), there is one local integration when processing 'attacked': this verb is integrated with the preceding RC pronoun as its subject. In contrast, there are two integrations at the point of processing 'attacked' in (6): this verb must be integrated as the verb for the subject 'the senator' (a local integration) and the object position of 'attacked' must be integrated with the RC pronoun 'that', a nonlocal integration. As a result of the extra nonlocal integration, the processing load at 'attacked' is larger in (6) than in (5), resulting in longer reading times at this word. Furthermore, reading times are slow in both sentence types for the verb 'admitted', a point of long-distance integration with the subject 'the reporter' in both sentence types. Reading times are relatively faster for the other words in the sentences, because integrations at all other positions are local.

Interestingly, aphasic (speech loss) stroke patients understand the subject-RCs in sentences like (5), but they do not understand the object-RCs in sentences like (6), as evidenced by their inability to reliably answer questions about the object-RCs. This suggests that the brain damage suffered by these aphasic patients has reduced the available resources for processing sentences.

An interesting question raised by a distance-based theory of integration cost is how distance is quantified. It appears that complexity may depend not only on the number of words or syllables between two integration points but also on the complexity of the intervening discourse structures. In particular, the ease or difficulty of constructing and/or accessing the referents in the intervening material affects the complexity of integrations across these referents. For example, people read the verb 'attacked' in the object-RC in (6) more quickly when the subject of the RC 'the senator' is replaced with a pronoun such as 'I' or 'you'. This decrease in complexity is arguably due to the fact that the pronouns 'I' or 'you' indicate highly accessible referents in the discourse – the speaker/writer and the hearer/reader – whereas 'the senator' refers to an individual who is not part of the current discourse, in a single sentence paradigm. Reading times for the embedded verb 'attacked' also decrease substantially when there is a referent for the subject noun-phrase (NP) 'the senator' in the current context. This result provides more support for the discourse-based integration cost metric, assuming that it is easier to access a structure for a referent that has just been built than it is to build a structure for a new referent.

Integration distances provide a partial explanation for the extreme complexity of (2). The integrations at the words 'attacked' and 'admitted' are all substantially longer in (2) than in (6), with the inclusion of the RC 'that John met at the party' modifying the NP 'the senator'. Such long-distance integrations, in combination with storage costs at these processing states, may be too complex for the limited capacity of sentence-processing resources. In contrast, all integrations are local in the control for (2) in (4).

The processing of ambiguous structures provides further evidence that longer-distance integrations are more costly. Consider (7):

The bartender told the detective that the suspect left the country yesterday. (7)

The adverbial 'yesterday' can be associated with either the most local verb 'left' or the earlier verb 'told'. The more local integration is strongly preferred. This preference is consistent with the hypothesis that people attempt to minimize integration costs when faced with ambiguity.

At the same time that the process of integration is going on in understanding a sentence, it is also necessary to store the partially processed structures. Both structural integration and storage consume computational resources. According to the DLT, the resources required for storing a partially processed structure are proportional to the number of incomplete syntactic dependencies at that point in processing the structure. As a result, processing load increases when the number of incomplete syntactic dependencies increases. Results from processing ambiguous structures further support the hypothesis that the sentence comprehension mechanism is sensitive to the number of incomplete dependencies in a structure: at choice points, structures with fewer incomplete dependencies are preferred over structures with more incomplete dependencies.

It should be noted that the DLT is just one theory of computational resource use in sentence comprehension. According to an earlier theory, ambiguity resolution is guided by two principles: a locality principle (like the integration component of the DLT), and a principle known as Minimal

Attachment, which prefers phrase structures involving fewer phrase structure rule applications. This theory and the DLT make largely the same predictions with respect to processing ambiguous inputs. It remains an open question precisely how resources constrain sentence interpretation.

INFORMATIONAL CONSTRAINTS THAT AFFECT PROCESSING LOAD

The difficulty of an integration depends not only upon its resource use, but perhaps even more importantly upon the informational complexity of the resulting structure. Recent work has demonstrated that people's preferred interpretations of (temporary) ambiguities in sentences are affected by factors such as (1) the frequency of the different lexical entries for the word being integrated; (2) the plausibility of the meaning of the resultant structure in the world; and (3) the context that the sentence is uttered in. Consider sentence (1) once again:

The dog walked to the park had been chewing the bone. (1)

The preference for initially analyzing the word 'walked' as a past tense verb rather than a passive participle verb is driven by a number of factors. First, the past tense lexical entry for 'walked' is much more frequently used than the passive participle lexical entry for 'walked', which is used in the passive interpretation. Second, although it is plausible for a dog to be walked, it is even more plausible for a dog to be walking, because there is a general bias to treat animate beings as agents or experiencers of events. Third, there is more syntactic storage cost associated with the passive participle structure at the point of processing 'walked': the passive participle structure requires at least a verb to make a complete sentence (and possibly also a modifier for the verb 'walked'), whereas the past tense structure requires no further words to make a grammatical sentence. Note that integration costs do not have a bearing on the preference, because both potential integrations of the word 'walked' are local.

Now consider (8), a sentence with the same structural ambiguity as in (1), but which does not cause processing difficulty:

The evidence examined by the lawyer turned out to be unreliable. (8)

Like the verb 'walked', the verb 'examined' is ambiguous between a past tense and a passive participle. There are three differences between this ambiguity and the ambiguity in (1) that make the ambiguity in (8) much easier to resolve as a passive participle. First, the relative frequencies of past tense and passive participle lexical entries for the verb 'examined' are less biased towards the past tense reading. Second, and most importantly, plausibility information is highly biased towards the passive participle structure: it is plausible for evidence to be examined, as in the passive participle interpretation, but it is not plausible for evidence to examine something. Third, syntactic storage costs are less biased in favor of the past tense reading, because unlike the past tense entry of 'walked', which is optionally intransitive, the verb 'examined' obligatorily requires a noun phrase object. Thus there is a smaller difference in storage costs between the past tense and passive participle structures than for 'walked'.

Referential context also strongly affects people's initial interpretations of ambiguous structures, as evidenced by monitoring people's eye movements while they listen to commands spoken to them over headphones. Consider the command in (9):

Put the apple on the towel in the box. (9)

In a context with only one apple, there is a strong preference to interpret 'on the towel' as the goal for the verb 'put', even if the apple is already on a towel. But in a context with two apples, one of which is already on a towel, the phrase 'on the towel' is initially analyzed as a modifier of the apple, specifying the apple's source location.

Another informational factor which affects people's initial interpretations of an ambiguous input is the intonation of the speech signal. Intonational (or prosodic) properties include variations in the pitch, amplitude, and duration of individual speech sounds and larger segments, as well as the place of pauses. Intonational phrasing which is consistent with the target syntactic structure helps sentence understanding, and intonational phrasing which conflicts with the target syntactic structure makes sentence understanding more difficult.

IMPLICATIONS AND OPEN QUESTIONS

The details of the relative timing and strengths of the resource and informational constraints are currently not known. An influential early hypothesis in the sentence processing literature was the modularity hypothesis: that syntactic preference constraints (constraints related to the resource constraints described here) apply first, followed by informational constraints such as context and plausibility. This hypothesis predicts that there should be reanalysis effects (small garden-path

effects) in instances where syntactic preferences favor one interpretation, and plausibility and/or contextual constraints favor another interpretation. Recent work using eye-tracking methods has failed to observe such a reanalysis effect. For example, there is no measurable initial preference for the goal interpretation of the phrase 'on the towel' in sentence (9) when the visual context favors the source location, despite the fact that syntactic preferences favor the goal interpretation. As a result, an interactive position has gained in popularity, in which resource and information constraints apply immediately to the available alternatives.

The interacting constraints have been described here as if they are all independent of one another. However, this may not be the case. Many researchers argue that language is implemented in a highly interactive architecture, such as a connectionist neural network of some kind. What may superficially look like independent constraints may be emergent properties of such an architecture. Much further research is needed to investigate this issue.

CONTENTS

Mechanisms of sentence processing during language comprehension are described on the basis of behavioral and electrophysiological evidence. The major principle underlying human parsing mechanisms is the principle of simplicity, which leads the parser to construct the simplest syntactic structure whenever possible.

INTRODUCTION

Humans communicate primarily by means of language, mostly in the form of sentences. Sentences allow the relation and qualification between different entities in the real world to be expressed. In most languages, sentences contain at least a subject (animate or inanimate) and a verb (qualifying an action or state). In principle a sentence can be infinitely complex (multiple embedding of sentences) and still be grammatical; however, the human parser has been shown to be able to deal with only two or three embeddings at most (Bach *et al*., 1986). Although human parsers do have processing limitations, their ability to process incoming information on-line is remarkable, as is their capability to produce semantically coherent and syntactically correct sentences on-the-fly.

CREATION AND ATTACHMENT OF SYNTACTIC CONSTITUENTS

The building of sentential structure, which serves the purpose of creating an interpretable form, must be considered a process in which a number of mechanisms interact. These include the integration of previously predicted or unpredictable, and thereby unexpected, constituents. This may be illustrated by imagining the extent of the parser's knowledge when the processing of a sentence input begins. While the subject and the verb are obligatory components of every sentence and can therefore be anticipated, complements of the verb become predictable only with the processing of the verb. A determiner or a preposition allows the prediction of nominal complements and thereby the on-line construction of a noun phrase or a prepositional phrase. By contrast, modifying elements important for the interpretation of a sentence, such as prepositions, adverbs, or relative clauses, are generally not predictable and therefore become relevant to processing only at the point in time when they are encountered.

Prediction and integration of obligatory constituents

Most sentence processing models assume in a more or less explicit fashion that the prediction of sentential components plays a significant role during language processing (Gibson, 1998). It is generally assumed that sentence structure is built up in accordance with principles of simplicity that state that only those syntactic constituents necessary for a minimal structure are postulated. Given a language that displays a restricted degree of freedom with regard to the positioning of sentential arguments but does not mark their grammatical function, there are two possibilities of interpreting an ambiguous initial argument. Take for example the relative pronoun *who* in English relative clause constructions such as *the man who visited the ambassador* versus *the man who the ambassador visited*. Following a principle of minimal structure building, a subject interpretation of *who* is preferred as it allows the prediction of only one further constituent, whereas an object interpretation requires the prediction of both a verb and a subject.

Why language processing follows such criteria of simplicity, which are possibly of a general

cognitive nature as they appear to be related to working memory capacities, can be shown when comparing the processing of subject-first and object-first structures in a case marking language such as German. In German, the grammatical function of sentential arguments is overtly marked morphologically and their ordering is relatively free. With unambiguously marked elements in sentence initial position it is immediately clear whether the structure consists of at least three constituents, namely an object, a subject and the verb (if the initial argument is marked for accusative) or, of at least two constituents (if the initial argument is marked for nominative). Results from reading time studies and event-related brain potential (ERP) studies show that the identification of an object in sentence initial position leads to an increase of processing effort. Interestingly, the integration of the dislocated object at its base position induces further processing costs.

For structures containing an ambiguous initial constituent, such processing costs may be avoided by assuming that the structure contains only a single argument; i.e. an initial subject. Thus, the subject interpretation of an initial argument as well as the preference for a subject-first order in transitive structures results exclusively from the endeavor of the human language processing system to create simple syntactic structures. The validity of such a principle, which is generally known as minimal attachment, is also evident when there is a choice with respect to the syntactic complexity of the complement selected by the verb (e.g. *Ruben knows the answer* versus *Ruben knows the answer is correct*). In this case also, the component with the least number of nonterminal nodes is selected – in the present case, the reading with a nominal object complement (Frazier, 1987).

Integration of modifiers

The integration or attachment of modifiers constitutes a further crucial aspect of sentence structure building. As mentioned above, modifier attachment is not a matter of processes that affect the foundations of a sentence but of mechanisms that serve to integrate additional components (Frazier and Clifton, 1996). For example, the prepositional phrase *with the tiara* in the sentence *the king surprised the maid with the tiara* is an interpretationally relevant constituent, yet its presence or absence has no effect on the grammaticality of the sentence. In contrast to obligatory constituents (e.g., subject or verb), modifiers can generally not be predicted and the processes determining their integration are therefore not affected by the complexity-related criteria discussed in the last section.

From a linguistic perspective, an interesting aspect of modifier integration is the difference between various types of modifier. While there are no syntactic dependencies between a prepositional phrase and the noun it modifies, such dependencies are present between a noun and a relative pronoun coindexed with it. Assuming that the human language processing system endeavors to unify the features of head noun and relative pronoun, this unification should encompass not only obligatory syntactic features, such as gender and number, but also facultative ones, such as case and thereby grammatical function. While these unification mechanisms can be observed in the resolution of ambiguous contexts (in German, for example, the case of a marked relative pronoun may be transferred to the ambiguous head noun for the purpose of ambiguity resolution), it is not yet clear whether and how such mechanisms influence attachment preferences. In any case, it cannot be excluded that they are at least partially responsible for the differences observable between the attachment preferences for various modifiers (Konieczny and Hemforth, 2000).

Nonsyntactic influences

A still open question concerns the influence of extrasyntactic factors such as context or plausibility on the building of sentential structure. It appears to be uncontroversial that these factors influence the interpretation of a sentence, for example in the attachment of modifiers. However, it is not clear whether they have an effect on the initial structural analysis of a given sentence or only later during processing. Examples from English indicate an immediate influence of factors such as animacy (compare, for example, *the defendant examined by the lawyer* versus *the evidence examined by the lawyer*, where the prepositional phrase *by the lawyer* gives rise to processing difficulties only in the first but not in the second case). However, data from German, a language allowing both subject-initial and object-initial structures, show that syntactic preferences dominate even when they induce an implausible interpretation. Thus, in the sentence *die Blinde beobachtete die Ärztin* [*the blind woman watched the doctor*] the ambiguous initial noun phrase is interpreted as the subject, even though this is actually implausible, excluded by the semantics of the verb. Further evidence against assuming that all information is initially accessible is

provided by studies by McElree and Griffith (1995) and Friederici (1999, 2002).

PROCESSING OF FILLER-GAP RELATIONS

The perspective on the building of syntactic structures that was presented in the last section presupposes certain basic assumptions, one of which will be discussed in more detail in the following. Both in theoretical and in experimental linguistics there is a debate with regard to the question of whether noncanonical word orders are derived by means of movement operations and whether these are psychologically real in the sense that they may be experimentally captured.

The examination of so-called filler-gap dependencies – the relation between a constituent in a noncanonical position (filler) and its base position (gap or trace) – has a long tradition within psycholinguistics. A starting point for such studies was provided by the attempt to explain experimentally observed preferences with regard to grammatical function (especially the subject preference for an ambiguous initial argument, for example in Dutch, German, or Italian). The observed preference for subject-initiality was derived by means of structurally motivated differences in the distance between the filler ($_i$) and its gap ($_{-i}$). The distance is smaller in subject-initial structures (e.g. *the wombat$_i$ that$_i$ $_{-i}$ saw the hunter*) than in object-initial structures (e.g. *the wombat$_i$ that$_i$ the hunter saw$_{-i}$*). The perspective argued for here is that such preferences may be derived by criteria of simplicity with respect to syntactic structure building, thus speaking against the assumption that preferences result from the filler-gap relation in and of itself. This, however, excludes neither the existence of a filler-gap relation nor its relevance for language processing.

Under the assumption that the gap associated with a dislocated constituent is psychologically real, one should expect this trace position to be experimentally detectable during on-line processing in a manner similar to arguments in a transitive structure. Nicol *et al*. (1994) investigated sentences such as *the policeman saw the boy$_i$ that the crowd at the party accused$_{-i}$ of the crime*, and were able to show a re-activation of the dislocated argument *the boy$_i$* at the anticipated gap position. However, results such as this have been criticized, in as much as in an SVO (subject–verb–object) language such as English, in which the verb and the trace position are adjacent, an anticipation of the gap/trace cannot easily be dissociated from a re-activation of the arguments at the position of the verb. Thus, the re-activation at a position immediately following the verb *accused* need not be the result of anticipating the trace of the dislocated element but could just as well reflect the integration of the argument into the verbal frame and therefore be the result of the processing of the verb.

Data from SOV languages such as German can help to clarify this issue. They provide evidence against the 're-activation at the position of the verb' and therefore in favor of 'trace anticipation'. For example, in sentences with a topicalized object such as *dem Richter$_i$ ist ein Krug$_{-i}$ zerbrochen* [*the judge broke a jug*], the initial dative-marked object *the judge* has been shown to be re-activated before the verb is reached, at the actual trace position (Muckel and Pechmann, 2000). The view that traces are anticipated is further supported by studies examining the processing of *wh*-clauses. Indirect (embedded) object-initial questions such as *Peter fragte, wen am Sonntag nach dem Unfall der Gärtner besuchte* [*Peter asked whom the gardener visited on Sunday after the accident*] show a higher processing load than their subject-initial counterparts. In an event-related brain potential (ERP) study, a sustained negativity set in immediately after the identified filler *wen* [*whom*] had been processed and continued until the subject *der Gärtner* [the gardener] was reached (Fiebach *et al*., in press).

Several pieces of evidence indicate that the dislocated argument is integrated before the verb is processed. First, the additional processing costs for object-initial structures (in the form of the sustained negativity) disappear once the subject is encountered. Second, the processing of the subject elicits a particular ERP component that is associated with increased integration cost (integrative P600), which in this case may be seen as an index of the initial object's integration. These data are a clear argument in favor of the psychological reality of traces.

Thus, filler-gap dependencies occupy a special place within sentence processing and they are associated with an increase of processing costs. Following the principle of simple structure building, it appears that a sentence without dislocated constituents is always preferred over one which entails the postulation of such dependencies.

SYNTACTIC RE-ANALYSIS

Structure building of the human sentence processing system also includes the need to analyze unexpected events and, in the case of a problem, to integrate the new input into the existing structure either by means of a local correction or through a

re-analysis of the previously built structure. In this regard, one may dissociate two separate processes, diagnosis and re-analysis (Friederici, 1998). During diagnosis, the parser must recognize the cause of the local processing problem. During the re-analysis that follows, the language processing system must solve the identified problem by re-interpreting the current input or altering the structure already built. The relation of both processes to one another has been the focus of many studies. One major question is how the processing costs observed experimentally are distributed over both operations. Are the costs only due to diagnosis (Fodor and Inoue, 1994), or is it that re-analysis (i.e. the extent of the corrections required) induces such costs? Or, alternatively, do both play a part in determining the processing problems observed in behavioral studies?

Diagnosis

As stated, a necessary prerequisite for syntactic re-analysis occurring is that the human language processing system recognizes a violation, be it a violation of syntactic structuring principles or an incompatibility with a structural preference. Thus, re-analysis may already fail because the parser does not even recognize the violation. This is, for example, observable in … *and what a performance by the man who some of us thought that maybe the pressure of being the winner of Wimbledon might not let him win* or in the German example *Welcher Jäger aus dem Schwarzwald beobachtete der Gärtner [which-nominative hunter from the black forest observed the-nominative gardener*]. Both the resumptive pronoun *him* in the English sentence and the second nominative NP der *Gärtner* [*the gardener*] in the German sentence induce an ungrammaticality which, however, is not perceived during processing. The ungrammaticality in the first example even makes the structure easier to process. Just as problematic are the structures in which parsers falsely recognize a violation of a preference-based expectation (illusion of ungrammaticality) the source of which, however, they cannot locate. This occurs, for example, in grammatical but not processable structures such as the English sentence *the daughter of the pharaoh's son admires himself* or the German sentence *dass Caroline die Studentin hilft* [*that the student helps Caroline*]. In the first case, the processing problem occurs because the reflexive pronoun *himself* cannot be bound to the head of the phrase (*the son of the daughter of the pharaoh*) owing to a wrong interpretation of the complex noun phrase (*the daughter of the son of the pharaoh*). In the second case the interpretation fails because it is not possible to interpret *Caroline* as a dative object in a noncanonical position owing to a lack of case marking. Thus, in both cases it is the inability to categorize the problem that leads to an abortion of processing. Whether this may be taken as an argument that diagnosis alone is responsible for the cost of so-called garden path effects will be discussed in more detail below.

Before turning to this question, however, we will consider a further aspect of diagnosis that touches upon fundamental questions of human language processing. With regard to the question of whether the initial integration of a word into the existing structure is based not only on syntactic, but also semantic, contextual, or world-knowledge information, we have already cited the papers of McElree and Griffith (1995) and Friederici (1999, 2002). Both argue on the basis of experimental findings that different violations such as (a) phrase-structure and (b) thematic/semantic violations are detected at different points in time (e.g. (a) **some people rarely books* versus (b) *some people alarm books* or (a) **der Honig wurde im geschleudert* [**the honey was in the centrifuged*] versus (b) *der Honig wurde im Keller ermordet* [*the honey was murdered in the cellar*]. The results show that phrase structure information is accessible to the parser earlier than thematic/semantic information. Furthermore, examples such as **der Honig wurde im ermordet* [**the honey was in the murdered*] which violate both the syntactic and the thematic/semantic requirements show that the diagnosis of a phrase structure violation may block thematic/semantic processes following it. These findings suggest that both the structure building and the analysis of a sentence proceed in a hierarchical manner with the parser first analyzing word category information before taking non-structural factors into account.

Re-analysis

While behavioral experimental techniques (such as reading- or reaction-time studies or eye-tracking experiments) cannot always provide an insight into the fine-grained temporal structure of experimentally observable processing problems and thereby do not allow conclusions as to whether these stem from diagnosis or re-analysis, the measurement of ERPs provides the possibility of unraveling these processes. This is again illustrated by an example from German. Assuming that an ambiguous initial constituent is preferentially interpreted as a subject, the re-analysis required for the revision of such a preference can be shown to differ depending on the type of clause in which the

re-analysis is initiated. Thus, the re-analysis required in an object relative clause such as *das ist die Botschafterin, die die Minister eingeladen haben* [*this is the ambassador who the minister invited*] is apparently much less extensive and thereby less costly than that in an analogous object-initial complement clause such as *Peter hörte, dass die Botschafterin die Minister eingeladen haben* […*that the minister invited the ambassador*]. In terms of ERP effects, this is shown by the fact that both the latency and the duration of the positivity are functionally dependent on the ease/difficulty of re-analysis processes (P345 versus P600/syntactic positive shift) (Friederici, 1998). This difference in the ease of re-analysis between relative clauses and complement clauses is derivable from a structural perspective. In relative clauses, only the position of the trace that is coindexed with the initial constituent must be 'relocated' (from after *die Minister* to after the relative pronoun *die*), whereas in complement clauses an additional position must be created for the clause initial object (after *die Minister*). Thus, it appears that the cost of processing is influenced by the type of re-analysis required.

To summarize, there is evidence that processing costs are caused by both diagnosis and re-analysis processes. While the ERP reflection of diagnosis cost differs in polarity (negativity/positivity) as a function of violation type (outright syntactic violation versus incompatibility with a structural preference), the costs of re-analysis are always expressed in a positivity. Outright syntactic violations like in **der Honig wurde im geschleudert* [*The honey was in the centrifuged*] induce an early left anterior negativity (ELAN) followed by a late positivity (P600). Translating this into processing costs, both the diagnosis of the phrase structure violation (in form of the ELAN) and the attempt at a structural re-analysis (visible in the P600 component) contribute to these. Violations of structural preferences such as object-first structures, in contrast, only elicit positivities which, however, are shown to house two factors, one reflecting processes of diagnosis (a positivity with an occipital distribution) and one reflecting the actual processes of recomputation (a positivity with a centro-parietal distribution) (Friederici *et al*., 2001).

SERIAL VERSUS PARALLEL PROCESSING

A further question that is central to psycholinguistic research is concerned with whether language processing proceeds in a serial fashion (Frazier, 1987), with only one analysis carried out at a time, or in a parallel fashion (at least for subjects with good working memory capacity – Just and Carpenter, 1992). This question is often equated with the debate as to whether language processing proceeds in a modular (Frazier, 1987) or an interactive (MacDonald, 1994; McClelland *et al*., 1989; Marslen-Wilson and Tyler, 1980) fashion, but it must be stated clearly that both questions are actually orthogonal to one another.

With respect to modularity/interactivity – whether all types of information are available to the parser at the same time (interactive) or the parser accesses these in a hierarchical manner (modular) – the above cited articles by Friederici (1999, 2002) and McElree and Griffith (1995) show that the latter (hierarchical access to information) is a basic property of the human language processing architecture. These studies used techniques which are highly sensitive to the temporal aspects of online processing.

By contrast, the data in favor of an interactive model – one claiming that syntactic and nonsyntactic information interact during sentence processing – are generally taken from studies employing experimental techniques that are clearly less sensitive to temporal processing aspects than event-related brain potentials or the speed–accuracy tradeoff method. Thus, the question of whether these two information types interact may be reducible to the question of *when* syntactic and nonsyntactic information interact.

One ERP study systematically crossing lexical-semantic incongruity with syntactic incongruity suggests that both information types are processed independently during the first 400 milliseconds (in the form of an N400 for lexical-semantic aspects and in the form of a left anterior negativity (LAN) for morpho-syntactic aspects), but interact about 600 milliseconds after the critical lexical item is encountered (Gunter *et al*., 2000). Further research must reveal to what extent these findings generalize over different linguistic material with respect to the question of whether language processing proceeds in a modular or in an interactive manner. There are a large number of different theories in this regard, ranging from the assumption that the parser only has access to a single (syntactically based) analysis to the diametrically opposed assumption that the parser calculates all alternatives at all times. The latter appears implausible, especially in view of the existence of clear parsing preferences. With regard to the models that are situated between the two extremes, several theses are particularly worth mentioning: first, the assumption that the parser locally calculates several

alternatives but only continues with one (local or momentary parallelism; e.g. Altmann and Steedman, 1988); second, the idea that the parser calculates various alternatives, which are then pursued hierarchically, with a preference for one analysis (ranked parallel) (Hickok, 1993). Let us consider some of the structures discussed above in order to examine this controversy more closely.

One variant of the serial approach assumes that modifiers, in contrast to obligatory constituents, are first associated with the structure and only integrated when sufficient information of other types (e.g. verb and world-knowledge information) is available. Such an approach can explain, for example, why so-called NP–V ambiguities exhibit no measurable reaction time difference on the prepositional phrase between the sentences *he saw the butcher with the binoculars* and *he ran over the hamster with the birthmark*. These findings, however, cannot *per se* be taken as evidence for or against serial or local/ranked parallel parsing, as one could argue that secondary processing mechanisms, though active, may not be relevant with regard to the basic structure of a sentence (Frazier and Clifton, 1996).

Evidence that the parser does not always make a local decision with respect to structural analysis, and that it is not principally restricted to a single analysis, stems from the domain of object–object ambiguities. While both intuitively and experimentally there is no evidence between a final verb that selects for an accusative and a verb requiring a dative object (e.g. *der Professor wollte Studenten unterstützen/helfen* [*the professor wanted to support/help students*]), a preference for an accusative interpretation of the ambiguous object *Studenten* manifests itself when the argument is no longer adjacent to the verb (e.g. *der Professor wollte Studenten, die die erste Prüfung nicht bestanden hatten, unterstützen/helfen* [*the professor wanted to support/help the students who had not passed the first exam*]). This example clearly shows that the immediate disambiguation on the following element does not reveal the underlying, and perhaps still developing, accusative preference for a locally ambiguous object.

There is, however, also uncontroversial evidence that the parser tends to make decisions immediately, even if they could theoretically be postponed until the next element has been encountered (Crocker, 1994). This is the case, for example, in English NP–S ambiguities (*Stefan knows the paper/the paper shows some problems*) and in German subject–object ambiguities (*welche Radfahrerin beobachteten die Polizisten* [*which bike rider did the policemen watch*]), in which the disambiguating element is the verb adjacent to the ambiguous NP.

In summary, it can be said – and thus we return to the discussion of the first section – that the human language processing system follows economy criteria insofar as the parser always attempts to attain an interpretation of a sentence using the simplest structure or the simplest analysis, drawing upon one structural analysis only. Taking the data presented here into account, however, such a perspective is plausible only under the assumption that the basic architecture of the parser is ranked parallel. Only the assumption of such an architecture can explain the immediate assignment in ambiguous contexts, the strength with which different alternatives appear, the problem of increased processing costs in disambiguating regions, as well as the postponement of an analysis. While it appears clear that structural or syntactic factors are initially responsible for the hierarchical ordering of the alternatives stemming from an ambiguity, nonstructural parameters appear to influence this process at some point.

Sign Language

Introductory article

Diane C Lillo-Martin, University of Connecticut, Storrs, Connecticut, USA

CONTENTS

Practitioners of sign languages use movements of their hands, face, and body for communicating what language speakers convey using their mouth, tongue, and vocal chords. The natural sign languages of Deaf communities have the properties of human language, including grammatical structure at the phonological, morphological, and syntactic levels.

INTRODUCTION

Communities of Deaf people all over the world have developed sign languages, conveying by movements of the hands, face, and body what spoken languages convey using the mouth, tongue, and vocal chords. These sign languages are distinct from the spoken languages used around them, and from each other, although they share properties with both. Research over the past 40 years has established that sign languages satisfy the criteria for natural human languages, both in form and in function. Researchers have worked to determine the grammatical properties of sign languages, and how they are acquired and represented in the brain.

By far the greatest attention has been given to American Sign Language (ASL), the sign language used in the United States and parts of Canada, and this language will be the focus here. However, the sign languages of Europe have been studied in some detail, as well as Israeli Sign Language, Japanese Sign Language, Brazilian Sign Language, and others. Much further research is needed on all sign languages, but current studies have begun to reveal similarities and differences between the world's sign languages, an area of especial interest for its potential to reveal those aspects of language which are modality-dependent, those which are universal, and those which vary by language regardless of modality.

One of the fundamental goals of the study of language as a cognitive phenomenon is the determination of its essential properties. The search for *universal grammar* involves going beyond the surface differences between languages to find their deeper similarities of structure and organization. The study of sign language is an important part of cognitive science because it enables linguists to further separate out effects of the modality of expression from true universals of language. Those properties of spoken and signed languages which hold are the true linguistic universals, while those properties specific to spoken or signed languages are probably due to particular aspects of the modalities.

PHONOLOGICAL AND MORPHOLOGICAL FEATURES OF SIGN LANGUAGE

Sign Language Phonology

In 1965, William Stokoe published his *Dictionary of American Sign Language on Linguistic Principles*. For the first time, the signs of ASL were presented in terms of their formational components – handshape, location, and movement. Prior to the publication of Stokoe's dictionary, signs were thought of holistically, like mimes or gestures. What Stokoe showed was that signs have parts: that signs can be decomposed into smaller, meaningless units which combine in different ways to produce different words – just as words do in spoken languages. Stokoe began to show that there is a phonology of sign language. Figure 1 shows pairs of ASL signs which differ only in their location, or in their handshape.

In Stokoe's dictionary, the parts of a sign were represented in the order location–handshape–movement, but this sequence does not represent the linear order of a sign. Instead, Stokoe assumed that these components were produced simultaneously – unlike the component pieces of a spoken word which are produced sequentially. This

Figure 1. Pairs of ASL signs differing only in (top) location; (bottom) handshape.

feature was considered a major difference between spoken and signed words. Other researchers highlighted this modality effect, and assumed that theories of the phonology of sign languages would have to accommodate this difference.

However, in the 1980s, researchers brought forth evidence that the phonology of ASL crucially involves sequential segmentation, just as in spoken languages. Actually, spoken language researchers were beginning to notice important effects of simultaneity in spoken language phonology, captured in theories of autosegmental phonology and feature geometry. These theories provided the tools for capturing the nature of both signed and spoken languages as having both simultaneous and sequential aspects.

Thus were born models of sign language phonology which separated out the beginning, middle, and end of a sign. For example, Sandler's theory identifies for many signs the beginning location as the initial segment, the movement as the middle segment, and the ending location as the final segment. The hand configuration, which may remain constant or make very limited changes across the duration of a sign, is represented on a separate tier, and autosegmentally spreads across the segments. A simplified representation of a typical monomorphemic sign is provided in Table 1.

Table 1. Schematic diagrams of phonological structure

Single sign	*Combination of two signs to form a compound*			
HC	HC_1	+	HC_2	→ HC_2
L M L	L_1 M L_2		L_3 M L_4	L_2 M L_4

The representation of signs as in Table 1 allows the sign phonologist to explain how signs change when combined into compound words. For example, when the compound sign FAINT is formed by combining the signs for MIND and DROP, the compound is reduced practically to the form of a single sign. The compound begins where the sign MIND ends: at the forehead. It moves to the location where the sign DROP ends using one movement, thus taking the overall shape of a single

sign. The handshape used in MIND is lost completely; only the handshape of DROP is used. This combination of the feature specifications for two different signs merging into one sign involves assimilation, a phonological process whereby one part of a word becomes more similar to an adjacent word.

Rules like assimilation are an important part of the arsenal of phonologists attempting to explain the patterning of units within a word. Sign language phonologists have worked most extensively on developing the most parsimonious representations of signs, refining the hierarchies used to describe handshapes, or the models which best allow for the depiction of how signs change in different contexts. (*See* **Phonology**; **Phonology and Phonetics, Acquisition of**)

Sign Language Morphology

In some ways, ASL has more robust and complex morphology than English does. It is like Swahili in that verbs may show agreement with both their subjects and their objects. It is like Diegueño in that other verbs, expressing location and movement, may combine information about the type of entity with detailed spatial information. It is like Greek in that verbs may be marked to show the intensity and duration of the actions they depict.

As with the earlier studies of ASL phonology, researchers have been impressed by the 'simultaneity' of ASL morphology. Most morphological processes in ASL do not involve prefixation or suffixation, the most common forms of morphological processes in spoken languages. Rather, in many cases the movement of a sign may change, or the handshape or location may change, to indicate the addition of morphemes. Because of the way morphemes combine in sign languages, many morphemes can be expressed using a single syllable (a sequence of a location, one movement, and another location). While such nonconcatenative processes are present, they are relatively rare in spoken languages; however, they are the norm in sign languages.

There are two areas of ASL morphology which have received much attention, and they will be summarized here. They are the use of classifiers with predicates of motion and location, and the marking of subject and object agreement on verbs.

Classifiers in sign languages are handshapes which represent the entities being described by predicates indicating existence, location, or movement. The classifier may indicate a semantic group, such as land and air vehicles, or two-legged beings; or it may indicate the size and shape of the entity, such as thin, round, and flat, or deep and boxy. The movement of the sign represents the core meaning, such as travel in a particular direction. Modifications of the movement may indicate a bumpy terrain, or slow, deliberate motion. Using classifiers, sign language can lay out a detailed specification of the spatial arrangement in a story or description. It is difficult to find English translations for classifier sequences, and skillful manipulation of classifiers is considered one of the hallmarks of excellent sign language story-telling.

The area of space in front of a signer is used by verb agreement as well as classifier verbs. To mark agreement, a verb (usually) moves from the location of the subject to the location of the object. For example, suppose the signer wishes to say 'I teach her', referring to a woman on her right. The sign for TEACH will move from a location close to the signer's body, towards a location close to the woman. If the signer wished to say 'She teaches me', the sign for TEACH would move in the opposite direction: from the woman to the signer. The same process is used with abstract locations representing referents not present in the situation. In this way, the sign marks agreement with the subject and object by indicating the referent using their location. An illustration of this agreement system is given in Figure 2.

One interesting fact about agreement in sign languages is that not every verb marks agreement. Classifier verbs and some others indicate spatial locations but not necessarily subject/object agreement. A third class of verbs fails completely to mark agreement. 'Plain' verbs are produced the same way regardless of the locations of their subjects or objects. Both semantic and phonological factors help to determine which verbs mark agreement. For example, verbs which take inanimate objects do not mark agreement. Likewise, verbs which require continued contact with the body do not indicate agreement.

SYNTACTIC FEATURES OF SIGN LANGUAGE

Notation

SIGN Signs are indicated using upper-case English glosses with approximately the same meanings.

$_{a}$**SIGN**$_{b}$ Subscripts before or after a gloss indicate the use of morphological spatial locations.

nm
SIGN Nonmanual markers are indicated using a

line above the glosses for the signs with which they co-occur.

American Sign Language

One of the most interesting aspects of the syntax of ASL is the large variation in word order found. This is a dimension on which languages may differ greatly; some languages have a relatively strict order of elements, while others permit considerable flexibility. English is among the stricter languages; most sentences comply with the 'basic' word order subject–verb–object, although there are processes for changing word order, such as topicalization and passivization. Japanese allows variability for placement of the noun phrases of a sentence, although the verb must always be final. Serbo-Croatian has a great deal of variability: the subject, verb, and object may appear in any ordering with respect to each other. However, the various orders are used in different contexts – they have different pragmatic effects, such as focusing or topicalizing elements.

It is generally agreed that the basic word order of ASL is subject–verb–object (SVO). However, this order may vary, but in different kinds of context. Like Serbo-Croatian, much of the word order variation found in ASL is for different discourse or pragmatic effects. The topic of a discourse is often expressed first. An element which is focused is often expressed last. To complicate matters, the subject or the object in an ASL sentence may frequently be unexpressed. When there is sufficient information in the context for the referent to be understood (such as from verb agreement), it may be left out. So, all of the examples given in Table 2 (and more) would be acceptable ways to say 'the boy ate an ice cream', in different contexts.

The examples given in Table 2 have some indications for nonmanual markers (the line above certain signs), but not all relevant nonmanual markers have been indicated. Although most signs are

Table 2. Word order variation in ASL

Example sentence	*Order of elements*
BOY EAT ICE-CREAM t	S V O
ICE-CREAM, BOY EAT t t hn	O S V
BOY, ICE-CREAM, EAT t hn	S O V
ICE-CREAM, EAT, IX(boy)	O V S
BOY EAT hn	S V
EAT, IX(boy)	V S
EAT ICE-CREAM t	V O
ICE-CREAM, EAT	O V

produced by the hands, movements of the body and head and specific expressions of the face are also used in the grammar of sign languages. These nonmanual markers are used to mark questions, conditionals, and relative clauses, among other things. In the examples of Table 2, the 't' nonmanual indicates the topic of a sentence (signaled mainly by raised eyebrows and a prosodic break), while 'hn' indicates a head nod, which often accompanies material at the end of a sentence.

Nonmanual markers can be compared to intonation in many ways. Like intonation, the nonmanual marker of a particular construction (such as a question) 'spreads' across a certain domain. The marker for a yes/no question (illustrated in Figure 3), which consists of raised brows and a forward head tilt, co-occurs with the whole question, as the examples in Table 3 indicate.

The examples we have seen so far are all simple sentences with only one clause. Of course, ASL permits syntactic recursion, a process which

Figure 3. Nonmanual marker indicating a yes/no question.

Table 3. Spread of the yes/no question nonmanual marker

	ynq STUDENT ALL PASS TEST 'Did all the students pass the test?'
Unacceptable	ynq *STUDENT ALL PASS TEST

embeds one phrase inside another. An example of a sentence with three embeddings (from the work of Carol Padden) is given below. (The notation IX refers to an indexical pointing sign – a pronoun.)

IX(me) $_1$TELL$_a$ WOMAN $_a$TELL$_b$ MAN
$_b$PERSUADE$_2$ GO THERE PARTY IX(me)
'I told the woman to tell the man to
persuade you to go to the party.'

Cross-linguistic comparison

It seems that sign languages around the world share many grammatical properties, such as a preponderance of nonconcatenative morphology, classifiers, verb agreement, and nonmanual grammatical markers. However, there are some interesting ways in which sign languages differ, and others will probably emerge from future research.

One way in which sign languages differ from each other is in basic word order. While ASL and Brazilian Sign Language have SVO as their basic order, German Sign Language and Japanese Sign Language have the basic order SOV. Moreover, Brazilian Sign Language and German Sign Language (and others) have an element often glossed AUX, which marks agreement in sentences with plain verbs. ASL has no such sign. The presence or absence of AUX in a sign language may be correlated with other syntactic properties. This is one of the topics sign language syntacticians are now researching.

THE ACQUISITION OF SIGN LANGUAGE

Only 5–10 percent of Deaf children are born in Deaf, signing families. These children, like hearing children, receive linguistic input from birth, by watching their parents signing to and around them. Since this population is most comparable to the majority of children studied in spoken language acquisition research, it has received the bulk of the attention of sign language research. We will focus on this group, leaving aside the issue of sign

language acquisition by deaf children born in hearing families.

In general terms, Deaf children acquire ASL in much the same way that hearing children acquire their native languages. They acquire the language by exposure to it; they are not taught it by parents or educators. They do so along a timeline much like that for spoken languages, hitting major milestones in the same range of ages as hearing children do. This should be emphasized since, given the difference in modality, things could have turned out quite differently. The similarities are striking evidence of the biological nature of language.

In fact, there seems to be one difference, which is extremely relevant to the study of modality effects on language. For some years, researchers claimed that the first words produced by signing children (appearing at an average age of about 8 months) came some months before the first spoken words (an average age of about 10–11 months). This difference at such an early stage could indicate that the onset of language is not biologically determined. However, closer examination determined that both children exposed to sign and children exposed to speech used similar communicative gestures at an early age. When the same criteria for distinguishing a word from a gesture were used, the onset of words in speech and sign became much closer. Also, the first truly symbolic words in signed and spoken language both come at around 12 months. If there is a difference between signed and spoken language development in the appearance of first words, it seems this difference is actually rather small, and it can easily be explained by considering the different physical development of the articulators of spoken and signed languages.

It is also clear that beyond the first words, other linguistic milestones emerge at comparable ages. For example, in both sign and speech the first word combinations into simple sentences come at around 18 months. Early development of word order, verb agreement, and more complex constructions seems to be entirely comparable to that of spoken languages.

Like speaking children, signing children make relatively few errors in language development. One common type of error involves the substitution of one handshape or location for another (as illustrated in Figure 4). Two-year-old children tend to use short sentences, but they follow the adult language in the way that they are formed, merely missing some elements of elaboration. The core properties of the language are acquired by children before they are 5 years of age.

Figure 4. Child's production of the sign CRACKER uses the wrong location; the adult sign is made at the elbow.

Unlike other aspects of the grammar, some nonmanual markers in ASL seem to be acquired relatively late. Nonmanual markers like that for yes/no questions, where no manual sign also indicates the grammatical function, are acquired early, but markers like the *wh*-question marker are acquired later – and even when children begin to use the *wh*-question nonmanual they may not do so consistently. However, when they do use such markers they rarely, if ever, make mistakes in its spreading. (*See* **Syntax**; **Language Acquisition**; **Pragmatics, Formal**)

APHASIA IN SIGN LANGUAGE

It has long been observed that damage to specific areas of the left cerebral hemisphere results in impairments of language; while damage to the right hemisphere may result in impairments of spatial cognition. Since sign languages use spatial information so intricately, an obvious question is whether language deficits following brain damage would be as strongly left lateralized for sign language as for spoken language.

A series of studies, mostly conducted at the Salk Institute in La Jolla, California, indicates that sign

language is left lateralized, just as spoken language is, and that damage to the right hemisphere does not significantly impair even the spatial aspects of sign language. Deaf (and occasionally hearing) ASL signers, who experience brain damage in the temporal and parietal regions of the left hemisphere, may experience significant disruptions to language. In fact, different types of disruptions are caused by damage to different areas, in ways very similar to the differences between Broca's and Wernicke's aphasias for spoken languages. The signing of some patients may be slow and effortful, mostly devoid of functional elements; while others may sign fluently but nonsensically, with frequent paraphasias.

Right hemisphere damaged signers may experience severe impairments in spatial cognition, showing classic symptoms such as left neglect. However, their signing is not impaired overall, and even their use of signing space is much like that of age-matched controls. It seems clear that the brain's lateralization for language is based on the cognitive function rather than the modality of expression.

However, this is not to say that there is no evidence for differences in the neural control of signed and spoken languages. Some recent studies using new technologies for studying the neural processing of intact subjects have indicated that, while the left hemisphere's involvement is definite, there may be more right hemisphere involvement in the processing of sign language as compared to spoken languages. Some of these studies have included as one subject group hearing individuals who, growing up in a Deaf household, are native signers. The inclusion of this group allows the researchers to determine whether potential differences between the neural control of signed and spoken languages are due to the nature of the language or to the user's sensory abilities. While some differences are clearly due to sensory deprivation (Deaf signers may use areas of the brain which normally serve audition for visual–spatial processing), others seem to be related to early language use: those who grow up signing use more of the right hemisphere to process sign language than those who grow up speaking do for spoken language.

These recent findings are still preliminary, and much more work remains to be done. However, it is important to search for the ways in which sign languages may be controlled differently from spoken languages, and to inquire into the causes of such differences. Eventually, a full understanding of the nature of signed and spoken languages, including structure, acquisition, and neural control, will help researchers to construct the optimal model of the language faculty. (*See* **Aphasia**)

IMPLICATIONS OF SIGN LANGUAGE FOR UNIVERSAL GRAMMAR

To the extent that sign languages adhere to the principles of universal grammar (UG), they provide support for the hypothesis that a set of properties hold for language qua language, with limited variation possible in the abstract parameters which define linguistic options. Presumably, the principles and parameters say nothing about modality, so sign languages should not differ radically from spoken languages. In particular, if the language faculty is autonomous, then it might be expected that modality effects in sign language would be restricted to the interface between language and input/output. That is, sign languages, having visual input, would have different phonological features, and potentially different types of phonological realizations from spoken languages. However, the languages would not differ in areas of syntax, whose computations would be blind to details of the surface form. Such a model of the architecture of the language faculty is presented in Figure 5.

Although much more research needs to be done, many sign linguists believe that ASL and other sign languages do not violate the principles of UG. The grammatical properties shown by sign languages

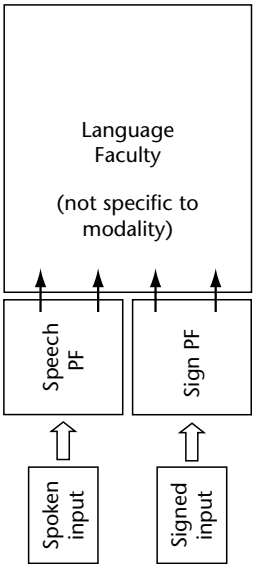

Figure 5. Modular representation of the language faculty. Differences between signed and spoken languages are restricted to the interface. PF, phonological form.

are remarkably similar to those found in the range of spoken languages studied. Even in the area of phonology there are striking similarities between sign and spoken language, although of course there are important differences as well.

There are, however, some possible challenges for the conclusion that sign languages fall perfectly within the range of variation permitted by UG. This is not to say that the hypothesis that sign languages are governed by the same UG as spoken languages is invalid, but that certain potential modality effects need to be more deeply considered and fully explained.

One such difference concerns the use of space. As described above, sign languages use spatial distinctions to represent abstract referents or spatial locations. As one consequence, pronominal signs must pick out particular referents unambiguously. Pronouns may be directed toward any location with which a referent has been associated – thus it is not possible to list all the possible surface pronoun forms of a sign language. Does this mean the lexicon of sign languages must be indefinitely long?

One resolution of this problem is to consider all the various pronoun signs as realizations of two lexical forms: the first person form, and the non-first person form. Many syntacticians use referential indices for pronouns to keep track of reference, co-reference, and disjoint reference. Under the present hypothesis, the difference between sign and spoken languages is that the referential indices for pronouns are overtly realized in sign. That is, in a particular context, the 'she$_1$' which refers to Sally is produced differently from the 'she$_2$' which refers to Jane, in signed languages but not in spoken languages. This kind of solution places the locus of the difference between signed and spoken languages within the domain of what is realized phonologically, consistent with the autonomy hypothesis.

A second type of problem comes from considering the nature of sign languages as a group. Although sign languages do not seem to go outside the range of variation permitted by UG, it has been noticed recently by sign researchers that they display characteristic properties as of a language family – and this fact has not been captured by linguistic theory. Since the properties shared by all sign languages, such as the referential use of spatial locations in verb agreement and pronouns, are clearly related to the sign modality, it is important for linguistic theory to address these similarities and generalizations.

Thus, linguists in general are interested in the study of sign languages. Research on sign language is vital to a complete understanding of the nature of universal grammar. Sign languages allow linguists to test their proposed principles and parameters, and they provide the advantages both of understudied languages, and more importantly, of testing the proposals for their application across modalities. The study of sign languages reveals true linguistic universals.

Spatial Language

Intermediate article

Stephen C Levinson, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands

CONTENTS

The study of spatial language is concerned with the systematic properties of spatial descriptions in natural languages, that is, the description of where things are, or the description of moving bodies.

SPATIAL COGNITION AND LANGUAGE

There are two reasons why the study of spatial description in language might be of special interest to cognitive science. First, space is a central cognitive domain for any roving animal, and human thinking is deeply spatial, reflecting no doubt this ancient phylogeny. The role of gestures, figures and diagrams, geometry, and maps in our thinking all attest to this fundamental role that spatial thinking plays in our cognition. In linguistics, this idea that spatial notions form the foundation for much of our nonspatial concepts is known as 'localism', much evident in cognitive linguistics. Second, language seems to offer a window on the inner world of spatial concepts – in the case of the honey bee for example, we know more about spatial cognition from the communication system than from direct observation of other behavior. However, optimism that we might find a uniform core of human spatial communication may be misplaced: due to the complexity of human cognition, the conceptual systems that underlie language display little of the metric precision of our perceptual systems and are quite variable, being deeply interlocked with cultural concepts (see Bloom *et al*., 1996). They must therefore be studied in their own right, even though it turns out that there are close interrelations between nonlinguistic spatial cognition and linguistic concepts. (*See* **Spatial Representation and Reasoning**; **Spatial Cognition, Psychology of**; **Spatial Disorders**; **Cognitive Linguistics**)

In a tradition that goes back to Kant and beyond, an orthodoxy has grown up that holds that naive human spatial cognition, as reflected in language, is universally egocentric and anthropomorphic in character, and characterized by such universal primitives as ON, IN, AT, and so forth (see e.g. Miller and Johnson-Laird, 1976; Lyons, 1977; Herskovits, 1986). Such spatial concepts are often put forward as good candidates for innate concepts, reflected universally in language (see e.g. Landau and Jackendoff, 1993). Readers are left with the impression that such notions as 'to the left of', 'in front of', 'on', etc., are universally expressed, and moreover that they are coded in limited parts of speech, especially adpositions (prepositions and postpositions). This impression is deeply misleading – recent cross-linguistic work shows that there is no such uniformity in either the semantics or the formal expression of spatial distinctions across languages. This article details these more recent findings, and their consequences for the language–cognition interface.

THE SEMANTICS OF SPACE

Fundamental Concepts

The details of the semantics of spatial description are quite complex and vary considerably across languages, but the general outlines tend to follow rather simple functional principles, as follows (see Levinson, 1996 for details). The Newtonian concept of space as an infinite, abstract three-dimensional envelope plays relatively little role in naive spatial conception – rather, the Leibnizian view of space as a system of relations between things is predominant (some exceptions are noted below). In particular, one object, the *figure* (or theme or trajector, in alternative terminologies), is located by reference to another, the *ground* (or the landmark or relatum). When figure F and ground G are contiguous, it is often sufficient to say in effect 'F is at G', where 'at' glosses some kind of contiguity relation. However, languages may subdivide contiguity into different kinds of relation, such as superadjacency,

subadjacency, containment, and so forth (as in 'The ball is on the table/under the cloth/in the bowl'). This kind of relation is called *topological*, following Piaget. Where G is relatively large compared to F, it may be helpful to subdivide G into parts, and say in effect 'F is at the X-part of G' (as in 'The book is in the back of the car'). Place-names or *toponyms* may be thought about as an elaborate subdivision of a territory for just this purpose. (*See* **Piagetian Theory, Development of Conceptual Structure**)

When F and G are displaced in space, a more complex solution to spatial location is required: we now need an indication of the direction from landmark G in which to search for F. To specify a direction, we need an angular specification, and natural languages provide this in *polar* (rather than Cartesian) *coordinates* mostly based on G. Such coordinate systems are called *frames of reference* in the psychological literature, and it turns out that languages use just three main types. One type uses the system for partitioning objects into parts already mentioned, and projects an axis from the centre of G through a named part to determine an angle or direction, specifying in effect 'F is to the X-side of G', as in 'The ball is at the rear of the truck'. This kind of coordinate system is called the *intrinsic* frame of reference because it relies on reference to the inherent or intrinsic parts of objects (although this terminology is misleading – different languages have quite different ways of assigning parts to objects). Another type uses the bodily axes of the viewer, front and back, left and right, and maps this coordinate system onto the landmark object G, so that we can talk, for example, of F as to the left of G (the mappings are subject to different transformations in different languages, as will be explained). This kind of system is called the *relative* frame of reference (it is often also called the *deictic* frame of reference, but this is misleading, as the viewer whose bodily coordinates are used need not be the speaker, and all frames of reference can have the speaker as the ground object). The third and final kind of system uses abstract, antecedently fixed bearings, a bit like our North or East. Such systems are called *absolute* or 'geocentric' or 'environmental' frames of reference, and all languages use such a system in the vertical dimension, as in 'The lamp is above the table'. But it has only recently been documented that some languages use such systems on the horizontal plane to the exclusion of the relative frame of reference (see Levinson, 1996; Pederson *et al*., 1998).

The properties of motion description are somewhat different. Motion can, of course, be described as located in a place, in which case the systems already mentioned are relevant, but normally the interest is in the direction of motion, or at least in where it is originating or terminating. Again we talk about the figure (the object in motion), but we may need to distinguish multiple grounds, especially the *source* and *goal* of the motion. The specification of source or goal alone does not give us an angle or vector of motion (a fully specified direction) – it only tells us that the motion progressively increased or decreased the figure's distance from the landmark or ground object (a radial trajectory towards or away). Source and goal together do fix a vector, as in 'He went from London to Birmingham', but many languages do not permit source and goal specification in one clause. Languages which use the absolute frame of reference often use fixed bearings to determine a vector, roughly as in 'He left the village northwards'.

One omnirelevant location is the place of speaking, the *deictic centre*. This location may be the ground in any location or motion description, and in principle it is not different from any other landmark, but in practice languages tend to code it specially, for example in demonstratives ('this' versus 'that'), deictic adverbs ('here versus there'), and deictic verbs of motion ('come' versus 'go', 'bring' versus 'take'). (*See* **Indexicals and Demonstratives**)

Languages tend to treat space as a single large semantic field; for example, most languages have a single shared root meaning 'Where?' used across topology, frames of reference and motion description. But this large field tends to be systematically subdivided, so that motion versus location, and within location topology versus frames of reference, are distinguished as important subdomains organized distinctively in both form and meaning, as in Figure 1, and linguistic descriptions should treat these subdomains individually.

Cross-linguistic Variation and Underlying Universals in Spatial Language

Recent investigations have shown that there is much more cross-linguistic variation in spatial language than had been supposed. The semantic parameters involved can be quite various and differently interconnected. Consider first the distinction between location and motion – Talmy (1983) argued that these are deeply interlocked, and indeed location can be thought of as a special case of motion (consider e.g. the parallelism of English 'He is out of the room' versus 'He went out of the room'). However, many languages use entirely

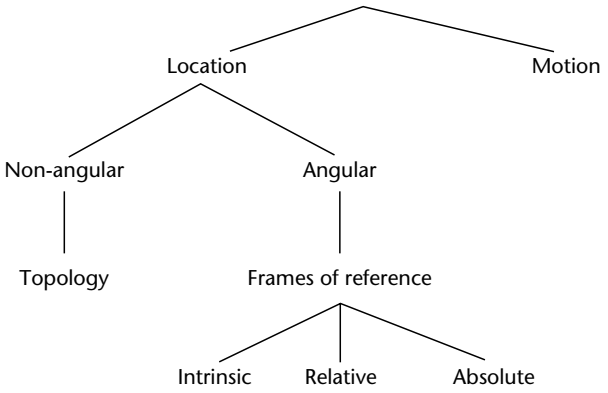

Figure 1. Some important subdomains of spatial language.

different semantic and formal resources in these two domains, so that no such parallelism can be presumed.

Consider the topological subdomain. As mentioned, many authors have presumed that notions like ON, IN, and AT would be universally coded in adpositions (capitals here denote supposed semantic primitives). But in fact there are no easy generalizations of this kind – for example, central Australian languages often conflate IN and UNDER, Japanese conflates ON and OVER, and they do so in different parts of speech, spatial nominals and postpositions respectively. However, variation is not random. Detailed comparison of many languages using standardized stimuli shows that the topological subdomain seems to form a single, universal multidimensional similarity space – the space is very variably subdivided by different languages, but in doing so they conflate into single lexical concepts only neighboring spatial relations. The semantic parameters in this space are at a much more abstract or componential level than ON; if that is conceived of as unattached contact with the vertical support provided by a horizontal surface, then it is notions like *contact*, *adhesion*, *superposition*, *horizontal supporting surface* that form the dimensions of the space. Moreover, these notions are encoded in various parts of speech in different languages: in grammatical case, adpositions, spatial nominals (special minor form classes of nouns), and frequently in locative verbs. Many languages have a small form class of locative verbs, the choice of which makes distinctions concerning the shape and orientation of the figure and its relation to the ground, and some languages have large sets of such verbs that code detailed figure–ground configurations, such as containment within a bowl-shaped ground, or wedged between two supports, as in Tzeltal.

Turning now to the ways of indicating angular direction between figure and ground, the intrinsic frame of reference is by far the most widespread of coordinate systems – indeed a case can be made for the intrinsic frame being universal, at least in vestigial form. However, the way in which objects are partitioned and assigned named sides or facets is very variable. Some languages (like Zapotec) use a fixed armature, assigning a 'top', 'bottom', and designated 'sides' (one can think of this as a superimposed box, as it were, where 'top' is always the vertically uppermost surface). Some languages (like Tzeltal) use an orientation-free system of internal object geometry: the longest axis has names associated with the end faces according to their shape, and similarly for the secondary axis, and so on. Such a system is intriguingly like the system David Marr (q.v.) imagined must be involved in visual object recognition. Yet other languages like English involve a complex mix of orientational and functional criteria, so that the 'top' of a bottle remains the 'top' whichever way up the bottle is (unlike in Zapotec), but the notion is tied to canonical orientation of the artifact. Miller and Johnson-Laird (1976, p. 403) sketch an algorithm for such part-assignment in English, involving such factors as the leading facet in typical motion (the 'front' of a truck), the facet with perceptual apparatus (the 'front' of a camera), the characteristic orientation of the user to the object (as in the 'front' of a desk). Despite the evident complexities, children learn the application of these terms in English earlier than other spatial relations.

The relative frame of reference involves, as mentioned, mapping the body axes, front/back, and left/right, onto the ground. Despite the fact that Kant and many other theorists have assumed the primacy of these axes in our naive spatial conception, many languages make no systematic use of them in this way – that is, they have no locutions of the kind 'The boy is behind the tree' or 'The boy isleft of the tree' (note that such a language may have a term for 'left hand' but makes no generalization of this concept to spatial regions). Many Australian and other languages around the world are of this kind. When languages do provide such locutions, the interpretations can be very various. Note that in English, the 'front' of the tree is the side facing the speaker or observer, thus rotating the speaker's front and back, while 'left' and 'right' are not rotated. One interpretation of this is that the observer's body axes are mapped under reflection onto the ground. In contrast, in

Hausa and many other languages, the observer's axes are translated without reflection or rotation, so 'left' and 'right' remain as in English, but 'front' and 'back' are reversed – 'The boy is behind the tree' now means the boy is between the speaker or observer and the tree (yet the term 'behind' applied to myself means just what it does in English). Hausa thus adopts the convention that the speaker and the tree are in single file, as it were, while English acts as if speaker and tree were confronting each other. Finally, in a few languages, full rotation of the axes occurs under mapping onto the ground: now the 'front' and 'back' of the tree are as in English, but 'left' and 'right' are reversed.

These relative systems may originate as generalizations of the intrinsic system onto ground objects such as trees which are not easily assigned 'fronts', 'backs', or other facets. This would account for the fact that relative systems always occur with associated intrinsic systems, and like intrinsic systems are largely coded in a series of nominal expressions. Thus in English 'The boy is in front of the tree' is unambiguously relative, but 'The boy is in front of the truck' is ambiguous between the intrinsic reading (at the front end of the truck) and the relative reading (the boy is between the observer and the truck). But many languages do not allow this ambiguity – if there is a possible intrinsic interpretation, then that pre-empts a relative one. The ambiguity in English has prompted theorists to assume that the terms themselves are not semantically specified one way or the other, and that frames of reference are psychological in character, not linguistic (Miller and Johnson-Laird, 1976, p. 404). But in many languages the intrinsic and relative systems are clearly distinct in construction, and in English the distinctions can be made linguistically (as in 'at the truck's front').

The absolute frame of reference used on the horizontal plane will be unfamiliar to most readers except in discourse about geography, where *North* may really be thought about as 'up' on a map, that is, intrinsically. However, many languages use an absolute frame of reference for nearly all spatial discriminations for objects separated on the horizontal plane, speaking thus of 'the northern knife' or 'your western knee' and so forth. There are again many different types. Some languages, like most Australian Aboriginal ones, have fully abstract cardinal direction systems, like our North, South, East, and West, except that they may be skewed in different directions and are likely to have precise quadrants or arcs associated with each. Orthogonal axes are normal, but not invariable, and quadrants of application may be equal (of 90 degrees) or not. Another common kind of system (found e.g. in Nepal and MesoAmerica) uses major inclines in local geography, with an uphill versus downhill major axis, and an 'across' minor axis (the directions further specified by landmarks). A third common type of system (found e.g. in Arnhem Land and Alaska) uses the major axis of river drainage to provide 'upstream'/'downstream' and 'across' axes. Prevailing winds are also a common source of inspiration, as in Eskimo wind direction systems, which in naming up to sixteen directions around the compass card allow precise subdivisions down to 22.5 degrees. It should be stressed that although these latter systems may seem hooked to local environmental conditions, these systems are mostly abstracted off this ecological background, and have become fully abstract fixed bearings, which do not vary when the landscape varies or when used outside traditional territories. Such systems often have considerable linguistic importance, forming a systematic underlying set of oppositions, a grammatical category, which shows up in different lexical and morphological sets – for example, such languages are likely to have, in addition to nouns denoting the directions, motion verbs meaning 'to go north', etc., and demonstratives meaning 'that northern one', etc. Incidentally, absolute systems of spatial description are the only naive spatial concepts that seem to surpass in abstraction the Leibnizian view of space as consisting only of relations between things. A description such as 'the southern edge' or 'going east' does not rely on a figure–ground relation – instead of the relation to the ground an abstract spatial vector is specified in a Newtonian space. In addition to this abstract quality, these systems are of considerable interest to the cognitive scientist because they require speakers of such languages to constantly and correctly reckon their orientation with respect to these fixed bearings, a point that we will return to.

Clearly not all languages use all three of these frames of reference (intrinsic, relative, and absolute), but some do. Some languages use the intrinsic system alone, and others use the absolute system alone, or with only traces of the intrinsic system. The only constraint appears to be that the relative frame is dependent on the intrinsic one. This relative freedom of occurrence is intriguing, since the different frames have rather different spatial and logical properties. For example, unlike the intrinsic frame, both the relative frame and the absolute frame map axes from a larger space onto the figure–ground relation – hence when the

figure–ground configuration is rotated, the intrinsic description may remain constant, but not the relative or absolute descriptions. Relative and absolute frames thus support logical transitivity and converseness (e.g. if A is north of B, and B is north of C, A is north of C), unlike the intrinsic frame. However, if one rotates the viewpoint (e.g. by walking around to the other side of the array), the figure–ground relation changes in a relative description (what was to the left becomes to the right), but not in an absolute description. Thus it is only absolute descriptions that sustain full logical inferences under different viewpoints – they are clearly the logically superior systems, but require a significant cognitive overhead, namely constant mental orientation.

In summary, then, the semantic distinctions made in spatial descriptions vary quite widely across the world's languages, and there are no high-level concepts of the order of IN or FRONT OF or LEFT OF that turn up universally in languages. Nevertheless, there seem to be underlying constraints on the semantic spaces involved in each subdomain, such that, for example, the topological space seems universally specified as a single similarity space, languages can draw from only three frames of reference, each based on polar coordinates, and so on. Another area of surprising diversity is the way in which such distinctions are coded – there are no universal tendencies for spatial relations to be coded in just one or two parts of speech, but rather the tendency is for spatial information to be distributed through the clause, in nominals, case, adpositions, and spatial predicates.

THE COGNITIVE CONSEQUENCES OF LINGUISTIC DIVERSITY

Many species (ants, bees, fish, birds, and bats) have quite extraordinary spatial and navigational skills, often based on such exotic senses as polarized light detectors, echo-location, and magnetoreceptors. All the evidence points to native human spatial perception as being indifferent to poor, as generally in the primate order. Western subjects, for example, displaced to an unfamiliar location, can rarely point to home-base, or even a recent waypoint, at much better than chance levels.

The diversity of linguistic systems for spatial location points to the special role that culture plays in human spatial thinking. The same point is suggested by the elaboration of different navigational traditions and by the technological development of a prosthetic sense of direction through maps, compasses, and satellite systems. The acquisition of spatial language by children also suggests that most spatial concepts in language are anything but 'natural', being learnt relatively late. The facts of acquisition, as far as we now know them, are as follows. Western children clearly learn topological spatial terms first, starting at about age two, proceed to intrinsic uses, and about the age of four have relative usages of 'front' and 'back'; but 'left' and 'right' terms lag far behind, with relative 'left' and 'right' often not being fully mastered before 11. This development is in line with predictions from Piagetian Theory, where topological concepts are held to be conceptually simpler than the Euclidean geometry underlying frames of reference. But children whose native languages have fundamentally different spatial systems from European languages do not seem to start from a common universal notional core, and then gradually diverge – rather they seem to adapt to the local system of categories from the beginning (Bowerman and Choi, 2000). Thus some children learning languages with intrinsic and absolute frames of reference, but no relative frame, do not seem to learn the intrinsic system before the absolute one, but rather at the same time or even partially in reverse order (Brown and Levinson, 2000). All of this suggests that in this domain the child must construct the relevant categories – they are not given by innate endowment as some authors have supposed. (*See* **Navigation**; **Piaget, Jean**)

Nevertheless, cultural and linguistic concepts of space can be shown to have profound cognitive consequences. For example, speakers of languages where the absolute frame of reference is predominant must run a constant background mental computation of absolute direction, reproducing in cultural 'software' what ants and bees do in 'hardware' through specializations for solar compass estimation. Pointing experiments show that such peoples, in contrast to speakers of relative languages, are capable of great accuracy in direction estimations without special attention during motion. Further, experiments on nonverbal memory and inference on these same subjects show that they code spatial scenes in memory in terms of fixed bearings, and not in terms of, for example, left and right, as Western subjects do. This can be shown using the distinct properties of relative and absolute frames of reference under rotation – for example, if subjects are shown an arrow facing left and south, are asked to memorize it, and are then rotated 180 degrees, and asked to pick the similar stimulus from a pair of arrows, one facing right and south, and one left and north, speakers of relative languages will pick the

north-facing arrow because it preserves leftness, but speakers of absolute languages will pick the right-facing arrow because it preserves southness. When embedded in a reasoning task, such manipulations are good tests for unreflective coding strategy, and the results show systematic effects of the semantics of the native language on the subjects' mental representations for general reasoning (see Levinson, 1996; in press). These are among the strongest Whorfian effects of language on cognition that have been demonstrated. (*See* **Whorf, Benjamin Lee**; **Linguistic Relativity**)

As mentioned at the beginning, spatial thinking seems to play a special role in human thinking. Further evidence of this comes from a pervasive phenomenon associated with speaking, namely gesture. Although the functions of gesture are not fully understood, it is clear that gesture co-occurs especially with talk about space, and although part of the motivation is communicational (especially in the case of pointing), part is conceptual – gesture seems to help the formulation of spatial messages (see McNeill, 2000). Interestingly, absolute speakers gesture while retaining the correct bearings of events, while relative speakers tend not to, indicating shared frames of reference in language and gesture. Finally, a matter of special interest is the encoding of spatial information in languages coded in a spatial medium, namely sign languages, where it turns out that there is no single, 'natural' solution to the depiction of space. (*See* **Sign Language**)

Speaker Recognition

Advanced article

Diana Van Lancker, New York University, New York, New York, USA
Jody Kreiman, University of California, Los Angeles, California, USA

CONTENTS

Voices, like faces, communicate personal and emotional information, and figure importantly in nearly every human encounter. From puberty on, barring disease or accident, personal voice quality is a robust, distinctive signature of each individual human existence. Much information about the speaker is revealed in the speaker's voice, including age, sex, emotional and physical state, personality, socioeconomic status, geographic history, and attitude towards the listener and the topic under discussion.

INTRODUCTION

The terms 'voice' or 'voice quality' are often used (especially by speech pathologists or otolaryngologists) to refer to those aspects of sound that are due solely to vocal fold vibration. Terms like 'breathiness', 'roughness', 'hoarseness', and 'clarity' are often used. Changes in the rate of vocal fold vibration contribute to alterations in perceived voice pitch and intonation, and changes in the manner of vibration produce differences in voice timbre (corresponding to the characteristic amplitudes of the series of overtones of the fundamental frequency). However, the notion of voice quality is also construed more broadly when discussing talker identity. 'Speaker recognition' refers to any attribution of identity on the basis of a voice. Speech is produced when the acoustic laryngeal source (the sound energy arising when pulses of air pass through the vibrating vocal folds) is shaped acoustically by the vocal tract. Vocal tract filtering produces resonance peaks and valleys in the acoustic voice signal, which contribute significantly to perceived speaker identity. As the jaw, soft palate, tongue, and lips move, the resonance characteristics of the vocal tract change, giving rise to particular patterns of variation that characterize individual speakers. Other parameters, including intensity (loudness) and its range and variation, rhythm and speaking rate (e.g. words per minute, word or syllable durations, number and duration of pauses), and use of lip rounding or pharyngeal tension or other pronunciation habits, may also cue speaker identity. Although these characteristics can be described and labeled (Laver, 1980), no stable weighting or hierarchical arrangement of all of these components serves to specify an individual human voice. Nor do we understand how listeners select cues or elements from the acoustic voice pattern to achieve speaker recognition.

HUMAN RECOGNITION OF VOICES

Voice recognition has been studied in such diverse disciplines as forensics, biology, evolution, human development, phonetics, psychology, sociolinguistics, neuropsychology, and engineering. Forensic concerns, including the reliability of 'earwitness' testimony and expert reading of spectrograms ('voiceprints'), have motivated many studies of voice (Hammersley and Read, 1996). Much of this research has proceeded pragmatically to establish appropriate guidelines for using voice records in court.

The results of different studies often appear contradictory (Kreiman, 1997). For example, seeing a face while hearing a voice may aid recognition, but may also distract the listener and result in poor learning of the voice. Both male and female voices have been found by different researchers to be easier to recognize overall, and listeners of both the same and different sex have been found to show an advantage. Other factors, such as length and content of the speech sample, quality and context of the speech, time since hearing the voice, and psychological state of the listener, in various combinations, may influence listeners' abilities to accurately identify voices.

Listeners are better at identifying voices speaking a language they know, and they apparently remember voices more easily after active conversation than after passive listening. However, speakers differ in how memorable their voices are, and recognition rates across similarly designed studies vary. Experts generally conclude that neither eyewitness nor earwitness testimonies should be held as incontrovertible evidence in court.

Vocal patterns allow many animals to identify and locate kin without visual contact (Cheney and Seyfarth, 1980). Bats, vervet monkeys, pigtail macaques, chimpanzees, certain species of birds, and timber wolves recognize the individual voices of their offspring, and some species of monkeys can associate the cries of an infant with its mother. For humans, depending on the voice sample and listening conditions, recognizing a familiar speaker requires at most three seconds of speech. The voices of famous individuals can be recognized at well above chance levels when listeners can choose responses from a list of names, but recognition is less certain when listeners must freely identify the speaker. The most rudimentary acoustic material may suffice to cue the identity of the voice (Remez *et al*., 1997).

Studies examining the effects of acoustic manipulations on voice recognition indicate that very varied cues can specify individual voice patterns. For example, for one speaker, precise pronunciation and large pitch variations may be salient, but another voice may exhibit breathiness and long vowels (Van Lancker *et al*., 1985). Converging evidence from acoustic manipulations, mimicry, and neuropsychology suggests that a familiar voice is stored and processed cognitively as a pattern, or 'Gestalt'. In contrast, in dealing with unfamiliar voices, listeners rely on auditory–acoustic features in a comparative and detailed manner, perhaps comparing the perceived features to a template for an ideal or 'average' speaker (Kreiman and Papcun, 1991).

Voices play an important role from the earliest stage of child development. Newborn infants can pick out their own mother's voice from a set of maternal voices (DeCasper and Fifer, 1980), suggesting that voices are differentiated very early in development. In the first year after birth, infants show more interest in words spoken in a familiar voice. A study of school-age children reported that developmental schedules are different for recognizing familiar and unfamiliar voices, in that children recognize classmates' voices as well as adults do, but have relative difficulty distinguishing unfamiliar voices.

For many years, speech perception studies avoided the issue of voice differences, instead seeking consistent cues to speech understanding that were believed to be independent of the personal voice information. However, it has become increasingly clear that the speaker's voice forms an integral part of words stored in auditory memory (Palmeri *et al*., 1993). Meanings remembered from speech samples are affected by the listeners' perceptions of the speakers' abilities, intentions, and opinions as derived from the speakers' voice patterns (Geiselman and Bellezza, 1977). This 'incidental memory' for voice information is nearly as substantial as when subjects are asked to intentionally remember voice information.

VOICE RECOGNITION ABILITY AND DISABILITY

There are large differences in normal abilities to discriminate among voices, recognize voices, and learn new voices. Callers by telephone expect to recognized by voice: when the person they are calling hesitates, due to an initial person-identification failure, there may be brief 'trouble' in the interaction (Schegloff, 1979). In everyday life, listeners mistake one voice for another. In 'tip of the ear' slips, a listener fails to identify a voice that seems familiar. In laboratory testing, people may be able to describe the auditory details of a voice sample that should be familiar to them, or distinguish it from other voice samples, but still not recognize the identity of the voice. The reverse may also occur (Van Lancker, 1991).

CEREBRAL LOCALIZATION OF SPEAKER RECOGNITION

For over a century, it was believed that the left hemisphere was the sole arbiter of communication through the medium of speech. However, early studies of hemispheric specialization for processing of voice quality demonstrated that patients with right temporal and parietal damage performed worse than those with left hemisphere damage when asked to discriminate among voices spoken in different dialects (Assal *et al*., 1981). Later studies of phonagnosia – voice perception deficits – used the voices of famous male entertainers played to subjects who had suffered a stroke to one cerebral hemisphere (Van Lancker and Canter, 1982). Again, right hemisphere damage significantly interfered with recognizing familiar voices, whereas patients with left hemisphere damage

recognized the voices, in many cases as well as normal listeners. Even severely aphasic patients, who could not understand what was being said, knew who was saying it.

Further studies in neurological patients demonstrated that voice recognition (perception of familiar voices) and voice discrimination (perception of unknown voices) are separate abilities (Van Lancker *et al*., 1988). Brain lesions can interfere with one ability while leaving the other unaffected. Brain imaging studies have shown that most patients with deficits in their recognition of familiar voices have right parietal lobe lesions. In these studies, difficulty discriminating among unfamiliar voices occurred in cases of lesions involving the temporal lobe of either the right or the left hemisphere. Thus, voice recognition and discrimination are not dependent on each other and have different neuroanatomic substrates (Kreiman, 1997).

MACHINE RECOGNITION OF VOICES

Individuals cannot 'forget' or 'misplace' their voices, as they can their identification badges. This fact means that reliable automatic voice recognition protocols are convenient, powerful additions to many security systems. Commercial speaker recognition systems perform well in many applications, with false recognition and false elimination rates as low as 1% (Kunzel, 1994).

Two tasks should be distinguished here. The most common ('speaker verification') involves deciding if a speaker (the 'client') is in fact who he or she claims to be. In 'speaker recognition', on the other hand, no identity claim is made by the client. Instead, the system either decides who the speaker is from a database of known speakers or determines that the client is unknown.Verification thus involves matching a client's voice to a single target, while recognition involves comparing the client to a large number of targets: a much more difficult task. Although the precise analysis techniques and statistical matching algorithms vary (Campbell, 1997), the general procedure is as follows. A cooperative speaker who wishes to be recognized is recorded under ideal conditions with good-quality equipment. On subsequent occasions, the speaker enunciates clearly and makes no attempt at vocal disguise. The utterance is analyzed acoustically and compared to the previously created template for the speaker the client claims to be. Matches are based on low-level, mathematically derived, computationally efficient acoustic parameters, and not on high-level, psychologically derived parameters like those that listeners appear to use (Campbell, 1997). A statistical index of the match is created. If the index exceeds some threshold, the person's identity is verified or the speaker is recognized.

Voice recognition by machine differs substantially from how human listeners recognize voices, and the design and performance of automatic systems are not very informative about human behavior. The unlimited-set task performed by listeners is much more difficult than the highly specific matching task performed by most machine algorithms. In human speaker recognition by listening, much less control is possible than in automatic systems. Speakers say whatever they want, and may shout, stutter, mumble, whisper, disguise their voices, or imitate another speaker. Environmental noise – traffic, the voices of other speakers, telephone static – is often present, or the voice sample may be poorly recorded, for example on a low-quality answering machine. Often, the speaker could be virtually anyone – whereas an automatic system usually need only compare an unknown voice sample to the stored template for the one person the speaker claims to be.

Finally, in machine recognition algorithms the threshold for 'recognition' can be set explicitly. Such thresholds are usually rather strict, to minimize incorrect identification of imposters. This necessarily means sometimes excluding clients who should be recognized. However, a level of appeal is possible in machine recognition protocols. For example, workers denied access to a secure area (perhaps because a cold has altered their voice qualities) can normally contact a human security guard who will check their identification. On the other hand, human listeners' thresholds for recognizing a voice – the amount of evidence they require to associate a voice with an identity – cannot be consistently manipulated, and listeners' confidence in their responses has no statistically significant relationship to the accuracy of their identification. Further, no level of appeal is available in forensic applications, where an incorrect identification may result in conviction of an innocent person.

Statistically, given comparably constrained listening conditions, humans do not recognize voices as well as machines do, but in real life they face a much harder task. They separate the target voice from noise, possibly involving a background of other voices; they map this uncontrolled, degraded signal onto some decayed memory trace. Then, from an apparently limitless repertory of potential targets accumulated over many years, listeners somehow recognize the talker. We still have much

to learn about the human ability to recognize speakers, and it continues to amaze.

Speech Error Models of Language Production

Intermediate article

Joseph P Stemberger, University of British Columbia, Vancouver, British Columbia, Canada

CONTENTS

Some models of language production use speech errors (malfunctions of language processing) as evidence for the organization of the language system.

INTRODUCTION

Some models of language production have been developed to account for the involuntary errors that occur during speaking. The ways in which a system malfunctions is assumed to reveal details about how information is represented, about how the system is structured, and about the nature of processing. It should be noted that no model has been developed solely on the basis of information about errors. All models are also based partly on information about correct production and are of types that have been developed for other aspects of language. Most models are restricted to adult language systems, but a few network models additionally are concerned with learning (though none of these address actual developmental data). After a brief review of the levels of language and of the basic kinds of speech errors that occur, I address models that are heavily based on error phenomena and evaluate how well they account for what is known about speech errors. (*See* **Aphasia**; **Language Acquisition**)

LEVELS WITHIN THE LANGUAGE PRODUCTION SYSTEM

Before we can address errors, it is necessary to review the types of information and processes that are basic to language, as well as the degree to which these are organized into separate modules. Table 1 presents a typical picture of language production. Some models have separate modules for each function, while others merge all the intermediate levels into one. (*See* **Speech Production**; **Modularity**)

Models vary in the degree of seriality between levels in the system (serial modularity). In a fully serial system (which no model uses), processing at one level goes to completion before any processing begins at the next level down. Hesitations during speech suggest at least a cascading serial system: as soon as partial information is available at a given level, it is passed on to the next level down, so that processing may begin there. However, once information has been passed to the next level, the speaker does not return to the higher level to process it further. In a cascading parallel system, in contrast, as soon as partial information is available at the lower level, it is passed back to the higher level, and may affect the final outcome of processing at the higher level. Processing at higher levels nevertheless goes to completion earlier than processing at lower levels. In a fully parallel system, all levels are processed simultaneously; the levels need not be discrete, and information from all levels can be intermixed. It should be noted that, in order to check the accuracy of the message at all levels, the monitoring function reverses the order of processing from bottom to top; a speaker may decide, on the basis of information at a lower level, to make changes at a higher level, leading to apparent effects of, for example, phonological information on lexical processing.

TYPOLOGY OF SPEECH ERRORS

All levels of the language system can be involved in error. However, errors in message formulation and in motor processing are difficult to detect and are rarely studied. The bulk of studies (and models) have focused on phonological errors, followed by

Table 1. Basic functions in language production

Message-formulation	Deciding what information to encode for speech production
Lexicon	Encoding meaning into individual words
Syntax	Ordering of words (including inflectional morphology)
Phonology	Constructing the pronunciation of a word at an abstract level
Phonetics/motor processing	Constructing a more detailed and more concrete representation of the pronunciation of a word
Monitoring	Making a final decision about the appropriateness of the content; if an error is detected, production is halted and the error is repaired

work on lexical errors, morphological errors, and (a distant fourth) syntactic errors.

Errors bear up to seven different relations to the intended target (Table 2). Rule application errors are possible only in systems that contain rules, and can be treated as nonbasic. For example, the morphological regularization error *choosed* for 'chose' can be viewed either as the overapplication of a morphological rule (the past tense *-ed* rule), or as the substitution of a regular past tense pattern (*base+ed*) for an irregular (lexically idiosyncratic) past tense pattern. There is also ambiguity relative to other error types. Consider the following error:

target bite block
error bLite block

This can be analyzed as an addition error, because the element /l/ (anticipated from the next word) was added where no element appeared in the target word. However, it can also be analyzed as a substitution error involving a higher-level unit: the onset /bl/ (anticipated from the next word) was substituted for the target onset /b/. It is possible to create a theory-neutral typology of errors, but the actual mechanisms underlying errors may differ substantially in different theories.

Another important dimension is the relation between the target and source words (Table 3); different relations have different statistical properties. Contextual errors result from interference between two elements that are both appropriate for a given utterance. For example, in *why was see shurprised* instead of 'why was she surprised', there are two consonants that are both a part of the utterance, but they have been produced in reversed order. In this example, the two interacting elements are part of the same unit at one level (the same sentence), but are part of different units at a lower level (two different words); in other errors, the two interacting consonants may be in different sentences, or in the same word. Noncontextual errors do not involve interference from another element in the context. Examples include use of the wrong word or phoneme (e.g. *hair* for 'feathers'), blending two competing words into one (e.g. *flaste* for 'flavor' plus 'taste'), regularization, and (apparently) random loss or addition of words or phonemes.

Table 2. Relation of an error to the target

Substitution	Wrong element
Deletion	No element where an element is required
Addition	An element where no element should be present
Blend	One element with characteristics of two competing elements
Rule overapplication	A rule applied that should not have
Rule underapplication	A rule should have applied, but did not
Combinations of the above	

MODELS OF LEXICAL REPRESENTATION

There are three main approaches to the representation of lexical items, plus an orthogonal issue.

Lexical Item as Information Store

A lexical item is a location in long-term memory wherein is stored all relevant information about a word: its meaning, syntactic properties, pronunciation, spelling, etc. Gaining access to the lexical entry gains access to all information within the entry. This is possible only within symbolic models (e.g. Garrett, 1975). (*See* **Symbolic versus Subsymbolic**)

Lexical Item as Node with Pointers

A lexical item contains no information. It is a node that is connected to different types of information. Connections come in from semantic and syntactic units that are relevant to the item, and go out to

Table 3. Relation between target and source words

Contextual	Location: Directionality:	Within-unit Anticipation	Between-unit Perseveration	Exchange
Noncontextual				
Combined contextual and noncontextual				

phonological and syntactic units. The function of a lexical item is to map semantic activations onto phonological activations. This is characteristic of local connectionist and similar models (Dell, 1986; MacKay, 1987; Stemberger, 1985; Berg, 1988). (*See* **Spreading-activation Networks**)

No Lexical Items

Semantic activations are mapped directly onto phonological activations with no intervening levels. This is possible only within distributed connectionist and similar models (Dell *et al*., 1993; Vousden *et al*., 2000). (*See* **Connectionism**; **Language, Connectionist and Symbolic Representations of**)

Meaning versus Phonological Form

One orthogonal issue is whether the lexical units are semantically based or phonologically based. Following Levelt (1989), many models have both. Lemmas are accessed on the basis of meaning, which in turn lead to the access of form-based lexemes. For example, homophones like *need* and *knead* correspond to two different lemmas, but to a single lexeme. From lexemes, the phonological representation of the word is then constructed.

MECHANISMS OF RETRIEVAL AND PRODUCTION

We may distinguish between mechanisms to retrieve information, and mechanisms that combine different items once they have been retrieved (though many connectionist models do not make this distinction). We can also distinguish the mechanisms in terms of search versus spreading activation. The next section presents details about models and evaluates them. (*See* **Lexicon, Computational Models of**; **Lexicon**)

Symbolic Models

Motley *et al*. (1983) proposed that all errors arise through competition, either between closely related items (in noncontextual errors) or between two elements slated to be produced within some chunk of speech. Competition could be between lexical items, phonological elements, or syntactic structures. However, detailed proposals about processing have not been made. The spirit of their proposals has been instantiated in network models.

Garrett (1975) proposed a serial cascading model that relied on search mechanisms. The result of message formulation is a semantically based pattern, which is compared to lexical entries. Words are accessed in several stages. (1) A lexical item (=lemma) is located in the lexicon via search (of an unclear nature but presumably involving pattern matching). Errors at this stage result in a wrong word that is semantically related to the target; any additional phonological resemblance to the target is due to chance. (2) The word's form (=lexeme) is accessed from a phonologically organized list. Errors at this stage result in a word that is phonologically related to the target but not semantically related. (3) Occasionally, two contextually synonymous words are both accessed; they compete for copying into the same syntactic position, leading to word blends.

Other types of error occur when lexical items are inserted into syntactic structures (which are accessed in parallel; the exact interplay between lexical items and syntactic structures has not been spelled out). (4) The syntactic structure includes inflectional affixes and closed class words as a part of the structure. Errors can occur in which the wrong structure is selected, leading, for example, to use of an uninflected form or of the wrong inflected form. Errors can also occur in which a word is inserted into a structure in which it is not supposed to occur, leading, for example, to violations of subcategorization and selectional restrictions. (5) The phonological form is then inserted into the sentence. Two kinds of errors can arise at this stage. In the first, a target word is inserted into the wrong location in the sentence structure, displacing some other word. The displaced word may be inserted in the slot that had been intended for the first word (leading to the transposition of words), or the first word may be

inserted in both slots (leading to the anticipation or perseveration of the word). Second, sound errors may occur. Because inflectional affixes and closed class words are already a part of the structure, they are never involved in phonological errors. Further, two inflectional affixes may never be transposed. (Stemberger (1985) shows that closed class lexical items and affixes do take part in morphological exchange errors and phonological errors, but at rates lower than those of open class items. He argues that this may be a frequency effect, since high frequency words in general show low rates of phonological errors.)

Shattuck-Hufnagel (1979) provides further detail about the insertion process. There is a scan-copier that copies the words from the lexicon to the syntactic slots, one phoneme at a time. To keep track of where it is in the copying process, the scan-copier notes what has been copied (by checking off the segments as they are copied) as well as the surrounding segments and the syllable structure (so it can return to the right word to copy the next segment). Errors may occur when the scan-copier fails to check off a copied segment. The unchecked segment remains available for copying, and may be erroneously copied into a later word, leading to a perseveration. Errors may also occur when the scan-copier (after copying a segment) returns to an incorrect location and copies whatever segment is there; this is an anticipation or perseveration. Because the scan-copier keeps track of the segments to be copied and their location, these errors tend to involve segments that share many features with the target segment, occur in a similar location in the word and in the syllable, and occur in the vicinity of similar consonants and vowels. The erroneously copied segment is checked off. When the scan-copier reaches the location where the erroneously copied segment should have been, it cannot copy the segment because it is checked off. The only free consonant is the original target segment that was not copied when it should have been, so that consonant is now copied. The result is that the two consonants have exchanged places. Exchanges are predicted to be the most frequent type of error. In a minority of instances, the first miscopied segment is not checked off, and so is additionally copied into its rightful place, resulting in an anticipation error. (No mechanisms were provided for noncontextual phonological errors, but perhaps these are the result of miscopying individual features.)

Shattuck-Hufnagel (1979) proposed that the monitor searches for errors, and can correct them. This monitor gives rise to 'incomplete' errors, in which the speaker anticipates a later phoneme, but stops speaking and corrects the error before reaching the word that is the source of the miscopied phoneme. (Such errors are ambiguous between anticipation and exchange errors. Dispute over the nature of these errors prevents us from evaluating the fact that Shattuck-Hufnagel's model predicts that exchange errors predominate.) Levelt *et al*. (1991) point out that the monitor can lead to 'mixed' errors involving both semantic and phonological similarity to the target word. Semantically related word substitutions can be spotted by the monitor as being phonologically dissimilar to the speaker's intended target. Phonologically related word substitutions can be spotted as being semantically dissimilar to the speaker's intent. Word substitutions that are related to the target along both dimensions are less likely to be detected by the monitor, and so mixed errors are more likely than mere chance, even though there is no direct influence of the phonological level on the lexical level.

Network Models: Local Models

A very different alternative is presented by work within an interactive activation model (also known as a local connectionist model: Dell, 1986; Stemberger, 1985; Berg, 1988; with a similar approach by MacKay, 1987). In these models, elements are accessed via spreading activation rather than via search. Initially, a meaning-based representation for a sentence is activated. Activation spreads from active semantic units over connections to words and syntactic structures that express those meanings. Word units such as {DOG} and {CAT} sum the activation that arrives over many connections. The two word units are in competition, and inhibit each other (i.e. lower each other's activation levels). The most active unit is the one that has the most activation from semantic units, and it inhibits all competitors. As those competitors decrease in activation levels, the winner is 'disinhibited', and increases in activation level, until some upper bound is reached; this is known as the 'rich-get-richer' principle. If the wrong word has the greatest activation level, it wins, leading to a semantically related word substitution. If two words are equally activated, both win; competition between them is passed down to lower levels in the system, where some phones from each word win, leading to a blend error. Activated words spread activation to their component phonemes. Activated phonemes spread activation back to words. If a non-target word gains too much activation, it may inhibit the

target word, resulting in a phonologically related word substitution. The model correctly predicts that mixed errors will be statistically overrepresented, since the erroneous word sums activation from both semantics and phonology. Noncontextual phonological errors result when some non-target phone erroneously has the most activation, and inhibits the target phone. This is especially likely if the non-target phone shares features with the target phone, and thus sums activation from target feature units. Different words in the same sentence are partially active at the same time, and pass activation to the phonological units, resulting in interference between words. If the interference is sufficient, a contextual phonological error results. This is especially likely if the two interfering phonemes share a lot of features, and if they occur in similar parts of the word, and if they occur in words that contain the same phonemes. It should be noted that apparent ordering errors (such as anticipations or exchanges) occur during the accessing phase of processing. These models easily derive perseveration and anticipation errors because they are a single accessing error, but exchange errors, which involve accessing errors at two locations, are predicted to make up a small proportion of total errors; because of the frequency of incomplete errors, this prediction is difficult to test.

Competition between two elements need not end up with a single accessed element. Structures may be altered to accommodate both competitors. If two nouns compete, a compound noun can be produced (e.g. *in the ancient stick-time* for 'in ancient times' plus 'in the sticks'). If /p/ and /l/ compete, a /pl/ cluster can be produced. Stemberger (1990) demonstrates that competition between /p/ and /l/ is more likely to be resolved as a cluster than as a single consonant. He also demonstrates that syllabic /r/ (as in the North American English pronunciation of *bird*) is less likely to replace a vowel than to be added to an onset or coda cluster (e.g. for 'Berkeley bus' *Berkeley brus*, not **Berkeley berse*).

Stemberger (1985) emphasizes that there may be 'gang effects'. Many competitors with low levels of activation can reinforce the same output, if they are all very similar phonologically. For example, a nonce past tense form such as *yecked* can be produced in the absence of morphological rules as a blend of the base form *yeck* (which is the most activated form but not a clear winner, because it is not semantically appropriate to the past tense) and many low-activated past-tense forms, especially if they are phonologically similar to *yeck* (such as *pecked, checked, wrecked*, etc.). High-frequency phonemes that occur in large numbers of words are reinforced in a similar way and are less likely to undergo errors.

MacKay (1987) provides a position intermediate between symbolic and connectionist models. Noncontextual errors are accessing errors, with similar mechanisms and properties as in interactive activation models. Contextual errors, in contrast, are not accessing errors but relate to incorrect execution of correctly assembled structures.

Stemberger (1985) also assumes that every word in a sentence is accessed and held active. A command is then given to execute the sentence, and the words and their sounds are then produced in the target order. Execution errors may occur at this point: a word or a segment shows up one or two units too early. Unlike accessing errors, these result in grossly non-English word and consonant sequences (such as *rpinciple* for 'principle' and *she was the driving bus* for 'she was driving the bus'). Such errors are rare, but most models do not account for them.

Network Models: Distributed Models

These models do not distinguish different intermediate levels (though they could be modified to do so). In principle, information is mapped from semantic input to phonological output in one step (via an intermediate layer of hidden units). These models involve spreading activation, but there is no interaction between input and output except in coarse time steps. The focus of these models is on learning, rather than on structure or attention to the full range of error types.

Dell *et al*. (1993) present a recurrent network model. Inputs could in theory correspond to the meaning of whole sentences but in practice were either random patterns or the orthography of the target word, and the system learned to output a single word at a time. However, if proposition-sized (or larger) meaning patterns were to be used, the system could in principle learn to produce whole sentences. The system outputs a single segment-sized unit at a time, as a set of phonological features. Because the input does not change during the entire word (or sentence), context units are added to keep track of progress through the word. The activation of the hidden units is copied onto internal context units, and the activation of the output units is copied onto external context units. Both sets of context units serve as input to the hidden units on the next segment-sized iteration. The external context units tell the system to

produce, for example, the segment in *cat* that is first (/k/, first iteration), that follows /k/ (/æ/, second iteration), or that follows /œ/ (/t/, third iteration), or that follows /t/ (nothing, fourth iteration). The internal context units give more complex information, so that in a word with a repeated phoneme (e.g. *perplexed*) the system can produce different segments after the first and second tokens of /p/.

Because of the limitations on the nature of the input, the model could not deal with syntactic errors, word ordering errors, or between-word contextual phonological errors. However, noncontextual errors occurred, at both the lexical and phonological levels. Both semantically related and phonologically related word substitutions occurred, with a predicted overrepresentation of mixed errors. Word blends also occurred, especially at points where the two synonyms shared a phoneme. It was found that errors were most likely to occur at the beginning of the word. It was found that sharing phonemes with other words in the lexicon (high neighborhood density) decreased error rates. This model can account for frequency effects (lexical and phoneme), effects of position in a word, and similarity between phonemes (features and syllable position).

Vousden *et al*. (2000) present another distributed model of a very different sort: OSCAR (Oscillator-based Associative Recall). The system takes meaning-based input, and has a simultaneous representation of all phonemes in the output unit. Potentially, an entire sentence can be encoded in the output, but the implementation uses the word as the output, and does not address lexical retrieval or syntactic processing issues. The system outputs phonemes in a way that encodes serial ordering. There is a series of oscillators of various duration. Durations can be as short as a syllable or as long as a long sentence (or even a higher unit). A phoneme is associated with a given value for all the oscillators. Two phonemes are similar if they have a similar set of feature vectors or they are associated with similar states in the oscillators. For example, in *big cat*, the /b/ and /k/ are both at a certain point in cycle of a syllable-sized oscillator; the /ɪ/ and /æ/ are both at the same later point; and the /g/ and the /t/ are both at an even later point. But the /b/ and the /k/ are at a different point for an oscillator with a long cycle (and so they are produced in different syllables). The model was tested against the following error findings and did well. It can account for

- the proportion of errors that are contextual versus noncontextual,
- the proportion of errors that are anticipations versus perseverations versus exchanges (under the assumption that anticipations are more common than exchanges),
- the fact that errors involve phonemes with similar features,
- the syllable position effect (as a strong tendency, not an absolute), and
- the effect of distance (contextual errors decrease as a function of distance between the two sounds).

It cannot, however, handle cross-position effects, where /p/ and /l/ are more likely to be blended into the onset /pl/, or syllabic /r/ is more likely to become part of an onset than a nucleus. Nor can it account for the fact that two phonemes are more likely to interact if they are preceded or followed by identical phonemes. It does a mixed job of dealing with other effects as well.

CONCLUSIONS

Models of speech production based on errors show the same range of variation as other processing models, and have been used to address similar issues (such as symbolic versus subsymbolic representations and processes, search versus spreading activation, etc.). Computer-implemented models tend to deal with a subset of error types, with much success, but it is unclear whether they will be successful when a fuller range of phenomena are addressed. Serial models have an inability to deal with interactions between levels (such as mixed errors) in an integral fashion but can add additional components (such as a monitor) to derive such effects. No model has attempted to deal with the full range of error phenomena that are attested.

CONTENTS

Speech perception is the process of recognizing the words and speech sounds of a spoken language. Specific acoustic cues in the speech signal contribute to the identification of phonemes, minimal linguistic contrasts that distinguish different words from each other.

INTRODUCTION

Speech perception is the process of recognizing the words and speech sounds of a spoken language. As in most perceptual research, the fundamental issue in speech perception is explaining perceptual constancy, specifically, in this case, how we recognize certain sound patterns as being 'linguistically equivalent' despite large differences in the physical properties of the acoustic signals that reach our ears. For example, how does a listener recognize the word 'dog' spoken rapidly in connected speech by a small child as somehow equivalent to 'dog' uttered slowly in isolation by a large man?

In order to understand perceptual constancy, we also need to investigate the complementary problem of how we perceive the meaningful linguistic differences that differentiate one word from another – how we tell 'bit' from 'bet' or 'right' from 'light', for example. It may be useful here to emphasize that perceiving a meaningful linguistic difference is not the same as perceiving 'any old difference' in what you hear. Although the study of auditory psychophysics has revealed much about the basic limits of our ability to tell one acoustic signal apart from another, these findings do not necessarily help us understand the perceptual equivalence of spoken words. Unlike psychophysical 'sensory equivalence', where beyond a certain point listeners may be *unable* to distinguish between two physically different stimuli, the 'perceptual equivalence' of 'dog_1' and 'dog_2' as spoken by the child versus the grown man exists regardless of a listener's awareness that the two utterances differ acoustically.

Speech perception is nevertheless closely linked to our more general-purpose auditory sense. To a lesser extent speech perception is also tied to how we visually process human faces in motion: viewing the motions of a talker's lips and jaw is known to help people identify speech sounds and recognize words. In some unusual instances in which sound and image do not coincide (like a badly dubbed movie), a view of the talker's lips can actually partially 'override' the acoustic signal, changing perceivers' judgements about what they are hearing.

THE SPEECH SIGNAL

The study of speech perception is closely related to the study of phonetics, that is, the measurement and description of the physical speech signal in terms of its acoustic characteristics, and the physiological/anatomical properties and actions that give rise to this signal. The human vocal tract includes those parts of the mouth and throat that can be used to modify the air stream issuing from a talker's lungs. A partial list of these speech articulators includes the vocal folds (the valve-like structure atop the trachea), the oral cavity of the inner mouth, the nasal cavities, the tongue, and the lips. The articulators constrain the airflow in particular ways, resulting in a pattern of pressure changes at the listener's ear. A speech waveform (see Figure 1) is a graphical display of how this displacement of

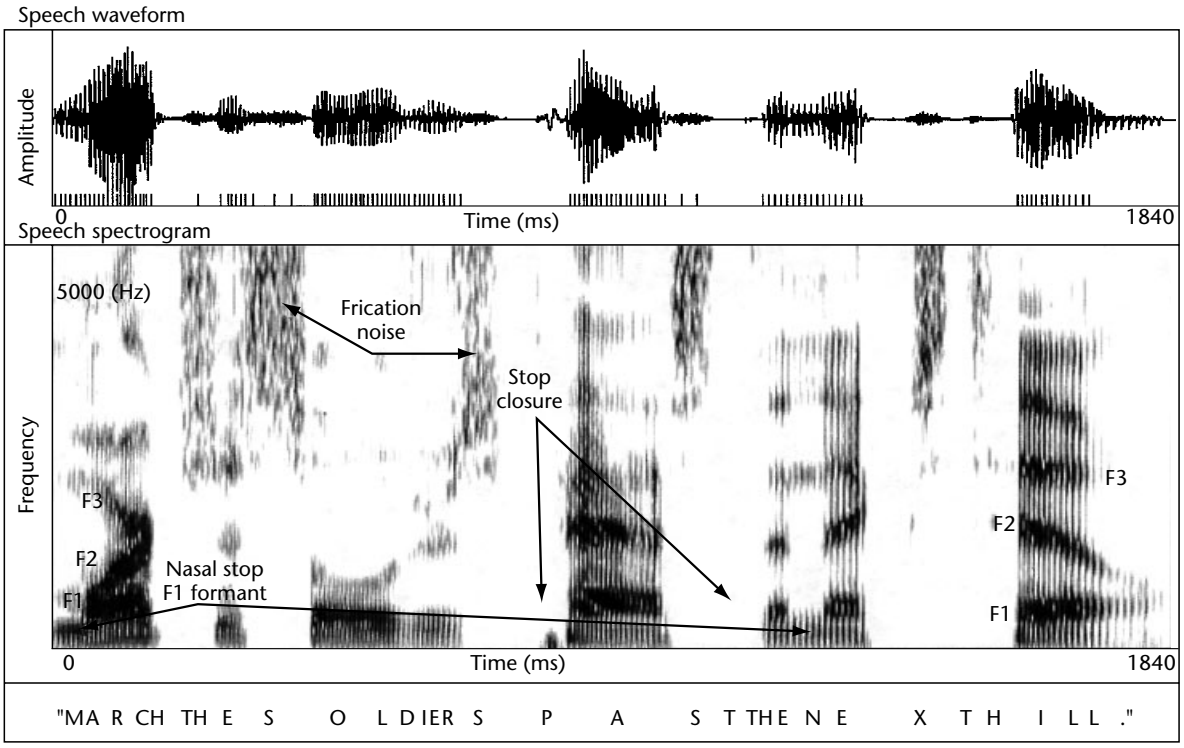

Figure 1. Wide-band speech spectrogram with examples of well-studied acoustic cues to phoneme identity as labeled. (Higher frequencies have been made more intense for purposes of illustration.)

air particles at a particular location in space changes as a function of time. The greater this displacement, the louder the sound, typically.

Speech sounds are complex signals in that not only does the overall pitch of a voice rise and fall during an utterance, but the speech waveform itself can be analyzed as the simultaneous combination of sounds of different frequencies, where the relative loudness of these contributing frequencies varies from moment to moment. Some of the basic acoustic properties of human speech can be represented using a visual display called a spectrogram (see Figure 1). A spectrogram shows how the intensities of the different component frequencies of the speech signal change relative to each other, over time. Typically, the x-axis of a spectrogram represents the passage of time in milliseconds, running from left to right, while the y-axis represents frequency in units called hertz (Hz), with low frequencies plotted near the origin and higher frequencies above. Shaded areas indicate the presence of acoustic energy at particular frequencies, over time.

A cochleagram resembles a spectrogram except that a cochleagram incorporates what is currently known about the sensitivity of the human ear to different frequencies at different intensities. For example, although it is true that at low intensities, the mid-frequencies (around 1000–5000 Hz) are actually perceived as louder than either very low frequencies or very high frequencies, it can generally be said that at a given intensity, the ear is more sensitive to small frequency changes (measured in terms of Hz) at the lower end of the frequency range (e.g. $< \sim$6000 Hz) than equal-sized changes in terms of Hz at very high frequencies. Listeners are also more likely to notice a change in loudness at already low intensities than when exposed to an equal-sized air pressure change at the high end of the intensity range. Thus, frequency in a cochleagram is often graphed on a logarithmic frequency scale, and relative loudness (darkness) plotted according to an analogously adjusted intensity scale. Other auditory effects on the signal, such as the perceptual enhancement of sudden onsets of intensity, can also be incorporated. Although these auditory-model-based methods of representing the speech signal at the level of the peripheral nervous system are still relatively new and undergoing revision, they potentially offer a more accurate picture of the speech signal as it enters the central nervous system.

In a wide-band spectrogram, each of the semi-regularly spaced vertical striations corresponds to

one opening and closing cycle of the vocal folds. During speech, as air is pushed out of the lungs, the flapping of the vocal folds creates a quasi-periodic 'buzz'. This 'buzz' is called the fundamental frequency, or 'F0', and is defined as the rate at which the vocal folds flap open and shut. F0 is among the most basic characteristics of a human voice and its average value (e.g. ~120 Hz for an adult male) contributes to the perceived pitch of a speaker's voice. During fluent speech, the vocal folds vibrate about two-thirds of the time. Talker-controlled adjustments of F0 play a major role in perception of sentence intonation and word stress.

An important acoustic property related to F0 are its harmonics. Speech, like other complex sounds based on a periodic noise source, tends to contain energy not just at the fundamental frequency, but also at frequencies called harmonics, that are integer multiples of F0. So, for example, if the F0 value is 100 Hz, its harmonics would include 200 Hz, 300 Hz, 400 Hz, etc. The actual intensity of each harmonic is determined by other aspects of the vocal tract configuration, so that some harmonics might be particularly intense while others are weak or inaudible.

In wide-band spectrograms of carefully articulated speech, vowel sounds are visually quite prominent, usually characterized by vertical F0 striations and dark bands of horizontally running formants. Formants are concentrated regions of acoustic energy created (usually) through the enhanced intensity of certain harmonics and the attenuation of other harmonics due to the natural resonance characteristics of the vocal tract (that is, factors such as its shape, size, and composition). The lowest frequency formant is typically referred to as 'F1', the next highest formant as 'F2', and so on. F1 typically ranges between 270 and 850 Hz, F2 between 850 and 2700 Hz. In a spectrogram, steeply sloping formants indicate rapid changes in the resonant frequencies due to articulator movement and are typically referred to as formant transitions.

The relative positioning along the frequency dimension of F1, F2, and to some extent, F3 helps to perceptually distinguish the different vowel sounds. Low-frequency first formants, as in vowel portions of the words 'wh*o*' or 'h*e*', result from the central body of the tongue arching up towards the roof of the mouth. The further back in the mouth this arching occurs, the lower the F2 frequency. The F2 of 'wh*o*' is much lower than the F2 in 'h*e*', for example. Relative duration is also used to distinguish some vowels: for example, the vowel in 'b*e*t' is typically shorter than the vowel in 'b*a*t', thereby helping to distinguish the two sounds even though their formant values are quite similar. Some information about vowel identity is also present in the rapid formant transitions that initiate and conclude a vowel sound flanked by consonants.

Consonant sounds can be roughly sorted along three major articulatory dimensions: (1) manner of articulation (the way and degree to which the articulators constrict), (2) place of articulation (where the constriction occurs in the vocal tract), and (3) voicing (whether the vocal folds are vibrating during articulation).

Fricative consonants are produced via a narrow but incomplete closure of the articulators and are primarily characterized by intervals of aperiodic noise at particular frequencies – that is, energy not structured into formants, but instead 'smeared' across a band of frequencies, without emphasis of particular harmonics. In American English, the fricatives [s] as in *s*ue, [ʃ] as in *sh*oe, [z] as in *z*oo, and [ʒ] as in a*z*ure, have noise energy concentrated at the higher frequencies (higher for [s] and [z] than for [ʃ] and [ʒ]) and are of relatively long duration, while [f] as in *f*in, [ɵ] as in *th*in, [v] as in *v*at, and [ð] as in *th*at, have shorter durations and consist of weaker energy spread over a wider frequency range.

Stop consonants involve making a complete vocal tract closure which is then abruptly released, allowing pressurized air to escape (as in [b], [d], and [g], for example). Abrupt intervals of near-silence in a spectrogram can therefore indicate the presence of stop consonants. The release of a stop closure is necessarily marked by a very brief high-frequency noise burst, the intensity and frequency of which tends to vary predictably for the different stop consonants. This release burst is sometimes followed by additional aspiration noise generated at the open vocal folds just prior to the onset of vibration. The nasal stops, [n] as in ra*n*, [m] as in ra*m*, and [ŋ] as in ra*ng*, differ from other stops in that they involve, in addition to the oral cavity closure, the opening of a passageway into the nasal cavities through which air escapes during the oral closure. Due to this alternative routing, nasal stops have a low (< 300 Hz) but relatively intense first formant (also called the nasal murmur) during the oral constriction and some higher formant structure, weakly visible on a spectrogram above about 2000 Hz. Additional classes of sounds in American English include the liquids ([l] as in *l*ip, [ɹ] as in *r*ip) and glides ([j] as in *y*ou, [w] as in *w*oo), both of which involve only partial constriction, permitting strong 'vowel-like' formant structure.

Each of these 'manner' classes (fricative versus stop versus nasal, etc.) contains sounds

distinguished from each other only by place of constriction in the vocal tract. Invariant acoustic cues for distinguishing the various places of articulation have proved elusive, making perception of place contrasts a long-standing area of study. In the case of stop consonants, acoustic information known to contribute to perception of place contrasts includes the frequency and rate of change of F2 and F3 transitions into (or out of) adjacent vowels. The distribution of frequency components present in the brief release burst, in the case of nonnasal stops, and within the prolonged frication noise, in the case of fricatives, can also serve to help cue place of articulation.

UNITS OF RECOGNITION

The 'speech sound categories' we have been referring to, [p] versus [b] for example, are more commonly referred to as *phonemes*. If you remember doing 'phonics' exercises as a child just beginning to learn to read the English language, you are already somewhat familiar with the notion of a phoneme. Phonemes are basically those sound contrasts that a language community uses to distinguish one word from another – the type of contrast which distinguishes the words 'pig' from 'big' or 'pit' from 'pat', for example. Do not confuse the printed alphabetic letters of English with phonemes – English spelling only partially reflects phonemic information. The letter sequence 'sh', for example, represents just one phoneme, [ʃ], in the International Phonetic Alphabet (IPA), a system of notation similar to the pronunciation key used in dictionaries.

It is important to realize that different languages use different sets ('inventories') of phonemes. To illustrate, although the difference between [l] and [ɹ] may seem obvious to an American English speaker, there are languages, such as Japanese, which do not utilize [l] and [ɹ], but use instead a phoneme [ɾ], usually described as a 'flap'. Monolingual speakers of Japanese perceive instances of American [l] and [ɹ] as both highly similar to the phoneme used in their own language, and tend to have difficulty discriminating American [l] from [ɹ]. Similarly, although speakers of Hindi distinguish between a [t]-like sound produced with the tongue-tip up against the front teeth and a [t]-like sound produced with the tongue 'retroflexed' (curled up and slightly back, hitting against the alveolar ridge, the hard ridge behind the front teeth), American English listeners listening to the Hindi phonemes will tend to label both as representing instances of the English phoneme [t].

Despite its seemingly simple functional definition, there are serious drawbacks to trying to use the phoneme as the basis for a perceptual unit of analysis. In particular, during fluent speech, the articulators can be shown to move into position for an upcoming sound (or sounds) even while the current sound is still being produced. This causes the acoustic cues to particular phonemes to be 'overlapped' in time with each other, interacting in complex ways for different combinations of phonemes. This interaction between successive phonemes is usually referred to as co-articulation. Co-articulation across adjacent phonemes has motivated researchers to propose larger units of analysis that subsume more of the surrounding acoustic context. One promising candidate is the syllable. A syllable is typically defined as consisting minimally of at least a vowel, with, optionally, one or more immediately preceding or following consonants. Adopting the syllable as the fundamental unit of analysis does not, however, fully eliminate the contextual problems faced by the phoneme since co-articulation often extends across multiple syllables and even across multiple words in an utterance. The prevalence of co-articulation is one of the most formidable challenges faced by speech researchers.

THE MOTOR THEORY OF SPEECH PERCEPTION

In the early 1960s, after working extensively on trying to develop a fluent and naturalistic-sounding reading machine for the blind, experimental psychologist Alvin Liberman (1918–2000) and his colleagues at Haskins Laboratories began to seriously consider the inherent difficulties in building a complementary machine able to recognize speech from just a representation of acoustic information. Would the machine lack crucial information that a real human listener possesses? The relative speed and accuracy with which humans recognize speech, despite the lack of invariant cues in the acoustic signal, led Liberman to speculate that listeners achieve perceptual constancy in speech through reference to their own internalized knowledge about how speech sounds are articulated. For example, Liberman and colleagues pointed out that the acoustic cues for a [d] at the beginning of a syllable differ depending on the vowel that follows due to co-articulation, yet a description of [d] as 'a constriction at the alveolar ridge' is applicable in all vowel contexts. This 'motor theory of speech perception' hypothesized that listeners use knowledge about the effects of

co-articulation on their own productions to recognize other people's attempts to produce the various phonemes.

Electromyographic techniques revealed, however, that patterns of motor activity at the level of the articulator muscles and joints map no less variably to perception than do acoustic patterns. Both within and across individual speakers, articulatory variability was shown to be quite high even when the perceptual result was relatively stable. Evidence of the development of normal speech perception skills by humans unable since birth to control their speech articulators was also problematic. Motor theory therefore underwent revision, such that listeners were assumed to extract abstract 'higher-level' motor commands for intended phonetic 'gestures' rather than information about low-level, externally observable motor activity. With this change, however, motor theory's primary hypothesis became extremely difficult, if not impossible, to test. Researchers, however, continue to explore the idea that the role of the speech perceiver as also evolutionarily developed to be a speech producer should contribute a potentially valuable source of information.

Motor theory is historically important for having generated a wealth of experiments focused on acoustic cues. Numerous studies were conducted showing that many different patterns of acoustic information could yield the same phonemic percept, and also that the same acoustic pattern could be perceived differently given different surrounding contexts. Even though these studies were successful at debunking the notion of invariant acoustic cues to phoneme identity, they failed to yield truly convincing positive evidence that speech perception is based instead on recognition of articulatory gestures.

Motor theory also gained prominence as a theory of speech perception which argued for a strongly modular organization of cortical speech-processing mechanisms. In a number of ingenious experiments, Liberman and his colleagues found evidence that the human brain is predisposed to interpret speech and speech-like stimuli differently from other auditory stimuli. A variety of experimental situations were constructed to demonstrate the 'special' processing of speech signals, 'duplex perception' and 'categorical perception' being the most well-known examples.

THE DIRECT REALIST APPROACH

The direct realist approach to perception has a long history in the sub-area of philosophy known as epistemology. Epistemology is concerned with how humans acquire knowledge and arrive at beliefs about the world. Philosophers define 'direct realism' as the claim that the world has properties that exist regardless of our ability to perceive them, and that what we do perceive is objective – that we perceive the world more or less as it exists. Direct realism contrasts with other epistemological claims such as 'phenomenalism' (which argues that we cannot access the physical world directly since all information about our environment is mediated via our sensory and cognitive systems), and 'representationalism' (which says that physical objects cannot meaningfully be said to exist outside of how they are perceived).

The direct realist approach to speech perception was strongly influenced by the writings of the sensory psychologist James J. Gibson (1904–1979). Although Gibson discussed direct perception largely in terms of vision and haptic (kinesthesis touch) perception, Carol Fowler and her colleagues at Haskins Laboratories have been widely recognized since the 1980s for their efforts in applying Gibson's ideas to the study of speech perception.

In his work, Gibson argued that objects in the world have affordances, which he defined as characteristics that provide the perceiver the opportunity to interact with the object in a specific way. For example, a flat door panel affords pushing but does not afford pulling in order to open it. Furthermore, Gibson suggested that stimulus information arrives at the sensory receptors already in a form that permits 'immediate' recognition of these affordances – that is, that no further processing of this information is required for perception, particularly, no inference-making, either conscious or unconscious.

Direct realists propose that speech is directly perceived like any other meaningful sound in one's environment, in terms of identifying the physical object(s) that imparted structure to the intervening medium (usually air). Listeners do not consciously perceive the intermediate acoustic structure, but rather the source responsible for it. Perceiving speech is therefore the act of identifying vocal tract configurations that could have given rise to particular air pressure patterns, that is, recognizing affordances such as 'could have been articulated by constricting the lips'. Resembling motor theory, the perceived events in direct realism are therefore vocal tract gestures rather than acoustic cues. According to the direct realist approach, these abstract gestures are not tied exclusively to the auditory modality, but can be perceived via a variety of intervening media, for example,

cutaneous sensation in the case of 'Tadoma', a method of identifying words from touching a talker's moving lips and jaw.

The most radical implication of a direct realist's view of speech perception is the idea that investigating stages of information processing during perception is irrelevant to the scientific endeavor of speech scientists. Although it seems possible that knowledge of some physical affordances may be innate or instinctual, recognizing other affordances would seem to involve some degree of prior experience or learning. The role of learning and memory in the development and function of direct perception was not well explicated by Gibson. If these cognitive factors can be shown to play a role in perception, it is not clear if the 'directness' of perception is preserved. The time course over which spoken language emerges as a skill in young children makes it difficult to understand how perception of speech can be purely direct.

What types of empirical research are suggested by the direct realist approach? One area of work has examined the speed and accuracy with which listeners can repeat back spoken syllables; results suggest that speech can be repeated more quickly than a model with many intermediate steps of processing between perception and production would predict. Other studies have examined how listeners are influenced by tactile information about a speaker's articulations – especially when the two sources of information (auditory and tactile) are deliberately designed to conflict with each other. Fowler interprets the finding that phoneme identification can be influenced by stimulation via the relatively unfamiliar intervening medium of skin deformation as evidence of speech perception taking place in terms of identifying articulatory gestures, not recognition of patterns in the intervening medium.

EXEMPLAR MODELS OF SPEECH PERCEPTION AND SPOKEN WORD RECOGNITION

An active area of current research addresses the question of the degree to which memories for speech experiences are stored *intact* in memory. The two extreme positions on this issue are usually referred to as the prototype hypothesis and the exemplar hypothesis. Prototype theory claims that a representation of an average instance of a given lexical item emerges over multiple exposures and that the details of each acoustic signal (which vary from instance to instance) are *averaged out* of the stored representation and are difficult or impossible to retrieve. That is, as a listener experiences situations in which the word 'dog' is uttered multiple times or by different talkers, a representation that is an 'average' instance of 'dog' is created in the listener's brain. The exemplar hypothesis, in contrast, argues that a detailed representation is stored for each and every instance of a word that has been encountered, with no information loss occuring during the storage process.

For many years, the assumption that storage space in the brain was relatively limited favored the notion that memory could be used most efficiently by storing a prototype (perhaps formed by averaging each new instance with the existing prototype), instead of exemplars. Recent developments suggest, however, that the memory capacity of the brain was significantly underestimated, and that storage of acoustic details may actually make listeners' speech perception skills more robust and flexible. In order to test the exemplar hypothesis, experiments have been conducted to see if listeners show evidence of storing exemplars. A number of studies have demonstrated retention of instance-specific information over time, even though listeners may not necessarily be able to consciously report memory for exemplar details. Evidence for instance-specific memory is often indirect (for example, in terms of relative reaction times in word identification tasks). Note that a purely 'exemplar' view is probably not correct either since there is also evidence that people tend to store or generate information about prototypes. Exemplar models make interesting and specific predictions about how spoken word recognition ability unfolds as a function of experience. Two areas in which these claims are actively being tested are child language acquisition and second/foreign language learning.

CONCLUDING REMARKS

Further efforts are needed to integrate what is known about speech perception at the level of the phoneme into accounts of spoken word recognition and sentence processing. Researchers also need to reevaluate carefully the role of acoustic variability in light of the insights offered by exemplar models of speech perception. Continued empirical study of how acoustic cues are used in different languages, the development of these perceptual skills in infants, and the effects of different forms of hearing impairment on speech sound discrimination, will be crucial to advancing our current understanding of speech perception and spoken language processing.

CONTENTS

Automatic speech recognition is the attempt to use a machine to derive the linguistic message from a speech signal.

INTRODUCTION

The linguistic message of a speech signal originates in a speaker's mind. The speaker converts it to speech sounds, considering the intended recipient of the message and any feedback the recipient might be providing. Human listeners can generally determine a functional equivalent to the speaker's intended message quite effortlessly. However, this task represents a difficult challenge for a machine. (*See* **Speech Perception and Recognition, Theories and Models of**)

Automatic speech recognition (ASR) in its unrestricted sense would probably require emulation of human intelligence. While some believe this can be achieved in the foreseeable future, many others believe that it is still far away, despite apparent advances since the criticism of this field by John Pierce (1969).

The general problem of ASR can be seen as that of finding a mapping from the space of all allowable acoustic signals to that of all meaningful messages. Each space grows with the length of the message. Even when the length of the message is bounded, the mapping is many-to-one, since the speech signal carries information from many sources and many different speech utterances may carry the same linguistic message. The message may be produced by different speakers; a speaker may speak slower or faster; the acoustic environment may change; the health or emotions of the speaker may be reflected in changes of voice; and so on. Thus, ASR must deal with significant nonlinguistic variability in the data. We have limited understanding of how this is done by human listeners.

ASR typically incorporates a model of the speech production process. Such a model should generate all possible acoustic sequences for all legal linguistic messages. The model is trained using a large number of different acoustic signals, which are associated with their corresponding word sequences. Recognition may then be done by testing all possible word-sequence models to find the one that would produce the acoustic signal best matching the actual signal being recognized.

The difficulty of ASR varies greatly with the complexity of the task, which may range from recognition of a few anticipated voice commands uttered by a single speaker, to transcribing conversational speech of an arbitrary speaker in realistic noisy environments.

BASIC PRINCIPLES

The goal of ASR is to find the most likely sequence of symbols representing the linguistic message in the speech signal, given the acoustic data. In essentially all current ASR systems, an intermediate goal for the recognizer is to determine the likelihood of possible sequences of speech-sound states, where these states typically correspond to parts of phonemes. (*See* **Phonology**; **Phonetics**)

The input to the recognition process is a digitized version of the electric signal from the microphone that represents changes in acoustic pressure at some distance from the mouth of the speaker of the message. The signal typically undergoes further information-reducing transformations before being used in the evaluation of the likelihood of each

possible sub-phonetic state sequence, that in turn determines the likelihood of each possible word sequence.

In general, the outcome of the recognition process is a list of hypothesized word sequences, where 'words' here mean some tokens from a predefined recognition 'lexicon'. The hypothesis is generated by a decision process that aims to produce a 'most likely' word sequence w given the input signal x. This can be expressed mathematically by the so-called 'maximum *a posteriori*' decision rule (using the concept of conditional probability) as

$$w = \arg\max_i P(w_i|x) \tag{1}$$

where w_i represents the i^{th} word sequence from the lexicon and the conditional probability is evaluated over all sequences from the lexicon.

The word sequences w_i are not represented by the acoustic signals but are actually represented by their models $M(w_i)$:

$$w = \arg\max_i (P(M(w_i)|x)) \tag{2}$$

where w is a sequence of symbols representing the linguistic message in speech, $M(w_i)$ is a model of the sequence w_i, P is the posterior probability of the model given the acoustic input, and the maximum is evaluated over all models.

Bayes' rule:

$$P(M(w_i)|x) = \frac{P(x|M(w_i))\,P(M(w_i))}{P(x)} \tag{3}$$

can be applied. Since the probability $P(x)$ is the same for all choices of i, it can be ignored during recognition, and equation 1 then simplifies:

$$\begin{aligned} w &= \arg\max_i (P(M(w_i)|x)) \\ &= \arg\max_i (P(x|M(w_i))P(M(w_i)) \end{aligned} \tag{4}$$

The probability distributions are in practice unknown, and must be estimated, using parameters that are trained on speech samples, in order to solve equation 4. So strictly speaking, each probability is also conditioned on the dataset from which its estimators were trained. Usually, the acoustic estimators of $P(x|M(w_i))$ are trained from speech data and the estimators for language probabilities $P(M(w_i))$ are trained primarily from written text. (*See* **Machine Learning**)

The acoustic modeling is done as follows. Acoustic input is represented by a series of vectors, each of which represents a short segment of the acoustic signal (typically 10 to 20 milliseconds). The feature vectors usually represent spectral properties of these short segments of the speech signal, typically transformed further into some other set of variables (most typically 'cepstra', which are the discrete fourier transform of the log spectra). The analytic methods that generate these features are designed to preserve relevant linguistic information while alleviating unwanted variability due to nonlinguistic sources (such as microphone sensitivity). The data x are then represented by a sequence of vectors v.

If all word sequences w_i in the lexicon were of the same physical length, and enough examples of each sentence were available for estimating the distribution of acoustic data for the sequence, then models $M(w_i)$ could be derived by estimating probability distributions of the training data for all anticipated word sequences. Then the probability $P(v|M(w_i))$ of the unknown sequence v could be directly estimated using pattern classification techniques. However, such models would take no advantage of the temporal structure of the sentence.

In practice, word sequences differ in length because of the different speaking styles of individual talkers. Furthermore, there are usually an insufficient number of examples of complete utterances to train the models in this way. Therefore, the acoustic model is broken into subsets of smaller submodels m representing phrases, words, phonemes, and most typically smaller units such as parts of phonemes. These smaller units (which we have already referred to as 'states') may be shared among many different words.

Assuming the statistical (conditional) independence of the submodels, the overall probability $P(x|M(w_i))$ can then be expressed in terms of local probabilities $P(v|m)$. Efficient heuristic search techniques for solving equation 4 from local probabilities $P(v|m)$ have been developed. Temporal variability is typically handled by dynamic time alignment of the incoming speech representation with the stored models. This time alignment attempts to find the path of the best match by local comparisons between possible model state sequences to find the most probable representation for the incoming speech vectors.

The sub-word units (e.g. phonemes) do not need to be recognized categorically before the decisions are made. They merely represent units that are shared between different words in the lexicon and whose choice is dictated by considering the required lexicon, its distinctive symbolic representation by the chosen phonemes, and expected variations in pronunciations of the words in the lexicon. The hypothesized word sequences are

formed by a heuristic search that in principle considers the probabilities of the states in all the phonemes in the vocabulary. The hypothesized word sequence is chosen via a competition between various paths that are evaluated at the end of the acoustic input. The evaluation is derived from equation 4, consisting of the product of all local acoustic likelihoods corresponding to a state sequence, combined with appropriate language probabilities for each word sequence. The combination of local scores into scores for the entire utterance assumes conditional independence (independence when conditioned on the state variable) and the Markov property (that for both words and states, only a limited history need be considered to represent the probability of moving from one to the next).

In practice, the least viable hypotheses are pruned from the search to save on computation, so not all possible hypotheses are actually considered. 'Search errors' (caused by dropping seemingly unlikely hypotheses) are fairly uncommon, however.

The difficulty of an ASR task derives partly from the acoustic confusability of the words (for instance, the digits in English are much less similar to one another than the spoken alphabet, which contains pairs such as 'E' and 'B'), but also from the linguistic unpredictability of words in context, since a strongly predictable word permits use of a language model that can counteract acoustic ambiguity. For instance, if a language model only permits the words 'yes' or 'no' at a particular point in a dialog, the similarity between 'no' and 'go' will not be a concern. The difficulty of an ASR task in terms of this linguistic unpredictability is typically measured by the 'perplexity', which is equal to the number of equiprobable words for which the prediction is as difficult as for the original task (Jelinek, 1997).

Acoustic inputs are typically assumed to be limited to speech utterances that are anticipated during the current ASR task (closed-set recognition). This of course limits the difficulty of the task. On the other hand, this makes ASR vulnerable to inputs from outside the closed set (such as words outside the vocabulary, silences between words, breath noises, or noise in general). Words outside the vocabulary are sometimes handled by a so-called 'garbage model', which may allow for matching of these unanticipated acoustic inputs.

The language model generates a probability $P(M(w_i))$ for each given sequence of words w_i. As mentioned above, this probability is constructed by finding the product of individual conditional probabilities under the model of words given 'word histories', where the 'word history' typically refers to a few words prior to the current word. The probability of a group of n words can be approximated by the product of terms that are each dependent on $n-1$ previous words, using the Markov assumption. The resulting estimate is called an 'n-gram probability'. A simple example of this approach is the approximation of the word-sequence probability by the product of bigram probabilities:

$$\begin{aligned} &P(w(n),\ w(n-1), \ldots w(1)) \\ &\sim P(w(n)|w(n-1))\, P(w(n-1)|w(n-2)) \\ &\ldots P(w(1)) \end{aligned} \tag{5}$$

In large vocabulary-recognition tasks, the language model can be somewhat more complicated, including longer n-grams for common sequences, word-class probabilities, etc., and can incorporate either interpolations or switches between the different submodels. In smaller tasks, the language model can simply consist of lists of words that are allowed to follow each other.

The basic plan of an ASR system is summarized in Figure 1.

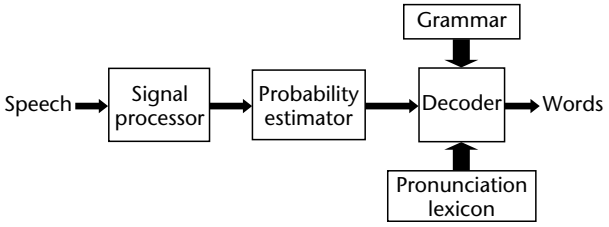

Figure 1. Overall plan of a speech recognition system.

ACOUSTIC PROCESSING

Speech is first converted to an electric signal that represents acoustic pressure changes at the microphone. It is then amplified, filtered, sampled, and digitized to facilitate further processing. 'Short-term analysis' converts consecutive overlapping short segments of the signal (about 20 ms long) into feature vectors (e.g. in steps of 10 ms). Some information-rate reduction typically occurs at this stage, with the primary goal of reducing the non-linguistic variability from the speech signal while retaining characteristics that are useful for distinguishing between different speech sounds.

Feature design may incorporate some of the characteristics of human auditory perception, since the effect of speech on the listener may be a primary cause of the linguistic message being reconstructed by the listener (Hermansky, 1998).

While this view is not universally accepted, most current ASR systems incorporate methods that emulate some of the basic properties of human hearing.

PATTERN CLASSIFICATION

At this stage, the feature vectors are compared (typically in a probabilistic sense) to models that represent precomputed representations of speech. The best match of the sequence of incoming feature vectors with the acoustic and language models provides an estimate of the linguistic content of the speech segment. The models may be in the form of templates of feature-vector sequences in the case of the simplest ASR systems (more common in the 1970s and 1980s), while in modern systems they may be stochastic models for words or phonemes. As already mentioned, the designer typically decides on the architecture of the models. The lexicon of the application is also formed at this stage, incorporating common pronunciation variations of the words that are modeled. Similarly, the language model is chosen. In both cases, the final forms are determined by some combination of designer decisions and training from data. The model parameters are learned by training from speech data for which the word sequences are known. The phonetic sequences are typically not known, even for the training data, so having good pronunciation models is essential for associating phonetic sequences with the data. During training, the model parameters are learned, taking into account the uncertainty in these sequence labels. (*See* **Pattern Recognition, Statistical**)

HIDDEN MARKOV MODELS OF SPEECH

Most ASR systems incorporate the kind of speech representations known as 'hidden Markov models' (HMM). These are stochastic models with unknown (hidden) variables for which probability density functions are learned from training data, and for which the Markov property (ignoring all but recent history in estimating probabilities) is assumed. Each model consists of a sequence of states, the identities of which are hidden from the observer. Each state has certain stochastic properties for transition to other states and for the emission of feature vectors. The HMM associates identical stochastic properties to all feature vectors emitted by a given state, in principle with no statistical dependence between the vectors; however, the learning process modifies parameters based on all of the states, so that in some sense there is a dependence on all of the speech and on all models within the statistics for each frame. (*See* **Markov Decision Processes, Learning of**)

SUB-WORD UNITS

Small-vocabulary ASR systems may use models for whole words or even complete utterances. However, it is hard, if not impossible, to train models for all words in large-vocabulary systems, since many examples of each are required in order for the system to effectively learn the model parameters. Consequently, there is usually a need for sub-word-based models, which can be dynamically assigned to different words in the vocabulary.

The most often-used sub-word units are phonemes or phoneme-like units. A sequence of these units may be compared to 'beads on a string': the feature emission statistics are derived from a single probability density function. In order to better approximate the dynamics of speech production, HMMs for ASR are usually composed of multiple (typically two to five) states for each phonemic sound unit. Furthermore, the phoneme classes typically are further subdivided into different contextual classes (e.g. with particular neighbors to the left and right). This is done in order to better represent the wide variability in sounds that could be associated with any particular phoneme, for which a primary cause is the coarticulation between neighboring speech sounds due to the inertia in the vocal apparatus. Since using all allowable contexts would lead to a large number of context-dependent phoneme classes, the context phonemes are often clustered into larger classes, thus keeping the number of sub-word units reasonably small. In large systems, acoustic probabilities from differing contexts and degrees of clustering are integrated together, much as in the language models. (*See* **Word Recognition**)

Distributions of the feature vectors associated with each state of the acoustic HMM are usually assumed to be emitted according to a multivariate Gaussian mixture model (GMM), which consists of a weighted sum of Gaussians. All the means, covariances (typically variances only) and weights are estimated from the training data using iterative procedures that are based on the learning method called 'expectation maximization'.

During training, each GMM is presented with examples of feature vectors along with class membership (or class distribution) for each vector. This allows for estimation of the distribution of feature vectors within each class. In simpler systems, there

is one GMM for each sub-word class; in more complex systems, there is some parameter sharing between classes. During the classification, an unknown feature vector is compared to each state of the GMMs. This process generates a probability for each state of the GMM to have produced the feature vector. The resulting set of probabilities is used in the search to find the most likely sequence of models that explains the observed sequence of feature vectors.

To simplify the estimation and to reduce the number of parameters that need to be estimated from the data, the elements of the feature vector are assumed to be uncorrelated with one another. This assumption allows the use of diagonal covariance matrices in the model (i.e. variances only), which reduces the number of parameters of the model significantly.

GMMs are not the only way to represent distributions for feature vectors. Some systems use 'codebooks' that hold tables of probabilities for each quantized feature vector and each phoneme type. A very different approach is based on a system that computes the posterior probability $P(m|v)$, which can then be transformed via Bayes' rule to a scaled version of the more typical likelihood $P(v|m)$. One such structure is the so-called 'multi-layer perceptron' (MLP) neural network, which can be hybridized with an HMM system for ASR (Morgan and Bourlard, 1995). The MLP is an inherently nonlinear classifier, and it often appears to be more suited to unusual feature distributions. The hybrid system is also inherently discriminative, in that the learning process has the goal of choosing parameters to distinguish between target and non-target classes. Discriminative approaches can also be applied to GMM-based systems, but this greatly increases the complexity, and typically yields only moderate gains. Discriminative training potentially allows the system to focus on class boundaries rather than on centers of distributions. (*See* **Connectionism**; **Connectionist Implementationalism and Hybrid Systems**; **Connectionist Systems, Learning in**)

The phoneme is an idealized unit that does not always correspond to real acoustic events observed in the data. Efforts continue to derive alternative units directly from the data.

PROBLEMS WITH THE STOCHASTIC APPROACH

Speech is used for communication. A fundamental principle of communication theory is that the most likely events carry the least information. It is therefore unavoidable that the distributions of events both in the acoustic space and in the language model are long-tailed, and that the most information-rich events occur in the tails of distributions of the training data. In order to get reliable estimates of these rare but important events using stochastic training, very large training databases would be required. But in practical applications of the technology, the amount of training data is always limited, so it seems unavoidable that the most important rare events are represented in the stochastic model least accurately. For this reason, much of the effort in the field has focused on ways to smooth statistics from rare but pertinent data with statistics from larger sources of data that are less specific to the ultimate task.

In general, the stochastic approach to ASR favors mean trends in the training data. For instance, a database that is 80% male and 20% female will tend to generate parameters that will yield much better recognition for males than for females. ASR applied in conditions that were not well represented in the training data is likely to perform poorly, unless the test set variability introduced by the varying conditions is handled by some other means. The required amount of training data also increases with the increasing complexity of the model.

On the other hand, models of the speech communication process that are both simple and accurate do not yet exist. It is an open question whether it is only a matter of time until such a powerful model is developed, or whether there are strong reasons for looking for alternatives to the current stochastic style of approach to ASR.

CURRENT RESEARCH

Feature Extraction

Features typically represent some aspects of the short-term spectral envelope of the speech segments, processed by very simple models of human auditory perception that emulate unequal spectral resolution of human hearing (Bridle and Brown, 1974; Mermelstein, 1976; Hermansky, 1990). The spectral envelopes are easily corrupted by external factors, and various schemes are applied during feature extraction to alleviate these effects. Among the most often-used normalization techniques are: subtracting the mean from the time trajectory of each feature and normalizing the variances of utterances; and filtering the time trajectories of features to suppress slow and fast

changes that may be outside the typical rates of change for speech components (Hermansky and Morgan, 1994). These so-called static features, which represent the instantaneous shape of the spectral envelope, are often augmented with dynamic features such as time derivatives, representing the time evolution of the feature trajectory in the vicinity of the static vector (Furui, 1986). A promising approach is to optimize the feature-extraction module by learning discriminant transformations from the speech data (Hermansky, 1998). Interestingly, such an optimization appears to yield feature extraction techniques with properties that are consistent with those of human hearing. In general, feature-extraction methods are now beginning to incorporate time contexts significantly larger than 20 ms.

Adaptation

Some ASR systems that can take advantage of learning from the target speaker (particularly for offline processing) address the anticipated variability in the data by adaptation of the statistical parameters (Woodland *et al*., 1996). The adaptation can be either supervised or unsupervised. In supervised adaptation, the speaker is asked to produce speech with known linguistic content and the ASR system parameters are adjusted to best match the appropriate sequence of models. In unsupervised adaptation, the learning is done during recognition of speech with an unknown message, using the unadapted recognizer itself to give a first estimate of what was said. Since there are many applications for which a single speaker may provide much of the input, the adaptation may also deal with predictable changes in the pronunciation of a particular speaker.

Incorporating Multiple Subsystems

Requirements for the amount of training data grow with the size and the complexity of the stochastic model. One way to simplify the model (or, alternatively, to improve performance for a model of a given size) is to break it into several parts. If these different partial models have different properties, they can potentially complement one another to improve the system's robustness to variability during testing. Different parts of the spectrum may be used to develop separate probability estimators. Alternatively, feature vectors with differing temporal properties may be used together. Discriminant systems can be used to generate feature vectors for standard GMM-based systems classification (Hermansky *et al*., 2000).

Finally, many researchers are working to combine word-sequence hypotheses from several complete recognizers.

In each of these approaches, the performance seems to improve if the subsystems make, at least to some extent, different errors.

Building More Prior Knowledge into an ASR System

Current HMM-based systems appear to make only minimal assumptions about the nature of speech. In fact, researchers have shown that such a system can be used for handwriting recognition essentially by changing only the feature-extraction module. Certainly the feature-extraction module is an obvious place to incorporate more information about the speech signal, and this has usually been done by emulating dominant properties of human speech perception. Another approach involves applying dynamic stochastic models (e.g. Ghitza and Sondhi, 1993). Segmental models have also been developed, in which statistics associated with a complete phonetic segment are incorporated, as opposed to only those associated with a single 20 ms feature vector (e.g. Ostendorf *et al*., 1992).

Finally, representations of semantic structure, long-distance dependencies, and dialog state models are likely in the future to be important sources of predictive information for language models. CONTENTS

'Statistical methods' refers here specifically to statistical methods in computational linguistics. This represents a new body of practice in computational linguistics that has become standard since the 1990s.

INTRODUCTION

Since the early 1990s a new body of practice has become standard in computational linguistics. It is known variously as *corpus-based*, *empirical*, or *statistical methods of language analysis*, most common being the simple rubric *statistical methods*. Present-day computational linguistics differs from 'traditional' computational linguistics in the pervasiveness of probabilities in its theoretical models, the centrality of large data collections, including *text corpora* and *treebanks*, and the emphasis on rigorous empirical evaluation. The change in computational linguistics is part of a larger shift to statistical methods in computer science, particularly in artificial intelligence, pattern recognition, speech recognition, and machine learning. (*See* **Information Theory**)

THE RE-EMERGENCE OF EMPIRICAL LINGUISTICS

American Structuralism

The statistical paradigm has strong precedents in American structural linguistics. One of the major aims in structuralism was the development of procedures for taking a representative corpus of raw language data and determining the elements of which it is composed (the sounds and words of the language) and the conditions on their distribution. The motivation was methodological and philosophical: one wished to report only what was evident in the data, thereby avoiding the speculation and subjectivity that had been characteristic of earlier 'philosophical' linguistics. Bloomfield famously wrote that 'the only useful generalizations about language are inductive generalizations' (Bloomfield, 1933, p. 20). Only the observable regularities in the data were of concern. Unobservables – in particular, meaning – had no place in structuralist descriptions.

Two important classes of linguistic elements are phonemes and morphemes. In the structuralist view, they are not abstract postulates, but rather, features of the data. Structuralist procedures for identifying phonemes and morphemes (and other aspects of structure) are generally known as *discovery procedures*, but in a real sense they are not so much concerned with *discovering* elements of structure as with *defining* them. A phoneme (for example) is defined to be what a given procedure returns when applied to the data. Faced with two alternative phonemicizations, a structuralist does not ask which one is correct. Definitions cannot be right or wrong. In the words of Harris, 'they differ not in validity but in their usefulness for one purpose or another (e.g. for teaching the language, for describing its structure, for comparing it with genetically related languages)' (Harris, 1951, p. 9, n. 8).

Current computational linguistics takes a similar stance on the question of truth. Unlike structuralism, it does not eschew 'deep' or 'hidden' models – witness the discussion of stochastic grammars below – but its concern is utility rather than Platonic truth, and it insists on rigorous evaluation of model utility against a quantifiable measure of success at some task.

Current computational linguistics also follows structuralism in its interest in mechanically inducing from a corpus the elements of the language and the conditions on their arrangement. There are obvious parallels between some of the structuralist procedures and newer statistical methods. For example, one of the procedures that Harris used to segment a corpus into morphemes is the following. Consider an utterance, for example,

/hiyzklev^{e}r/ 'he's clever'. Count the number of phonemes that could have occurred after /h/. That is, among all utterances in the corpus beginning with /h/, how many distinct segments appear in the second position? In Harris's estimate, there are nine (the English vowels and semi-vowels). After /hi/, there are 14 possibilities; after /hiy/, 29; after /hiyz/, 29; and after /hiyzk/, 11. Morpheme boundaries occur where the number of possibilities is highest, the intuition being that the constraints on succession are more stringent within a word than between words. Hence morpheme boundaries are defined to occur after /hiy/ and /hiyz/, but not after /h/ or /hiyzk/.

If we consider *probabilities* of phonemes instead of just *possibilities*, a natural analogue of Harris's proposal is to measure how much phoneme probabilities are affected by the context:

$$p(\text{phoneme} \mid \text{context}) \,/\, p(\text{phoneme}) \qquad (1)$$

The measure (1) is precisely the measure proposed by Stolz (1965) in an experiment to induce phrase boundaries. In information theory, the average of the logarithm of (1) is called *mutual information*; it is a key measure of coherence in modern statistical methods, and is commonly used to induce phrases.

In a similar way, the structuralist use of substitutability to define natural classes of elements has modern parallels. In structuralism, the class of nouns is defined as a class of elements that appear in similar contexts. Information theory provides a mathematically well-founded measure of substitutability: two elements are intersubstitutable if the *divergence* of their distributions is small. The divergence between distributions p and q is the average (with respect to p) of the log of $p(x)/q(x)$. It has been used for constructing classes of similarly distributed elements (Finch, 1993).

Language Models

As the previous discussion suggests, information theory is an important tool for putting structural induction procedures on a firmer mathematical foundation. Information theory was motivated by the problem of transmitting information over a *noisy channel*. To transmit text (for example) over a telegraph wire with maximum efficiency and minimum error, it is necessary to identify the redundancies, which is to say, the regularities, in the text. This is precisely the task that the structuralists had set for themselves (though with a very different motivation).

In his seminal work on information theory, Shannon introduced the following problem, which has become known as the *Shannon Game* (Shannon, 1951). Take a random text and uncover it one element (e.g. one letter) at a time. At each point, the task is to predict the next element; it is not revealed until you guess correctly. The quantity used to measure difficulty in guessing is effective vocabulary size or *perplexity*: this is the vocabulary size that would cause a random guesser to make the same number of mistakes as you make. Your estimate of the text's perplexity is a measure of how good you are as a guesser. But Shannon also showed that there is a limit on how good any guesser can be. This *Shannon limit* is the inherent perplexity of the text (Shannon, 1948).

Algorithms that play the Shannon Game are known as *language models*. (To be precise, a language model is a probability distribution over all possible sequences of elements, and its ability to play the Shannon Game, as measured by its perplexity, is the measure of its quality as a language model.) A simple family of language models is the family of n-th order *Markov models*, which approximate the conditional probability $p(x_t|x_1 \ldots x_{t-1})$ of an element x_t given the corpus up to time t as $p(x_t \mid x_{t-(n-1)}, \ldots, x_{t-1})$, the probability of x_t given the preceding $n-1$ elements. Shannon showed that Markov models of increasing order converge to the Shannon limit: by choosing n large enough, the true distribution over language elements can be approximated arbitrarily closely.

However, Chomsky criticized Markov models (Chomsky, 1956). First, he emphasized that any given Markov model accounts for dependencies only up to a certain distance, leaving a residue of longer-distance dependencies not captured. Second, he pointed out that simple frequency counts are not adequate for estimating any but the lowest-order Markov models.

Concerning the first criticism, Markov models are mathematically useful because of their extreme simplicity, and they are surprisingly effective in practice, but they are obviously inadequate for many purposes, particularly for representing language semantics. (Unlike structuralism, modern computational linguistics is very much concerned with language meaning.) Soon after Chomsky defined context-free grammars, stochastic versions were explored, and have since been well developed; they are discussed below.

The second of Chomsky's criticisms is in part addressed by moving to more expressive grammars, and in part it is a technical issue concerning

estimation of model parameters in the face of *sparse data*. This has been a major topic in speech recognition, and very sophisticated *smoothing* techniques have been developed to address it.

Causes of the Revival of Statistical Methods

In the late 1970s, Shannon's noisy channel model, and Markov models in particular, were applied to speech recognition by Jelinek and his colleagues. The speaker is approximated by a Markov model, and the channel includes both the conversion of words into sounds and the transmission of the sounds to the hearer. The setting as a whole is approximated by a Hidden Markov Model (HMM), a generalization of Markov models to the case in which the elements of the text are not directly observable (Baum *et al*., 1970). The result was a dramatic improvement in speech recognizer performance, and by the mid-1980s virtually all work on speech recognition was based on HMMs. (*See* **Speech Recognition, Automatic**)

The state of the art in speech recognition systems is the trigram Markov language model, which predicts each word on the basis of the preceding two words. A trigram model is obviously a poor model of language – for example, if one generates text by random sampling from the distribution it defines, the results cannot be mistaken for real English text. However, it has proven remarkably difficult to improve on trigrams. Only since about 2000 have more sophisticated models been developed that significantly outperform trigrams.

Early on, HMMs were applied to the problem of assigning parts of speech to words (the *tagging* problem). That work, when it became known in the computational linguistics community, was the proximate cause of the surge of interest in statistical methods.

The impressive performance of statistical taggers attracted the attention of computational linguists, but the reason the statistical approach so quickly became the dominant paradigm is because it directly addressed several issues that had frustrated computational linguists immensely.

First was the desire for *robustness*. Real user input is noisy: it is full of misspellings, unanticipated syntactic constructions, and so on; and computational linguistics to that time had failed to develop genuinely noise-tolerant systems. A hallmark of statistical techniques is their noise tolerance.

Second was the desire for *portability*. Applying a manually constructed system to a new subject domain or a new language requires a prohibitive effort. By contrast, algorithms based on statistical methods can be adapted to new domains or new languages by training them on language corpora, and collecting and annotating corpora is usually easier than adapting systems by hand.

A third issue that had frustrated at least some computational linguists was the lack of measurable progress in the field. The statistical approach provides objective measures of success. One desires models that *generalize*: models that capture genuine regularities, not idiosyncrasies of a given data set. A model that captures idiosyncrasies is said to *overfit* the training data. Generalization is measured by a model's performance on a *test set* that is representative of the universe of data of interest, but never seen during construction or training of the model.

Kinds of Statistical Methods

For expository purposes, statistical methods can be divided into three broad classes, which we consider in the following sections: corpus statistics, generative models, and classification and clustering.

CORPUS STATISTICS

Corpus statistics are descriptive statistics that operationalize linguistic concepts. They are closest in spirit to the structuralist procedures, though with an important difference: the operationalizations are not taken to *define* linguistic concepts, but to *approximate* them. Examples are the use of mutual information as a measure of coherence, and divergence as a measure of distributional (dis)similarity. As mentioned above, they can be used to induce grammars; they can also be used to induce lexical information. Mutual information, for example, is used to identify multiword terms such as 'stock market'. Other targets of lexical acquisition include subcategorization frames and selectional restrictions.

GENERATIVE MODELS

A second class of statistical methods involves probability distributions over families of structures. They can be classified by the complexity of the structures involved. Stochastic finite-state automata define distributions over strings, stochastic context-free grammars define distributions over trees, and stochastic attribute–value grammars define distributions over attribute–value structures.

For each class of grammars, there are three main questions of interest: how probabilities are attached

to a grammar in such a way as to give a well-behaved probability distribution to the structures generated by the grammars; how the most likely structure can be computed for an arbitrary input; and how the probabilities in the stochastic grammar can be estimated from a sample.

Finite-state Automata (Hidden Markov Models)

A finite-state automaton (FSA) consists of a set of states, and a set of arcs leading from one state to another. Finite-state transducers of the most familiar sort (called 'Mealey machines') associate output symbols with arcs. In stochastic FSAs, however, it is more common to use automata that associate output symbols with states ('Moore machines'). Machine computations consist in alternately producing an output symbol from the current state ('emission'), then following an arc to a new state ('transition'). (*See* **Finite State Processing**)

In a stochastic FSA, a probability distribution is associated with the outputs from a given state, and a probability distribution is placed on the outgoing arcs from a given state. 'Hidden Markov Model' is another name for a stochastic FSA of this type. The probability of a computation is the product of probabilities of the individual emissions and transitions constituting the computation. The string generated by a computation is the concatenation of the strings generated in each emission step. The *derivation* of a string is the computation – that is, the sequence of states – by which it was generated.

A Hidden Markov Model is hidden in the sense that the derivation of a string cannot in general be uniquely determined. Nothing prevents there being more than one state that emits a given output symbol. To determine the most likely derivation, one can in principle enumerate all derivations of the string and compute their probabilities. This is impractical for strings of any length, inasmuch as the number of derivations increases exponentially with the length of the string. (*See* **Natural Language Processing, Disambiguation in**)

Fortunately, there is an algorithm (the *Viterbi algorithm*) for computing the most likely derivation in time linear in the length of the string. The Viterbi algorithm is a special case of dynamic programming. The key observation is that the most likely partial derivation leading to state q at string position t consists of the most likely partial derivation leading to some state q' at the previous position $t-1$, followed by the transition from q' to q. Instead of keeping track of all (exponentially many) partial derivations at position t, we need only keep track of the most likely partial derivation for each state q at t.

The discussion up to now has assumed that transition and emission probabilities are given. In practise, however, they are not given, but must be estimated from a *training corpus*. A *labeled corpus* is one containing not only natural-language text, but also the sequence of states that the HMM passed through to generate the text. With a labeled corpus, we can essentially estimate HMM probability parameters by counting. For example, the probability of a transition from state q_1 to state q_2 is estimated as the relative frequency of transitions from q_1 to q_2 among transitions out of q_1 in the labeled corpus.

With an *unlabeled* training corpus, in which only the text is available, the sequence of actions taken by the HMM is unknown, and its probabilities obviously cannot be estimated by simple counting. In this case, the standard algorithm is the *forward-backward algorithm*, which is a special case of the *Expectation-Maximization (EM)* algorithm (Dempster *et al*., 1977). One begins with arbitrary parameter estimates – for example, uniform probabilities. The probability of every possible derivation is computed, and one pretends that a derivation occurs a fractional number of times, in proportion to its probability. This gives one a labeled corpus, from which new probabilities can be estimated by relative frequency. One then repeats the process with the new probability estimates. It can be shown that this method improves the probability estimates at each iteration, measuring goodness by the standard *maximum likelihood* criterion.

Even counting relative frequencies involves some subtleties. It is complicated by the *sparse data problem*: the fact that many unobserved actions fail to occur only because the training corpus is not large enough. Indeed, in most cases of practical interest, the majority of possible actions fail to occur even in the largest available corpora. Methods to address the sparse data problem are known as *smoothing methods*. A large variety of them have been studied (Chen, 1996). The easiest is simply to pretend that every possible action occurred at some low frequency. That is, one adds a small count (usually 1 or 1/2) to every count, including the zero counts, before taking relative frequencies. Much better smoothing methods are available; the most commonly used are *Katz back-off* and *deleted interpolation*.

In addition to speech recognition and part-of-speech tagging, stochastic FSAs have applications in *entity recognition* (that is, detecting references in

text to people, companies, dates, times, monetary amounts, and so on) and *partial parsing* (recognizing the major phrases and clauses of a text without completely parsing it).

Stochastic Context-free Grammars

The next more complex grammar class comprises the context-free grammars. A context-free grammar consists in a set of rules of form $A \rightarrow Y_1 \ldots Y_n$, in which A is a nonterminal symbol and $Y_1 \ldots Y_n$ is a (possibly empty) sequence of mixed terminal and nonterminal symbols. $Y_1 \ldots Y_n$ is said to be an *expansion* of A.

A derivation begins with a single, distinguished, nonterminal symbol S. At each point in the derivation, the leftmost nonterminal symbol is replaced with one of its expansions. The derivation continues until no nonterminal symbols remain. A derivation is equivalent to a parse-tree. Each node in the tree represents an expansion: the parent node is labeled with the nonterminal A that is being expanded, and its child nodes are labeled with the expansion symbols $Y_1 \ldots Y_n$.

In a stochastic context-free grammar (SCFG), probabilities are associated with expansions. For any given nonterminal symbol, the probabilities of all its expansions sum to one. The probability of a derivation is the product of the probabilities of the expansions constituting the derivation.

One can modify practically any context-free parsing algorithm to recover the most likely parse. For example, the *CKY parsing algorithm* proceeds as follows. The grammar is assumed to be in Chomsky-normal form, meaning that all expansions are of the form $A \rightarrow B\ C$ (two nonterminals in the expanded form) or $A \rightarrow a$ (one terminal in the expanded form). This assumption involves no loss of generality, as any CFG can be converted to an equivalent grammar in Chomsky-normal form. All possible parse-tree nodes are constructed, in order of increasing width, where the width of a parse-tree node is the number of words of input it covers. For each triple (X,i,w), where X is a nonterminal category, i is a start position, and w is a width, only the most probable subtree is recorded. Since (X,i,w) is constructed out of subtrees of smaller width, all its possible components are guaranteed to exist. (*See* **Parsing**)

There is also a specialization of the EM algorithm, known as the *inside-outside algorithm*, that can be used to estimate the probabilities of an SCFG from unlabeled data. Unfortunately, grammars trained using the inside-outside algorithm produce parse-trees that are not useful for sentence interpretation. This is attributed to the fact that the inside-outside algorithm is designed to minimize sentence perplexity; it has no source of information concerning sentence meaning. As a practical matter, stochastic parsers are trained using labeled data, known as *treebanks*.

Stochastic Attribute–Value Grammars

For our purposes, attribute–value structures can be thought of as directed acyclic graphs (DAGs) with labeled edges. DAGs differ from trees in that DAGs contain *re-entrancies*: nodes that have multiple parents. DAG nodes represent either parse-tree nodes or their values for given attributes. For example, a singular noun phrase can be represented as a node labeled 'noun phrase' linked by an edge labeled 'number' (an attribute) to a node labeled 'singular' (a value). The constituents of the noun phrase are distinguished by edges with labels 'child 1', 'child 2', etc.

Attribute–value structures are generated by attribute–value grammars. Rules in an attribute–value grammar are context-free rules equipped with constraints. Constraints determine the re-entrancies in the DAG. For example, the rule

$$S \rightarrow NP\ VP;\ NP.number = VP.number$$

specifies that the node representing the noun phrase's value for attribute 'number' is the very same node as the one representing the verb phrase's value for 'number'.

Attribute–value grammars are stochasticized by attaching weights to their rules. The probability of a DAG is the product of weights of the rules that define it. Unlike in the finite-state and context-free cases, however, the rule weights cannot be called probabilities. In the finite-state and context-free cases, structures are built up of a number of independent stochastic decisions, and because of the independence of local decisions, the probability of the structure as a whole is the product of local decision probabilities. In the attribute–value case, re-entrancies introduce dependencies among local decisions. Global probabilities are defined as products of local weights, but because of the dependencies among local decisions, the weights are not local probabilities.

Stochastic attribute–value grammars are essentially a variant of *Markov random fields* or *graphical models*. There is a considerable literature on estimation of graphical models (Lauritzen, 1996). For stochastic attribute–value grammars, estimation methods that have been considered include varieties of *Iterative Scaling*.

No tractable exact parsing algorithm is known for stochastic attribute–value grammars. Because of the dependencies among substructures, dynamic programming is not possible. For practical purposes, a common technique is to use stochastic context-free parsing to obtain a small set of candidate structures, which are then evaluated using the full attribute–value grammar.

The unavailability of a dynamic programming algorithm also means that there is no advantage in attaching weights solely to local rules. Typically, weights are attached to features that span much more of the structure than a local expansion.

Specialized Generative Models

Specialized generative models are often developed for specific tasks. Prominent examples are *corpus alignment* and *machine translation*. Corpus alignment involves lining up sentences or smaller phrases between corpora in two different languages, one of which is a translation of the other. Machine translation can be thought of as a similar task, but one in which the problem is to generate the source-language text that would align best with the (observed) target-language text. There have been efforts to estimate fairly direct transfer models, as well as efforts to equip more traditional 'deep' translation models with probabilities.

CLASSIFICATION AND CLUSTERING

There is a lively interchange between computational linguistics and machine learning. New machine-learning techniques are continually introduced into computational linguistics, and the unique challenges of language learning stimulate new directions of research in machine learning.

A central topic in machine learning is classification. The aim of classification is to determine which of a fixed number of classes a given item belongs to. Classification is a supervised learning method – the learning algorithm is given a training corpus of correctly classified examples. A simple example of a classification problem in computational linguistics is prepositional phrase attachment. One widely used data set is constructed from verb phrases of the form 'verb – noun phrase – prepositional phrase', for example 'was selling machine parts from Dresden'. The task is to classify each such example as 'noun attachment' (parts that are from Dresden) or 'verb attachment' (they were sold from Dresden). Generative models can be used in service of classification, but classification can also be done without generative models. A wide variety of classification techniques have been applied to computational linguistic problems, including classification and regression trees (CART), decision lists, Naive Bayes, likelihood ratios, and margin-based methods such as support vector machines (SVMs) and boosting.

Another area of especially strong interaction between machine learning and computational linguistics is unsupervised learning. In unsupervised learning, the training material is not labeled with correct answers. An example is clustering, which is used to induce classes of words, for example in language modeling or in the induction of selectional restrictions.

Intermediate between supervised and unsupervised learning is *bootstrapping*. In bootstrapping, the algorithm is given a very small amount of labeled data, and a large amount of unlabeled data. It can be viewed as supervised learning with supplementary unlabeled data, or as unsupervised learning in which the labeled set is used to give names to the clusters. It has been successfully applied to word-sense disambiguation and named entity classification, among other things.

SUMMARY

Statistical methods have become the standard paradigm in computational linguistics. They can be placed in the historical perspective of American structuralism, though they derive more immediately from statistical speech recognition and Shannon's noisy channel model. They can be grouped roughly into descriptive statistics, generative models (stochastic finite-state, context-free, and attribute–value grammars), and machine-learning methods (classification, clustering, bootstrapping).

Stress

Advanced article

Harry van der Hulst, University of Connecticut, Storrs, Connecticut, USA

CONTENTS

Stress is a phonetic manifestation of accent, which marks the phonological head of the word.

INTRODUCTION

In this article, I will discuss the phenomenon of linguistic stress as it applies to words. Units that are larger than words (such as phrases and sentences) can be said to have stress too, but I will not touch on these larger units here. Right away, in the very next section, I propose to shift our attention to the notion of accent, which I define as more fundamental than stress. Stress, as we shall see, can be seen as a phonetic manifestation of accent. I will provide a typology of the various ways in which accent is manifested besides through stress.

MANIFESTATIONS OF ACCENT

It seems prudent first to make an attempt to define what stress is, or, at least, how I will use the term in this article. Starting with what most people who are able to read this article know (i.e. people who know English), let us consider the following pairs of English words:

convíct cónvict
protést prótest
pervért pérvert (1)

If one pronounces these words, pairwise, one will notice a difference that seems to involve the (relative) prominence of the syllables that the words are composed of. Let us capitalize the prominent syllables:

conVÍCT CÓNvict
proTÉST PRÓtest
perVÉRT PÉRvert (2)

Stress, as I will define it, is (relative) syllable prominence. It is now fair to ask what is meant by 'prominence'. This brings us into the realm of phonetics, i.e. the study of the way speech is produced and perceived. Relative prominence corresponds, on the one hand, with greater articulatory effort in production and, on the other, with greater salience, or audibility, on the perceptual side. Stressed syllables, then, stand out and are easier to perceive than the unstressed, or lesser stressed syllables. Greater articulatory force can be the cause of several effects that can be measured by investigating the details of production, or the physical properties of the produced acoustic signal, e.g.:

Phonetic properties of stressed syllables
- The stressed syllable has greater duration
- The stressed syllable is louder (greater amplitude)
- The stressed syllable is pronounced at a higher pitch (higher fundamental frequency)
- The segments are pronounced with greater precision (3)

This list is not meant to be finite, nor is it couched in the latest language of the trained phonetician. Also, some or all of the phonetic properties may be exclusively or primarily manifested in only a part of the syllable such as its vowel or its rhyme. Whatever the details, a stressed syllable will differ from unstressed syllables in having 'more' of whatever 'stretchable' property any syllable may have (such as duration, pitch, loudness, manner of articulation).

Following researchers such as Hyman (1977), I propose to reserve the term 'stress' for prominence as signaled by the above collection of cues. Then, I will also follow these researchers in saying that stress, in the sense just defined, is a phonetic manifestation or exponent of an abstract property, accent.

Before we address the question of how accent is to be formally understood, let us include another

language in the discussion, namely Safwa (Bantu). Consider the following words or word combinations:

a'mi-ino	'teeth'
ga'mi-ino	'the very teeth'
mi-ino'	'it is teeth'
inko'ombe i'im-bisi	'uncooked beans'
inko'ombe m-bisi'	'the beans are uncooked'

(4)

Again, I have provided certain vowels with what is often (and appropriately) called an 'accent mark'. As in the case of English, speakers of Safwa perceive the syllables that contain these accented vowels as more prominent than the surrounding syllables. When we now look at the articulatory and acoustic properties of the vowels in question, it turns out that what distinguishes them from other vowels in the word is just (or mainly) their relative higher pitch. Thus, the relevant vowels are singled out by only one of the properties that cue the presence of accent in English. But if 'stress' is the collection of all the properties in (3), we cannot say that Safwa has stress. So what *do* we say? The obvious answer may be that Safwa has pitch. We can now capture the difference between English and Safwa terminologically by referring to the former as a stress-accent language and the latter as a pitch-accent language, as proposed in Hyman (1977).

Before we discuss the matter of accent locations, it will also be important to see that the accents can be cued by phonological properties instead of, or in addition to, nondistinctive phonetic cues, although the line between what is called 'phonetic' and what is called 'phonological' lies in different places for different researchers. One important way in which word accents can reveal themselves is by function as anchoring points for some of the tones that make up the intonation melody. (Because these tones, being pitch events, link to word accents, researchers often refer to them as 'pitch-accents', not to be confused with Hyman's notion of pitch-accent introduced earlier.) An intonation melody in a language like English consists of one or more 'pitch-accents' (which can be high tone, low tone, or a contour) and additional boundary tones coming at the beginning or the end of whatever word stretch of the sentence the melody is associated with (cf. Gussenhoven, 1984). This word stretch is usually called the 'intonational phrase', a unit that need not coincide with a syntactic phrase. In the following example the 'pitch accent' is taken to be a high tone (H), and no boundary tones are assumed:

```
H                    H
|                    |
In California they count votes manually
```

(5)

Both *California* and *manually* have several syllables, yet the H tone links to the one that we would call stressed or accented. I am not making a universal claim here on how intonation melodies are anchored to the 'text'. In languages other than English the tune-to-text rules may be different. In any event, in languages that work like English in this respect, 'pitch-accents' function as cues for word accent.

A second nonphonetic cue for accent lies in the notion of phonological contrast. Regularities in the phonological (or phonotactic) patterns of words can be broken down into statements about the inventory of phonological segments (or phonemes) and the possible combinations of these segments. It is not unusual to make statements about the segment combinations in terms of syllables, assuming that a well-formed word is a combination of well-formed syllables (plus, possibly, extra consonants at the beginning or end of the word). It is well known, however, that some syllables allow more segment types and more combinations than others, and at this point it will not come as a surprise to learn the syllables that allow more segment types are the ones that are accented.

Finally, we need to consider yet another type of cue. In English, the sound [p^h] (aspirated p) is restricted to initial position in accented syllables (if not preceded by an /s/). In unaccented syllables, instead, the sound [p] is found. In addition, in syllable final position we always only find [p]. Traditionally, [p^h] and [p] are called allophones (realizations) of one lexical phoneme /p/. The lexical representation of words only has a segment /p/. The aspirated segment is derived by an allophonic rule that forms part of the mapping from the lexical into the postlexical representation. Now, since [p^h] only occurs in accented syllables, its presence is a cue of accent. Thus, one might say that English has a postlexical constraint that bars the segment [p] from a stressed syllable onset. A process 'add aspiration' (called a 'repair rule' in some frameworks) ensures that the lexical form /pin/ is rendered as [p^hin] at the postlexical level. To account for the fact that English has no contrast between /p/ and /p^h/, we assume that the lexical phonology has a constraint that bars a phoneme /p^h/ altogether.

Both levels, then, are characterized by a set of 'wellformedness' constraints, and both levels are served by repair rules that will change forms

that violate these constraints before they can be accepted at that level. Lexical constraints can be violated by new words that are produced by the morphology or that enter the language through deliberate new formations or by loan words. Postlexical constraints can be violated by the forms that are provided by the lexical phonology. Postlexical constraints, unlike lexical constraints, are subject to variables that include style and rate of speech as well as sociolinguistic variables.

All the differences between the contrastive options that can occur in accented syllables and in unaccented syllables, as well as the differences in syllable types that are allowed in these two circumstances, are clear examples of phonological (or phonotactic) cues for accent.

Summing up, we have seen that the location of accent in English can be signaled by at least the following cues:

Cues for accent in English
- Inherent stretchable properties (duration, pitch, loundness, manner)
- Anchoring of intonational tones
- Lexical-phonotactic constraints
- Postlexical 'phonetic' constraints (and the processes that serve them) (6)

All of the above undermines the term 'stress-accent' because they show that accent is manifested in much more than just stress, which only covers the first item in (6). However, it strengthens the more important point that we must separate the notion of accent from the cues that signal its location. Large portions of the lexical and postlexical phonology are determined by the difference between the presence or absence of accent.

ACCENTUAL REPRESENTATIONS: A TYPOLOGY

In the preceding discussion, we have been assuming that accent is a local property of one particular syllable in the word. If this where so, a proper and simple representation of accent would be to assign some sort of mark to the syllable in question (or its vowel), much as in done in dictionaries or transcriptions where accent is marked by an 'accent mark' (as in our example in 1). This practice, although tolerable for some purposes, is inadequate for two reasons, which will almost sound contradictory. First, the use of a local accent mark fails to explain that accent is a 'once-per-word' property, i.e. only one syllable in the word can be accented. Accent is, as is often said, a culminative property. Thus, in order to represent accent formally in the phonological representation of words, it must that there can be only one accent. The second reason for thinking that the accent mark is inadequate is that words apparently can have more than one accent. Consider the examples:

an'tielope,
cro'codi,le (7)

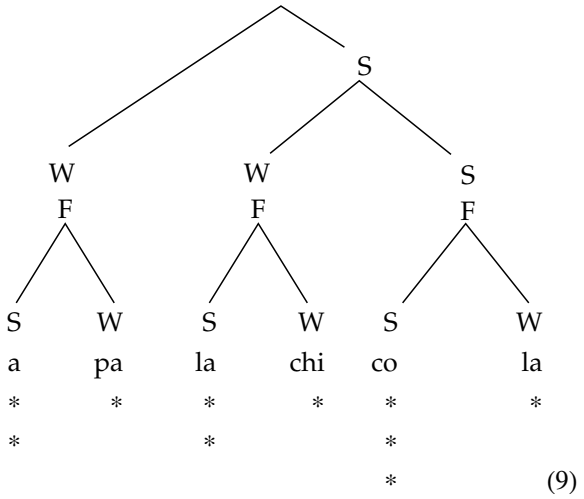
In English, if more than one syllable precedes the accent, a second accent is possible, often indicated by a second type of accent mark. The second mark is said to be a nonprimary or secondary accent (or secondary stress), as opposed to the primary accent (stress). The reader will realize that a contradiction between the two inadequacies of the local accent mark is apparent: the potential presence of a secondary accent does not invalidate the claim that there can be only one primary accent. However, there can be more than one secondary accent:

a, pa la, chi co' la (8)

Secondary accents clearly are a linguistic manifestation of rhythm. In some languages words can have an even greater length than six syllables, and in those cases words can have three rhythmic secondary accents or more. Hayes (1995) describes or refers to many cases of this type.

There are two views on the relationship between primary accent and secondary accent(s). In this section I will focus on one of these. The other view is discussed in the next section.

One view is that a primary accent is basically a promoted secondary accent. In this view, in other words, primary accent is determined on a foundation of secondary accents. A point in favor of this idea is that, in the examples in (7) and (8), the distribution of primary accents seems to follow the same rhythmic pattern that characterizes the secondary accents, in that an accented syllable is typically followed by an unaccented syllable. Hence each accent seems to create a strong–weak domain. Metrical theory formalizes this idea by assuming that the string of syllables of a word is organized in a sequence of binary trochaic (i.e. left-strong) feet. Essentially, a word is compared to a line of verse. The sequence of feet is then organized into a right-strong structure that designates the rightmost foot as the strongest foot in the word:



(9)

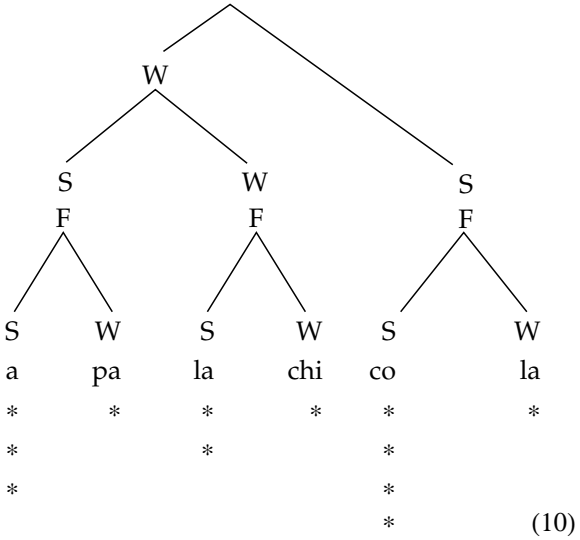
(Here, and in (10), ignore the 'grid' with asterisks, for a brief while.)

The terms 'strong' and 'weak' refer to the idea that accent is a relative notion. A syllable is said to be 'stressed' by virtue of being more prominent than a neighboring syllable. In later work, however, the idea has been expressed that a syllable by itself (e.g. in a monosyllabic word) can also be said to be stressed. In this way, one can make a difference between stressed monosyllabic words and unstressed monosyllabic words, the latter often called (phonological) 'clitics'. In line with the second, nonrelative view on stress/accent, it was also suggested to replace the terms 'strong' and 'weak' by the terms 'head' and 'dependent'.

The feet are binary branching, headed constituent, restricted to two syllables (we call that 'bounded'). The tree structure that organizes the feet is also thought of as binary branching, but not bounded because it can contain more than two feet. The idea that the phonological string of phonemes (just like the string of words that makes up sentences, and the morphemes that make up words) is organized in a headed (most likely binary branching) structure has become widely acknowledged. A systematic account of this view on phonology can be found in the framework of dependency phonology (Anderson and Ewen, 1987), that, in its earliest work, predates metrical phonology. (Below the level of the foot, we find that segments are organized into headed syllables consisting of binary headed syllabic constituents like onset and rhyme.)

Why is the structure in (9) adequate as a representation of the accentual structure of *apalachicola*? Notice, first, that only one syllable can be exclusively dominated by nodes labeled S, or head, (and the root node). This syllable, then, is the head of all heads, the ultimate head (UH), of the word and that seems an adequate formal representation of the notion of primary accent. Second, secondary accents are uniformly represented as heads of feet. The structure in (9) suggests that the two feet preceding the primary accent are not equal because they are structurally different within the word tree structure.

Indeed, according to speakers of English, the nonprimary accent on the first syllable is stronger than the nonprimary accent on the third syllable (which is sometimes called a 'tertiary accent'). Is (9) an adequate representation of that difference? It would be, if we posit the axiom that the more deeply embedded a weak foot is, the weaker it is. However, one might also wish to consider the structure in (10) that more directly shows that the second foot is subordinate to the first:



(10)

To date, it has been difficult to decide on such matters, which has seduced some researchers into using nonbinary organization of feet resulting in a 'flat' structure.

The issue can be resolved quite easily, however. After the introduction of metrical theory, there have been a number of 'internal debates' on certain notational issues (cf. Halle and Vergnaud, 1987, and van der Hulst, 1999). Confusing to the relative outsider may be the use of so called metrical grids. Originally, Liberman and Prince (1977) introduced two simultaneous structures to account for the accentual structure of words, the tree, and the grid. The grid consists of a series of columns, one for each syllable, the height of which indicates the degree of accent. The principle in (11) derives the grid from the tree:

Tree–grid correlation
In any constituent the head has one more asterisk than its dependent. (11)

Notice, how in accordance with this principle, the grid in (10) nicely makes a three-way distinction between three degrees of accentual strength, whereas the grid in (9) does not have the same distinction.

Given that the grid is merely an interpretative device, one might argue that it is strictly speaking redundant. Realizing this, for a brief while, reseachers considered abandoning the tree rather than the grid, thus giving up on constituency. Others argued that grids had to be abandoned. Halle and Vergnaud (1987) argue that constituency should not be eliminated, but to please all parties they adopt a notation that uses the grid, enriched with brackets to indicate constituency, which is not different, of course, from using the headed tree structures (although it does have the typographical advantage of not having to draw tree structures).

English, apparently has left-headed feet, with the rightmost foot being the head foot (cf. Kager, 1989, for many details and discussion):

English accent
- foot: left-headed (iterating through the word from right to left)
- word: right-headed (12)

The framework of metrical theory has shown to be very productive in accounting for cross-linguistic variation in accentual patterns by assuming that we can find variation along the two parameters (see (13)):

word \ foot	left-headed	right-headed
left-headed	initial syllable	second syllable
right-headed	penultimate syllable	final syllable

(13)

Feet must be assigned iteratively if the word has more than two syllables, and it must therefore also be specified whether this iteration works from right-to-left or from left-to-right, since that will make a difference in case the number of syllables in the word is uneven. For English, since the head foot is on the right, it can easily be shown that the iteration is from right-to-left. With the head foot being on the right, the location of primary accent would be dependent on the number of syllables in the word if the iteration was left-to-right, as shown in (14):

```
head right          *                       *   2
left-to-right  (*     *)     (*     *     *) 1
               (* *)(* *)  (* *)(* *)(*) 0

               1  2 3 4    1   2 3 4 5      (14)
```

I use here the bracketed grid notation mentioned above. Level 0 represents all the stressable units (the rhymes). On level 1 we represent the foot heads, and level 2 is for the word head. If a language were to have a system like that in (14), the location of the primary accent would be penultimate in words that have an even number of syllables and final where the number of syllables is odd. This description certainly fails to apply to English, which therefore must have right-to-left footing.

(Systems of the type in (14) have been claimed to exist, but I will argue below that metrical algorithms should not produce them directly. Thus, I will assume that the direction of footing is not independent from the edge choice for the head foot. Since in English the head foot is on the right, footing must be from right-to-left. I shall return to this issue later.)

We now turn to a factor that may influence and interrupt the regular way in which syllables are gathered into feet. So far, we have assumed that syllables are gathered in groups of two, monosyllabic feet arising only where we run out of syllables. In some languages, however, certain types of syllables (called 'heavy') may not appear as the dependent in a foot. This property is called 'weight-sensitivity'. The weight of a syllable is determined by its intrinsic, phonological properties. There are various types of intrinsic weight, and weight is typically (perhaps exclusively, depending on the analysis) binary: i.e. languages will split the set of syllables in to two, one called 'heavy', the other called 'light':

heavy	*light*
long vowel	short vowel
closed syllable	open syllable
checked vowel	unchecked vowel
low vowel	nonlow vowel
high-toned vowel	low-toned vowel
full vowel	reduced vowel

(15)

The first three types in (15) have also been called 'moraic weight', where the heavy syllables contain two units in their syllable rhyme – these units are called 'moras' (or weight units). In the remaining three cases (for which we might adopt the term

'sonority weight'), the heavy syllable is more salient by virtue of its greater aperture, its higher pitch, or its more complex articulation.

Intuitively, it may be seem clear that the properties in the left-hand column give more prominence to a syllable (or its rhyme) in terms of duration (long vowel, checked vowels, closed syllables, full vowels), high pitch, loudness (open vowel), manner of articulation (full vowel) – precisely those factors that can be found as phonetic cues of accent. It seems obvious that syllables that have more of those properties intrinsically (i.e. as distinctive properties) are reluctant to appear in positions that typically have fewer of them, i.e. unaccented positions. Conversely, syllables with such intrinsic properties will 'attract' accent.

The assignment of feet can also be influenced by lexical irregularity. Thus for example in Polish, which has weight-insensitive penultimate primary accent, some words have irregular final or antepenultimate accent. How can we account for that? The answer is that irregular final accent is achieved by assigning a lexical mark to the final syllable, and adding the convention that syllables with such marks may not appear in the dependent position of the foot. Elsewhere, I have referred to such marks as 'diacritic weight'. Such marks usually are historical residues of an earlier situation in which the relevant syllables had intrinsic weight. After a language has lost, e.g. a vowel length contrast, the accents can stay in the same position and thus, in a sense, become unpredictable. Thus, there are two types of weight:

Sensitivity of foot assignment: *the dependent cannot dominate*
- A syllable having certain phonological properties (intrinsic weight)
- A lexically marked syllable (diactritic weight) (16)

Lexical accent structure can be sensitive to both diacritic and intrinsic weight (English).

The antepenultimate exceptions require another type of lexical encoding: for example encoding the final syllable as being disregarded by the metrical algorithm. This is called 'extrametricality'.

LEXICAL AND POSTLEXICAL STRUCTURE

In the preceding section, I have proposed that the direction of footing and the edge choice of the head foot are correlated:

Direction (left-to-right) = head foot left
Direction (right-to-left) = head foot right (17)

Thus, with left-headed feet, we have assumed only two possible systems:

a. *Initial accent*

left-headed	*	*
left-to-right	(* *)	(* * *) 1
	(* *)(* *)	(* *)(* *)(*) 0
	1 2 3 4	1 2 3 4 5

b. *Penultimate accent*

right-headed	*	*
right-to-left	(* *)	(* * *) 1
	(* *)(* *)	(*)(* *)(* *) 0
	1 2 3 4	1 2 3 4 5

(18)

The English system presents a variety of (18b). If, however, the direction of foot assignment does not have to correlate with the choice of the head foot, two further systems can be produced:

a.

right-headed	*	* 2
left-to-right	(* *)	(* * *) 1
	(* *)(* *)	(* *)(* *)(*) 0
	1 2 3 4	1 2 3 4 5

b.

left-headed	*	*
right-to-left	(* *)	(* * *) 1
	(* *)(* *)	(*)(* *)(* *) 0
	1 2 3 4	1 2 3 4 5

(19)

In (19a), which is identical to (14), where the direction is from the left, and the head is on the right (the parameters have opposite values, so to speak), we derive a system in which the location of primary accent is actually dependent on the number of syllables; in even-numbered syllables primary accent is penultimate, while in odd-numbered words, it is final. (19b) would have initial accent in both cases, but the rhythmic structure would be odd. I am not aware of any such systems being reported in the literature. As mentioned in the previous section, systems as in (19b) do seem to occur, but they are rare. In only a few cases do we find that primary accent is truly dependent on rhythm. However metrical theory, with its bottom-up procedure of first building feet and then the word structure, predicts that the cases in (19) should be just as common as these in (18). Given their rarity, I would like to argue that we might want to exclude the possibilities in (19) from our basic apparatus.

We can do this by somehow assigning primary accent first. With primary accent in place, we can then account for rhythmic structure in terms of the assignment of secondary accents that typically 'ripple or echo away' from the primary accent. Rather than stipulating the order in which primary accent and secondary accents are assigned in terms of rule ordering, we can attribute the two aspects of the overall accentual pattern to the lexical and postlexical phonology, respectively.

Lexical and postlexical structure, which I will call here 'phonotactic' and 'prosodic', respectively, may differ in a number of ways. This supports the idea that there are, in fact, two algorithms. In (20) I give a number of examples of such differences:

	Lexical	*Postlexical*	
Foot	weight-sensitive	weight-insensitive	(English)
	weight-insensitive	weight-sensitive	(Finnish)
	left-headed	right-headed	(BigNambas, Marind)
	right-headed	left-headed	(Taga, Dari, Uzbek)
Word	right-headed	left-headed	(English)
	left-headed	right-headed	(Turkish)

(20)

In standard approaches to metrical structure, such mismatches are not interpreted as evidence for two structures but as evidence for rules that transform an initial lexical structure into a later structure (not necessarily referred to as postlexical). This is a typical derivational approach, stemming from the tradition of generative phonology. For example, Halle and Vergnaud (1987) propose that in English feet are assigned from right-to-left giving a right-headed tree and thus primary accent at the right edge. Then, to account for the fact that the secondary accents come from the left, they 'erase' all feet except the head foot and assign feet for a second time, now from left-to-right. In my approach, the apparent conflict between right-to-left and left-to-right footing is taken as evidence for a two-level analysis.

One might now ask how we can account for the cases in (19a) in which, contrary to the majority situation, primary accent does seem to be dependent on the prior existence of rhythmic structure. Space limitations prevent me from discussing this issue in detail. In this case, we need to say that the assignment of postlexical structure is such that the dependent in the postlexical feet cannot be rhythmically strong, while the distribution of rhythm is accounted for in terms of lexical footing. What remains to be explained is why in such cases the head of rightmost foot in the postlexical structure prevails over the ultimate head of the lexical structure (which is on the first syllable).

SOME FURTHER ISSUES

This article has discussed issues of representation and typology, but certain important issues that involve accent/stress have not been dealt with. I will mention two such issues briefly here.

This article has focused on word level accent. In this domain, it is relevant to consider the relationship between the accentual pattern and the morphological structure. One expects that only lexical metrification can be sensitive to morphological structure. Indeed, it has been argued that, for example, the English 'stress' rule is applied within domains that can be smaller than the word if the word is morphologically complex and either compounded or affixes with so-called level 2 affixes. I have not discussed the phenomenon of accent at higher levels than the word, but it should be clear that phonological structure is also relevant for syntactic organization. Here, going beyond the domain of the lexicon, the distinction between phonotactic and prosodic organization no longer applies. A discussion of higher level prosodic structure and its relation to syntactic structure requires a separate article (cf. Nespor and Vogel, 1986). I have also not discussed phenomena involving rules that 'shift' stress as in the famous pair (…) *thirteen'* versus *thir'teen* (men), where the location of accent in *thirteen* differs depending on the syntactic or prosodic context. In line with the suggested analysis of English stress, the different locations correspond to the lexical primary accent (right edge) and the postlexical primary accent (left edge). In the form *thir'teen* the postlexical primary accent has taken over primacy from the lexical accent in order to avoid a stress clash between the accent on *teen* and *men*. Rhythm, then, is an important determinant of the distribution of postlexical accents, not only at the foot level but also at higher prosodic levels. A full discussion of such shifts is also beyond the scope of this article. A thorough discussion of many of the relevant facts and analyses can be found in Visch (1999).

Finally, one might ask whether all languages are accentual at the word level. I suspect that the answer is affirmative. We have seen that accent determines much more than pitch or stress. It seems almost inconceivable to me that we would come across languages that would lack all of the possible cues for accent. We have also seen that accents correspond to the notion (ultimate) head, where this head is just a part of the overall structure that organizes the phonological structure of the word. Expecting to find languages that lack such hierarchical structure at the word level is like

expecting to find languages in which sentences are linear strings of words without any syntactic organization.

Syntactic Encoding and Syntactic Choice

Advanced article

Padraig G O'Seaghdha, Lehigh University, Bethlehem, Pennsylvania, USA

CONTENTS

Syntactic encoding creates a representation intermediate between a nonlinguistic conceptual level and a subsequent phonological level containing word forms. Lexical selection contributes to construction of a syntactic frame. Syntactic persistence, a form of implicit memory, suggests that syntactic structure is partly isolable from content. The relation between conceptual and syntactic formulation is a crucial question that is ripe for further exploration.

INTRODUCTION

Speakers continuously inject nonlinguistic thoughts into linguistic molds as they talk. Standard language production theory (e.g. Bock and Levelt, 1994; Garrett, 1975; Levelt, 1989) postulates a message level in which ideas and other mental contents are represented in a variety of prelinguistic codes. The theory is largely agnostic on the nature of these codes. There are two primary stages in the conversion of a message to the linguistic forms that eventually enables articulation to proceed, syntactic encoding and phonological encoding. This entry addresses the first of these, syntactic encoding. (*See* **Speech Production**)

The idea or message necessarily precedes its encoding. This, combined with the requirement of fluency in speech, means that syntactic encoding is incremental (de Smedt, 1996). That is, syntactic encoding need not proceed in elaborate full-sentence packages but rather progresses as soon as some viable component is ready for transmission to the next level of encoding. But what is viable? The answer to this is partly determined by the two-part nature of syntactic encoding itself. (*See* **Language Production, Incremental**)

The standard account distinguishes two primary subprocesses of syntactic encoding: functional encoding and positional encoding. At the risk of oversimplification, functional encoding begins with the activation and selection of key content words, and positional encoding involves the sequential arrangement, or linearization, of these words with their grammatical affixes, and of additional function words. Activation of potential keywords triggers certain syntactic options and restrictions. Properties such as number and gender of nouns as well as syntactic requirements of verbs are made available at the functional level when words are first activated (Garrett, 1975). Thus, for example, it has been shown that number agreement errors are determined at the functional level rather than by proximity in positionally specified speech (e.g., Bock and Miller, 1991). Likewise, classic studies of natural speech errors (e.g., Garrett, 1975) show that whole word errors mainly involve mis-selection of words performing similar grammatical roles in separate phrases. This highlights two crucial points: that units are defined by their syntactic functions, and that syntactic encoding at the functional level certainly reaches beyond the current phrase. (*See* **Speech Error Models of Language Production**)

This article first examines how lexical elements are selected and how they influence the sequencing process called linearization. It then briefly considers some recently discovered properties of syntactic structures as distinct mental entities that are at least partially dissociable from specific lexical or message content. An overarching constraint on language production is that more or less simultaneous and stable representations at one level are translated into smaller sequenced linguistic pieces at the next. The most crucial of these translations, that from thought into language, is discussed.

LEXICAL ACTIVATION AND SYNTACTIC CHOICE

In encoding a message, a speaker must select lexical items and sequence them according to the rules of the language. Most theorists assume that these

processes are intimately connected. At the functional level, key content words are activated, leading to the construction of syntactic fragments. The initial activation of content words is necessarily strongly influenced by the organization of the prelinguistic message (Bock, 1986; de Smedt, 1996). Thus, other things being equal, factors such as animacy influence the grammatical roles assigned to nouns (McDonald *et al*., 1993). Most importantly, verbs play a key role in functional assignment, influencing the selection and subsequent ordering of other words in the sentence.

To illustrate, consider a transaction in which Sue puts money in the hands of the curator of the poverty-stricken Museum of Dead Languages. In English, we may describe this event using the verb *give* or the verb *donate*. If *give* is chosen, the speaker may say either *Sue gave the curator money* OR *Sue gave money to the curator/ museum*. However, if *donate* is used, the speaker must say *Sue donated money to the museum*. Thus, in the process of incremental sentence generation, one or both of the verbs may be activated. Further, if *give* is activated, either alone or together with *donate*, two configurations of the remainder of the sentence are available. Finally, *give* prefers an animate but *donate* an impersonal recipient. The options for each verb are summarized in Figure 1.

The flexibility entailed by the existence of choice may pre-empt conflict and abet fluency if speakers choose the most available option without hesitation (Ferreira, 1996). However, in other circumstances, competition may arise at the choice points of verb selection and sentence continuation (see Dell and O'Seaghdha, 1994; Stallings *et al*., 1998). The configuration in Figure 1 presents a number of processing options. (*See* **Choice Selection**)

- *Give* and *donate* may compete for selection either by direct contest between their representations or indirectly via a selection mechanism that assesses their absolute or differential fitness (see Dell and O'Seaghdha, 1994).

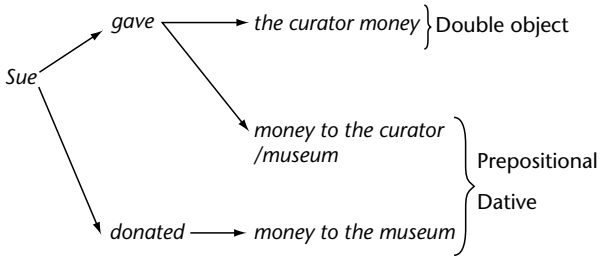

Figure 1. Some syntactic options for describing an act of pecuniary generosity.

- If *give* is ascendant, the alternative direct object and prepositional dative continuations may likewise compete directly or indirectly for selection. This contest may be between the structures themselves, between elements within them (in this case the *curator/museum* and the *money)*, or both.
- Most interestingly perhaps, even in the case that *donate* is not selected, its allegiance with the prepositional dative option may dispose the preferred *give* to that option. Evidence from the *fast priming* paradigm in sentence comprehension (Trueswell and Kim, 1998) suggests that verbs activate their syntactic preferences automatically and so may change the landscape for syntactic choices even when they are not overtly present.

This kind of sensitivity to verb preferences can be accounted for by constraint-based approaches in which statistics of use are coded with verbs (MacDonald *et al*., 1994). Verb preferences may influence not only the choice of local syntactic structure for immediately following words but also the ordering of entire phrases in postverbal position. Thus, Stallings *et al*. (1998) proposed that verbs that tend to have their objects nonadjacent in a variety of syntactic structures tend to show that disposition generally. More broadly, the constrained and sometimes rather arbitrary choices afforded and imposed by lexical options require that thinking, at least if it is to be expressed in words, be cognizant of syntactic obligations (Slobin, 1996). (*See* **Constraint-based Processing**; **Syntactic Form Frequency: Assessing**)

SYNTACTIC STRUCTURE PRIMING

The suggestion above that *donate*'s structural requirement for the prepositional dative might attract *give* toward that option is an instance of the intriguing phenomenon known as *syntactic structure priming*. Bock (1986) first brought this into the limelight using a paradigm in which participants were exposed to sentences in particular configurations and then described pictures bearing no meaningful relation to the preceding sentence. She found that speakers tended to echo the structure of preceding sentences in their descriptions of the pictures. Anecdotal evidence of such echoing existed before, but it lacked empirical substantiation and theoretical pertinence. Bock, her colleagues, and other researchers have now expanded the theoretical and empirical horizons considerably.

- The effect appears to be structural and not linked to semantics (Bock and Loebell, 1990).
- It is persistent over many intervening structurally unrelated sentences, and so is not a function of short-term

activation (Bock and Griffin, 2000). The exercise of a syntactic choice appears to leave a relatively enduring trace.

- It has been mimicked by a sequential learning model in which the structural effects are captured by long-lasting weight changes (Dell *et al*., 1999). Bock and Griffin identify these adjustments as 'dynamic vestiges' of processes involved in mastering the skill of actual speech production. (*See* **Implicit Learning**)
- However, the processes involved may be more abstract than this because syntactic structure priming occurs whether the persisting influence originates in a previously produced sentence or in a previously heard or read sentence. (*See* **Production–Comprehension Interface**)

Syntactic priming is akin to structural persistence at the lexical level (e.g., Church and Fisher, 1998). The latter kind of structure priming is observed in cases of lexical repetition among speakers called cryptomnesia, and both processes may be implicated in the phenomenon of conversational coordination (e.g., Branigan *et al*., 2000). Finally, both lexical and syntactic persistence, not mere retention of a literal record, appear to be necessary to explain the accuracy of immediate complex sentence recall (Potter and Lombardi, 1998).

HIGH-LEVEL PLANNING PROCESSES AND SYNTACTIC DECISIONS

Until recently, the preoccupation of psycholinguists with lexical and sentence-level processes has resulted in neglect of higher discourse-level issues. Much of the work on discourse level planning for production has been conducted by computational linguists in relative isolation from psycholinguistics (see Andriessen *et al*., 1996). However, the ongoing ferment in language production research has recently begun to work its way into the upper echelons of the language processing system.

The key question in this recent work is centered around an old question which we may call the Wundt–Lashley problem. The general problem arises between any two levels of planning for production when the functional requirements at the two levels lead to noncoincident organizations (see Lashley, 1951). The particular form of the problem that originates with Wundt (1900) concerns the coordination of nonlinguistic conceptual representations with linguistic ones. This problem may be more difficult than translation between levels of linguistic representation, especially if, as Wundt believed, conceptual representations are not subject to the same temporal sequencing imperatives as linguistic ones. In Wundt's view, conceptual representations are in important respects simultaneous and atemporal, whereas linguistic representations are strongly time-bound. The problem then is how to transduce the atemporal into the temporal. Wundt proposed a solution – that speech is planned conceptually in simultaneous components of at least the size of a clause, and then encoded syntactically in smaller phrase-sized chunks – that has received good support from two recent studies.

Griffin and Bock (2000) took a very direct approach by examining the timing of eye fixations during inspection of simple scenes under varying instructions. Patterns of eye fixations showed that speakers first apprehended an entire event before proceeding to elaborate the linguistic structure via a more gradual process in which eye fixations and lexical-phrasal choices were strongly correlated. This method shows great promise of providing further insight into processes at the conceptual–lexical interface during syntactic encoding.

Using a less direct measure, sentence initiation time, Smith and Wheeldon (1999) examined the scope of conceptual and syntactic planning in more complex sentences. They found that conceptual planning included at least an entire clause, often with partial look-ahead beyond it, and that syntactic encoding was primarily regulated by phrase structure. The broad consistency of the findings of Smith and Wheeldon with those of Griffin and Bock (as well as with earlier studies by Dell and O'Seaghdha, 1992; Ferreira, 1991; Meyer, 1996, among others) despite use of very different methods inspires confidence. Although the experimental study of conceptual–syntactic coordination has barely begun, further progress in this important underresearched area of cognitive science is imminent.

Syntactic Form Frequency: Assessing

Intermediate article

Marc Brysbaert, Royal Holloway College, Egham, UK
Don C Mitchell, University of Exeter, Exeter, UK

CONTENTS

Syntactic form frequency research aims to find out how often words and sequences of words in a given context fulfil particular syntactic roles in a sentence. This is achieved by analyzing representative samples of text or speech materials. The research is motivated by the findings that artificial grammars perform better when they take syntactic form frequencies into account, and that humans also seem to be sensitive to this kind of information.

THE NEED FOR ASSESSING SYNTACTIC FORM FREQUENCIES

Syntactic form frequency refers to the number of times words and sequences of words in a given context fulfil particular syntactic roles in a sentence. When a human or a machine tries to convey a message, it is important not only to use the correct words, but also to assign the correct roles to the different parts of the sentence (i.e. to explain 'who did what to whom'). This is equally vital when listeners or readers try to recover the meaning intended by the speaker or the writer.

The assignment of the correct syntactic structure is less straightforward than it might seem. First, the structure of a sentence is not uniquely defined by the position of the words in the sentence. Although the order subject–verb–direct object–indirect object is the basic order in English, this is by no means the only possible sequence (as shown by the examples 'Lyn gave Charles the pencil' and 'The pencil was given by Lyn to Charles'). Conversely, small differences in word order can introduce large differences in meaning (compare 'He showed her baby the pictures' with 'He showed her the baby pictures'; Frazier and Clifton, 1996). Second, many sentences include regions that allow more than one interpretation, even when the parser is able to make a distinction between the subject, the verb, and the object. For instance, in the sentence 'The cop informed the motorist that he had followed…' the final clause could either be a complement structure ('… that he had followed the instructions') or a relative clause ('…that he had followed the whole day, that …'). In principle, the number of syntactic ambiguities grows exponentially with sentence length. This became apparent when one of the first artificial grammars was applied to some example input sentences (Martin *et al*., 1983):

List the sales of products in 1973.
(3 analyses possible: the products in 1973, the sales in 1973, or the listing in 1973) (1a)

List the sales of products produced in 1973.
(10 analyses possible) (1b)

List the sales of products produced in 1973 with the products produced in 1972. (455 analyses) (1c)

Not all possible syntactic forms occur equally often, however. Some are more frequent than others. Because researchers believe those differences in frequency are important both for practical purposes (e.g. to build an artificial language device) and to understand the ways in which humans interpret the syntactic structure of sentences (see below), they have tried to get more precise estimates of the relative frequencies of different structures.

FINDING CORPORA

To assess syntactic form frequencies, one needs corpora. Usually, these are machine-readable text files that consist of written texts or transcriptions of human speech. Most of the corpora that have been collected are available on the internet and can be found relatively easily with the existing search engines. Ideally, a corpus must be very large and

contain a representative sample of general language. The larger the corpus, the more reliable the frequency estimates become and the more representative the corpus is for the kind of texts covered. In the early days of corpus research, corpora with one million words were considered huge; nowadays, owing to the massive availability of digital text sources, corpora can include up to a billion words. One much used source of corpora, for example, is the CD-ROMs made available on a yearly basis by newspaper publishers.

The problem of the representativeness of the corpus depends to some extent on the research question. With respect to syntactic structures there is, for instance, the fact that newspaper publishers have their articles text-edited before publication. This may raise problems for a researcher who is interested in actual usage within a certain language community (as opposed to use prescribed in grammar textbooks). Another limitation of newspapers and magazines is that they cover only a limited range of language registers (i.e. language use in a particular context). Therefore, a few corpora with a wider variety of texts have been collected for research purposes. Unfortunately, most of these corpora are rather limited in extent (to a few million words). Another source of corpora that is currently attracting a great deal of attention is the internet, where in discussion groups and in chat channels millions of sentences are produced weekly on a great variety of topics and without any stylistic supervision.

A final concern with the existing corpora is that most are based on written texts. This raises a number of issues. One is the extent to which the calculated syntactic form frequencies on the basis of written materials can be extended to spoken materials. Another is that written materials may tell us little about the language children are exposed to during their preschool years.

ESTIMATING FREQUENCIES

After the corpus has been chosen (or assembled), the sentences must be parsed in order to gain access to the different syntactic forms and frequencies. Depending on the research question, two different strategies are used. For some topics (for example, the development of an automatic sentence parser) the breadth of coverage is important. This means that the program must be able to handle a great variety of texts, but that it does not usually have to provide a full analysis of the sentences and may make occasional mistakes (in general, a two to four percent error rate is acceptable). For other topics (such as the resolution of specific syntactic ambiguities) the analysis must be complete and accurate. In this case, however, the amount of material that has to be handled is much more limited.

Thus far, there is no easy technique that produces flawless results for the parsing of large text corpora, not even parsing by humans, unless very stringent criteria are adhered to. Reporting on their first experiences with the annotation of a corpus (i.e. the addition of markers that make it easy to retrieve and analyze information about the language), Marcus *et al*. (1993) reported that trained human annotators needed 44 minutes on average to tag 1000 words (hence requiring nearly 100 working days to go through a corpus of one million words) and showed an inter-annotator disagreement of 7.2 percent. Part of the problem is that the syntactic structure of a sentence can become quite complicated when the sentence is long and contains nested structures. Another reason is that a lot of sentences are ambiguous at a purely syntactic level and can have the ambiguity removed only by looking at the meaning of the sentence or the discourse context.

The performance of the annotators in the study of Marcus and coworkers was twice as good (in terms of both speed and accuracy) when the materials were preprocessed by an automatic parser and needed to be corrected only for the mistakes made by the algorithm. As a result of this finding, the annotation of large corpora nowadays is nearly always carried out semi-automatically (that is, the sentences are first parsed by a computer program and the output is then post-edited by humans). In this case, however, care has to be taken to avoid the possibility of annotators being biased by the suggestions of the algorithm. Luckily, owing to the efforts of previous researchers, in many cases it is not necessary to annotate a new corpus. For many research issues, one can make use of an existing corpus that has already been tagged. This is done, for instance, to test linguistic and psycholinguistic hypotheses, or to measure the performance of newly developed software and to provide the training input for these computer programs.

For other research topics, researchers do not need a fully parsed corpus. Often, their question is confined to one particular syntactic structure or to a small set of words, about which they want an in-depth analysis. For such purposes, it is usually feasible (and desirable) to do the analysis by hand. Sometimes this can be achieved simply by scanning the corpus for particular words or combinations of words. An example of this type of research concerns the issue of to which syntactic form

frequencies humans are sensitive when they are parsing sentences.

TYPE FREQUENCY VERSUS TOKEN FREQUENCY

Another issue researchers have to face when they are assessing syntactic form frequencies is how to define the different categories. In frequency counts, there is always the issue of which instances to group and which to separate, because there is rarely a full mapping of verbal forms with theoretical categories. Consider the word 'that'. It can have at least three syntactic functions, as shown below:

He showed the girl that painting. (demonstrative pronoun) (2a)

He showed the girl that he was strong. (complementizer) (2b)

He showed the girl that he had just met that he was strong. (relative pronoun) (2c)

In addition, the syntactic function of 'that' in (2a) overlaps with the function of the words 'this', 'these', and 'those', raising the question whether they have to be grouped or not. This problem is known as the issue of type versus token frequency. Roughly, types refer to theory-based distinctions, whereas tokens refer to the number of occurrences of these types in a corpus (e.g. the number of times 'that' is used as a demonstrative pronoun, as a complementizer, or as a relative pronoun). Mitchell *et al*. (1995) listed some examples of syntactic form frequency distributions that differed significantly depending on how the types had been defined (a phenomenon these authors called the grain-size problem). For instance, in the examples above, it may be that the word 'that' is used much less often as a demonstrative pronoun than as a complementizer after the sequence 'he showed the girl', but the same need not be true for the more general syntactic categories introduced by the word 'that' (i.e. a noun phrase versus a complement clause).

THE USE OF SYNTACTIC FORM FREQUENCIES

Syntactic form frequencies are useful for two purposes. First, it has been shown that automatic sentence parsing algorithms (such as those needed for artificial speech perception) perform better when they take into account not only the syntactic features of the individual words and phrases but also the frequencies of the different syntactic forms given the preceding context. So, when confronted with the sentence 'She put the dress *on the rack*', the algorithm will do a better job in interpreting the ambiguous final phrase 'on the rack' when it takes into account the probability of such a prepositional phrase following the verb 'put' versus the probability of such a phrase following the noun 'dress' (as in 'She saw the dress on the rack'). By taking this probabilistic information into account, the computer may be more likely to come to the correct attachment.

Second, information about form frequencies is important to find out whether humans also make use of this kind of probabilistic information when they are parsing a sentence, and if they do, whether this information is used immediately or in a second, reanalysis stage after the initial analysis has failed. The first theories of human sentence parsing assumed such information did not play a role in the initial syntactic analysis because of the limitations in working memory capacity. More recently, researchers have argued that the build-up of the syntactic structure by the human parser cannot be understood without taking into account this type of information. Still others (e.g. Mitchell *et al*., 1995) accept an influence of syntactic form frequencies, but only at the level of the syntactic structure, not at the level of the individual words that make up the sentence. As this debate is largely based on comparisons of corpus findings with experimental reading data, assessment of syntactic form frequencies has become an important research tool in psycholinguistics as well as in (computational) linguistics.

CONTENTS

Research shows that young children adhere to core grammatical principles early in the course of language development. Experimental studies of child language confirm the theory of universal grammar, and support the continuity assumption for language development.

INTRODUCTION

From the vantage point of linguistic theory, all normal children are expected to have full command of a rich and intricate system of linguistic principles as soon as these principles can be assessed, roughly around age three. Experimental investigations of child language, however, have often led to a different picture of language development. Several studies are interpreted as showing that language learning takes several years, and that children make numerous missteps along the way. The article begins by reviewing the reasons, based on current linguistic theory, for anticipating the rapid growth of linguistic knowledge. Then it turns to the laboratory, to consider a sample of findings that do not sit well with the expectations of linguistic theory, as well as some findings that do comport with theory.

PRINCIPLES AND PARAMETERS

Despite the complexity of human languages, children rapidly converge on a grammatical system that is equivalent to other members of their linguistic community. This remarkable acquisition scenario unfolds every day, all across the globe, yielding the truism that any human child can learn any human language. To explain the universal mastery of language in the species, linguists have sought more and more restrictive theories of the knowledge that is acquired. These theories restrict the space of possible human languages while still providing explanatory accounts of a range of linguistic phenomena. The result of these linguistic investigations is a road-map for grammar formation, a universal grammar, which establishes the boundaries on the space of possible human languages. The crossroads on the road-map must be clearly marked, so different learners can take different roads to acquire any one (or more) of the roughly 6000 existing languages in just a few years.

The road-map children use to plot a course in grammar formation enables them to project beyond their experience, rather than being securely tied to it. Children are therefore expected to form grammars that deviate in certain respects from those of adult speakers of the target language. But, like Rome, all roads lead to the same destination; at some point, children achieve a stable state that is equivalent to that of adults in the linguistic community. From this perspective, the 'errors' that arise in the course of language acquisition are not the result of defective grammars; rather, language-learners sometimes speak a foreign language (metaphorically speaking). This is the continuity assumption: the proposal that child language can differ from the language of the linguistic community only in ways that adult languages can differ from each other. As a general research strategy, advocates of the continuity assumption advance explanations of behavioral differences between children and adults which postulate minimal differences in cognitive mechanisms.

As children navigate the terrain of universal grammar, they will face forks in the road, leading to different classes of grammars. The different routes are the parameters of natural language. Presumably, there are only a finite number of

parameters, each one with a limited number (perhaps two) of innately specified values, or settings. The values of a parameter may be intrinsically ordered: if the language that is generated on one setting of a parameter properly contains the language that is generated on another setting, then the parameter must be set initially to the value that generates the smaller language. This is the subset condition on parameters. Children's adherence to the subset condition obviates the need for negative evidence that informs children that certain expressions are not permitted in the local language. It is widely acknowledged that negative evidence (e.g., corrective feedback) does not occur in sufficient quantity to be a major contributor to language development. Adherence to the subset condition ensures that parameters can be changed on the basis of positive evidence alone; that is, on the basis of input from other speakers. In cases when parameters are not constrained by the subset condition, children are free to try out various options before they settle on a grammar that is equivalent to that of an adult speaker in the linguistic community. However, the linguistic options are severely constrained in advance of any experience, so, at some point, every normal child is able to successfully stabilize on a grammar for the local language. (*See* **Learnability Theory**)

Experience matters with the principles and parameters model, just as it does with other models of language development. After all, children exposed to English learn English, and children exposed to Basque learn Basque. Once children achieve a stable state, however, there appear to be no lingering reminders of any wrong turns that children might have taken in the course of grammar formation. It is as if each child had access to all the primary linguistic data at once and had reached the stable state instantaneously. The idea of instantaneous acquisition is an idealization, of course. But the fact that the actual course of language development does not leave any indelible marks on the adult grammar is important for linguistic research. This fact permits linguists to investigate the grammars of human languages without concern for any childhood 'errors' that are made in language development. But any actual missteps in language development must somehow be set straight, to redirect children to a grammar that is equivalent to that of adults. Setting a new course requires positive evidence from speakers of the local language. Depending on the properties of the input available to children, it is conceivable that children spend some time using grammars that differ in certain respects from those of other speakers and which are more like grammars used by speakers of other human languages.

This leads us to ask how long such developmental 'stages' last. If parameter values can be revised on the basis of simple and readily available features of every child's linguistic experience, then the stages of language development should not last long at all. The logic of the situation dictates that the available evidence for parameter setting must be both simple and abundant (Lightfoot argues that all parameters can be set with simple input). If the evidence needed for parameter setting were exotic or required excessive computational resources, then some (perhaps many) children would not encounter the requisite data, or would be unable to perform the necessary computation. These children would not successfully converge on an adult grammar. Of course this does not happen: all normal children learn to speak the language of the local community. Therefore it is safe to conclude that the evidence for parameter resetting is simple and readily available. So, *ceteris paribus*, children should rapidly converge on the target grammar.

THEORY VERSUS DATA

In contrast to the expectations of linguistic theory, experimental assessments of child language paint a different picture of the course of language development. The experimental findings often suggest that language learning takes many years, and that children make numerous missteps along the way. We will review some of the recalcitrant data (from the standpoint of linguistic theory), and we will review several ways researchers have attempted to deal with them.

It has been amply demonstrated that the experimental findings do not accurately reflect children's underlying linguistic knowledge in some cases; several of children's apparent difficulties have turned out to have been experimentally induced. The data from experiments in child language have withstood scrutiny, however, in other cases. Still, there are other avenues to explore short of abandoning linguistic theory. One useful observation is that the emergence of linguistic knowledge may be impeded by aspects of child development that are known to take time, such as the accrual of real world knowledge. Or if a linguistic structure requires computations to be performed within more than a single component of the language apparatus, this could delay language development. For example, some syntactic constructions coincide with specific speech acts, and others are associated with particular stress

patterns. It could take time for children to master the so-called interface conditions that relate these particular linguistic structures to the relevant speech acts or stress patterns.

Here is the structure of the remainder of this article. First, we use the acquisition of relative clauses to illustrate how the experimental assessment of children's linguistic competence is fraught with methodological perils, sometimes leading to the erroneous conclusion that children's grammars are deficient. Then we report the findings of an experimental study that successfully probed children's knowledge of a linguistic constraint on both form and meaning, called the 'head movement constraint'. To illustrate children's difficulties at the interface of linguistic systems, we consider two examples. The first is a linguistic constraint on the interpretation of pronouns like 'him' and 'her'. In adult grammars, the interpretation of pronouns receives assistance from both phonological and pragmatic principles, but the confluence of syntactic knowledge and these nonsyntactic properties apparently takes time for some children to grasp. The second example of late acquisition is a parameter that involves children's production of Why-questions. We review the findings of a longitudinal study of one English-speaking child's Why-questions, in which both adultlike and nonadult constructions were recorded. We conclude that the child's nonadult Why-questions represent a genuine parametric option, but one for which parameter resetting requires the child to adjust the range of speech acts that are associated with auxiliary raising in English. The final discussion briefly turns to the syntax of two-year-olds to provide evidence that some parameters are set quite early in the course of language acquisition.

THE EMERGENCE OF RELATIVE CLAUSES

An example of the apparently late acquisition of syntactic knowledge was uncovered in research conducted in the 1970s. In several studies children were found to commit systematic errors in responding to sentences with a restrictive relative clause. Children's errors appeared in experiments using an act-out methodology. These studies found that four- and five-year-old children consistently acted out sentences like (1) in a nonadult fashion.

The dog pushed the sheep that jumped over the pig. (1)

When asked to act out the meaning of (1) the majority of the child subjects had the dog push the sheep and then jump over the pig. For adults, (1) is understood to mean that the sheep jumped over the pig. Children's nonadult responses led researchers to claim that children assigned a structure that was appropriate for conjoined clauses, as if sentence (1) had the structure appropriate for (2), according to which the dog, not the sheep, jumped over the pig. Accordingly, this proposal was called the *conjoined clause analysis*.

The dog pushed the sheep and jumped over the pig. (2)

Using other experimental procedures, it was demonstrated that English-speaking children and Italian-speaking children have mastery of sentences with a relative clause at a much younger age, even before their third birthday The innovation in procedure was motivated by the observation that a sentence with a restrictive relative clause, such as (1), bears two kinds of presuppositions. First, felicitous use of the noun phrase, *the sheep that jumped over the pig*, presupposes that there are at least two sheep in the conversational context. If there is only a single sheep, there is no need to add a modifier; the speaker could just as well have said 'The dog pushed the sheep.' In short, a restrictive relative clause is appropriate when some restricting needs to be done. The second presupposition of sentence (1) is that the event mentioned in the relative clause (the jumping event) should have taken place prior to the event mentioned in the main clause (the pushing event).

In research that evoked high error-rates from four- and five-year-old children, neither of these presuppositions was satisfied. Only one sheep was present in the experimental workspace for (1), and no event occurred prior to the presentation of a test sentence; the child's task was simply to 'act out' the test sentences from scratch, using objects that were placed in front of him or her in the experimental workspace. Based on these observations, two experiments were designed to satisfy the presuppositions associated with relative clauses.

In one experiment, additional sheep were added to the workspace for a sentence like (1). This simple change resulted in a much higher percentage of correct responses by children, including children as young as three. A second experiment provided even more compelling evidence that young children command the principles underlying relative clause formation. Using an elicited production technique, pragmatic contexts were constructed to satisfy the presuppositions of restrictive relatives. The task required children to distinguish (verbally)

one salient figure from a set of identical figures, by describing some action that it alone was performing. The child subjects described the figure (and what it was doing) to a blindfolded person; this person then removed the blindfold and attempted to pick out the referent of the child's description. Using the elicited production task, even children as young as 2.8 consistently produce well-formed relative clauses (e.g. *Point to the kangaroo that's eating the strawberry ice cream*). Thus, the apparent late acquisition of restrictive relative clauses can be explained away as an experimental artifact.

The moral is that it is not possible to test the predictions of linguistic theory without the assistance of appropriate experimental methodologies.

THE HEAD MOVEMENT CONSTRAINT

The next example illustrates the claim that children do not venture beyond the boundaries established by universal grammar. The discussion focuses on a linguistic constraint known as the *head movement constraint*. Interpreted more broadly, the constraint restricts children to hypotheses based on structure-dependent linguistic operations, but not those solely based on linear order. Consequently, the space of possible human languages becomes so restricted as to exclude even apparently simple rules that are compatible with much of the primary linguistic data available to children. The example is Chomsky's parade case of 'the logical problem of language acquisition', the formation of Yes/No questions.

The formation of Yes/No questions is interesting because, as Chomsky observed, the principles for forming these questions are more complex than meets the eye, at least when the focus is simple examples. A structure-independent hypothesis such as 'move the first {*is, can, will*, …} to the front of the string of words' yields the right results in forming Yes/No questions from many simple declarative sentences, as (3) illustrates.

(a) Bill can play the sax. ⇒ Can Bill play the sax?
(b) The sky is blue. ⇒ Is the sky blue? (3)

However, the simple structure-independent hypothesis 'move the first {*is, can, will*, …}' produces the wrong Yes/No questions for sentences that contain a relative clause, such as (4). In the Yes/No question corresponding to (4), the auxiliary verb, *is*, following the entire subject noun phrase (NP), *the man who is feeding a donkey*, has to move, as in (5). Moving the first occurrence of *is*, from inside the relative clause (*who is feeding a donkey*), results in a deviant Yes/No question, (6).

The man who is feeding a donkey is happy. (4)

Is the man who is feeding a donkey _ happy? (5)

*Is the man who _ feeding a donkey is happy? (6)

On one linguistic analysis, Yes/No questions are formed by 'local' movement. The auxiliary verb that moves is the inflectional head, I, of the inflection phrase (IP) projection; movement of the auxiliary verb in I takes it to the adjacent head position, C, within the CP projection (see Figure 1). Movement of phrasal heads is governed by the head movement constraint, a putatively universal linguistic principle. According to the head movement constraint, the heads of phrases can *only* move locally, as in I-to-C movement. I-to-C movement of the first occurrence of *is*, from inside the relative clause in (4), would violate the head movement constraint, because this would move the auxiliary verb past the heads of *two* phrasal projections. Metaphorically, a relative clause is an island, where linguistic elements are stranded.

We noted that the structure-independent hypothesis is consistent with much of the input children encounter, so it is reasonable to suppose that some children would adopt it unless this kind of hypothesis is ruled out in advance of any experience. Children who succumbed, however, would face three tasks in converging on the adult grammar. First, they would need to figure out that Yes/No questions are formed by I-to-C movement. This requires complex input, such as (5). But even if such complex input were available in the primary

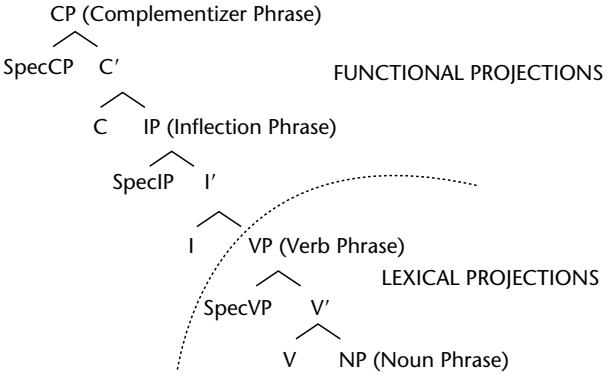

Figure 1. The hierarchy of syntactic projections (head-complement order as in English).

linguistic data, these children would also require access to negative evidence, such as corrective feedback, to accomplish the second task, which is to expunge the nonadult sentences, such as (6), from being produced by their grammars. Without negative evidence, both the local and the nonlocal movement options could coexist in children's grammars. Specifically, positive evidence (for adding 5) and negative evidence (for removing 6) would have to be available in sufficient quantities during the relevant stage of language development.

The third task children would face is that of learning the prohibition against nonlocal movement of heads: the head movement constraint. Even if children were able to rid their grammar of the unacceptable sentences, this would not explain why all languages enforce a ban on the nonlocal movement of the heads of phrases. The explanation, according to the theory of universal grammar, is that the head movement constraint is not learned from experience but is innately specified. One hallmark of innate specification is early emergence. If young children demonstrate knowledge of the constraints that characterize adult grammars, such as the head movement constraint, that would compress the acquisition problem considerably, and would correspondingly strengthen the argument for innate specification. (*See* **Innateness and Universal Grammar**)

To test young children's knowledge of the head movement constraint, an experiment was developed to elicit Yes/No questions from children. The experiment used a toy figure, Jabba the Hutt (from *Star Wars*), and some pictures. Each child was asked to pose questions to Jabba the Hutt. To elicit Yes/No questions, instructions to the child were couched in the carrier phrase, 'Ask Jabba if …' Following each question, Jabba the Hutt was shown a picture and responded 'Yes' or 'No'. The experimenter inserted a variety of declarative sentences into the carrier phrase, including (4). The result is (7).

Ask Jabba if *the man who is feeding a donkey is happy*. (7)

The outcome was as predicted by the theory of universal grammar. It was found that as soon as children could be tested, shortly after their third birthday, they never produced incorrect Yes/No questions like (7). Therefore, there is no evidence of a stage at which children produce structure-independent Yes/No questions, in violation of the head movement constraint.

Advocates of the continuity assumption contend that the head movement constraint is not learned but is innately specified as part of the theory of universal grammar. No one produces ill-formed Yes/No questions, such as (6), but no one tells children that such questions are ill-formed; yet even young children know this. By incorporating constraints on form and meaning, children's grammars go beyond the primary linguistic data along several dimensions. These phenomena are the stock in trade of nativists, because these phenomena form the basis for poverty of stimulus arguments for innate linguistic knowledge.

THE BINDING THEORY

This section continues the discussion of linguistic constraints: the principles of the *binding theory*. Like the head movement constraint, the principles of the binding theory explain why language users judge certain sentences to be unacceptable, and why they judge certain acceptable sentences to lack particular meanings. There are three principles of the binding theory, A, B, and C. Each one governs a different type of noun phrase. We will discuss two of the three principles, principles A and B. Principle A governs the placement of reflexive pronouns, as in (8). The indices i, j, k,… are used to indicate the interpretive options that are available in (8); if two expressions have the same index, then one of the expressions is said to be referentially dependent on the other. Roughly, two expressions that are related in this way are interpreted as referring to the same individual(s) in the conversational context. In (8), the reflexive pronoun *himself* is referentially dependent on the noun phrase *Papa Bear*, so the sentence means that Bill said that Papa Bear covered himself. Illicit referential dependencies are marked by an * . In (8), the reflexive pronoun *himself* cannot refer back to *Bill*, so the sentence cannot mean that Bill said that Papa Bear covered Bill. (*See* **Binding Theory**)

Bill_i said that Papa Bear_k covered $\text{himself}_{*i/*j/k}$

Principle A: a reflexive pronoun *must* be referentially dependent on a local noun phrase. (8)

The second principle of the binding theory, Principle B, governs the use and interpretation of ordinary pronouns, like *him*, *her*, and *them*. Consider the example in (9) in which the reflexive pronoun in (8) has been replaced by the accusative pronoun 'him'. Notice that the pronoun 'him' can

be referentially dependent on 'Bill' but not on 'Papa Bear'. So, (9) can mean that Bill said that Papa Bear covered Bill. It can also mean that Bill said that Papa Bear covered some other male individual, other than Papa Bear or Bill. What it cannot mean is what (8) must mean, that Bill said that Papa Bear covered himself.

Bill_i said Papa Bear_k covered $\text{him}_{i/j/*k}$

Principle B: a pronoun *cannot* be referentially dependent on a local noun phrase. (9)

Young children's knowledge of the principles of the binding theory has been the subject of much research, including cross-linguistic investigations. Regardless of methodology, the findings of experimental research reveal a strikingly similar pattern of linguistic behavior for both children and adults in response to sentences governed by Principle A, disallowing those meanings ruled out by the principle. By contrast, children and adults sometimes give different responses to sentences like (10). Some English-speaking children, for example, accept sentence (10) as a description of a story in which Papa Bear covered himself.

Papa Bear covered him (10)

On one account, children's acceptance of referential dependence between 'him' and 'Papa Bear' in (10) appeals to children's lack of real world knowledge. This proposal is based on the observation that there are special circumstances in which even adults accept an interpretation of sentences like (10) which takes the pronoun to be referentially dependent on the name. One such circumstance is where Papa Bear is behaving in a manner that is uncharacteristic of bears. In such circumstances, the interpretation in question is possible because the two NPs represent the same referent, Papa Bear, in two different guises. It is also worth noting that adults allow this interpretation only if the pronoun receives stress, as indicated by the upper case letters in (11). On this account, children must learn from experience what is characteristic or expected (e.g., of bears), and they must learn how stress is associated with interpretation.

Papa Bear covered HIM (11)

In summary, the late acquisition of syntactic knowledge has been explained by invoking real world knowledge as well as the lack of knowledge of an interface condition on the application of a linguistic principle: its association with stress.

WHY-QUESTIONS: A CASE STUDY IN CONTINUITY

As mentioned in the introduction, the continuity assumption supposes that children and adults share a common core of linguistic knowledge. Essentially, child language can differ from adult language only in ways that adult languages can differ from each other. So far, the literature that we have reviewed on child language is consistent with the continuity assumption: children do not appear to entertain grammatical hypotheses that extend beyond the boundary conditions imposed by universal grammar (UG). Advocates of a principles and parameters theory should not be surprised, however, if some English-speaking children exhibit some features of grammar that appear in other Germanic languages, Romance or East Asian languages, in the absence of evidence for these properties in the primary linguistic data. Evidence of children's nonadult (but UG-compatible) productions may be the strongest argument for the theory of universal grammar. An argument of this kind can be made using evidence from the acquisition of Why-questions.

Some languages make finer distinctions than others do. In some languages, Why-questions are found to show a different pattern of word order from questions formed with other Wh-phrases (e.g., Who-questions, What-questions). For example, in French, *pourquoi* (why) cannot remain *in situ* in questions, and cannot undergo stylistic inversion. In Spanish, and Basque also, Why-questions show a different pattern; in contrast to other Wh-phrases, adjacency is not maintained between Why-phrases and the verb. Whatever underlies the (semantic) distinction among Wh-phrases in these other languages, the distinction is clearly blurred in the grammar of English. Why-questions are formed in the same way as other questions; they exhibit I-to-C movement and, therefore, manifest the same pattern of word order.

The kind of 1-to-1 mapping of form and meaning that is characteristic of French, Basque, and Spanish is also found in the language of English-speaking children. That is, English-speaking children often differentiate Why-questions from other questions, by failing to carry out I-to-C movement in their one-clause Why-questions. The following examples are from a transcription of the speech of a child, A.L., at 3.5 years. All of the examples were from a 3-week period.

Why you have your vest on?
Why she doesn't have any hanger?
Why he's woofing?
Why that guy has tookened Walker?
Why he's following the guy?
Why that kind of thing could break? (12)

In contrast to these one-clause Why-questions, which lacked I-to-C movement, during the same period A.L.'s two-clause Why-questions consistently showed I-to-C movement. One explanation of this fact is that in two-clause questions, the syntax forces the auxiliary verb to raise from I to C. In two-clause questions, such as (13), the moved Why-phrase moves over a sentence barrier, in contrast to one-clause Why-questions, as in (12), where *Why* may be generated in place, and not moved to sentence-initial position.

Why do you think he goed in the paddling pool?
Why do you think that Gonzo went in that truck? (13)

In short, A.L. was clearly able to produce adult-like structures, with I-to-C movement of the auxiliary verb; this was characteristic of A.L.'s more complex Why-questions, but not of the simpler Why-questions. Before the experimental tools were developed to elicit complex questions from children, accounts of question formation in early child language were often misdirected by placing undue emphasis on their inability to perform I-to-C movement. Experience presumably informs children like A.L. that one-clause Why-questions should not be distinguished from two-clause Why-questions. But this takes time, because A.L.'s grammar distinguishes between them. The existence of abundant counter-examples in the input from English-speaking adults must seem inexplicable to children like A.L.

To recap, the case of Why-questions offers further evidence of delayed acquisition but is also in keeping with the continuity assumption. The account we have presented appeals, once again, to the natural seams (or parameters) of natural language. According to the continuity assumption, child language should develop along these seams, though child language can diverge from that of adults until the pressure of experience ultimately propels them towards a grammar that is equivalent to that of adults, but children are never expected to try out a language that violates core principles of universal grammar.

FIRST STEPS IN LANGUAGE ACQUISITION

The younger children are, the more their grammars appear to differ from those of adults. When children first begin to speak, their utterances are composed of just one or two words and, in the absence of context, it is often difficult to determine the meanings they are attempting to convey. One might suppose that this early stage of language development poses a serious threat to the continuity assumption. Examination of cross-linguistic data, however, especially of languages with rich morphological systems, leads to a picture that is consistent with the continuity assumption.

In English, syntactic categories like nouns and verbs carry little morphological information, making it difficult to assess children's knowledge of the morphological properties of the language. The observation that young children often leave off what little morphology English has (for example, the third-person singular *-s* in *he walks*, the past tense *-ed* in *he walked*, the genitive *-s* of *mommy's sock*, and so on) contributed to an initial pessimism about the continuity assumption. Based on children's omissions, some researchers proposed that the grammars of young children contain only lexical (content-bearing) projections such as verb phrase (VP) and noun phrase (NP) but do not contain functional projections that carry grammatical information, such as inflection phrase (IP, which carries tense and agreement) and complementizer phrase (CP, which hosts question words). More specifically, one claim was that functional projections mature, being biologically timed to emerge later in language development.

In contrast to English, Dutch, German, and Italian are languages with rich morphological paradigms. The results of research on the acquisition of these languages weigh in against the idea that children's grammars initially generate only partial syntactic phrase markers. Although children learning these languages do make errors of omission, as do their English-speaking counterparts, when children learning these other languages use inflection, overwhelmingly they use it correctly. Several studies have documented these facts for children under 2.6. For example, a study of person inflection by three Italian-speaking children found the percentage of correct usage at between 97 to 99 percent. Similarly, a study by Poeppel and Wexler of a German-speaking child (age 2.1) revealed

agreement errors of only 3 percent. Children's correct use of agreement is compelling evidence that they have access to the functional projection, IP, where information about agreement is maintained. The same study revealed mastery of linguistic principles that involve both the IP projection and the CP projection. For example, the child Andreas proved to be aware of the fact that, in German, (1) finite verbs must be raised to C and must be preceded by some other constituent (the verb second, or V2 effect), and that (2) infinitival forms remain in final position. To demonstrate that Andreas moved finite verbs to C, they analyzed utterances of at least three words. This ensured that a verb in C position could be distinguished from a verb in final position. Aged 2.1, Andreas produced finite verbs in C position in 95 percent of the utterances that were analyzed. In short, the cross-linguistic data support the view that the full inventory of functional projections is available in early grammars.

These German data also provide compelling evidence that the verb movement parameter is set early. This parameter encodes variation in the position in the phrase structure in which a finite verb appears. In some languages (e.g., German), the verb is in the Complementizer position; in others (e.g., French) it is positioned in the Inflection position, or it can remain inside the verb phrase (as in English). Data from languages other than English provide important evidence that indicates children set the relevant parameters early. For example, young children acquiring French can be shown to know that finite verbs appear to the left of negation (= *pas*) in Inflection (that is, in I), and infinitival forms must appear to the right of the negative form. In a study of young French-speaking children, finite verbs appeared to the left of *pas*, as in (14a), 97 percent of the time. If a verb appeared to the right of *pas*, it was an infinitive, as in (14b).

a. elle roule pas (Grégoire 1.11)
she roll not
'It doesn't roll'
b. pas rouler en vélo (Philippe 2.2)
not roll-INF on bike
'Not go by bike' (14)

It is more difficult to establish what young English-speaking children know about verb movement. It is not easy to evaluate this by investigating negation, because there is a complicating factor; in negative sentences, the dummy verb *do* appears to the left of negation (e.g., *He does not like cheese*). However, even before children acquire do-support, their production of sentences with negation suggests that they know that main verbs remain inside the verb phrase. Negative imperatives, as in (15), also illustrate this fact.

Not sing in the car! (A.L 1.11)
Not go here! (15)

In early child grammars, there are one or two apparent counterexamples to the conclusion that children's nonadult productions are mainly errors of omission, and not errors of substitution. One of these is the phenomenon known as 'optional infinitives' or 'root infinitives'. Although children learning languages like Dutch, German, and French appear to know that finite verbs must raise (in accordance with the verb movement parameter), they do not always raise the verb to the appropriate position. Instead, they sometimes produce utterances with a (nonfinite) infinitival form of the verb. The error is shown for French in (14b), and for German in (16).

du das haben (Andreas 2.1)
you that have-INF
'You have that' (16)

English has no special infinitival form; the dictionary form of the verb (e.g., *to eat*) is the same as the verb stem (i.e., the form of the verb when it is stripped of inflection). Given this fact, combined with the word order facts of English, it is difficult to see whether English-speaking children also produce infinitival forms. It has been argued, however, that their frequent failure to use the third-person *-s* ending and the past tense *-ed* inflection is a manifestation of the same phenomenon.

Children's optional infinitive errors are a potential problem for the continuity assumption, because root infinitives are not a core phenomenon of adult languages. On one current account, optional infinitives arise because the young child's grammar has not matured, and children can optionally omit tense or agreement features from a phrase structure representation. Omission of agreement results in an utterance with default (accusative) case; omission of tense results in children's failures to produce present or past tense marking. Another account attempts to further minimize the differences between child and adult grammars. The only difference on this account is that children do not require clauses to project up to the CP level; until this knowledge matures, children allow truncated structures. A third account is more in keeping with the continuity assumption: children's syntax is intact but optional infinitives result from a processing bottleneck

that sometimes prevents children from merging the inflection and the main verb. Only time will tell whether the optional infinitive phenomenon represents a genuine violation of the continuity assumption or if it can be squared with it.

CONCLUSION

Empirical investigations of the acquisition of syntactic knowledge have reached a new level of maturity in recent years. If developments in methodology and theory keep pace, we will continue to achieve a deeper understanding of children's universal mastery of syntactic competence, and we will find out if the continuity assumption can be maintained.

Syntax

Introductory article

Colin Phillips, University of Maryland, College Park, Maryland, USA

CONTENTS

Syntactic theory aims to explain how people combine words to form sentences, and how children attain knowledge of sentence structure.

GOALS OF SYNTACTIC THEORY

Syntactic theory aims to provide an account of how people combine words to form sentences. A common feature of all human languages is that speakers draw upon a finite set of memorized words and morphemes (i.e. minimal meaning-bearing elements) to create a potentially infinite set of sentences. This property of *discrete infinity* allows speakers to express and understand countless novel sentences that have never been uttered before, and hence forms the basis of the creativity of human language. Syntactic theory is concerned with what speakers know about how to form sentences, and how speakers acquire that knowledge.

For example, speakers of English know that 'dogs chase cats' and 'cats chase dogs' are possible sentences of English, but have different meanings. Speakers know that 'chase dogs cats' is not a possible sentence of the language, and that 'cats dogs chase' is possible in specific discourse contexts, as in 'cats, dogs chase, but mice, they flee'. Speakers' knowledge of possible word combinations is often referred to as the *(mental) grammar*.

An accurate model of a speaker's knowledge of his or her language should minimally be able to generate all and only the possible sentences of the language. For this reason, syntactic theory is often known as *generative grammar*. In the 1950s, early attempts by Noam Chomsky and others to create explicit generative grammars quickly revealed that speakers' knowledge of syntax is a good deal more complex than had been anticipated. Research on syntactic theory has relied primarily upon speakers' intuitive judgments about the well-formedness ('grammaticality') of sentences of their language. Since grammaticality judgments can be gathered relatively easily, syntactic theory has amassed a large database of findings about an ever more diverse set of languages.

The complexity of syntactic knowledge sharpens the problem of how language is learned. Research on language acquisition has demonstrated that children know much of the grammar of their language before they are old enough to understand explicit instruction about grammar. Therefore, a primary challenge for syntactic theory has been to understand how a child can learn any language, relatively effortlessly, and without explicit instruction. Research on comparative syntax has met this challenge by seeking to characterize human languages in terms of universal syntactic properties, which may reflect the child's innate knowledge, and non-universal clusters of syntactic properties that pattern together across languages, and hence may be learned as a group. Thus, the study of comparative syntax and the study of language learning are closely related. (*See* **Innateness and Universal Grammar**)

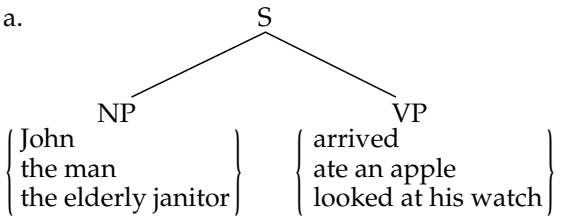
FUNDAMENTALS OF SYNTACTIC THEORY

Discrete Infinity

Almost all accounts of the discrete infinity property of natural language syntax start from the notion that sentences consist of more than just sequences of words. In the minds of speakers and listeners, sentences are hierarchically structured representations, in which words are grouped together to form phrases, which in turn combine to form larger phrases. For example, a minimal sentence of English, such as 'John arrived', contains a subject and a predicate, but the roles of subject and predicate may be replaced by phrases of arbitrary complexity. By representing possible subjects and predicates as *noun phrases* (NPs) and *verb phrases* (VPs)

respectively, the structure of many possible sentences (S) can be captured. This basic 'template' for sentences of English can be expressed as a tree structure, as in (1a), or as a phrase structure rule, as in (1b).

a.



b. S → NP VP (1)

Just as rules like S → NP VP provide templates for sentences, templates can also be specified for the internal structure of noun phrases, verb phrases, and many other phrase-types. Even a small number of phrase structure rules and a small lexicon can generate large numbers of sentences. With only the five phrase structure rules in (2) and a 30-word lexicon (consisting of 10 nouns, 10 determiners, and 10 verbs) 122,100 different sentences can be generated.

S → NP VP
VP → V NP
VP → V
NP → Det NP
NP → N (2)

Rules that allow a phrase to be embedded inside another phrase of the same type are known as *recursive* rules. Coordination (3), modification (4), and sentential complementation (5) all involve recursion. They can thus be invoked arbitrarily many times in a single sentence. Such rules increase the expressive power of the grammar from merely vast to clearly infinite. There are obvious practical limitations on the length and complexity of naturally occurring sentences, but such limitations are typically attributed to independent limitations on attention and memory.

NP → NP Conj NP
VP → VP Conj VP
Conj → *and* (3)

VP → VP PP
NP → NP PP (4)

VP → V S′
S′ → Comp S
Comp → *that* (5)

Although the rules listed in (1)–(5) fall far short of the expressive power of English, even this small fragment shows how natural language syntax uses finite means to generate infinitely many sentences. (*See* **Phrase Structure and X-bar Theory**)

Motivating Structures: Constituency

The syntactician's toolbox includes a number of structural tests that can be used as aids in diagnosing sentence structures; for example, *constituents* of sentences can generally be conjuncts in coordinate structures, as is shown for NPs and VPs in (6a, b). Other tests that show the constituency of VPs include substitution of the expression 'do so' for a VP (7a), and fronting of the VP to a clause-initial position (7b).

a. Wallace fetched[$_{NP}$ the cheese] and [$_{NP}$ the crackers]
b. Wallace[$_{VP}$ sliced the cheese] and [$_{VP}$ opened the crackers] (6)

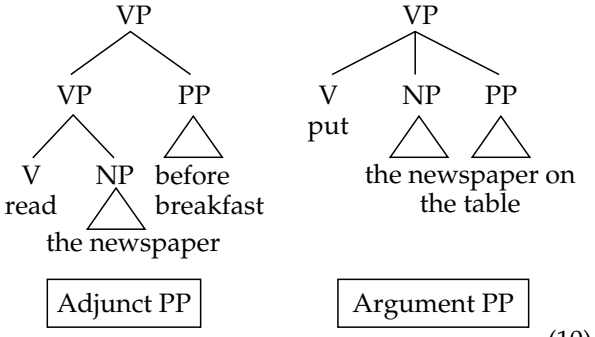
a. Wallace [$_{VP}$ read the newspaper] and Gromit [$_{VP}$ did so] too.
b. Wallace wanted to [$_{VP}$ impress Wendolene], and [$_{VP}$ impress Wendolene] he did. (7)

Constituency tests like those shown in (7) can be used to demonstrate that prepositional phrases (PPs) that are adjuncts (i.e. optional phrases) of VP recursively expand the VP, whereas PPs that are arguments of the verb (roughly, required phrases) do not. (8) shows that when *do so* substitution applies to a VP containing an adjunct-PP, the PP may be targeted or ignored by *do so* substitution. This indicates that there is a smaller VP-constituent that excludes the adjunct-PP. In contrast, (9) shows that an argument-PP cannot be ignored by *do so* substitution. If the argument-PP is 'stranded' by substitution (9b), the result is ungrammatical (indicated by the asterisk). This indicates that argument-PPs are contained within the smallest VP constituent. These contrasts motivate the VP-structures shown in (10).

a. Wallace [$_{VP}$[$_{VP}$ read the newspaper] [$_{PP}$ before breakfast]], and Gromit [$_{VP}$[$_{VP}$ did so]] too.
b. Wallace [$_{VP}$[$_{VP}$ read the newspaper] [$_{PP}$ before breakfast]], and Gromit [$_{VP}$[$_{VP}$ did so]] [$_{PP}$ at lunchtime] (8)

a. Wallace [$_{VP}$ put the newspaper [$_{PP}$ on the table]], and Gromit [$_{VP}$ did so] too.
b. *Wallace [$_{VP}$ put the newspaper [$_{PP}$ on the table]], and Gromit did so [$_{PP}$ on the floor]. (9)

Adjunct PP : VP → VP PP
Argument PP : VP → V (NP) PP

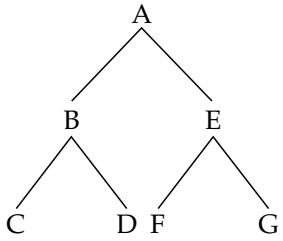


(10)

Motivating Structures: Hierarchy

In addition to tools that show which groups of words form constituents, other tests diagnose the *hierarchical* relations among positions in a structure. A striking finding of syntactic research is that many grammatical phenomena are sensitive to a structural relationship known as *c-command*, which is similar to the logical notion of *scope*. A node c-commands its sister and any nodes contained inside its sister. Thus, in the structure in (12), node B c-commands its sister, node E, and nodes F and G contained inside its sister. On the other hand, node C c-commands its sister, node D, and no others.

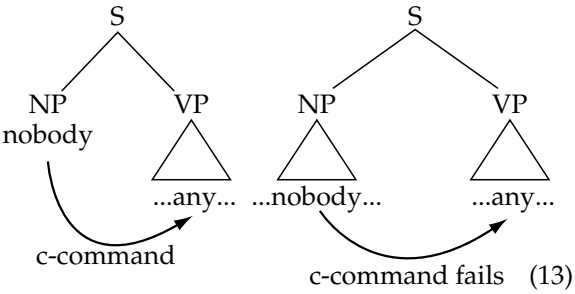
C-Command
A node c-commands its sister and all nodes dominated by its sister. (11)



(12)

One syntactic phenomenon that is sensitive to the c-command relation involves *Negative Polarity Items* (NPIs), such as 'anybody' or 'ever', which are only possible when they are c-commanded by an appropriate licenser, typically a negative expression such as 'not' or 'nobody'. NPIs are possible when the negative expression c-commands the NPI (13a–d) but are impossible when the negative expression fails to c-command the NPI (13e–h), because the negative expression is embedded inside a subject NP.

a. Wallace didn't find any cheese.
b. Nobody found any cheese.
c. Wallace didn't think that he would ever refuse cheese.
d. Nobody thought that Wallace would ever refuse cheese.
e. *[$_{NP}$ The fact that Wallace didn't like the cheese] amazed anybody.
f. *[$_{NP}$The fact that nobody liked the cheese] amazed anybody.
g. *[$_{NP}$ The person that Wallace didn't notice] thought that Gromit would ever return.
h. *[$_{NP}$The person that nobody noticed] thought that Gromit would ever return.



(13)

Multiple Roles: Transformations

In any sentence, each word or phrase occurs in a unique position in the linear sequence of words. However, many words and phrases appear to participate in *multiple* structural relations in the sentence. A central concern of syntactic research since the 1950s has been to understand how individual phrases can assume multiple roles in a sentence.

The multifunctionality of phrases has been most fully explored in the case of NPs. First, speakers represent the *thematic role* of each NP in a sentence. *Agent* thematic roles are canonically realized on subject NPs, *theme* thematic roles are canonically realized on direct object NPs, and thematic roles such as *goal*, *beneficiary*, or *location* are canonically realized inside PPs (14).

Wallace sent the flowers to Wendolene
agent *theme* *goal* (14)

However, it is important to distinguish thematic roles from *grammatical relations* such as *subject* and *object*, since thematic roles can be realized in different grammatical relations. The theme argument of the underlined verb 'steal' is realized as a direct object in the active sentence in (15a), as a subject in the passive sentence in (15b), and as the subject of a higher clause in the raising construction in (15c).

a. The penguin stole the diamond.
theme *active*

b. The diamond was stolen by the penguin.
theme
c. The diamond seemed to have been stolen.
theme

It is also important to distinguish thematic roles and grammatical relations from the structural positions in which NPs receive their *scopal* interpretation. In English, the scope of *wh*-phrases such as *who*, *what*, or *which boy* is marked by their surface position: they are positioned sentence-initially in direct *wh*-questions (16a), and in clause-initial position of an embedded clause in indirect *wh*-questions (16b).

a. Which story did the teacher know that the children like?
theme
direct object
matrix scope
b. The teacher knew which story the children always like.
theme
direct object
embedded scope (16)

In English the scope of quantified NPs such as 'every boy' is not encoded in surface word order, with the consequence that sentences like (17) are scopally ambiguous. However, in other languages, such as Hungarian and Japanese, the scope of quantificational NPs is often fixed by surface word order.

Some student answered every question correctly.
some > every: *a single student got all the questions correct*
every > some: *for each question, there was at least one student who got it right* (17)

Since speakers must distinguish for any NP a representation of its thematic role, its grammatical relation, and its scope, it is important to ask how these different structural positions are related to one another. One well-known answer to this question is that speakers represent multiple structures for each sentence, one structure each for thematic role assignments, grammatical relations, and scope relations. The thematic representation is typically known as the *deep structure* (or *d-structure*) of the sentence, and it is related to the other levels of representation – *surface structure* (or *s-structure*) and *logical form* (LF) – by transformational processes which move NPs from thematic positions to positions associated with grammatical relations, and scope positions. This *Transformational Grammar* approach was proposed by Chomsky in the 1950s and has been elaborated and modified by many linguists since that time.

(18) shows a sample transformational derivation of a *wh*-question. The NP 'who' receives the theme thematic role as the sister of the verb in the d-structure representation in (18a). In (18b) it moves to subject position of the embedded passive clause. Finally, in (18c) it moves from subject position to its clause-initial scope position. Following a now standard elaboration of the transformational approach, (18) represents the residue of movement as phonologically null elements known as *traces* (*t*).

a. the announcer believed had been elected who
b. the announcer believed who_i had been elected t_i
c. who_i did the announcer believe t_i had been elected t_i (18)

Some alternative approaches share with Transformational Grammar the assumption that sentence structure representations consist of multiple levels, but deny that there is a derivational relationship among the levels of representation (e.g. Lexical Functional Grammar, Categorial Grammar). Other approaches assume that the thematic, grammatical relation, and scope properties of an NP are all represented in a single enriched phrase structure, but that only one of these positions is normally encoded phonologically (e.g. Head-Driven Phrase Structure Grammar: see further below).

Types of Dependencies

Speakers' syntactic representations encode a variety of structural relations among words and phrases. The most basic relations are the groupings of words and phrases that form hierarchical constituent structures. These relations can be expressed entirely in terms of *sisterhood* and *dominance* among phrase structure nodes. The discussion above has introduced a number of other syntactic relations, or *dependencies*.

The syntactic relation between a pronoun or reflexive and the NP from which it takes its reference is known as a *binding* dependency. Such dependencies have been studied extensively under the rubric of *Binding Theory*.

a. Wallace_i likes himself_i *local*
b. Wallace_i thinks that Wendolene likes him_i *nonlocal* (19)

(*See* **Binding Theory**)

In *VP-ellipsis* constructions the VP in the second conjunct is dependent on the VP in the first conjunct for its interpretation (20). Transformational analyses of *wh*-questions (21a) and relative clauses (21b) treat the relationship between the *wh*-phrase and the trace as a binding relation between a *wh*-operator and a variable.

Wallace $[_{VP}$ likes cheese$]_i$ and Gromit does $[_{VP}\ ]_i$ too. (20)

a. Who$_i$ did the voters elect t_i
b. The man who$_i$ the voters elected t_i (21)

(*See* **Ellipsis**)

A leading question in research on referential dependencies involves how closely related the different types of referential dependencies are: does each type of dependency follow independent principles, or do they follow the same principles?

CONSTRAINTS ON DEPENDENCIES

Wh-movement and related phenomena have been among the most extensively investigated topics in syntactic research, giving rise to a wealth of findings. By virtue of the length of *wh*-dependencies, syntacticians can manipulate which structural positions participate in the *wh*-dependency, and which structural positions the dependency crosses. *Wh*-dependencies have thus served as a kind of 'magnifying glass' for the investigation of syntactic dependencies.

Wh-dependencies can span many clauses, in fact arbitrarily many clauses, and thus they are often referred to as *unbounded dependencies*. In (22), the *wh*-phrase has been *extracted* from a number of embedded clauses, each of which is the *complement* (direct object) of the next higher verb.

Which candidate$_i$ did the court fear [that the public might conclude [that the voters had elected t_i]] (22)

However, in a tradition of research beginning with influential work in the late 1960s by John Robert Ross, it has been found that there are many syntactic environments which *wh*-extraction cannot cross. Following Ross's terminology, the environments that block extraction are known as *islands*, and restrictions on extraction are known as *island constraints*.

Relative clauses create islands for extraction (23a), as do indirect questions (23b), complements of NPs (23c), subjects (23d), and adjunct clauses (23e). Extraction from definite NPs or NPs with a possessor is highly marked, although indefinite NPs create no such difficulties (24). If a phrase is extracted from one conjunct of a coordinate structure, it must also be extracted from the other conjuncts (25a, b).

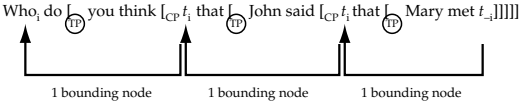
a. *Who$_i$ did the court upset the voters [who favored t_i]
b. *Who$_i$ did Bill wonder [whether his new outfit would shock t_i]
c. *What$_i$ did Sarah believe [the rumor that Ed was willing to spend t_i]
d. *Who$_i$ did [the fact that the president nominated t_i] upset the opposition party?
e. *What$_i$ did Wallace eat the cheese [while he was reading t_i] (23)

Who$_i$ did Sally hear a? the *Helen's story about t_i? (24)

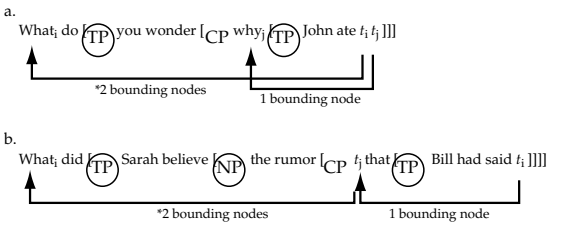
a. *What$_i$ did [Gromit read the newspaper] and [Wallace eat t_i]
b. What$_i$ did [Gromit read t_i] and [Wallace eat t_i] (25)

The examples in (22)–(25) raise the question of why *wh*-dependencies can be arbitrarily long as in (22), but not as in (23)–(25). Work on this question led to the proposal that, contrary to appearances, all *wh*-dependencies are *local*. If all *wh*-movement is local, proceeding one clause at a time, then apparent long-distance *wh*-movement turns out to be a series of local movements, each one targeting a landing site in the next higher CP (*Complementizer Phrase*), as in (26). If all *wh*-movement must be local, then it follows that relative clauses and embedded *wh*-questions create islands, because these are cases in which an intermediate landing site of movement is already filled (27a).

The best-known implementation of this proposal is the *Subjacency Constraint*, proposed by Chomsky in the early 1970s. In its original formulation the constraint blocks any *wh*-dependency that spans more than two *bounding nodes*, where the bounding nodes are defined as NP and TP (*Tense Phrase*: a more recent term for the 'S' node, recognizing *Tense* as the head of a clause). This formulation also explains the complex NP constraint violation in (23c) and (27b).



(26)



(27)

The proposal that a long-distance *wh*-dependency involves a sequence of local dependencies receives interesting support from a number of languages that show a syntactic residue of local movement. In certain varieties of Spanish, for example, subject–auxiliary inversion occurs in every clause in the path of *wh*-movement ((28): compare this to the English translation, in which inversion occurs only in the highest clause).

a. Juan pensaba que Pedro le había dicho que la revista había publicado ya el articolo.
Juan thought that Pedro him had told that the journal had published already the article
'Juan thought that Pedro had told him that the journal had published the article already.'

b. Qué pensaba Juan que le había dicho Pedro que había publicado la revista?
What thought Juan that him had told Pedro that had published the journal
'What did Juan think that Pedro had told him that the journal had published?'

c. *Qué pensaba Juan que Pedro le había dicho que la revista había publicado?
What thought Juan that Pedro him had told that the journal had published (28)

The island constraints restrict the nodes that a *wh*-dependency may cross. All of the examples presented so far involve extraction of a direct object *wh*-phrase. In addition, subject and adjunct *wh*-phrases in English are subject to tighter restrictions than object *wh*-phrases. For example, extraction of an embedded direct object *wh*-phrase is possible, irrespective of whether the embedded clause contains an overt complementizer 'that' (29a, b). However, extraction of an embedded subject *wh*-phrase is impossible if the complementizer is overt (29c). This constraint is known as the *that-trace constraint*, and it has been observed in many languages, as discussed further below.

a. Who$_i$ do you think t_i that John met t_i?
b. Who$_i$ do you think t_i John met t_i?
c. *Who$_i$ do you think t_i that t_i met John?
d. Who$_i$ do you think t_i t_i met John? (29)

There are also differences in extraction possibilities between argument *wh*-phrases such as 'what' and 'which books', and adjunct *wh*-phrases such as 'why' and 'how' (see Further Reading).

A long-standing goal of syntactic research on unbounded dependencies has been to uncover a set of general principles that can explain the full variety of constraints on *wh*-dependencies. Although there have been many different attempts to unify the constraints on movement, two observations have been pervasive, and have featured in many different theories. First, if movement is required to be *local*, then it is subject to *intervention effects*, when a required landing site of movement is occupied by another element. Second, movement paths that include noncomplement nodes (subjects or adjuncts) are consistently more restricted than paths that include only complement nodes (sisters of heads). (*See* **Constraints on Movement**)

CROSS-LANGUAGE SIMILARITIES AND DIFFERENCES

A fully general theory of the mental representation of syntax clearly must handle the facts of all human languages. In addition, cross-linguistic investigations are important to accounts of how natural language syntax is learnable. *Universals* of syntax, or *principles*, may be part of the child's innate endowment, and thus not need to be learned. *Non-universal* syntactic properties must also be learnable within the constraints imposed by the time and evidence available to the child. When a set of syntactic properties *covaries* across languages, it is possible that the learner only needs to learn one member of the set of properties in order to draw appropriate conclusions about the entire set. Thus, an important goal of cross-linguistic syntax research is to find clusters of covarying syntactic properties, or *parameters*. This *Principles and Parameters* (P&P) approach to syntax has been most intensively investigated in transformational approaches to syntax but it can be applied equally well to other syntactic approaches. (*See* **Government–Binding Theory**)

Research on comparative syntax has discovered a number of striking cross-linguistic parallels between languages that appear very different on the surface. An example from Mohawk serves as an illustration.

One constraint on pronouns in English is that a pronoun cannot co-refer with an NP that it c-commands. This constraint ('Binding Condition C') accounts for the contrast between (30a) and (30b). The pronoun inside the subject NP fails to c-command the direct object in (30a), thereby allowing co-reference. On the other hand, the subject pronoun c-commands the name inside the object NP in (30b), thereby preventing co-reference.

a. [$_{NP}$ The book that he$_i$ bought] offended John$_i$
b. *He$_i$ bought [$_{NP}$ the book that offended John$_i$] (30)

Unlike English, which exhibits strict subject–verb–object (SVO) word order, Mohawk, an Iroquoian language spoken in Quebec and upstate New York, exhibits free word order, allowing all six possible permutations of subject, verb, and object, and also allows 'discontinuous constituents' in the form of split noun phrases (31). Based on such properties, languages like Mohawk have sometimes been described as 'nonconfigurational'. However, Mark Baker has demonstrated that Mohawk exhibits similar configurational asymmetries to English, as the contrast in (32) shows. This contrast can be explained by Binding Condition C, just as in English, provided that we attribute some degree of underlying configurational structure to Mohawk sentences.

Ne kíke wa-hi-yéna-' ne kwéskwes
NE this FACT-1sS/MsO-catch-PUNC NE pig
'I caught this pig.' (31)

a. Wa-ho-nakuni-'
tsi Sak wa-hi-hrewaht-e'
FACT-NsS/MsO-anger-PUNC
that Sak FACT-1sS/MsO-punish-PUNC
'That I punished Sak$_i$ made him$_i$ mad.'
(co-reference possible)
b. Wa-shako-hrori-'
tsi Sak wa-hi-hrewaht-e'
FACT-MsS/FsO-tell-PUNC
that Sak FACT-1sS/MsO-punish-PUNC
'He$_i$ told her that I punished Sak$_i$.'
(co-reference impossible) (32)

The similarity between English and Mohawk is striking, given how different the languages appear on the surface. Furthermore, evidence from many other languages suggests that Binding Condition C is a universal of natural language syntax, which may be part of innate linguistic knowledge. Consistent with this suggestion, studies by Stephen Crain and his colleagues have shown that children exhibit knowledge of Binding Condition C by their third birthday, which is as early as it has been possible to test this knowledge. This finding has been replicated in children learning other languages (e.g. Italian, Dutch, Russian). It is particularly encouraging news for a child learner of Mohawk that Binding Condition C need not be learned, since it is unlikely that the presence of the constraint could be guessed from the input to the Mohawk child.

Although syntactic research has uncovered many universals of language, there are clearly many properties that vary across languages and hence must be learned. The search for parametric clusters of syntactic properties has turned up a number of cross-language correlations. The most useful correlations are those that link abstract (and hence difficult-to-observe) syntactic properties with more easily observable syntactic properties. For example, the *that-trace* constraint introduced above does not apply in all languages: it applies in English (33a), but not in Italian (33b). This is not easily inferred from the language input to children, since it is not easy to observe the *absence* of a particular construction. However, the availability of *that-trace* sequences correlates cross-linguistically with the availability of postverbal subjects, which are readily observable in the input to the learner. Italian allows postverbal subjects (34b), but English does not (34a). This connection has been reinforced based on the study of many other languages. Therefore, the child learner may be able to learn whether the *that-trace* constraint applies in his language, by observing whether postverbal subjects are available.

a. *Who$_i$ did you say that t_i has written this book?
b. Chi$_i$ hai detto che t_i ha scritto questo libro?
who have-you said that has written this book
'Who did you say has written this book?' (33)

a. *Have arrived many students
b. Hanno arrivato molti studenti.
have-3pl arrived many students
'Many students have arrived.' (34)

VARIANTS OF SYNTACTIC THEORY

Since the 1960s syntactic theory has undergone a number of changes, and has spawned a variety of different grammatical theories, each with a different title, such as Relational Grammar (RG), Head-Driven Phrase Structure Grammar (HPSG),

Lexical-Functional Grammar (LFG), Categorial Grammar (CG), Government-Binding Theory (GB), Tree Adjoining Grammar (TAG), etc. While it is tempting to view these as monolithic alternatives, to do so would be misleading.

First, all approaches provide only fragments of a full theory of grammatical knowledge; sometimes these fragments only partially overlap between approaches. Second, there are many fundamental points of agreement between the different approaches. Third, the differences among practitioners of the same general framework can be as large as or even larger than the differences between frameworks. The differences of opinion that engender different 'named' grammatical theories draw greater attention, but they have no special status. Therefore, rather than reviewing different named grammatical theories, this section focuses on a selection of fundamental issues on which syntactic theories diverge.

Syntactic Atoms and How They Combine

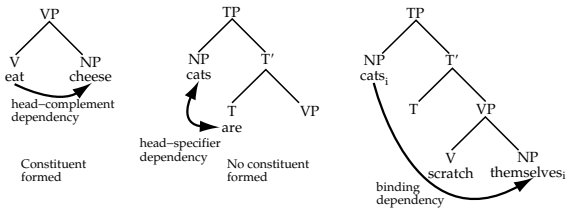
First, syntactic theories differ on the issue of what are the 'atoms' of syntax, that is, the pieces of sentences that are stored in a speaker's long-term memory. At one extreme are certain versions of Transformational Grammar (including the recent *Minimalist Program*), which claim that the atoms of syntax are smaller than words – either morphemes or individual syntactic features. Under this approach, underlying syntactic structures are formed by selecting a set of these atomic units, and combining them based on highly general principles of structure-building. Under this approach, syntax is responsible even for the formation of word-sized units. For example, an inflected verb such as 'runs' may be formed by independently selecting the verbal head 'run' and the inflectional head *[3rd person singular, present]*, and applying a transformation which combines them to form a complex syntactic head, which is spelled out as the word 'runs'.

At the other end are approaches that assume much larger atoms, in the form of templates for phrases or even clauses. Construction Grammar and some versions of Tree Adjoining Grammar are examples of such approaches. Under these approaches, the representation of idiomatic expressions is little different from the representation of other types of phrases. Construction Grammar has provided some insightful analyses of constructions that have been largely overlooked in mainstream transformational syntax. (*See* **Construction Grammar**)

Despite disagreements about the size of the atoms of syntax, there has been a quiet convergence of opinion on the role of the atoms of syntax. In early generative theories it was standard to distinguish the terminal elements of syntax (i.e. lexical items) from the phrase structure rules that determine how the terminals combine. In most current theories this distinction has been eliminated, and the work once done by phrase structure rules is replaced by a set of highly general conditions on how syntactic atoms combine. In these *lexicalized* grammars, information about the combinatorial possibilities of syntactic atoms is built into the lexical entries of the atoms themselves. Lexicalism is a common feature both of theories that assume very small syntactic atoms and of theories that assume much larger syntactic atoms.

Types of Structural Dependencies

A second issue involves the question of how syntactic elements enter into structural dependencies. As a starting point, in a typical phrase structure grammar syntactic elements enter into two basic types of dependencies, illustrated in (35). First, when syntactic elements enter into a *sisterhood* relation, this both forms a dependency between the two elements and creates a new syntactic *constituent*. Constituents may participate in a variety of different syntactic processes, such as coordination, movement, and ellipsis. On the other hand, many syntactic dependencies do not involve the formation of new constituents, for example subject–verb agreement and reflexive binding.



(35)

The phrase structure notions that create this division among structural dependencies continue to dominate thinking about syntax, but there are a number of interesting alternative proposals that reduce or eliminate this distinction. First, *Dependency Grammars* treat all syntactic dependencies in a parallel fashion, and do not single out constituent-forming dependencies as special (36).

Dependency Grammar representation of argument and agreement relations (36)

Combinatory Categorial Grammars (CCG) also reduce the division of dependency types, but in the opposite manner from Dependency Grammars. In CCG grammars, information about the elements that a syntactic atom may combine with is encoded in enriched category labels. For example, an intransitive verb such as 'run' might have the category label S\NP, read as 'a category that combines with an NP to its left to form an S'. Dependencies between syntactic sisters are formed by the rule of *function application*. Dependencies between non-sisters are also formed by function application, thanks to the mediating effects of *function composition* rules, which allow the combinatorial requirements of a syntactic atom to be passed up through a series of larger units.

By virtue of their more uniform treatment of structural dependencies, both Dependency Grammar and Combinatorial Categorial Grammars have led to innovative proposals about the treatment of constituency phenomena. Whereas most phrase structure grammars impose a clear boundary on which syntactic relations form constituents, DG and CCG do not. Therefore, these approaches have been used to analyze syntactic phenomena that do not fall straightforwardly under standard notions of constituency, such as 'nonconstituent coordination' involving subject–verb sequences. In CCG, flexible constituency relations are made possible by the introduction of *type raising* rules, which allow the combinatorial requirements of a category to be satisfied in a different order (38).

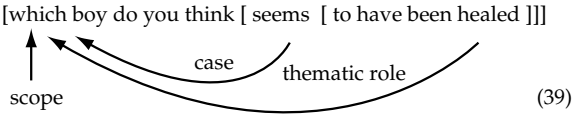
(38)

Multiple Roles: Alternatives to Transformations

All syntactic theories must address the fact that individual syntactic elements can enter into a variety of different structural relations. In a multiclause sentence, a single phrase may take scope in one clause, be case-marked by the predicate of a second clause, and receive a thematic role in a third clause (39).



(39)

Since the 1950s and 1960s, transformational approaches to syntax have famously argued that phrases can bear multiple syntactic roles because there are multiple syntactic levels of representation, which are related to one another via movement through a series of different structural positions. As a result, a leading area of research on transformational syntax has been the investigation of constraints on possible movement operations, as outlined above.

The syntactic frameworks *Lexical-Functional Grammar* (LFG) and certain versions of *Combinatory Categorial Grammar* (CCG) share with Transformational Grammar the assumption that words and phrases bear multiple roles because they appear in multiple different levels of representation. These approaches diverge from Transformational Grammar in the respect that they do not assume that each different level is a hierarchical constituent structure, or that the levels are related by movement transformations. LFG assumes independent levels of *a-structure* (argument structure: representation of argument/thematic roles), *f-structure* (function structure: representation of subject, object, etc. roles), and *c-structure* (constituent structure: surface syntax). There are rules for mapping between these levels, but the mappings are not assumed to be transformational. In some versions of CCG separate representations of *argument structure* and *surface structure* are posited. (*See* **Lexical-Functional Grammar**)

In *Head-Driven Phrase Structure Grammar* (HPSG) only one syntactic level of representation is assumed. This single level of representation combines words and phrases into the surface constituent structure that is familiar from many other syntactic theories. However, the terminal elements of these structures contain highly articulated feature structures, which encode a great deal of information about argument structure,

phonology, 'moved' arguments, and so on. Whereas transformational grammars use movement operations to handle the multiple roles problem, the same work is done largely internal to individual syntactic heads in HPSG. For example, a verbal head may encode the information that a *wh*-phrase, which is represented as the *focus* argument of the clause, is to be treated as the filler of one of the slots in the verb's argument structure list. Constraints on movement operations in transformational approaches must be replaced in nontransformational theories by related constraints on the relations between scope and argument slots. (*See* **Phrase Structure Grammar, Head-driven**)

Causes of Ungrammaticality

Standard approaches to syntactic theory assume a set of syntactic atoms and a relatively small number of formal principles or constraints that determine how these atoms may be combined to form sentences. A sentence is assumed to be grammatical if it violates no constraints. An ungrammatical sentence is a sentence that violates one or more constraints. Some variants of syntactic theory have explored broader notions of what causes a sentence to be (un)grammatical.

Functional grammars typically emphasize the role of meaning or of communicative efficiency in determining the well-formedness of a sentence. Such approaches typically do not appeal directly to semantics or processing efficiency to explain ungrammaticality. Rather, semantics or processing efficiency are used to provide a functional motivation for a set of formal grammatical constraints.

Both *Optimality Theory* and certain versions of the *Minimalist Program* question the standard assumption that a grammatical sentence is a sentence that violates no constraints. This characterization is replaced in these approaches with the requirement that a well-formed sentence is the *optimal* candidate from a set of possible structures/derivations for that sentence. In other words, a sentence may be deemed ungrammatical for the simple reason that there exists a better way of expressing the same thing. (*See* **Optimality Theory**)

CHALLENGES AND FUTURE PROSPECTS

Universal Grammar

The Principles and Parameters approach to syntax, which is compatible with any of the syntactic frameworks discussed above, aims to explain how a child can attain rich knowledge of any language. It does so by seeking universal syntactic principles and clusters of syntactic properties that covary across languages. Syntactic research since the 1970s has uncovered a wealth of cross-linguistic findings, and a number of good candidates for universals of syntax have been found. However, the search for parameters has met with mixed success. The prospect that each parametric cluster may be linked to an easily observable surface property of the language appears to be viable, but parametric clusters of properties appear to be both narrower and more numerous than originally expected. It remains to be seen whether all of natural language syntax, including the idiosyncrasies of each language, can be handled in terms of a Principles and Parameters approach.

The Unification Problem

Syntactic theories are theories that aim to characterize the mental representations underlying knowledge of language, and of how people acquire that knowledge. However, most syntactic theories characterize knowledge of which sentences are grammatical and which sentences are ungrammatical, with few suggestions about how speakers successfully access this knowledge in real-time speaking or understanding, or about how children acquire this knowledge. Even less is known about how to encode this knowledge in brain structures. The overall goals of syntactic theory may be significantly affected by findings in these areas. In addition, a complete syntactic theory will have to provide answers to questions about how sentence structures are learned, used in real time, and encoded in the brain.

Tense and Aspect

Advanced article

Carlota S Smith, University of Texas, Austin, Texas, USA

CONTENTS

Tense and aspect convey temporality in language. Tense relates situations to a reference time and the moment of speech. Aspectual information classifies events and states into situation types, and presents them from a perfective or imperfective viewpoint.

INTRODUCTION

The cognitive science perspective analyzes the formal systems of language in terms of the information they provide. Temporality is pervasive in human experience, and in language. Natural language expresses temporal information with the linguistic forms of adverbials, tense, and aspectual categories. The aspectual notion of temporality has to do with how situations unfold in time: it recognizes beginnings and endings, intervals, the dynamic and the static.

Tense and adverbials temporally locate the situation talked about in a sentence; aspect categorizes that situation. For instance, consider the temporal information in the sentences (a) 'Mary was opening the door' and (b) 'Mary opened the door'. The situations are located before the time of speech or writing; this information is conveyed by the verb tense. They are durative events with a final endpoint; this is aspectual information, conveyed by the verb and its arguments. In (a), the event is in progress: this information is conveyed by the auxiliary verb, which expresses the progressive aspectual viewpoint; in (b) the event is complete, conveyed by the simple verb form which expresses perfective aspectual viewpoint.

In what follows these statements will be explicated so that the reader will have a grasp of temporal location, aspectual situation type, and aspectual viewpoint. The next section is concerned with temporal location, tensed and tenseless languages, tense systems, the conceptual and semantic interpretation of tense, and the contribution of context. The following section discusses aspect: aspectual situation types and viewpoints, coercion, and global categories. The final section concludes with comments about the interaction between tense and aspect.

THE INTERPRETATION OF TEMPORAL LOCATION

Adverbials, Tense, and Time

Time is a single unbounded dimension without landmarks; it is analogous to space, though simpler. As space requires a landmark to indicate a position, time requires an orientation point to locate or anchor a situation. The speaker is the canonical center of linguistic communication: the basic orientation points in language are the speaker's place ('here') and the speaker's time ('now'). Linguistic forms that anchor to these coordinates are known as *deictic*. In sentences out of context, situations are located with respect to Speech Time, which is always the Present. Context can change the interpretation significantly. (Capital letters refer to times, lower-case letters to tenses.)

All known languages express temporal notions and divide time into the general notional categories of Past, Present, and Future. Strikingly, this holds for languages embedded in cultures that are very different from the Indo-European. The Hopi language, for instance, was thought by Benjamin Whorf to encode temporal distinctions entirely different from those of the West. But recent studies show that Hopi has a full, productive set of temporal adverbials which make the familiar distinctions.

It is important to distinguish between tense and time. Tense is not necessary for conveying temporal information: time adverbials suffice. There are languages without tense, but all languages have time adverbials ('yesterday', 'when John arrived', 'earlier', etc.). Situations are located at the moment of speech, Speech Time; or before or after Speech Time. Past and Future time are symmetrical in their relation to Speech Time, but their interpretations

are not entirely symmetrical. The Future is unknown, and so reference to it has the modal quality of prediction. Indeed, the English future *will*-future patterns with other forms that have modal force ('may, might', etc.).

In tenseless languages (Thai, Mandarin Chinese, classical Hebrew, and many others) temporal adverbials function with aspectual information to locate situations temporally. Temporal adverbials may give specific or relational times ('Mary called at noon/earlier'), or locate one situation in terms of another ('John left when Mary arrived'). Adverbials may be anchored to Speech Time ('now, yesterday, tomorrow') or a time specified in the linguistic context ('earlier, later').

This article will focus on English as a typical tensed language. The basic meaning of tense is deictic, anchored to Speech Time. Tense locates the situation in a clause by tacitly invoking two times: the time of the situation expressed, which I will call Situation Time; and Speech Time. A third time, Reference Time, is introduced below. The tense of a sentence locates the situation talked about from Speech Time. The common labels for tense reflect this: present, past, and future tense indicate times at, before, or after Speech Time.

Tense Systems in Language

Tense is a grammatical form associated with the verb, with temporal meaning. The category includes verb affixes ('Mary walk<u>s</u>', 'Mary walk<u>ed</u>'), infixes ('Mary r<u>a</u>n'), and perhaps verb auxiliaries such as the *will*-future in 'We will walk' ('will' also has modal meanings, beyond the scope of this discussion). Other forms that convey temporal meaning are not technically tenses.

Tense systems vary among languages. In a study of 64 languages, Dahl (1985) found that almost all have a past tense of some kind, and that over three-quarters of the languages have future tense. Present tense is often conveyed by the absence of an overt morpheme – it is unmarked, as in the English 'We <u>like</u> snow'. Tense is usually a suffix, though Bantu languages have tense prefixes. In less than half of the languages studied the future tense is conveyed by an auxiliary verb ('periphrastic' tense). The most common periphrastic tense across languages is the 'perfect', a complex construction with temporal and aspectual meaning. The perfect in English is conveyed by auxiliary 'have' and a participle, as in 'They <u>have locked</u> the door', 'They <u>had locked</u> the door'. Some languages have a partial tense system. Navajo, for instance, has verb affixes that convey Future time; sentences without them are located in the Past or Present.

Tenses may be 'absolute' or 'relative'. Absolute tenses relate to Speech Time, while relative tenses require a linguistically specified anchor time. The past perfect is a relative tense in English: for instance, in 'At noon they had locked the door' the adverbial 'at noon' provides an anchor time. Again, the modal 'would' allows a future-in-past interpretation requiring an explicit anchor: in 'Jane said last week that Bill would leave soon' the main clause provides the anchor for 'would' in the complement clause.

Degrees of remoteness from Speech Time are coded into some tense systems, including Aboriginal languages of Australia, some American Indian languages, and Bantu languages. Degrees of remoteness are more frequent and more complex for the past than the future. For instance Haya, a Bantu language, has a three-way distinction in the Past – today, before-today, remote – and a two-way distinction in the Future.

In English and in tensed languages generally, every independent clause has a tensed verb, known as a 'finite' verb. Most languages also have tenseless verb forms temporally dependent on the tensed verb in a sentence. The tenseless forms in English are bare stems ('I saw them <u>go</u>'), infinitives ('We want <u>to go</u>'), and participles ('<u>Singing</u>, John left'; '<u>Exhausted</u>, John left').

Tenses vary in interpretation: past and present tense do not always indicate Past time and Present time. For instance, the present tense with a past adverbial conveys Past time – the 'historical present', as in 'Last week, this guy comes up and offers me a lottery ticket'. The past tense may be anchored to a time in the Future. The variation can be explained by treating the semantic meaning of tense as relational: the present tense conveys simultaneity, the past tense anteriority, the future posteriority.

Conceptual Interpretation of Tense: Reference Time

There is an important conceptual dimension to temporal information. The speaker's centrality implies an organizing consciousness, a temporal perspective. The temporal perspective may differ from the time of a situation. Consider (a) and (b); they have the same truth-conditions yet differ subtly in meaning: (a) 'Henry arrived.' (b) 'Henry has arrived.' (a) is set squarely in the Past, while (b), a present perfect, has a Present perspective implying that the arrival is relevant to the Present. Hans

Reichenbach (e.g. 1947) noted this contrast and attributed it to a difference in perspective, or Reference Time. (a) has a Past Reference Time, while in (b) the Reference Time is Present. In both, Situation Time is in the past.

Reference Time explains the difference between the past and the present perfect tense. The past tense conveys that Reference Time and Situation Time are the same, prior to Speech Time. With the present perfect, Reference Time and Speech Time are the same, and Situation Time is prior. Generalizing, all tenses involve three times.

Shifted deixis is also clarified by the notion of Reference Time. Deictic adverbials such as 'now', 'in three days', etc., normally anchor to the moment of speech. But they can also anchor to another time, as in 'Mary sat down at the desk. Now she was ready to start work'. In the second sentence 'now' is anchored to the Past time, and suggests the temporal perspective of Mary. Certain effects of context on interpretation can also be explained with Reference Time. When there are simultaneous or overlapping situations, Reference Time gives an indispensable locus for the relation between them. (*See* **Reasoning about Time**)

Semantic Interpretations of Tense

In formal semantics the classical approach of tense logic was important as a research tool. It has now been supplanted by richer, more natural systems. Tense logic analyzes tense as a sentence operator that determines the time of evaluation for the proposition expressed. For a past tense sentence expressing the proposition P (past (P)), the truth of P is evaluated at a time prior to the moment of speech. Although reasonable for simple sentences, the approach cannot be extended to complex cases. Complex tenses do not function as nested operators, one within the scope of the other; and many predicted combinations do not occur. Further, the treatment does not extend to other temporal expressions. Adverbials are not operators on tense: in the sentence 'Mary left yesterday', 'yesterday' does not indicate a time prior to the time indicated by the past tense. Rather, the adverbial further specifies the time. The tense logic approach cannot deal with explicit or implicit contextual dependencies.

There is also an objection of a different kind. Tense cannot be an operator on a proposition, because nominal referents that figure in the proposition are temporally independent. To see this, consider 'Every fugitive is now in jail'. The referents of the subject noun phrase (NP) do not have fugitive status at the time of the sentence ('now'): they were fugitives at some earlier time. Another key example: 'The president was a fool'. There are two readings: either the person who is now president was a fool earlier during the presidency, or the person was a fool at an earlier time when not the president. These examples show that the NP referents are outside the scope of tense (Enç, 1986). The operator approach fails on both scopal and compositional grounds.

The referential analysis of tense, in which tenses refer to times, is now widely accepted. Tense information involves three times, following Reichenbach: Speech Time, Reference Time, and Situation Time ('event time' for Reichenbach). Each tense conveys information about the relation between Speech Time and Reference Time (SpT and RT), and the relation between Reference Time and Situation Time (RT and SitT). In the present tense, SpT equals RT; in the past tense, RT precedes SpT; in the future, RT follows SpT. For the simple tenses SitT and RT are the same; for complex tenses they differ. The notion of Reference Time is now well established; other parts of Reichenbach's original system have been revised and extended.

In current generative grammar, Tense heads its own functional projection and encodes semantic information. In dynamic semantic theories such as Discourse Representation Theory, tenses are associated with the appropriate relational information. The appearance of a given tense in surface structure licenses the introduction of times and conditions stating their relations in semantic representation (Kamp and Reyle, 1993). (*See* **Semantics, Dynamic**)

Context and the Interpretation of Tense

Context may affect the interpretation of tense. Information in the context may determine a specific time, as in 'anaphoric' interpretations of tense (Partee, 1984). For instance, in 'I didn't turn off the stove', the past tense implies a particular earlier time. In the sequence 'I went to John's party last night. Mary was there' the second past tense refers to the time specified by the first tense and time adverbial together.

Tense anchoring may also be determined by syntactic context. Complement clauses, for instance, may be anchored to a main clause time. Consider the complement clause in 'Tomorrow at midnight the Prime Minister will announce that he burned the documents an hour earlier'. The anchor time for the past tense in the complement is the Future time of the main clause. Unlike complement

clauses, relative clauses may be temporally dependent or independent. With relative tenses, an independent sentence may provide the anchor time: 'We arrived at noon. John had already left.' The past perfect and the adverb 'already' anchor to the time in the first sentence.

In discourse, tense is interpreted in three different patterns, according to the context. In narrative and procedural contexts tense conveys continuity; in descriptive contexts tense is anaphoric to an established time; in other contexts tense is deictic. (*See* **Discourse Processing**)

Finally, tenses have atemporal meanings in certain contexts. The past tense conveys irrealis in conditionals, as in 'If you left early I would be pleased', and politeness as in 'I wanted to ask you a question'. These meanings for the past tense are not unique to English, but are found in many languages of the world. (*See* **Story Understanding**)

ASPECT: INTERNAL TEMPORAL STRUCTURE

Aspect is a semantic domain that is reflected in the syntax and morphology of a language. Two kinds of aspectual information are conveyed about the eventualities, or situations, expressed in sentences. Situations are presented from a particular perspective, or viewpoint; and they are indirectly classified as a state or an event of a certain type.

Situation Type

Situation type information classifies situations according to their internal temporal properties. For instance, 'John is tall' expresses a state, 'John walked by the river' an event. Events may be telic, with natural final endpoints, or goals: 'John walked to school' is telic. The traditional term for such distinctions is *Aktionsarten* (kinds of action). The terms *situation* and *eventuality* are neutral between event and state.

Since Aristotle, situations have been classified by temporal features. The features are based in perceptual and cognitive abilities, and realized indirectly in language. Situation types are concepts, idealized classes of situations. Vendler (1967) distinguished four types, using the features static-dynamic, telic-atelic, and durative-instantaneous. The list below adds a fifth, semelfactives (Smith, 1997):

States: static, durative (know the answer, love Mary)
Activities: dynamic, durative, atelic events (laugh, push a cart, stroll in the park)
Accomplishments: dynamic, durative, telic events consisting of a nondetachable process with an outcome (build a house, walk to school, learn Greek)
Semelfactives: dynamic, atelic, instantaneous events (tap, knock, flap a wing)
Achievements: dynamic, telic, instantaneous events (win the race, reach the top)

Temporal features are concepts associated with classes of situations. They are realized when a situation unfolds in time. Situations with the feature [Dynamic] are events, and occur at successive stages in time. [Atelic] events can continue indefinitely, with arbitrary final endpoints. [Telic] events have an intrinsic final endpoint with a change of state. [Durative] events take place over an interval, while [Instantaneous] events occur at a moment, in principle. [Static] situations have an undifferentiated interval with no structure. States do not have endpoints: the coming about and ending of a state are events in themselves. Events take time, whereas states do not.

Abstracting away from duration, situations are classified as States, Processes, and Events, using the features [stative/dynamic] and [homogeneous/heterogeneous]. Situations have patterns of entailment due to their part structure. States and Processes are homogeneous, with no difference between part and whole. There is an entailment from part to whole that follows from this homogeneity: if one has done any walking, for instance, one has walked. When a State holds for an interval, it holds equally for any smaller interval of that interval; this is known as the sub-interval property. The classes differ in dynamism and in uniformity: States are Static and uniform, Processes are dynamic and less so.

Events are dynamic and quantized, with a heterogeneous part structure. For Events there is no entailment from part to whole: no proper part has the status of the event. Telic events have intrinsic bounds; they are instantaneous or involve an incremental process. In the incremental process, the part structure of the event maps onto that of the referent. The event proceeds incrementally and as it does so the referent is traversed, built, used up, etc. Take the event 'Mary ate an apple'. As the event progresses, more and more of the apple is eaten: at completion no more apple remains and no subpart is an event of eating an apple. The process realizes a homomorphism from the argument denotation to the event (Krifka, 1989). This analysis captures the close association between count and mass nouns ('an apple', 'wine') and quantized and nonquantized situations ('Lee drank a glass of wine/wine').

Situation types are realized by the verb and its argument, the verb constellation. The verb is key, but the nature of the arguments is also a factor. For instance, 'Lee ate apples' expresses an Activity, while 'Lee ate an apple' expresses an Accomplishment. In the latter the object is quantized, discrete. Some languages convey this difference by case marking: in Finnish, for instance, accusative case NPs are quantized, partive case NPs are not. Languages may have marked situation types, such as the Tentative in Mandarin, a limited event indicated by verb reduplication.

The temporal features have grammatical correlates with co-occurrence restrictions. For instance, the semantic property of dynamism is expressed by the progressive, verbs and adverbs of volition, and pseudo-cleft 'do'. Stative sentences do not appear with these forms: '*Mary was knowing the answer' or '*What Mary did was know the answer' (*indicates ill-formedness). Adverbs of duration occur with states and atelic events ('She walked for an hour'); adverbs of completion occur with telic verb constellations but are odd with atelics, e.g. 'She wrote the letter in an hour', '??She strolled by the river in an hour'. Due to such facts, situation types are 'covert' grammatical categories: recognized in the grammar though not morphologically marked.

Aspectual Viewpoint

Aspectual viewpoints focus situations like the lens of a camera. As the camera lens makes a scene available, so viewpoint makes visible all or part of the situation expressed in a sentence. The information made visible is available for semantic interpretation and pragmatic inference. The aspectual viewpoints of a language are usually signaled morphologically. The term *grammatical aspect* is also used.

The main aspectual viewpoints are perfective and imperfective. In English the choice between them is obligatory, conveyed by the form of the verb: the simple verb form is perfective, as in 'Mary swam in the pond', the *be+ing* auxiliary is imperfective, as in 'Mary was swimming in the pond'. Perfective viewpoints present situations as bounded, often with endpoints; imperfectives present ongoing situations with no information about beginning or end. The perfect is a special case, discussed below. The progressive, a type of imperfective viewpoint, appears neutrally only with non-statives: 'Mary is singing', '*John is knowing the answer'. There is a third type, the neutral viewpoint; it allows bounded and unbounded interpretations, depending on contextual information. The neutral viewpoint arises in sentences with no viewpoint morpheme; it is not applicable to English.

Aspectual systems differ most in the viewpoint component. English has one perfective and one imperfective viewpoint. Some have richer systems: Mandarin, for instance, has two imperfective viewpoints and three perfectives, none obligatory. In Russian, viewpoint information is salient and is conveyed by verb prefixes and suffixes. Linguistic expression of tense and aspectual viewpoint is distinct in some languages, intertwined in others. The two vary independently in English. In French, past tenses code aspectual viewpoint: the *imparfait* is a past imperfective tense, the *passé composé* and *passé simple* are past perfectives. Some languages, for example Finnish and Icelandic, have minimal viewpoint systems.

Perfective viewpoints generally present situations as discrete, bounded. If the situation is telic, the perfective expresses a completed event. The interpretation of completion can be demonstrated with conjunction. It is semantically contradictory to conjoin a perfective event sentence with an assertion that the event continues: '#Mary opened the door, but she didn't get it open'; '#Donald fixed the clock and he is still fixing it'. The English perfective presents statives as unbounded, as shown by the felicity of 'Mary knew the answer and she still knows it'. This is a language-particular feature; French perfective viewpoints present statives as bounded.

Imperfective viewpoints focus part of a situation, without endpoints. Since it is unbounded, the focused interval has the sub-interval property. Imperfectives of internal or preliminary intervals have an intensional component. They focus a stage of a process, which, if continued to its final endpoint, results in an event. Thus one cannot infer from a progressive 'They were building a house' that the building was completed. This gap between knowledge of the type of situation and its outcome is known as the Imperfective Paradox (Dowty, 1979). Imperfect viewpoints may also focus resultant intervals. For instance, the Japanese *-te iru* is an imperfective verb form that focuses resultant or internal intervals.

Coercion

People talk about situations in more than one way: states can be presented as events, events can be presented as states, and the endpoints are events. Language has mechanisms for 'coercion'

or 'situation type shifts' that change the class of verb constellations.

There is a basic-level set of associations between situations in the world and situation types. However, verb constellations typically of one type may be coerced into another. For instance, 'Teresa understood the problem' is a typical state; but with a point adverbial it changes, expressing an event: 'At that moment Teresa understood the problem.' Verbs such as 'start, begin' also convey this meaning. Coercion is triggered by material in the context, often adverbial.

Events and specific states can be coerced in generalizing-habitual sentences, for instance: 'Teresa always played tennis on Tuesday.' Such sentences are semantically stative, expressing a pattern of recurrence. Instantaneous events are coerced into processes with multiple stages with durative adverbials: 'John knocked at the door for five minutes.' There is a general rule for coercion, the rule of External Override. If an adverbial and verb constellation are incompatible, the feature of the adverbial coerces the verb constellation. Again, durative adverbials coerce telic verb constellations into atelics: 'Mary read a book for an hour.' This sentence conveys that Mary did some book-reading. Other examples of coercion include stative verb constellations with the progressive viewpoint, presenting a state as an event, as in 'I'm liking this play'.

The *perfect* coerces a situation into a consequent state, as in 'Mary has eaten dinner'. This is the aspectual meaning of the perfect. There is also a temporal component. Temporally, the perfect conveys that Situation Time precedes Reference Time. English has a constraint on adverbials and the present perfect: for instance, the sentence '*Mary has left yesterday' is impossible. Such adverbs are good with the pluperfect and future perfect, however, and in some other languages.

Supercategories include information from both aspectual situation type and viewpoint. The classes are Statives, homogeneous and unbounded; and Events, heterogeneous and bounded. They contribute differently to narrative time. Events advance narrative time; Statives do not. Whether a given sentence moves narrative time constitutes a test for its global aspectual category.

The class of Statives consists of basic-level states, perfects, habitual-generalizing sentences, and sentences with the progressive viewpoint. States are intrinsically unbounded; perfect sentences and habitual-generalizing sentences are stative by coercion. The progressive, a viewpoint, focuses dynamic situations without endpoints. Thus homogeneity arises in more than one way.

The class of linguistically realized Events consists of bounded, dynamic situations expressed with the perfective viewpoint.

INTERACTION BETWEEN TENSE AND ASPECT

Tense and aspect information interact at Situation Time. Depending on aspectual value, the situation of a sentence overlaps Situation Time, or is included within it.

The boundedness of a situation determines its relation to Situation Time. Bounded events are included in the Situation Time interval: for instance, 'Lee built a sandcastle yesterday' takes place within the interval of 'yesterday'. Ongoing events and states overlap or surround Situation Time. In the sentences 'Lee was building a sandcastle' and 'Henry was at school', the situations hold during Situation Time and are understood to hold before and after it.

There is a general constraint on linguistically realized situations in the Present which has far-reaching implications. The constraint allows only unbounded situations at Speech Time. Thus Present events must be ongoing, in English with the progressive: 'John is talking', 'Mary is drawing a circle'. The constraint involves a general principle of communication that is pragmatic and semantic. In the temporal perspective of the Present, there is a tacit convention that communication is instantaneous. The perspective of the present time is incompatible with a bounded event, because the bounds would go beyond the moment of the communication.

Languages realize the Bounded Event Constraint differently. In English, simple present event sentences undergo coercion and are interpreted as habitual statives, as in 'Tom feeds the cat', 'Sue speaks French'. Apparent exceptions include performatives ('I hereby christen this ship') and sports-announcer reports ('Now Jones throws the ball'). In these uses, time is telescoped into a notional moment. Russian has another strategy: present tense perfective sentences express Future time.

The constraint against bounded events in the Present explains an important pattern of temporal interpretation in tenseless languages. Commonly, states and progressives – both unbounded – are located in the Present, while bounded events are located in the Past. The Bounded Event Constraint prevents uncertainty about bounded events.

Typology

Intermediate article

William Croft, University of Manchester, Manchester, UK

CONTENTS

Typology is an empirical, cross-linguistic approach to the study of grammatical structures in the world's languages.

Typology is an empirical, cross-linguistic approach to the study of grammatical structures in the world's languages. The typological method was first formulated by Joseph H. Greenberg in the 1960s (Greenberg, 1966). The typological method consists of three steps: classification, generalization and explanation. In the first step, languages are classified into types. For example, English places its adjectives before nouns, as in *red book*, while Spanish places its adjectives after nouns, as in *libro rojo*. English and Spanish belong to two different types, adjective–noun and noun–adjective respectively. In the second step, the range of attested language types is compared to the range of possible language types, and generalizations (universals) are formulated that constrain languages to types attested or assumed to exist. Finally, explanations are offered for the universals. Explanations range from processing explanations to semantic-pragmatic explanations to diachronic (historical) explanations. As in any empirical science, typological research involves an interplay among classification of data, generalization, and explanation.

TYPOLOGICAL CLASSIFICATION: BASIC METHODOLOGICAL ISSUES

The classification of languages into grammatical types presupposes that there is a cross-linguistic basis for the comparison of grammatical structures in different languages. Languages in fact vary considerably in their grammatical structure. For example, many languages do not have a separate word class of adjectives. Typologists address this problem by comparing how meanings are encoded in grammatical form. Thus, to identify adjective–noun order in a language that lacks adjectives as a separate word class, one examines the order of words denoting properties such as 'red'. One thus examines the full range of grammatical variation without excluding certain grammatical types *a priori*.

A major challenge in typological classification is to construct a proper sample of the world's languages from which one may make valid generalizations or statistical inferences. In order to make valid generalizations, one must construct a variety sample which maximizes the likelihood of capturing all relevant gramamtical variation. In order to make valid statistical inferences, one must construct a probability sample which reflects the proportion of different types among the world's languages.

A variety sample is constructed by seeking the most diverse sample of languages for the size of the sample population. Typological diversity can be obtained by minimizing the likelihood that the languages in the sample are similar due to historical accident, that is by sharing a common ancestor or by contact. For example, English and German are both adjective–noun because they both belong to the Germanic language family. Finnish and Russian have subject–verb–object (SVO) order because of centuries of contact. Hence, typological diversity is maximized by constructing a genetically and geographically stratified language sample.

A probability sample is more difficult to construct. Statistically, a probability sample should contain only historically independent cases. However, some linguistic phenomena are so stable that reasonably large sample sizes will inevitably include genetically or geographically related language types. Also, the proportion of languages can be distorted by recent expansions of language families, such as Bantu and Austronesian. Various statistical techniques are used to address these problems.

Typology depends heavily on descriptive linguistic research, and various souces are drawn upon. Native language consultants provide the greatest detail in description but cannot be relied on exclusively in large studies. Reference grammars are the most practical source for large studies, and are adequate for basic grammatical phenomena, but cannot always be relied on for more specialized studies. Recorded texts are used for studies of grammatical phenomena connected to discourse.

IMPLICATIONAL UNIVERSALS AND COMPETING MOTIVATIONS

Typological generalizations are universals of language. The vast majority of typological generalizations are implicational universals: e.g. if a language has adjective–noun (AN) word order, then it also has numeral–noun (NumN) order. Implicational universals accommodate a certain degree of cross-linguistic variation. The implicational universal given above allows languages that are AN/NumN, NA/NumN, or NA/NNum; it excludes only languages that are AN/NNum.

Typological generalizations are formed by comparing attested language types to possible language types. Further research and larger samples may bring up counterexamples to proposed implicational universals. Sometimes the universal is refined to account for the putative counterexamples. In other cases, even when all types are attested, the frequency is often highly skewed, and this skewing calls for an explanation.

A competing motivations model is used to explain many typological generalizations. Explanatory principles (motivations) in this model cannot be simultaneously satisfied. The motivations compete; existing language types represent the range of most optimal satisfaction of the competing motivations. (*See* **Constraint Satisfaction**; **Optimality Theory**)

In the classic paper on typology, Greenberg (in Denning and Kemmer, 1990) demonstrated the existence of three common clause word orders, SOV, SVO, and VSO; he noted the existence of VOS and even OVS; the existence of OSV languages is still uncertain (see for example Comrie, 1989). Greenberg discovered a number of implicational universals linking clause order to a number of other clausal and phrasal word orders (see also Dryer, 1992).

Greenberg proposed a competing motivations model for word order patterns, using dominance (an inherent preference for one order, e.g. NA and NumN are dominant) and harmony (a parallel alignment of orders, e.g. NA/NNum and AN/NumN). The three language types in the example given above satisfy either harmony (NA/NNum, AN/NumN) or dominance (NA/NumN). The dispreferred type, AN/NNum, is disharmonic and neither order is dominant. In affix order, there is a harmony pattern which competes with a general suffixing preference.

Deeper explanations for word and affix order fall into two types, processing and diachronic. The most recent processing explanation of word order argues that human beings attempt to parse the constituents of a sentence as early as possible and as quickly as possible (Hawkins, 1994). Hawkins successfully predicts a frequency distribution of word order types reflecting degrees of optimality of the attested types for parsing. The processing account implies that harmonic word orders are most optimal, but also longer constituents are more optimally placed after their sister elements. Hawkins also argues for a processing account of affix order, based on psychological research on processing the beginnings and ends of words. The beginning of a word is most salient for word recognition, hence prefixes would interfere with recognition, and so most inflections are suffixes.

Diachronic explanations of word order rest on the fact that the same grammatical constructions are used for different word order patterns. In some cases, there is historical evidence of the extension of the construction from one word order pattern to another. A particularly common pattern is the extension of the noun–genitive construction for prepositional phrases: compare English *inside the house* (preposition–noun) to its historical antecedent *in the side of the house* (noun–genitive). Likewise, there is evidence that the position of inflections as prefixes or suffixes is a consequence of their position as independent words before they became affixed.

GRAMMATICAL CATEGORIES: MARKEDNESS, ECONOMY, AND ICONICITY

Languages vary in the grammatical categories they possess. Nevertheless, universals of grammatical categories exist. One class of such universals is markedness. The concept of markedness in typology differs considerably from the concepts given the same name in other linguistic theories. In typology, markedness is a property of conceptual categories or, more precisely, values of a category (e.g. the values 'singular' and 'plural' of the category

'number'). Typological markedness is a universal property of values of a category. Typological markedness is embodied in universals of the formal expression of the values of a category. Typological markedness accounts for many asymmetries in grammatical expression.

Typological markedness is manifested in two ways, structural coding and behavioral potential. Structural coding is the number of morphemes used to express a value. For example, in English plural is expressed with a suffix (*book-s*) but singular is expressed without any suffix (*book-Ø*). This asymmetry is evidence for the markedness of plural compared to singular. Not all languages are like English, in that they have symmetrical expression of singular and plural. For example, Lithuanian has overt coding of both singular and plural, and Mandarin has zero coding of both (i.e. there is no number distinction). Hence the typological markedness pattern must be formulated as an implicational universal: if a language overtly codes the singular value, then it overtly encodes the plural value.

Behavioral potential is the expression of other inflectional categories, or the range of distribution of the values of the category in question. For example, the English third person singular pronoun has three different forms that distinguish gender (he/she/it), while the third person plural does not distinguish gender (they). This asymmetry is further evidence for the markedness of the plural. Again, not all languages are like English: Spanish has gender distinctions in both singular and plural while Turkish has no gender distinctions in either singular or plural.

A competing motivations model can account for the variation between asymmetric and symmetric expression of category values. The asymmetric pattern is motivated by economy: express no more than one has to. Thus, one value can be expressed by zero. The value that is chosen to be zero is the most frequent value (there is a long established correlation between frequency of use and shortness of form). The symmetric pattern is motivated by iconicity: use a one-to-one mapping between meaning and form in an utterance.

The correlation of frequency with economy accounts for two other typological generalizations: the unmarked form is most likely to be irregular, and the unmarked form is most likely to form the base in the analogical leveling of morphological paradigms. Economic motivation has been explained in terms of an activation network model of morphological organization in which more frequent (i.e. less marked) word forms are more independently entrenched. Economy and iconicity also compete in the storage of morphemes and words and their associated meanings.

Economy and iconicity are both ultimately explainable as processing constraints. Economy is clearly a processing efficiency factor: minimize overt expression where possible, particularly in high-frequency values. Iconicity also represents processing efficiency. A simple mapping of meaning onto form is easier to store and to use in production and comprehension than a noniconic mapping, which will inevitably be more complex.

HIERARCHIES, PROTOTYPES, AND THE SEMANTIC MAP MODEL

Many grammatical categories have more than two values, and often those values are ranked on a hierarchy. For example, many languages have a dual number value as well as singular and plural, which leads to a hierarchy singular < plural < dual, such that singular is the least marked value and dual the most marked value.

Two hierarchies are manifested in many areas of grammar, the extended animacy hierarchy and the grammatical relations hierarchy. The extended animacy hierarchy is a composite hierarchy: first or second person < third person pronoun < proper name < human common noun < nonhuman animate common noun < inanimate common noun. The extended animacy hierarchy can be broken down into three constituent hierarchies, to which may be added the definiteness hierarchy:

- Person (speech act participant): first (speaker), second (addressee) < third (other)
- Referentiality: pronoun < proper name < common noun
- Animacy: human < animate < inanimate
- Definiteness: definite < specific indefinite < nonspecific indefinite

The extended animacy hierarchy allows constrained variation in the conditions on grammatical constructions. For example, in some languages, a verb agrees with only first or second persons, while in other languages, a verb will agree with first or second persons and nouns referring to humans. The hierarchy excludes a language type in which agreement occurs with first or second persons and inanimate nouns but not human or animate nouns.

The extended animacy and definiteness hierarchies operate in any construction that includes reference to a person, animal, or thing, including expression of number and gender; deixis; agreement of the verb, adjective, or noun; and case

marking in grammatical relations between a verb and its dependents.

The grammatical relations hierarchy was first discovered in constraints on the formation of relative clauses. A relative clause expresses the modification of a referent (the head noun) by a proposition (the relative clause itself). For example, in *the book that I wrote last year*, the head noun is book and the relative clause itself is that I wrote last year. There is a great variety of grammatical structures used to encode relative clauses, ranging from nonfinite participial clauses such as English *the child* SLEEPING *on the couch* to relative clauses that contain their heads, as in Imbabura Quechua. However, all relative clauses have in common the fact that the head noun has a grammatical relation to the verb in the relative clause. For example, in *the book that I wrote last year*, *book* is the object of *wrote*.

Languages impose different constraints on the grammatical relations allowed by specific relative clause constructions: for example, the English participial construction allows only subjects. The constraints conform to a single grammatical relations hierarchy (Keenan and Comrie, 1977): subject < direct object < indirect object < oblique < possessor. The grammatical relations hierarchy also controls the encoding of grammatical relations by agreement and case marking.

However, not all languages categorize grammatical relations in the same fashion. English categorizes the subject of intransitive verbs and the subject of transitive verbs in the same way but categorizes the object of transitive verbs differently. This pair of categories is implicit in the traditional terms 'subject' and 'object'; the terms 'nominative' and 'accusative' are also used. But many languages categorize the subject of intransitive verbs and the object of transitive verbs in the same way and the subject of transitive verbs differently. These categories are called 'absolutive' and 'ergative' respectively. The categories in these languages nevertheless conform to a universal hierarchy absolutive < ergative < …

The semantic map model is employed to represent variation in grammatical categories across languages. The semantic map model posits an underlying universal conceptual space. For grammatical relations, this conceptual space includes the semantic roles for transitive subjects (abbreviated A), transitive objects (P), and intransitive subjects (S). Grammatical categories of particular languages are represented as semantic maps on the conceptual space. The grammatical categories for case marking found in the world's languages are given in Figure 1.

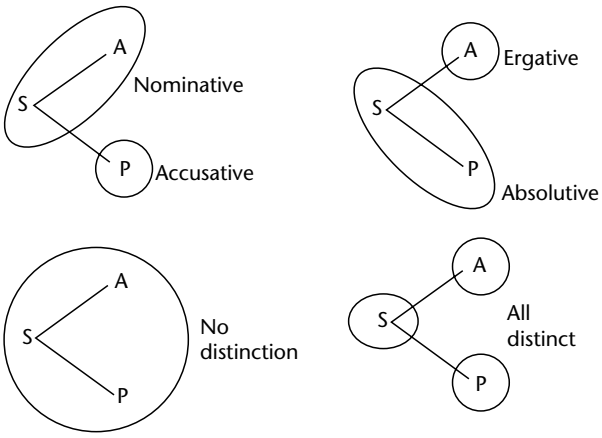

Figure 1. Attested semantic maps of grammatical relations defined by case marking.

Typological universals are represented as constraints on the structure of conceptual space. Grammatical categories may only be mapped onto connected regions of the conceptual space, represented by links between points. This constraint captures the fact that no language encodes A and P in the same way and S distinctly. The conceptual space itself is asymmetric from left to right in Figure 1, representing the hierarchical patterns nominative < accusative and absolutive < ergative. The highest grammatical relation in both hierarchies includes the leftmost role in the conceptual space. There is similar variation in the categories of objects of transitive verbs and ditransitive verbs (verbs with two objects), subject to the same constraints.

The semantic map model has been used to describe grammatical relations, number, aspect, modality, voice, indefinite pronouns, adverbials, and parts of speech. The semantic map model allows one to represent cross-linguistic variation in the grammatical categories of a language while simultaneously capturing universals across all languages regardless of the categories they employ. The conceptual space represents those universals, which are presumed to reflect the structure of the human mind.

Grammatical relations, animacy, and definiteness all interact in a complex way, leading to a wide range of linguistic structures for encoding grammatical relations in a variety of constructions. All of these interactions are subject to universal constraints which can be represented in the semantic map model. A variety of explanations has been offered for the typological generalizations found in the realm of grammatical relations.

In the encoding of grammatical relations, there is an association of the A role with higher animacy

and/or definiteness, and conversely an association of the P role with lower animacy and/or definiteness. This complementary pattern of association describes two prototypes. The prototypical (transitive) subject is a cluster of features <A role, high animacy, high definiteness>. The prototypical object is <P role, low animacy, low definiteness>.

Three explanations have been offered for the grammatical patterns that manifest the subject and object prototypes. A semantic explanation is natural agency: high animacy, particularly human status, is indicative of natural agency, and thus will be zero coded as A but overtly coded as P. A processing explanation is efficiency: a zero coded high animacy referent will be assumed to be A unless overtly coded as a P (or indirect object). Conversely, a zero coded low animacy referent will be assumed to be P unless overtly coded as A. The third explanation involves the pragmatic (discourse) notion of topicality: the subject represents the most topical participant in the verbal event, and highly topical referents are normally human and/or definite. Conversely, nontopical participants are those that are referred to by full noun phrases rather than pronouns (which represent continuing topics). A highly robust cross-linguistic universal is that the transitive subject (A role) is almost always pronominal in spoken language. Full noun phrases are found almost exclusively in the S and P roles, and this may account for the common occurrence of ergative categorization among nouns in contrast to nominative categorization of pronouns.

The typological prototype analysis has also been applied to parts of speech. As noted above, languages vary as to their parts of speech. However, there exist universals in the encoding of semantic classes in the relevant constructions, namely those for the propositional acts of reference, predication, and modification. These constructions are mapped in a conceptual space defined by semantic class and propositional act. Asymmetric typological markedness patterns among semantic maps for word classes across languages reveal the existence of typological prototypes for parts of speech:

- Nouns = <reference, objects>
- Adjectives = <modification, properties>
- Verbs = <predication, actions>

Nonprototypical points in the conceptual space for parts of speech are usually encoded by special grammatical constructions, listed in Table 1.

The prototypes for parts of speech can be accounted for by the characteristics of the semantic classes and their suitability for the discourse functions of the propositional acts. Object identity is unchanging and lasting over time. Objects are therefore most suitable for the function of reference, which opens a discourse file for an entity that will be used for an extended piece of discourse. Actions are dynamic, transitory processes. Actions are therefore most suitable for predications, which provide a continuous sequence of assertions in a discourse. Properties are values associated with objects on a single semantic dimension, and are most suitable as modifiers, which qualify the description of a referent. Other combinations of semantic class and discourse function are possible (see Table 1), but they are less suitable and hence are typologically marked. This is essentially a processing explanation for the typological generalizations underlying parts of speech constructions.

ICONIC MOTIVATION AND SYNTACTIC STRUCTURE

A number of aspects of syntactic structure conform to typological generalizations. These aspects can be accounted for by iconic motivation, this time in terms of syntactic structure and not merely categorization. Of these, the most robust universal is linguistic (grammatical) distance. Linguistic distance can be measured in terms of the degree of morphological or syntactic integration of two elements in a construction. Languages often have two or more constructions that differ structurally in terms of linguistic distance. These two constructions often have semantic differences in their use as well. The semantic differences sometimes define a difference in conceptual distance.

Table 1. Constructions in nonprototypical points of the conceptual space for parts of speech

	Reference	*Modification*	*Predication*
Objects	unmarked nouns	genitive, adjectivalizations, PPs on nouns	predicate nominals, copulas
Properties	deadjectival nouns	unmarked adjectives	predicate adjectives, copulas
Actions	action nominals, complements, infinitives, gerunds	participles, relative clauses	unmarked verbs

The iconic distance generalization is that if two similar constructions differ in linguistic distance and also in conceptual distance, the linguistically more tightly linked construction will be used for the conceptually tighter relation. This generalization has been found to hold for constructions indicating directness of causation, semantic integration of complement clauses to their main verbs, alienability of possession, and distinctness of semantic roles in reflexive events. The generalization also accounts for the ordering of inflectional and derivational affixes in words. The ordering of verbal inflectional affixes follows a hierarchy from nearest to farthest from the root: aspect < tense < mood < person/number agreement, which largely conforms to the degree of semantic effect of the inflection on the meaning of the root. More generally, derivational affixes, which substantially alter the meaning of the root, are closer to the root than inflectional affixes.

DIACHRONIC TYPOLOGY AND GRAMMATICALIZATION

Language types represent current states of language structure in a speech community. However, languages change, and language types therefore change as well. In diachronic typology, language types are treated as evolving entities. Diachronic typology involves two theoretical shifts. The first is the dynamicization of typology. It chiefly involves the reinterpretation of competing motivations as dynamic processes resulting in cross-linguistic variation, and the reinterpretation of semantic maps as the reflection of paths of change through conceptual space. The second shift is the discovery of universals of language change, in particular universals of grammaticalization.

Grammaticalization is the evolution of grammatical morphemes and constructions from full words and nonconventionalized grammatical structures. The most common grammaticalization processes are:

- full verb > auxiliary > tense–aspect–mood affix
- noun > reflexive pronoun > middle/passive voice affix
- verb > adposition
- noun > adposition
- adposition > case affix
- adposition > subordinator
- verb > subordinator
- emphatic personal pronoun > clitic pronoun > agreement affix
- cleft sentence marker > highlighter
- noun > classifier
- verb > classifier
- demonstrative > article > gender/class marker
- demonstrative or article > complementizer or relativizer
- collective noun > plural affix
- numeral 'one' > indefinite article
- numerals 'two' or 'three' > dual/paucal/plural affix

Grammaticalization involves three more or less simultaneous, unidirectional changes: phonological, morphosyntactic, and functional (semantic/pragmatic). Recent research has refined and narrowed the exact set of processes that are part of grammaticalization, in the light of putative counterexamples that have been posed in the literature.

The phonological processes involved in grammaticalization are reduction of phonological form and evolution from an independent word to a bound morpheme (compound or affix). The morphosyntactic processes in grammaticalization are the fixing of the word order of the construction; making the relevant morphemes obligatory; a reduction in the range of forms that can occur in the construction; and the eventual loss of independent syntactic status of the relevant morphemes. The functional processes are the idiomatic specialization of the meaning of the construction and the shift from a 'lexical' meaning to a 'grammatical' one. Grammaticalization can be illustrated by the evolution of the English motion construction *She is going to the store* to the future *She's gonna become an architect*. The phrase *is going to* is phonologically reduced to *'s gonna*, and *to* has lost its independent syntactic status. Only the contracted auxiliary is found with *gonna*. The meaning of the grammaticalized construction is specialized, and indicates future tense rather than a motion event.

The grammaticalization process can be explained as a cycle of change driven by the nature of communication. The first step in the cycle is the use of a novel, unconventionalized periphrastic expression for a particular meaning to avoid misunderstanding. The second step in the cycle is the conventionalization of that expression as the normal way to convey that meaning. The third and final step is the erosion or reduction of the that expression, phonologically and morphosyntactically.

CONCLUSION

Typological research has uncovered a wide range of empirical generalizations about grammatical structure by studying a representative sample of linguistic diversity. The universals discovered cover word and affix order, grammatical categories and relations, syntactic structures and processes of grammatical change. Explanations offered for the

universals uncovered by typology are formulated in terms of language processing, historical processes, and the coding of semantic and discourse- pragmatic concepts by grammatical categories and constructions. Although a significant body of empirical results has been produced in the past four decades, important language universals continue to be discovered.

Impairment of the ability to calculate; research into numerical impairments in patients with brain damage has revealed that human calculation abilities are composed of several distinct cognitive processes.

INTRODUCTION

What are the brain processes that underlie our fundamental numerical abilities such as calculation, estimation, and reading and writing numbers? A particularly successful line of research in answering this question has come from the study of impairments in numerical abilities as a result of brain injury.

While it was once thought that there was one calculation center in the brain that could be impaired (hence the term 'Acalculia' – the inability to calculate), it is now believed that there are many distinct numerical abilities. This change in our understanding is based on evidence that only some arithmetic abilities may be impaired as a result of brain injury, while others are spared. Individual brain-injured patients show some remarkably specific impairments. Note that these are not isolated cases: there are several documented reports of people with similar patterns of performance.

NUMERICAL IMPAIRMENTS AFTER BRAIN DAMAGE

Numeral Comprehension and Production Processes

A distinction has been drawn between the ability to perform calculations and the ability to comprehend and produce numbers. Patients such as the person known as D. R. C. reveal striking impairments after brain damage, for example the inability to remember simple arithmetic facts such as $2 \times 4 = 8$, even though other abilities such as comprehending and producing written and spoken numerals are unimpaired. This pattern implies the brain systems for comprehending and producing numerals are separate from those for calculation. Several cases with the same as well as the opposite pattern of impairment have been reported.

The ability to comprehend and produce numbers is also composed of several functional subcomponents. For example, some patients reveal highly specific impairments strictly limited to writing arabic numerals, such as writing down '100206' in response to hearing 'one hundred and twenty-six'. This example reveals that numerical processing has several distinct components, including numeral comprehension and numeral production (only production was impaired), verbal and arabic numeral processes (only arabic numeral production was impaired), and the ability to retrieve a single digit and the ability to put together several digits to make a larger number within one component (only number composition was impaired).

Dissociations between number and language processing

Skills such as reading 'number words' (e.g. 'five', 'sixty') were originally thought to be subsumed by language processes. However, at virtually all levels of processing, dissociations have been observed between numerical and linguistic abilities, suggesting a surprising degree of specificity in the human brain. There are several case reports of near-total impairment in one domain, with remarkable sparing of similar function in another. One brain-damaged patient reveals the ability to write numbers with remarkable ease, even performing complex arithmetic, while failing to be able to write simple words and even their own name. In contrast, other patients reveal word reading to be largely spared, while 'number word' reading was almost totally lost as a result of brain damage.

Localization of numeral comprehension and production processes

The brain regions involved in comprehending and producing written and spoken numerals generally

mirror those involved in written and spoken language, despite the apparent functional uniqueness of number processing. Impairment in producing spoken and written numerals (both word and arabic forms) nearly always originates from damage to left hemisphere language production areas, while impairments in comprehending spoken numerals typically results from damage localized to left hemisphere language comprehension regions.

In contrast, arabic numeral comprehension is distributed across both brain halves (or hemispheres) more than other numerical and linguistic abilities. Evidence from patients with disconnected brain hemispheres (which permits the study of each brain hemisphere acting independently) reveal excellent comprehension abilities in both hemispheres.

Impairment of Calculation

Evidence from people with brain damage, as well as those with normal and impaired development, has revealed that several independent cognitive processes are required in order to perform calculations such as 274×59. First, there is a distinction between the ability to remember simple arithmetic facts (such as $6 \times 4 = 24$), and the ability to perform calculation procedures (such as those required for carrying numbers in multidigit multiplication). Several patients with brain damage have impairments that are specific to either fact retrieval or multidigit calculation procedures, indicating that the ability to retrieve arithmetic facts and the ability to perform multidigit calculations are represented by different neural substrates.

Within the simple process of remembering arithmetic facts like $6 \times 4 = 24$, there are multiple processes involved. Brain-damaged patients have also revealed selective impairment of the ability to recognize the arithmetic operator (e.g. $+$ or $-$) and the ability to recognize the digits.

The independence of fact retrieval and numerical competence

Evidence from people with brain damage has revealed strong divisions between the ability to remember the answer to simple arithmetic problems (e.g. remembering $2 + 2 = 4$) and the ability to calculate an answer based on arithmetic principles. For example, one patient revealed a marked inability to retrieve previously known facts from memory (e.g. 8×7). However, given enough time the patient was able to answer a problem such as 8×7 by producing an elaborate strategy, such as using the answer to 8×10 and adjusting in accordance with the appropriate algebraic principle: $8 \times 7 = 8 \times 10 - 8 \times (10 - 7)$. Others patients are clearly able recall some facts, but are simply unable to use mathematical principles to derive other answers.

Representing arithmetic facts in memory

There is debate as to the form in which arithmetic facts are stored. One view is that arithmetic facts are stored in an abstract, meaning-based form that is not tied to a specific modality (e.g. spoken or written). In several cases of brain damage the patients have revealed calculation impairments that are consistent regardless of the form in which the problems are presented or answered. Perhaps more surprising is the fact that patients can successfully calculate in spite of severe impairments in representing the spoken form of numerals. For example, a patient can be presented with a problem such as '7×3', read the problem aloud as 'five times eight', say the answer as 'twenty-six' but nevertheless write the correct answer to the original problem: '21'. This pattern of performance appears incompatible with the notion that we store arithmetic facts purely in a sound-based form.

However, an alternative possibility is that arithmetic facts are stored and retrieved in a sound-based representation (like a nursery rhyme). According to this position, abstract magnitude representations are not related to arithmetic fact retrieval, but instead are involved in estimation and mathematical reasoning. Some people with brain damage are unable to determine exact arithmetic responses (e.g. $2 + 2 = 3$) but nevertheless can reject a highly implausible answer such as $2 + 2 = 9$, indicating that there is an approximate number representation which provides the meaning of numbers and may be separate from the process of retrieving exact arithmetic facts (Dehaene, 1997).

Localization of arithmetic processes

The ability to retrieve arithmetic facts from memory seems to be strongly localized to the left hemisphere. Patients with disconnected hemispheres perform at nearly normal levels in their left hemisphere, while having essentially no calculation abilities in the right hemisphere. A majority of fact-retrieval impairments are suffered as a result of left parietal lobe damage; more rarely they are the result of damaged subcortical structures and left language centers. In contrast, the ability to perform multidigit arithmetic appears to draw on the planning and working memory capacity of the frontal lobes (dorsolateral prefrontal cortex).

Exact and Approximate Calculation

Response latencies for determining the larger of two numerals (derived from healthy adults) suggests that we represent numerical quantities in terms of a magnitude representation similar to that used for light brightness, sound intensity and time duration. This magnitude representation is used to compare two or more numbers. Moyer and Landauer (1967) found that humans are faster at comparing numerals with a large difference (e.g. 1 and 9) than comparing two numerals with a small difference (e.g. 4 and 5). Further, when the differences between the numbers are equated (e.g. 2 and 3, versus 8 and 9), the smaller number pair (2 and 3) is compared more quickly than the larger number pair (8 and 9). These findings led to the conclusion that numerals are being translated into a magnitude representation along a mental number line with increasing imprecision the larger the quantity being represented (a psychophysical representation which conforms to Weber's law).

These magnitude representations are found in human adults, infants and children, and also in animals. This magnitude system allows us to meaningfully represent numerical quantities, estimate, and compare numerical quantities. It appears to be related to our representation of other magnitudes, such as time duration and distance (Whalen *et al*., 1999). A crucial challenge for the development of numerical literacy is the formation of mappings between the exact number symbol representations that are learned in school, and the approximate numerical quantity representations that are present very early in life.

There is strong evidence that parietal regions of both brain hemispheres represent numerical magnitude. Patients with disconnected hemispheres have revealed the ability to perform number comparison in either hemisphere (Dehaene, 1997). Electrical brain signatures during number comparison reveal that approximately 0.1 s, after the presentation of two numbers there is bilateral activation of the parietal lobes, and that the signature varies according to the difficulty of the comparison (Dehaene, 1996).

INTEGRATION: THE TRIPLE CODE MODEL OF NUMERICAL PROCESSING

Stanislas Dehaene and colleagues were the first researchers to provide a detailed theory of number processing that includes both the different functional components and their localization in the brain (Dehaene, 1997). According to the 'triple code' model there are three separate number systems in the brain: verbal, visual, and magnitude systems (Figure 1).

The verbal system is located in the left hemisphere adjacent to language areas, and is responsible for comprehending and producing spoken numerals, as well as storing arithmetic table facts in memory. The visual number system takes input from primary visual centers, and is used to recognize and produce numerals in written word and arabic forms. The magnitude system is located in the parietal lobe of both hemispheres, and provides the ability to estimate and compare numbers.

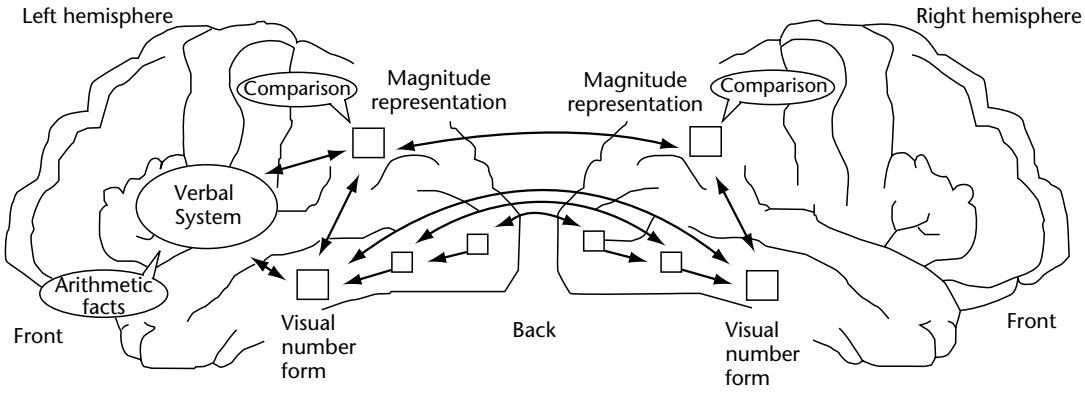

Figure 1. The triple code model of numerical processing is composed of three separate number systems. The verbal system is responsible for comprehending and producing spoken numbers, as well as storing arithmetic table facts such as $2 \times 2 = 4$ in memory. The visual system recognizes numbers written in arabic digit or written-word form. The magnitude system is responsible for deciding which of two numbers is the larger, estimating, and giving an approximate sense of how much a number represents.

According to the triple code model, even simple calculation (e.g. $8 + 9 = ?$) may require several processes and brain regions, including rote verbal memory (verbal system), elaboration (e.g. $8 + 9 = 7 + 10$, magnitude system), and strategy use (frontal lobes). This theory illustrates that even the simplest arithmetic (e.g. $2 + 2 = ?$) may require several processes and brain regions.

In summary, the cases of brain damage reported here reveal that acalculia is not a single impairment. Rather, we now know that many cognitive processes distributed across the brain together provide our arithmetic and numerical competencies. The challenge for the future will be the precise identification of the brain regions involved in arithmetic and the elucidation of how these regions work together to produce our considerable arithmetic abilities.

CONTENTS

Addictive drugs affect brain function by acting at specialized receptors for the endogenous chemical messengers that affect communication between nerve cells. The understanding of addiction depends on our understanding of these receptors, the brain circuits they are embedded in, and the functions that these circuits normally serve.

INTRODUCTION

Addiction is a term that is widely used but poorly defined, even by specialists (Maddux and Desmond, 2000). It is most commonly used to refer to compulsive drug-seeking and drug-taking behaviors, particularly when those behaviors are continued, despite repeated attempts to change, in the face of clearly harmful consequences. The term is also used increasingly to refer to compulsive eating, compulsive gambling, compulsive sexual behavior, and other compulsions that are maintained despite harmful consequences.

The 'official' definitions of the World Health Organization and the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association continue to change as theoretical, legal, and political factors influence the committees in charge. The major problem is that the distinction between 'ordinary' habits and the habits termed 'addiction' is subjective and quantitative rather than based on principle. There was considerable debate in the 1970s as to whether cocaine and nicotine are addictive; by the 1990s it was widely accepted that they are. Part of the problem was theoretical; in the 1950s and 1960s physiological dependence was taken as the defining property of addiction. However, it has become clear that cocaine and nicotine can establish habits as compulsive and harmful as those associated with heroin and alcohol, despite their lack of dramatic dependence syndromes. As the conceptual strength of dependence theory eroded (see below), addiction became defined less by physiological criteria than by subjective ones. The criteria for the terms 'compulsive' and 'harmful', central to the contemporary definition of addiction, are largely matters of personal judgment.

VIEWS OF ADDICTION

Negative Reinforcement View

Lower animals can be trained to work compulsively for intravenous injections of such drugs as cocaine, nicotine, amphetamine, and heroin; thus these drugs can serve as reinforcers, stamping in response habits much as food does for a hungry animal. Despite the fact that lower animals are not subject to the peer pressures or the stresses of poverty or city life that are often blamed for human addiction, it appears that all mammals are at risk of addiction to such drugs as cocaine and heroin. Laboratory rats and monkeys learn to self-administer intravenous heroin and will do so to the point of physical dependence; they learn to self-administer intravenous cocaine, and will do so to the point of death. Thus the observation that addictive drugs are reinforcers has become the common denominator of contemporary addiction theory.

A drug can be viewed as reinforcing because it is an extra 'treat' in one's life – like an after-dinner mint – or because it is a 'treatment' for a need state – like the aspirin that alleviates headache or the meat and potatoes that alleviate hunger and restore energy balance. The once-dominant negative reinforcement view of addiction held that drug-taking becomes compulsive when the nervous or metabolic system has adapted to continued use of a drug and the drug has become necessary for normal bodily homeostasis. The obvious and objective physiological distress of an opiate addict in the early stages of drug withdrawal – the defining evidence of physical dependence – gave rise to this view (dependence theory), which dominated

addiction theory until quite recently (Wise, 1987). In this view, initial drug-taking was attributed to peer pressure, thrill-seeking, or simple boredom, but subsequent drug-taking was seen as reflecting the need to self-medicate the withdrawal syndrome that soon developed. Because the dependence syndrome becomes stronger with continued drug use, apparent tolerance develops to dependence-producing drugs and progressively stronger doses of the drug are required to alleviate withdrawal distress. A variation of dependence theory, the self-medication hypothesis, raised the possibility that some individuals have preexisting conditions of stress or anxiety that, like withdrawal symptoms, are medicated by addictive drugs. This view was offered to explain why not all individuals who try addictive drugs come to take them compulsively. The view that all addiction reflects self-medication of preexisting distress syndromes has largely been discounted on evidence that happy, healthy animals, healthy suburban human adolescents – and, indeed, physicians – appear to be as readily addicted to cocaine or opiates as are the inner-city adolescents who were once the primary concern of addiction specialists.

Dependence theory, at least in its classic form, has largely been discredited as a sufficient explanation of addiction. Injections of heroin, the prototypical addictive drug, can establish compulsive drug-seeking and drug-taking even when it is available for too short a portion of each day to establish the classic opiate dependence syndrome (Deneau *et al*., 1969). Indeed, it has been found that the classic opiate dependence syndrome is alleviated by drug injections into the periaqueductal gray matter, whereas the reinforcing effects of the drug are caused when the drug is injected into the nearby ventral tegmental area (Bozarth and Wise, 1984). People with alcoholism often forgo alcohol during periods of maximum withdrawal distress, only to begin working for alcohol when withdrawal stress has largely subsided. Thus the notion that drug-taking is compulsive only when needed to alleviate withdrawal distress does not fit with the basic facts of even the most classic addictions: those of opiates and alcohol.

Nor does classic dependence theory fit with the facts of compulsive use of nicotine, cannabis, or cocaine. Extensive use of these drugs does not produce the classic somatic dependence syndromes seen with the opiates, barbiturates, benzodiazepines, or alcohol. The withdrawal symptoms associated with barbiturates, benzodiazepines, and alcohol are similar for all three classes of drugs, and are alleviated by drugs from any of the other classes, suggesting a common mechanism for dependence. The withdrawal symptoms associated with opiates are similar, and are partially alleviated by these agents and thus at least partially mediated by the same mechanisms. However, withdrawal from cocaine, amphetamine, nicotine or cannabis produces mild symptoms by comparison, and in the case of cocaine and amphetamine, the somatic withdrawal symptoms are the converse of those of opiates. The general mood associated with opiate withdrawal is hyperexcitability and irritability, whereas cocaine or amphetamine withdrawal is associated with hypoexcitability and depression.

Thus, although there is a withdrawal syndrome associated with termination of regular use of many drugs, there is no common somatic withdrawal syndrome that can explain the compulsive use of the full range of addictive drugs. For these reasons, classic dependence theory is no longer accepted as an explanation or a defining property of addiction (Wise, 1987). As discussed below, however, a variant of negative reinforcement theory remains influential.

Positive Reinforcement View

An alternative view of addiction holds that the primary motivation for drug-taking is the seeking of euphoria or a drug 'high' (McAuliffe and Gordon, 1974). Rather than simply returning the addicted individual to a normal feeling state, this view holds that the drug is taken because it produces a better-than-normal feeling state. This view is strengthened by the fact that humans and lower animals will work for electrical stimulation of certain brain regions, stimulation that brings a state of pleasure which satisfies no biological need and was never experienced in mammalian evolutionary history. The view that addictive drugs produce elevated states of pleasure also explains, as dependence theory does not, why addictive drugs are strongly habit-forming prior to development of dependence, and why there is such a strong probability of relapse after detoxification.

The negative and the positive reinforcement views are not mutually exclusive. The alleviation of withdrawal distress certainly brings pleasure, and it is difficult to imagine that a larger dose than is needed to alleviate pain would not be desirable to someone who is self-medicating. This would explain the fact that people given methadone to medicate withdrawal distress still desire and often use street heroin when it is available. In the case of heroin addiction, it is reported that

initial drug-taking results in drug euphoria, but that as chronic use progresses drug euphoria and positive reinforcement become progressively weaker while withdrawal-associated dysphoria and negative reinforcement become progressively more dominant factors in the maintenance of compulsive drug-seeking.

ADDICTION AND THE MESOLIMBIC DOPAMINE SYSTEM

The 1970s, when injected amphetamine and intranasal cocaine were becoming increasingly popular, brought the positive reinforcement view to the forefront of addiction theory. Cocaine users reported that cocaine caused euphoria and that no great distress was felt when the available supply of the drug had been used up. Nonetheless, the drug was taken compulsively for as long as it was available. It was widely accepted that this drug, when used by normal and successful individuals, was taken to 'get high' and not to self-medicate a withdrawal state or any preexisting abnormal distress state. As cocaine came to be taken by injection or by smoking freebase or 'crack' cocaine, it became much more obvious that this drug was strongly addictive. While many people became addicted to intranasal cocaine, intravenous cocaine or smoked freebase caused addiction much more rapidly, and 'graduation' from nasal use to smoking or injecting became a frequent consequence. Rats and monkeys given unlimited access to intravenous cocaine will take the drug to the point of death, losing a third or more of their body weight with a week or two of drug self-administration, punctuated by minimal sleep and food intake. This weight loss and sleep disturbance are not a withdrawal syndrome, however; they are exacerbated rather than alleviated by continued intoxication.

Cocaine is an inhibitor of monoamine neurotransmitter reuptake. The monoamine neurotransmitters are noradrenaline (norepinephrine), dopamine and serotonin; cocaine shares with amphetamine the ability to elevate the concentration of each of these substances in the junctions between communicating neurons. Whereas amphetamine causes the direct release of these transmitters, cocaine blocks their synaptic inactivation by blocking their reuptake by the cells that released them (thus prolonging and elevating their actions). The drug-induced elevation of extracellular dopamine levels accounts for the habit-forming effects of the cocaine and amphetamine; drugs that block the effects of dopamine block the ability of cocaine or amphetamine to establish drug-seeking response habits or preferences for the places in the environment where the drug has been experienced. Lesions of the mesolimbic branch of the forebrain dopamine projections also block the reinforcing effects of these drugs. Lesions or pharmacological blockade of the noradrenergic or serotonergic systems have no such effects. Dopamine-blocking drugs also eliminate the ability of normally rewarding brain stimulation to establish or maintain intracranial self-stimulation. Thus cocaine and amphetamine are habit-forming because they activate the reward system that was once termed a 'pleasure center in the brain' (see Wise and Bozarth, 1987).

Food, sex, and rewarding brain stimulation, as well as the addictive drugs amphetamine, cocaine, morphine, heroin, nicotine, cannabis, and alcohol, each elevate brain dopamine levels in the nucleus accumbens, where the mesolimbic dopamine system has its main termination. When cocaine, amphetamine, or heroin is self-administered, dopamine levels are elevated severalfold; animals allowed to self-administer these drugs do so whenever their dopamine levels fall to about 200% of normal. Food for hungry animals and sex for experienced males cause dopamine levels to increase, but the increases tend to peak at 150–200% of normal. Thus animals self-administering cocaine, amphetamine or heroin, at least, maintain their dopamine levels at higher values than are usually produced by the normal pleasures of life (Wise, 1998).

SITES OF THE REINFORCING ACTIONS OF ADDICTIVE DRUGS

The major classes of addictive drug act at receptors that are the normal targets of endogenous neurotransmitters or neuromodulators. Nicotine acts at the nicotinic class of receptors for the neurotransmitter acetylcholine. Cannabis acts at the receptors for the neuromodulator anandamide. Phencyclidine acts at the *N*-methyl-D-aspartate (NMDA) class of glutamate receptor. Opiates act at mu, delta, and kappa opioid receptors, receptors for the endogenous opioids enkephalin, β-endorphin, dynorphin, and endomorphin. Cocaine and amphetamine act at transporters for dopamine, noradrenaline, and serotonin, elevating the extracellular levels of these transmitters which then act at their own endogenous receptors.

Each of these drugs acts in multiple anatomical pathways, and thus is involved in multiple physiological functions. The sites of reinforcing actions of some addicting drugs have been localized, and each thus far identified is associated with the mesolimbic dopamine system or with the cells it targets

in the nucleus accumbens. Nicotine's reinforcing action involves nicotinic cholinergic receptors localized to the mesolimbic dopamine neurons themselves, stimulating these cells to fire and to release dopamine. Morphine and heroin have reinforcing actions on cells containing γ-aminobutyric acid (GABA) that are found near to the dopamine cells and that normally inhibit dopaminergic cell firing. The opiates inhibit the GABA-containing cells, thereby disinhibiting the dopaminergic cells and increasing their firing rates. The opiates also inhibit, as does dopamine, the medium-sized spiny output neurons of nucleus accumbens.

The psychomotor stimulants amphetamine and cocaine have their reinforcing actions at the dopamine transporters in the nucleus accumbens. Amphetamine reverses the transporter causing it to expel rather than take up dopamine, and cocaine blocks the transporter, blocking the reuptake of dopamine released from cell firing. Dopamine, in turn, acts at its own receptors on nucleus accumbens neurons. Phencyclidine blocks NMDA-type receptors for the excitatory amino acid transmitter glutamate, thus reducing the excitatory input to the medium-sized spiny output neurons of nucleus accumbens. Thus the direct or indirect inhibition of medium spiny neuron output from nucleus accumbens appears to be the critical common consequence for the reinforcing actions of each of these addictive drugs. Phencyclidine is also habit-forming when injected into the medial prefrontal cortex. Again, the drug's ability to block NMDA receptors accounts for its rewarding action, but it is not yet known which population of NMDA receptors or which type of cortical neuron is involved (Wise, 1998).

The sites of reinforcing actions of cannabis, alcohol, barbiturates, benzodiazepines, and caffeine remain to be identified. Some but not all of these are expected to prove to have rewarding actions involving the mesolimbic dopamine system or its associated circuitry.

CONTEMPORARY THEORIES OF ADDICTION

Classic dependence theory, attributing the compulsive dimension of addiction to the need to alleviate the somatic, largely autonomic, symptoms of withdrawal distress, has been described above. While the conscious desire to alleviate somatic withdrawal distress doubtless contributes to drug-taking in people who are addicted, it is no longer seen as the defining property of addiction. Contemporary addiction theories stress the actions of addictive drugs in the reward circuitry of the brain: the circuitry that is activated by the natural pleasures of life as well as by the laboratory rewards of brain stimulation and addictive drugs.

The psychomotor stimulant theory of addiction (Wise and Bozarth, 1987) suggests that the dominant sedative effect of a number of addictive drugs is unrelated to the addictive liability of these drugs. Rather, it postulates that even the addictive depressants and sedatives (e.g. opiates, alcohol, cannabis) activate the brain circuitry of arousal and forward locomotion. Forward locomotion – the central behavioral component of approach behavior – has been postulated to be the unconditioned response to all positive reinforcers. In the cases of amphetamine and cocaine, the prototypic psychomotor stimulants, drug-induced locomotion and stereotyped orofacial movements associated with activation of the mesolimbic and adjacent nigrostriatal dopamine systems dominate the behavior of intoxicated animals. With opiates and alcohol this action is not obvious because it is masked by the dominant depressive actions of strong doses of these drugs. These depressants activate the mesolimbic dopamine system, however; they cause locomotion and act as stimulants at low doses or in the early stages of intoxication, when only low levels of the drug have reached the brain. The psychomotor stimulant theory attributes the habit-forming effects of addictive drugs to their ability to activate the brain mechanisms of reward and approach behaviors, and attributes the high-dose depressant effects of the drugs to actions in other parts of the brain. The psychomotor stimulant theory fits well with current data on cocaine, amphetamine, opiates, and nicotine. While alcohol and cannabis each activates the postulated reward circuitry, the sites and circuitry through which they do so are not yet known. Whether barbiturates or benzodiazepines activate this circuitry is controversial, and evidence suggests that the habit-forming effects of caffeine are likely to involve an independent mechanism. Thus the psychomotor stimulant theory offers a unified theory for some, but probably not all, addictive substances.

The psychomotor stimulant theory also introduced the notion of 'incentive motivation' to addiction theory. Incentive motivation is a construct from learning theory, designed to deal with the circularity of reinforcement theory. A reinforcer is an object or event which, when made contingent upon a given act by a given animal, increases the probability of recurrence of that act. To suggest that reinforcement explains the act it is defined by is circular; it implies the teleological view that the

cause of an event can follow the event. It is the reinforcement history, not the coming reinforcer, that explains the probability of the act in question. Incentive motivational theory was an attempt to identify the precipitating precursor of the habitual act. It stressed the role of incentives that are present prior to the act – incentives that are attractive because of their past association with the drug – in eliciting and guiding the act. Incentive motivation is the principle by which addictive drugs are seen to establish conditioned place preferences: learned preferences for the portions of the environment where the drug has previously been experienced.

Advocates of the psychomotor stimulant theory pointed out – largely on the basis of observations from brain stimulation reward studies – that reinforcers not only have the ability to increase the probability of recurrence of acts that precede them, but that they (and their associated environmental predictors) have the ability to 'prime' a response habit, energizing the animal and focusing attention on the previously established habit. This proactive feature of reinforcers is the cornerstone of animal models of relapse to addiction. Because it encompasses the ability of a reward to precipitate anticipatory excitement and behavioral arousal as well as to consolidate the memory trace for recent acts, the psychomotor stimulant theory addresses drug reward (embracing both the proactive and the retroactive processes) rather than simply drug reinforcement.

Opponent process theory (Solomon and Corbit, 1973) is a negative reinforcement theory, a general view that subsumes classic dependence theory. However, whereas classic dependence theory attributed compulsion to the need to medicate somatic withdrawal distress involving the autonomic nervous system, contemporary opponent process theories (Dackis and Gold, 1985; Koob and Bloom, 1988) attribute the compulsive nature of addiction to neuroadaptations in the reward circuitry discussed above. The core postulate of classic opponent process theory is that homeostatic controls adjust in compensation for chronic intoxication, opposing the direct effects of the drug and desensitizing the nervous system to that drug. Such opponent processes are found in all the targets of a given drug, including the thermoregulatory system and neurotransmitter receptors in the gut. It is the unopposed effect of the postulated opponent-process neuroadaptations that explains the fact that the withdrawal symptoms associated with a given drug are the opposite of the acute effects of the drug. Thus, while one of the direct effects of opiates is to constrict the intestine and cause constipation, the compensatory relaxation, which is masked so long as the drug continues to oppose it, results in diarrhea when the drug wears off.

The contemporary versions of opponent process theory hold that the reward pathway itself becomes desensitized by chronic drug intoxication, and becomes progressively more difficult to activate by both normal rewards and by the addictive drug itself. This results in loss of responsiveness to (and, as a consequence, loss of interest in) the normal pleasures of life. It is also seen to result in the need to escalate the dosage in order to achieve the expected drug effect. Opponent process theory offers an explanation of tolerance and dependence, not only in the reward pathway but also in the autonomic nervous system and all the systems activated by a given drug. An early version of this theory that focused on the reward system was the dopamine depletion hypothesis (Dackis and Gold, 1985), which held that one consequence of such opponent processes is a decrease in extracellular levels of mesolimbic dopamine during psychomotor stimulant withdrawal. While there remains controversy as to its magnitude and significance, depletion of extracellular dopamine has been reported in animals withdrawn from cocaine, amphetamine, and opiates. Moreover, there is now evidence of development of multiple drug-induced opponent processes in the reward pathway.

First, animals undergoing withdrawal from amphetamine or cocaine have elevated brain stimulation reward thresholds; that is, it takes stronger stimulation of the reward system to motivate an animal undergoing withdrawal from psychomotor stimulants. While there is controversy as to whether there is tolerance or its opposite (sensitization) to the reward-specific effects of addictive drugs, under some circumstances animals have been shown to escalate drug intake as drug exposure is extended. Also, there is now considerable evidence for intracellular neuroadaptations within the dopamine system and within its target neurons in the nucleus accumbens following repeated cocaine and morphine treatments (Nestler and Aghajanian, 1997). Some of these neuroadaptations can be mimicked experimentally, and they reduce the effectiveness of cocaine in producing conditioned place preferences. Thus it is clear that opponent processes are called into play by chronic use of addictive drugs. It remains to be determined how important a role these neuroadaptations have in compulsive drug-taking. The neuroadaptations are clearly consequences of chronic drug intake, but it is not clear to what extent they become causes of subsequent intake.

Incentive salience theory (Robinson and Berridge, 1993), like contemporary opponent process theory, builds on the psychomotor stimulant theory, attributing the habit-forming actions of drugs of abuse to their ability to activate the reward circuitry associated with the mesolimbic dopamine system. Incentive salience theory, however, differs from opponent process theory in that it invokes proponent processes to explain the compulsive nature of addiction. It is well known that the psychomotor stimulant effects of amphetamine, cocaine, and opiates become progressively stronger with repeated intermittent intoxication. The incentive salience theory postulates that progressively increasing sensitivity to the drug gives drug-associated incentives progressively more control over behavior, and that it is this sensitization that makes drug-seeking compulsive. This sensitization has several known correlates, all involving the mesolimbic dopamine system and its associated afferents and efferents. Again, however, it is not yet clear what causal role psychomotor sensitization plays in the increasingly compulsive drug-seeking habits of addiction.

A major issue highlighted by incentive salience theory is the relative importance of the reinforcing effects of the drug (effects of the drug after it has been taken) and incentive motivational effects of the drug (effects related to the drug history and environmental associations with that history). Incentive salience theory calls attention to this underappreciated incentive motivational postulate of traditional learning theory by relating the specialist terms 'incentive motivation' and 'reinforcement' to their subjective correlates 'wanting' and 'liking'. One wants the drug prior to having it: this is the cognitive correlate of incentive motivation and is presumably elicited by drug-associated stimuli that are present before the drug is. One likes the drug after having it: this is the presumed cognitive correlate of the reinforcement that stamps in the stimulus–stimulus associations between the drug actions and the environmental stimuli in the situation in which the drug is encountered. Opponents of this view point out that reinforcing events need not involve conscious pleasure: monkeys have been trained to lever-press for painful footshock, and we can learn to drink initially noxious solutions if they contain alcohol.

CONCLUSION

Much has been learned – though much remains to be learned – about the neural basis of addiction. Many addictions result from the ability of the addictive drug to activate primitive brain circuitry involved in the formation of simple and normal response habits such as feeding and sexual activity. Most addictive drugs activate this system and do so more strongly than do the normal pleasures of life. The activation of this system by addictive drugs seems to be associated, at least initially, with pleasure, though the nature of the pleasure is vaguely and variously described by human subjects.

Repeated drug use leads to adaptations within the central and peripheral nervous systems, and these adaptations are usually opposite in direction to the acute effects of the drugs that produce them. When a drug is taken often enough to build up significant neuroadaptations, withdrawal symptoms opposite to the effect of the drug are seen when drug use is terminated. Such withdrawal symptoms can be aversive, and the self-medication of these withdrawal symptoms is reported to be a significant factor in the inability of people with addiction to simply discontinue the use of opiates and barbiturates. Against the claim that self-medication is a sufficient explanation of continued heroin use, however, is the fact that people given methadone to medicate withdrawal distress often continue to use street heroin when it is readily available. Alleviation of withdrawal symptoms seems to play a minimal part in other addictions, and compulsive drug-seeking can be established with some drug regimens that cause minimal signs of addiction.

If repeated use is sufficiently intermittent, the stimulant effects of addictive drugs can become progressively stronger. It has been suggested that this might explain the progressively stronger control of behavior by addictive drugs. Drug tolerance and drug sensitization have each been demonstrated, but the optimal conditions for the two are different. Tolerance most clearly results from chronic intoxication, whereas sensitization results from intermittent intoxication. Since addiction involves periods of prolonged intoxication and also periods of intermittent drug withdrawal, each factor seems likely to play some part in addiction. Pavlovian conditioning – association of the drug with the environment in which the drug is experienced – is known to contribute both to tolerance and to sensitization, and the degree to which each results from simple pharmacological exposure or rather to the interaction of the drug with the environment remains to be clarified.

It is widely assumed that stressful life experiences predispose some individuals to addiction, and the role of stress in addiction is a topic of

great contemporary interest. Some forms of stress can clearly reinstate drug-taking behavior in animal models, and a good deal of attention is turning from the factors that establish initial drug habits to the factors that can reinstate these habits once they have been broken. A priming 'taste' of the drug itself (such as just one drink or just one cigarette) is one of the strongest reinstating stimuli, and some stress stimuli are comparably effective. The mechanisms of interaction between stress systems and reward systems have not yet been identified.

The cognitive correlates of the various stages of addiction are complex and not well defined or identified. Pleasure, euphoria, craving, stress, wanting, liking, and satiety are terms frequently attributed to phases of addiction, but it remains to be determined which of these relate to causal factors and which to after-the-fact correlates.

D C Blanchard, University of Hawaii, Honolulu, Hawaii, USA

CONTENTS

Aggression and defense are important behavioral strategies throughout the animal kingdom, and are linked to activation of brain areas in the prefrontal cortex, limbic system, hypothalamus, and periaqueductal gray matter. While substantial progress has been made toward understanding the neural and neurotransmitter systems underlying defense, and the neurotransmitter and hormonal systems involved in aggression, the relationship between aggression and defense systems is poorly understood, as are the applicability of these findings to human aggression and violence.

INTRODUCTION

The medical, social, economic, and societal problems associated with human aggressive and defensive behaviors often create an incorrect view of these as essentially maladaptive or pathological. A comparative approach to analysis of aggression and defense is necessary to understand that these represent crucial life-crisis management strategies for all mammals and most inframammalian species. Research on situations eliciting aggression and defense and the hormonal mechanisms modulating them has provided information about the evolutionary functions of these biobehavioral systems, while work on their neural systems and pharmacological control may provide links to some specific psychopathological conditions.

In humans and in other mammalian species, agonistic interactions between members of the same species (conspecific) almost always consist of some mixture of aggressive and defensive behaviors. Both combatants are likely to be aggressive, as a nonaggressive participant could usually preclude or conclude the encounter by leaving. However, fights also typically involve pain and sometimes injury: that nonhuman animals always settle conspecific disputes by nonpainful or noninjurious displays is a myth. Thus self-defense is also typical of one or both participants in real-world encounters. This situation creates difficulties in making clear differentiations between aggression and defense, and has substantially hindered analysis of these two different patterns, and of their evolutionary functions.

STUDIES OF AGGRESSION AND DEFENSE IN ANIMALS

Laboratory studies can polarize aggressive and defensive tendencies of two combatants, making one extremely aggressive and the other exclusively defensive, in order to make the two behavior patterns easier to analyze. While such studies are not adequate for determining the range of conditions that will elicit aggression or defense, they do provide information on some focal antecedents for each of them, and enable relatively uncontaminated descriptions of the actual behaviors involved in the two biobehavioral systems. When findings from such laboratory research (typically involving rodents) are combined with ethological studies on a much broader range of mammalian and inframammalian species in their own natural habitats, a consistent view of the adaptive value of both aggression and defense begins to emerge.

CAUSES OF AGGRESSION AND DEFENSE

Offensive aggression is coming to be conceptualized as a behavior pattern elicited in the context of resource disputes, particularly in response to challenge (generally but not always from a member of the same species) to the individual's control over these resources or rights. While aggression may be adaptive in reducing conspecific challenge over crucial elements such as food, water, access to nesting sites or materials, and the like, in an evolutionary context a particularly valuable resource is access to a breeding partner. Thus male on male aggression is especially common during the breeding season, or in the presence of reproductive females. Similarly, for females offspring are a particularly important evolutionary resource, and many instances of female aggression occur in a maternal context. The common tendency to refer to such situations as involving 'defense' of mates, offspring or other resources produces an additional, but purely semantic, problem in conceptualizing the difference between the biobehavioral systems for aggression and defense. The defense system is a response to threat to bodily integrity. Aggression is a response to challenge to the individual's control of a resource. It does not aim at 'defending' the integrity of the resource, but in promoting the aggressor's claim to that resource. Successful aggression is thus an important means of social control.

Most mammalian species have evolved mechanisms that reduce or limit intraspecies aggression by limiting the circumstances under which one animal is likely to challenge another for crucial resources. Territoriality and dominance relationships are two such mechanisms. The first operates through avoidance by one animal or group of the territory of another animal or group, while the second involves recognition by animals within a group of the relative ranks of other animals, such that subordinates typically do not challenge those higher in rank to themselves. However, territorial encroachment and rank challenges do occur, and for most species acquisition of territory and rise in rank depend on successful aggression by the protagonist and sometimes its allies.

In contrast to these rather complex causes of aggression, defensive behaviors occur in response to bodily threat, from predators or from conspecific individuals. Antipredator situations provide an opportunity to describe and analyze these behaviors in situations that do not contain elements of aggression: predation is not aggression. Defensive behaviors represent attempts to avoid, evade, escape, conceal, bluff, threaten or otherwise neutralize threat from dangerous stimuli, thereby enhancing the animal's likelihood of coping successfully with the threat.

FACTORS CONTROLLING THE SUCCESS OF AGGRESSION AND DEFENSE

Successful aggression is adaptive, but aggression itself can be dangerous. This puts a premium on the ability of animals including humans to evaluate the probability of success prior to entering into an aggressive encounter. The individual's own history of victory or defeat is a particularly important determinant of future success in aggression, and a strong predictor of aggressive behavior. Members of most mammalian (and many other) species also pay particular attention to features of a potential opponent that indicate size, strength, health, and fighting ability, before entering a fight. Thus hyperexpression of such features becomes adaptive in discouraging challengers, a situation that has resulted in the evolution of ever-larger bodies (particularly for males of polygynous species, a factor in sexual dimorphism); more impressive weapon systems such as antlers; and enhancement of other body features that may be the focus of comparison, such as the mouth of the hippopotamus. Particular postures and movements that optimally present these features, sometimes eliciting retreat from a challenger, constitute many of the aggressive displays that have wrongly been believed to replace actual agonistic behavior in nonhuman animals.

Age and fighting ability are also factors in the success of aggression, and these are often evaluated in fights among pubertal and young adult males. However, play fights in prepubertal mammals appear to bear little direct relationship to adult fighting between the same animals: prepubertal males who later become dominant are less likely to initiate play fights than are those who later become subordinates, and the contact sites and behavior patterns seen in the fights of prepubertal mammals appear to be more similar to adult sexual behavior than to adult agonistic behaviors.

Successful defensive behaviors must counter the attacks of predators in addition to conspecific threats, and must be effective in a variety of habitats and situations. Thus few higher animals rely on a single type of defensive behavior. Most mammals appear to have a relatively consistent group of about half a dozen focal forms of defensive

behavior, with some of these emphasized or rarely used in a particular species, but all represented to some degree. Given this range of defensive behavior, the major single factor in the success of defense is how well the particular defensive behavior fits the situation, i.e. the specific threat stimulus and features of the environment relevant to the success of a particular defense. Thus, although the success of both aggression and defense relies on utilization of information about both the opponent and the situation, the topography or form of defensive behavior is geared more to features of the environment (such as presence of an escape route, location of places of safety, and distance between predator and self), while the form of aggression largely reflects features and behaviors of the opponent.

AGGRESSION AND DEFENSE IN THE RAT

Conspecific aggressive and defensive behaviors have been described in greatest detail in laboratory rodents, particularly the rat. Conspecific attack in rats involves elements of approach and investigation, typically focused on olfactory assessment of the sex, age, and breeding condition of the opponent. The attack itself involves attempts to bite the back and flanks of the opponent, as well as a number of maneuvers that enable the attacker to reach this location. Conspecific defense in rats also relies heavily on the targeting of the attack towards the back of the opponent, in that if the defender can remove this site from its attacker, it is relatively safe from being bitten. One general method of removing a target site for attack is flight, for which the countering attack tactic is chasing. The defensive animal may also adopt an upright posture facing the attacker; this keeps its back – the attacker's target – out of reach. An experienced defender can also pivot smoothly to maintain frontal orientation if the attacker attempts to circle around to the defender's back, utilizing a lateral attack sequence. This consists of the attacker arching its back and moving laterally toward the upright defender, sometimes pushing it off balance or lunging in a forward circular motion toward the defender's back and flanks. In an even higher-level defense tactic the rat lies on its back, again concealing the target of conspecific attack. However, the attacker typically stands over the supine defender, sometimes pushing at it to induce movement and reveal the back target.

These defense tactics are adaptive because laboratory rats, as well as wild *Rattus norvegicus* and *R. rattus*, are reluctant to bite targets other than the back of a conspecific opponent. In particular they fail to bite an opponent's ventrum, even if this is the only body area exposed. While the strength of this prohibition on biting particular targets may vary somewhat from one species to another, some targeting of bites and blows appears to be common across mammalian species. The specific target of attack is typically one in which there is relatively little chance of lethal damage. Thus such bites or blows may produce pain, discouraging further resource or status challenge from the other, without killing a conspecific that may be a relative, or part of the attacker's social group. Some dedicated structures, such as antlers, provide weapons that are used in offensive attack, and also serve as the target of this attack. Typically such structures are not used in defense against predators.

Antipredator defensive behaviors are much less dependent on defense of particular body structures, since the attacks of predators are typically aimed at vulnerable body sites rather than away from them. Thus while defensive tactics like flight remain adaptive, some defenses that are effective against conspecifics (such as lying on the back) would not be useful against a predator. For most mammals, flight is a dominant antipredator defense when an escape route is available or a place of safety within reach. Immobility, often involving specific freezing postures, is also a common defensive behavior. This may be adaptive by helping the prey animal to avoid detection or because some predators selectively attack fleeing prey. In close encounters, defensive threat followed by defensive attack may be highly effective in discouraging the attacker: typically, an injured predator is at a severe disadvantage in future hunts. When there is a potential rather than a clear and obvious threat (e.g. novel stimuli or predator odors) defenses such as flight and defensive threat or attack may be useless or even counterproductive. To such stimuli the most prominent defensive behavior is risk assessment, a highly motivated information-gathering pattern involving orientation to the potential threat source, sensory (visual, auditory, olfactory) scanning, and approach with a low-back posture that minimizes detection of the defensive animal while allowing it to investigate the potential threat source.

NEURAL MECHANISMS OF DEFENSIVE BEHAVIOR

Neural systems underlying defensive behaviors are the focus of intense research interest. They have been investigated using a variety of research

paradigms, including evaluation of behavioral effects of lesions or stimulation of particular brain sites, and analysis of regional intermediate early gene expression during confrontation with a threat source. These studies, in conjunction with tract tracing from cells in sites thus implicated, has yielded a detailed, and relatively consistent, view of the nervous control of particular defensive behaviors.

Studies of neuronal activation in association with aggression or defense have often used regional expression of c-*fos* messenger ribonucleic acid (mRNA) as a marker of activity in specific brain sites. A number of such studies, using a variety of different species (rat, mouse, hamster) and both conspecific defeat and predator exposure paradigms, have provided relatively consistent findings. Defensiveness is associated with activity in several limbic areas (e.g. amygdala, lateral septum), and in a ventral zone from the preoptic area through the hypothalamus to the midbrain periaqueductal gray (PAG) matter. Fos expression in both the septum and the central nucleus of the amygdala (CeA) following confrontation with a threat source (conspecific defeat) appears to vary from the initial to later exposures. Fos expression provides a good, though not necessarily comprehensive, overview of brain areas that respond to particular experiences or activities. However, Fos studies are somewhat difficult to interpret as they do not differentiate between areas that are directly involved in a particular function and those that respond to that function or to nonspecific events such as arousal, motor activity, or autonomic changes that may be associated with it. In addition, Fos does not indicate the organization of the systems that may be involved. Stimulation, lesion, and tract-tracing studies add significantly to systems research on defense, and such studies have shown that several of the areas in which Fos expression is seen during defense are indeed important in the elicitation and maintenance of defensiveness.

Stimulation of the PAG can elicit flight, freezing, and defensive threat responses in both rats and cats. These different responses are organized in terms of longitudinally coursing columns within the PAG. At more rostral levels, dorsal stimulation tends to elicit defensive vocalizations, while at more caudal levels such stimulation elicits flight and sometimes freezing. Stimulation of the ventrolateral column, in its caudal aspects, elicits an immobility response that has been variously interpreted as pain-related quiescence or as freezing. However, as lesions of this area sharply reduce kyphosis – an upright, crouched, posture shown by rat mothers during nursing – it is also possible that this area of the PAG is broadly involved with the maintenance of all active immobile reactions rather than with defense-related immobility only, or with specific types of defense-related immobility.

The dorsal premamillary nucleus of the hypothalamus has also received particular attention in a defense context. Lesions in this area appear to virtually abolish flight and freezing, and retrograde tracing studies indicate that it receives direct afferent connections from many of the telencephalic and diencephalic structures that show Fos expression after exposure to a predator. Other well-developed research efforts have been directed toward analysis of neural systems involved in specific defense-related behaviors. Siegel and his colleagues used combinations of lesions, stimulation, and local and systemic drug administration to characterize the control of defensive threat vocalizations (hissing) in the cat. They found that a number of sites in both limbic areas and in the ventral zone from preoptic area to PAG act to initiate and modulate this component of defense. Several such neurotransmitter-specific modulatory systems have been described, some involving direct connections from several areas of the amygdala to the PAG, while others consist of direct and indirect hypothalamic–PAG connections.

Similarly, Davis and his colleagues have concentrated on systems involved in potentiation of the startle reflex. Although the basic startle reflex is a simple three-synapse brain stem–spinal cord circuit, the amplitude of startle can be increased by conditioned cues (stimuli previously associated with shock) or unconditioned defense-enhancing manipulations such as testing in a brightly lit chamber. A particularly interesting finding is that the systems involved in conditioned and unconditioned potentiation of startle may be quite different: the CeA is strongly involved in conditioned potentiation, but is not crucial for unconditioned potentiation of startle, while damage to the bed nucleus of the stria terminalis abolishes unconditioned but not conditioned potentiation. These findings are consonant with the central role of the CeA in conditioning of freezing to shock cues, and with findings that CeA Fos expression changes with repeated threat exposure – all of which suggest that this nucleus may be more involved in plastic processes (learning, habituation) than in defense *per se*.

NEURAL MECHANISMS OF AGGRESSIVE BEHAVIOR

Research into the physiological mechanisms of aggression has tended to look at the pharmacological control of aggression rather than the specific neural systems involved in this behavior. Analysis of aggressive behaviors is additionally complicated by the fact that attack behaviors may involve offensive aggression, defensive attack, or predation; these may be difficult to differentiate under standard laboratory conditions. However, research programs have focused on sites in the hypothalamic area, with some differences in specific sites for different species. For example, in the hamster, vasopressin manipulations in the nucleus circularis, an area rich in vasopressin-expressing neurons, may profoundly affect aggressive behavior. However, in the rat, the nucleus circularis does not contain vasopressin-expressing neurons, suggesting that aggression changes associated with manipulations in this area must involve a different mechanism of action. In a number of hypothalamic sites, including the nucleus circularis (hamster), the intermediate hypothalamic area and part of the ventromedial nucleus (rat), electrical stimulation elicits an attack response, while lesions may reduce offensive attack. Neuronal tracing studies indicate connections to a number of areas similar to those implicated in defense, such as the prefrontal cortex, amygdala, septum and the PAG. Because stimulation and lesioning of some of these structures may impact both aggressive and defensive behaviors, it is not clear that the changes in one set of behaviors are independent of effects on the other. Similarly, because of the reliance of both aggressive behavior and sexual and maternal behaviors on pheromones, areas such as the medial nucleus of the amygdala that are strongly involved in the accessory olfactory system may influence both types of behavior. However, aggressive, defensive and reproductive behaviors appear to be well differentiated at the level of the hypothalamus. In addition, there are a number of hypothalamic sites in which stimulation elicits grooming, suggesting the existence of a number of roughly parallel systems in this area that are strongly involved in species-typical behaviors of great evolutionary importance.

Serotonin (5-hydroxytryptamine, 5-HT) is perhaps the most frequently investigated neurotransmitter in terms of effects on aggression. Deficiencies in serotonin have been implicated as potentially important in impulsivity and aggression in species ranging from lower mammals to humans. In the latter species, low levels of a serotonin metabolite in cerebrospinal fluid may signal reduced serotonin activity in the brain, which, interacting with other genetic and environmental factors, may be associated with instances of impulsive violence, or other impulsive actions. Two specific serotonin receptor subtypes, 5-HT_{1A} and 5-HT_{1B}, are of particular interest as the principal targets of a class of 'serenic' drugs that have proved to be extremely effective in reducing offensive aggression in a variety of animal models.

Vasopressin activity in the hypothalamus and related structures is associated with aggression enhancement, and serotonin may act at the level of the vasopressin receptor to modulate this behavior. In hamsters, pretreatment with fluoxetine, a serotonin reuptake inhibitor, increases serotonin levels in the anterior hypothalamus (an area known to influence aggressive behavior) and inhibits aggression. Systemic fluoxetine also reduces the increase in aggression seen when vasopressin is injected into the ventrolateral hypothalamus. This area contains both the 5-HT_{1A} and 5-HT_{1B} receptor subtypes, which have been particularly implicated in the control of aggression in animal models.

HORMONAL MECHANISMS OF AGGRESSION AND DEFENSE

The evidence for a relationship between hormones and aggressive behavior predates science: castration of male animals to reduce their aggressiveness has been common throughout human history. Testosterone generally enhances aggression across a range of mammalian species, including humans, but the relationship is highly variable, and may be more specific to times or situations involving reproductive behaviors, or dominance and territoriality related to reproductive advantage. One mechanism by which testosterone, like serotonin, may influence aggression is through hypothalamic vasopressin receptors. In the ventrolateral hypothalamus of male hamsters, vasopressin receptor binding disappears after castration, but can be maintained by treatment with testosterone. Findings that microinjections of vasopressin in this area enhance aggression in untreated male hamsters but fail to do so in castrates suggest that testosterone maintenance is important for the functioning of vasopressin receptors in this area.

Attempts to understand the mechanisms of the relationship between testosterone and aggression have emphasized that both testosterone and its metabolites may influence relevant neural systems and that the direction of effect may be different for some of these. In the brain, testosterone may

be aromatized to estradiol, or metabolized by 5α-reductase to dihydrotestosterone. The functional pathways underlying male aggression may be modulated by either of these metabolites, being either estrogen-sensitive or androgen-sensitive, at various points. A finding of particular interest, in view of the centrality of 5-HT_{1A} and 5-HT_{1B} receptors in reducing aggression, is that in male mice treated with androgens, stimulation of either 5-HT_{1A} or 5-HT_{1B} receptors or combinations thereof reduces aggression. However, in estrogen-treated males, only combined, high-dose, 5-HT_{1A} plus 5-HT_{1B} receptor activation was effective. In animals given testosterone, which metabolizes into both androgens and estrogens, aggression fails to decrease with low doses of 5-HT_{1A} or 5-HT_{1B} alone or in combination, suggesting that estrogens may protect the neural systems involved in aggression from suppression by serotonin receptor activation. These relationships may also reflect action at particular sites along the brain pathways serving aggression, in that estrogen or androgen treatments differentially modulate effects of microinjections of 5-HT_{1A} or 5-HT_{1B} agonists into the lateral septum, or the medial preoptic nucleus of the hypothalamus. Such findings suggest the possibility of complex modulation of aggressive behavior, or of aggressive behavior as elicited in different sorts of situations, by reproduction-relevant steroids. These interactions are also interesting in the context of widespread environmental or food contamination by estrogenic chemicals.

Anabolic steroids are not uncommonly used illegally by athletes to enhance the development of muscle mass. Reports of enhanced aggressiveness or irritability accompanying such use have spurred experimental studies in animals. High-dose anabolic steroid treatment during early adolescence increases the aggressive response of male hamsters towards intruders, and these increases may be partly ameliorated by treatment with vasopressin receptor antagonists in the anterior hypothalamus. Treated hamsters showed enhanced vasopressin fiber density and peptide content in this area.

Gonadal and adrenal steroid hormones may interact in complex ways in association with aggression and defense. Both corticosterone and testosterone levels respond to acute and chronic defeat, with the former increasing and the latter decreasing. In fact, high circulating levels of free corticosterone may contribute to reductions in testosterone. However, corticosterone has recently been reported to enhance offensive aggression in male rats, while adrenalectomy produces a more rapid but 'deviant' attack aimed at the head of the opponent. The specificity of this enhancement is not yet entirely clear, as other behavioral consequences of corticosterone are poorly understood, but reports that blocking the mineralocorticoid receptor by spironolactone dramatically reduced territorial aggression are consistent with a view that adrenal hormones may have an important permissive role in aggression.

AGGRESSION AND DEFENSE IN HUMANS

Studies of aggression in humans have largely consisted of criminological data and articles on laboratory elicitation of aggression-like behaviors in response to some type of insult, irritation or other provocation. In general there has been little attempt to differentiate between offensive and defensive aggression, although a case has been made for anger or moral outrage as the human equivalent of offense, elicited by challenge to important rights or resources of the individual. Conversely, it has been suggested that human aggression represents defensive aggression. Because of the complexity of human verbal representations (to self and others) of the rationale or motivation for behavior (particularly behavior that is considered socially undesirable), the task of determining whether a particular instance of aggression is primarily offensive or defensive may be extremely difficult. However, this distinction is important in the treatment of some individual acts of violence by virtually every legal system yet devised, and enhanced attention to the differences in behavioral, as well as circumstantial, aspects of violent acts may yet shed light on these differences. As noted above, human aggression findings such as those involving low levels of serotonin metabolites, or effects of anabolic steroids, serve as important spurs to experimental research in animals. However, research attempting to link cognitive factors in human aggression to the circumstances that elicit aggression in lower animals has been sadly neglected. Similarly, normal human defensive behavior has received little attention. However, the potential involvement of particular defensive behaviors in specific psychopathological disorders, notably various types of anxiety disorders, is receiving increasing consideration. This is due in part to agreement between the effects of drugs on particular defensive behaviors and their efficacy against relevant anxiety disorders, and also reflects specific similarities of behavior between major symptoms of the anxiety disorder and those of the parallel defensive behavior.

CONTENTS

Dementia is not an obligatory consequence of aging. Normal aging does, however, result in changes in cognition, caused by a combination of neurotransmitter abnormalities and alterations in the structure and function of the brain.

INTRODUCTION

The increasing proportion of older adults in the population of many countries has heightened interest in the cognitive and neural changes that accompany normal aging. The following sections elucidate the effect of aging on a range of cognitive capacities, and the neural changes that may explain the pattern of spared and impaired function. Particular attention is devoted to short-term and working memory (allowing the temporary storage and manipulation of information); declarative memory (requiring conscious awareness); and nondeclarative memory (formed without conscious awareness). The evidence presented here comes from behavioral studies in healthy volunteers (cognitive psychology), patients with brain lesions (neuropsychology), analyses of brain structure (volumetric magnetic resonance imaging) and observations of focal task-related changes in normal brain activation during performance of specific cognitive operations (functional neuroimaging using positron emission tomography or magnetic resonance imaging).

DECLARATIVE MEMORY

Long-term memory is broadly divided into two components: declarative and nondeclarative memory. Declarative (explicit) memory is formed with conscious awareness, and requires the participation of medial temporal lobe structures, including the hippocampus. Declarative memory is what we use to help us remember the items we need to pick up at the grocery store, or the name of a friend whom we haven't seen in years. In general, declarative memory is more affected by normal aging than is nondeclarative memory. As an example of declarative memory, read the following words, and try to remember them. After reading through the list, write down as many words as you can remember, without looking back at the list: table, orange, calendar, computer, paper, needle, napkin, chair, sneeze, movie, sleep, castle, build, lunch, flower, dragon, plant, cushion, dolphin, muscle.

SENSORY MEMORY (PERCEPTION)

The sensory systems are those through which we receive direct input from the world via receptors: touch, taste, smell, vision, and hearing. Our perception of that input, however, can be influenced by a number of factors, such as our internal state, or the context in which the sensation occurred. Imagine you hear a loud banging sound while you are walking by a construction site. Now imagine that you hear the identical sound while walking alone on a deserted street late at night. Although the sound (sensory information) is identical in the two instances, the interpretation of the sound (perception) may differ greatly because it occurs in different contexts.

Some sensory systems are degraded as part of the normal aging process. Most commonly, older adults experience hearing loss. By the age of 80 years the majority of older adults have significant hearing loss. They also have visual deficits, including poorer color and luminance contrast, and many

have a loss of central vision due to macular degeneration. Sensory and perceptual deficits can hinder adults' performance on many tasks. For example, Murphy and colleagues found that older adults are more affected by background noise when trying to remember word pairs than are young adults. These researchers proposed that part of this increased effect is due to degraded sensory representations, though attentional reductions probably also contribute. Older adults also may have more difficulty discriminating isoluminant colors such as blue and green, and are slower and less accurate on tasks that require color discrimination, such as color-naming tests, the Stroop Test, and the Wisconsin Card Sorting Test.

Nevertheless, with modifications to testing procedures (such as louder stimuli) most older adults are successfully able to perceive information. Perceptual priming, requiring visual processing, is spared with normal aging. Older adults are also able to repeat word lists or digit strings (presented either aurally or visually), suggesting that their sensory deficits are not profound enough to affect immediate memory. It is, nonetheless, important to control for perceptual confounds when interpreting the performance of older adults, and to match (equate) the perceptual capabilities of young and older adults (either by matching individuals or, more feasibly, matching the stimuli so that young and older adults perceive them equally). Without taking these measures, it is unclear whether impaired performance in older adults stems from a purely cognitive deficit or from impaired perception. Particularly in memory studies, reduced perception may result in older adults having a degraded memory representation, subject to faster disruption over time.

SHORT-TERM MEMORY AND WORKING MEMORY

Short-term memory is a limited-capacity storage buffer for information to be remembered over a very short duration (a few seconds). The term 'short-term memory' is commonly used to mean recent memory, but that definition is not used by cognitive psychologists. Short-term memory consists of two components: a passive information store and an active rehearsal system. Working memory, in contrast, not only stores information but also updates and manipulates that information.

Read the following words, and try to keep them in mind for 10 s: hill, milk, goat, tool, foot, pie. This type of storage requires short-term memory. To succeed in repeating the words 10 s later, you might also have felt that you were 'rehearsing' those words (e.g. internally vocalizing them) to allow yourself to remember them. This phenomenon highlights the active rehearsal component of short-term memory. Now, read the words again, look away, and this time try to say them in alphabetical order. Simply rehearsing the words is insufficient to complete this task; rather, you also need to manipulate the words to place them in the proper sequence. This task, therefore, requires working memory.

The most widely accepted model of working memory, proposed by Baddeley and Hitch, defines working memory as consisting of three components: the central executive, the phonological or articulatory loop, and the visuospatial sketchpad. The central executive controls the allocation of attention, as well as the coordination and monitoring of activities, while the phonological loop and visuospatial sketchpad are slave systems of the central executive that temporarily maintain and manipulate verbal and nonverbal material, respectively.

Short-term memory is usually spared with aging, whereas working memory shows age-related decrements. This decline probably does not occur equally across all components of working memory, but rather targets only a subset of processes. Three components probably account for the majority of age-related working memory decline: processing speed, storage capacity, and inhibitory ability.

Processing Speed

Older adults are known to have a slowed speed of processing. Salthouse and colleagues proposed that decreased processing speed could account for some of the age-related declines in cognition. They suggested that cognitive performance suffers because (a) the slowed mental operations cannot be carried out within the necessary time frame, and (b) the increased time between mental operations makes it more difficult to access previously processed information. Processing speed can affect encoding because the quality and availability of perceptual information degrades over time, so information that is processed quickly will be encoded more effectively and, therefore, will have a more durable representation or memory trace.

The hypothesis of a relation between processing speed changes and cognitive decline has been confirmed in a number of studies. Longitudinal studies have shown that changes in speed of processing

may predict longitudinal cognitive decline, and a number of researchers have found that controlling for speed eliminates age effects on various memory tasks.

Storage Capacity

Storage capacity is one component of short-term and working memory: the passive storage buffer that dictates how much information can be stored without rehearsal being used to 'refresh' that information. A reduction in storage capacity is likely to contribute to age-related working memory decline: older adults may be able to hold less information in mind. Reduced storage capacity could provide an alternate explanation to reduced processing speed. Thus, remembering what information was processed, or carrying out mental operations, would be restricted not by time pressure but by reduced storage capacity. Although storage capacity declines with age, it is not clear that this deficit is sufficient to explain the cognitive decrements in working memory that occur with aging.

Inhibitory Ability

Hasher and Zacks proposed the inhibitory deficit theory to account for changes in cognitive performance with age. 'Inhibition', in this theory, is the ability to ignore irrelevant information while focusing attention on pertinent information. The inability to filter out irrelevancies causes older participants' working memory to be filled with unneeded information, leaving less space for task-relevant memories. This explanation, therefore, is not completely dissociable from a storage capacity explanation for cognitive aging.

Researchers have found evidence for inhibitory deficits in older adults on a variety of tasks. Commonly used paradigms for assessing inhibition are task-switching or set-shifting. On these tasks, participants must first remember one set of rules or pay attention to one salient characteristic, and then must switch rules or attend to a different characteristic. Most investigators have found that these tasks are sensitive to aging effects, with older adults being less able to ignore the previously relevant information.

LONG-TERM MEMORY

Long-term memory can be divided into two categories: episodic and semantic. Episodic memory entails retrieving information from a particular episode, localized in space and time (e.g. remembering seeing the Eiffel Tower on your first trip to Paris), while semantic memory requires retrieving factual information independent of any specific episode (e.g. knowing that the Eiffel Tower is in Paris). Recall of the word list given at the beginning of this article required episodic memory. You had to bring the word to mind, and also correctly remember that the word was on the list you had just read. Accessing the meaning of the words, however, required semantic memory.

Episodic Memory

Episodic memory appears to be more affected by normal aging than other memory processes. All aspects of episodic memory are not affected uniformly, however.

Factual and source memory

Episodic memory can be subdivided into two components: factual memory and contextual or source memory. Normal aging results in a disproportionate impairment in source memory as compared with fact memory. Even when older adults remember a fact or event, they have more difficulty than younger adults pinpointing the specific contextual details, such as where and when they learned a fact. For example, Spencer and Raz tested young and older adults on a test requiring them to remember facts, some true and some fictitious (e.g. 'Angela Lansbury regularly consults with astrologists'). After a delay, participants were asked to complete the fact ('Angela Lansbury regularly consults with …'), and to say where they had learned the fact (experiment or elsewhere) and whether the fact had been presented on a blue or pink card. Older adults were disproportionately impaired on the source recall than on the fact recall.

Source memory is believed to rely on the brain's frontal lobes. Measures of frontal lobe function correlate with measures of source memory, and reductions in source memory have been shown to occur in amnesic patients with frontal lobe lesions. The frontal lobes are also critical for linking events together in time. Aging results in frontal lobe dysfunction, probably connected to the source memory deficits seen in older adults.

Recall and recognition

Older adults show poorer performance on recall tests ('What words were on the word list?') where no cue is provided, than on recognition tests ('Was "cloud" or "table" on the word list?') where retrieval cues are provided. In general, older adults show improved performance on episodic memory

tests when cues are provided during encoding or retrieval phases.

The source memory decrement, and the benefit provided to older adults with cues, are probably related to the robustness of the memory trace encoded by the older adults. Aging seems to affect the quality of the representation, such that general gist-based information is more easily encoded and retrieved than richer, item-specific information that includes not only the to-be-remembered information, but also the context in which it was learned. This hypothesis is supported by the finding that on recognition tasks, older adults are more likely than young adults to say that an item is 'familiar' (they feel they have encountered the item before), but less likely to say that they 'recollect' the item (remember something specific about the item's presentation).

Semantic Memory

One of the most readily reported complaints by older adults is their declining ability to recall the names of people and objects. Word finding difficulties are among the most severe deficits in normal aging. Naming deficits result in slower speed of picture naming, a greater number of speech disfluencies, and an increased number of tip-of-the-tongue effects.

Picture naming

Older adults' naming deficit is particularly pronounced for proper names, though studies have also reported longer naming times for nonproper objects. The difficulty may be related in part to deficits in associative memory: the ability to form associations between a name and an object may be reduced in normal aging.

Tip-of-the-tongue effect

The tip-of-the-tongue effect occurs when a person has access to a word's meaning, but is unable to produce the phonological code. Older people report more tip-of-the-tongue experiences with everyday objects and with proper names than younger people. In addition, the accuracy of available information during a tip-of- the-tongue state is higher for young than old adults. For example, younger participants are more likely to state correctly the first letter of the word they are trying to remember than older participants. As with naming deficits, tip-of-the-tongue effects are more pronounced for proper names than for everyday objects. Better performance with everyday objects may be related to what Burke and colleagues refer to as 'summation of priming'. With everyday objects, connections from a variety of semantic associates converge on the correct name; but with proper names, older adults are handicapped without this type of summation.

NONDECLARATIVE MEMORY

Nondeclarative (implicit) memory is encoded and strengthened, across trials, without conscious awareness. It encompasses a heterogeneous group of processes and kinds of performance, including skill (motor) learning, repetition priming, and classical conditioning. These domains rely on distinct and separable neural substrates. Because of the task diversity, and range of necessary neural substrates, it is perhaps logical that nondeclarative memory is not uniformly impaired with aging.

Skill (Motor) Learning

In the 1960s, Milner demonstrated that the amnesic patient HM, while unable to form new declarative memories, could successfully learn a new motor skill. She asked HM to perform a mirror tracing task, in which he had to trace the outline of a star seen only in mirror-reversed view. Over 3 days of practice, his error scores decreased dramatically, and he maintained the learning from one day to the next, but he had no conscious recollection that he had done the task before. Corkin and colleagues administered additional skill-learning tasks to HM, confirming that he generally showed preserved learning. Other investigators have also reported that amnesic patients can learn and retain motor skill learning without awareness of prior exposure to the task.

These results indicate that the brain structures that support conscious, declarative memory and which are damaged in amnesia (the hippocampus and other medial temporal lobe structures) are not critical for skill learning. Skill learning is thought to rely on the motor cortex, supplementary motor area, cerebellum, basal ganglia, and posterior parietal cortex. Older adults have reductions in the amount of dopamine and acetylcholine in the basal ganglia; they also show cerebellar dysfunction. These changes may result in slower acquisition of some motor learning tasks.

No consensus exists as to how skill learning is affected by aging. Researchers have found every possible outcome: equal performance in young

and older adults, better performance in older adults, and poorer performance in older adults.

Repetition Priming

Priming is broadly defined as a faster or biased response to a stimulus based on prior exposure to that stimulus, or a related stimulus. As an example of priming, try to complete these word stems with the first word that comes to mind: nap—, dol—, cas—, cus—, tab—, dra—. You may have responded with words from the list given at the beginning of this article, without being consciously aware that you had done so. This effect, based on prior exposure to a stimulus, is an example of repetition priming.

Priming is not a unitary construct; rather, multiple processes contribute to priming effects. For discussion purposes, we will divide priming into two categories: perceptual priming and conceptual priming. These types of priming are dissociable and rely on separate neural substrates.

Perceptual Priming

Perceptual priming is based on the sensory characteristics of a stimulus. For example, if participants are shown the pseudoword 'pabhan', they will later be more likely to recognize that pseudoword when it is flashed briefly, than another pseudoword flashed at the same rate. Keane and colleagues proposed that perceptual priming effects are mediated by a structural–perceptual memory system localized to the occipital lobe; this hypothesis has been supported by neuropsychological and functional imaging studies.

Older participants frequently perform as well as younger adults on perceptual priming tasks. For example, Schacter and colleagues presented young and older adults with black-and-white drawings of three-dimensional objects in either structurally possible or impossible configurations. When participants had to judge whether the briefly presented stimuli were possible or impossible objects, young and older adults showed the same magnitude and pattern of priming, with robust priming for possible objects and no priming for impossible objects.

The finding of spared perceptual priming with aging is consistent with its reliance on the occipital and temporoparietal cortex because aging is thought to spare primary cortices and modality-specific association areas, including the occipital lobe.

Conceptual Priming

In contrast to perceptual priming, conceptual priming relies primarily on the semantic representation of the stimulus. For example, if participants are first presented with the category word 'fruit', they will be faster at determining that the word 'apple' is a real word than if they were first presented with the category word 'furniture'. Keane and colleagues proposed that conceptual priming is mediated by a lexical–semantic memory system recruiting temporoparietal regions. This hypothesis has been supported also by neuropsychological and neuroimaging studies.

Some studies have reported age-related deficits in priming experiments that are conceptual in nature, including lexical priming and priming for new word associations. Other researchers, however, have reported spared performance in older adults. The discrepancy may have stemmed from different task designs, or individual variation within the older populations.

CLASSICAL CONDITIONING

One of the most commonly used forms of classical conditioning is the eyeblink response. In delay conditioning, a neutral stimulus (a tone) is followed repeatedly by a biologically relevant stimulus (an air puff to the eye), and the two stimuli coterminate. The measure of learning is the subsequent ability of the tone, by itself, to elicit a biologically relevant response (an eyeblink), the conditioned response. The strength of the conditioned response increases gradually with repetition, making it possible to document the number of trials needed to learn to a particular criterion. Older rabbits and older humans require significantly more trials than younger ones to acquire the association between the tone and the air puff, but considerable variability exists among older individuals. Results from neuroimaging and neuropsychology converge on the conclusion that the cerebellum is the critical neural substrate for delay conditioning. Because the cerebellum is affected by normal aging, the reduction in classical conditioning with normal aging is believed to result from less efficient cerebellar communication and output.

Trace conditioning differs from delay conditioning in that there is an unfilled interval between the offset of the neutral stimulus (the tone) and the onset of the biologically relevant stimulus (the air puff). The participant must therefore build up a representation, across trials, as to the relation between the tone and air puff. In addition to

cerebellar recruitment, the hippocampus is critical for trace conditioning. The hippocampal contribution is likely to stem from the fact that delay conditioning is not purely a nondeclarative memory task; conscious awareness of the relation is mandatory for successful conditioning.

On the trace conditioning paradigm, young and middle-aged adults condition at a similar rate, but older animals and humans are impaired. These deficits may occur at an earlier age than deficits in delay conditioning, and may be more pronounced.

AGE OF COGNITIVE DECLINE

Methods of Assessment

The age of cognitive decline can be assessed using one of two designs: cross-sectional or longitudinal.

Cross-sectional studies use data collected from individuals considered to be representative of an entire population, and interpret differences among those individuals as indicative of differences across two or more populations. For example, a cross-sectional study of aging might examine the performance of adults in their twenties, fifties and eighties. If the 80-year-olds performed more poorly than the other groups, this difference would be attributed to age. This design requires that groups be equated (matched) on as many variables as possible (e.g. overall intelligence and perceptual ability, as well as lifestyle, psychological and medical factors) to assure that group differences are due to age and not to other differences.

A longitudinal study avoids many of these confounds by tracking the same group of individuals across time, and comparing their performance at different time points. For example, a group of adults might be tested every 5 years for 20 years. Because each individual serves as his or her own baseline, the investigator does not have to worry about confounds such as intelligence or education level. Changes in overall health or perceptual ability over time must still be considered, and longitudinal studies can also be confounded by nonrandom drop-out rates (e.g. in a memory study, individuals who believe their memory is failing might be more likely to drop out of the study than those who believe their memory is good).

Cognitive Performance

The worsening performance across an extensive age range has led many researchers to divide the older adult population into 'young-old' and 'old-old' subgroups. This dichotomy was first proposed by Neugarten, who noted that these groups were dissociable not only by chronological age, but also by lifestyle changes. The young-old have fewer health limitations than the old-old, and the old-old are more likely to be widows or widowers than the young-old.

Researchers have used this dissociation to examine the progression of cognitive changes into the later decades of life. Most studies have confirmed that memory loss does not reach a plateau in the sixth or seventh decades; rather, memory decline continues throughout the later decades. Adults over the age of 70 years perform significantly worse on a range of recognition tasks compared with individuals in their seventh decade of life. Deficits in semantic memory and conditioning can also become more pronounced in the old-old.

The age at onset of decline differs depending on the type of function assessed. Semantic memory, as measured by tip-of-the tongue effects, has been found to be altered between the fifth and sixth decades. Woodruff-Pak and colleagues, however, found that eyeblink classical conditioning decrements began almost a decade earlier, with 40-year-olds showing significant impairments. Episodic memory, in contrast, remains relatively stable until around the seventh decade.

ANATOMICAL CHANGES

Longitudinal studies have found decreases in overall grey and white matter volumes with age, as well as increases in volumes of ventricular cerebrospinal fluid. The changes are not uniform across all brain regions, however. For example, the prefrontal cortex and medial temporal areas are more affected than primary association cortices. The pattern of neural changes helps to clarify why some types of cognition are particularly affected by normal aging, while other cognitive processes are relatively spared.

Hippocampus and Other Medial Temporal Lobe Structures

Hippocampal function is impaired by normal aging. Functional neuroimaging studies have shown that the hippocampus and other medial temporal lobe structures are less activated by memory tests with aging, and these functional changes often correlate with memory performance. A quantitative imaging study assessing the volume of different brain regions also found that hippocampal volume is significantly correlated with

performance on delayed recall tests. In fact, out of a variety of brain regions measured (including overall brain volume), hippocampal volume was the best predictor of delayed memory performance.

It is unclear whether there is substantial cell loss in this region, or whether the hippocampal dysfunction is related to neuropathological changes and cellular dysfunction affecting neuronal communication. On postmortem examination, adults over the age of 55 years typically show at least some entorhinal neurons that contain tangles, or where tangles are beginning to form. Brain neurochemistry also appears to be altered, with reductions in synaptic signaling. For example, long-term potentiation, thought to be a critical neural mechanism for learning and memory, is reduced with normal aging. Reductions in the number of NMDA (*N*-methyl-D-aspartate) receptors in the hippocampus, or reductions in the efficiency of the receptor, may mediate some of the age-related hippocampal dysfunction. Glucocorticoids, too, mediate hippocampal function, and increases in glucocorticoid levels may contribute to dysfunction.

Even studies that have found cell loss do not agree on which medial temporal lobe regions are most affected. While a number of studies found evidence for cell loss in the CA1 region of the hippocampus, not all studies have replicated this finding, using unbiased stereologic counting methods.

Cerebellum

Studies of humans, rats and rabbits suggest that the cerebellum, in particular the Purkinje (output) cells, is affected by aging. Older animals have fewer Purkinje cells, and those that remain have a reduced efficiency. Because Purkinje cells are the major output system of the cerebellum, damage to these cells results in dramatically reduced cerebellar output. Evidence for structural changes in humans comes from a magnetic resonance imaging (MRI) study showing significant negative correlations between age and grey matter volume in the cerebellar vermis and hemispheres.

Prefrontal Cortex

The function of the prefrontal cortex is affected by aging. Older adults perform more poorly than younger adults on tasks that measure frontal lobe capacities, including the Wisconsin Card Sorting Test and the Stroop Test. Neuroimaging studies have indicated changes in prefrontal activation, particularly in dorsolateral prefrontal cortex. Even on tasks where young and older adults perform at similar levels, prefrontal regions in older individuals show different patterns of activation, including recruitment of additional areas, and reduced activation in other regions relative to young adults.

As with the hippocampal region, it is unclear what neuropathological changes account for deficits in frontal lobe capacities. Researchers have proposed that neuronal shrinkage, or reductions in the number of presynaptic terminals, may be responsible for some of the age-related impairment. Axonal abnormalities may also underlie age-related deficits. In a volumetric MRI study, Double and colleagues found frontal lobe white-matter atrophy, suggestive of reductions in axonal processes. They suggested that slowed cognitive processing may occur because of a decrease in the speed of nerve conduction due to such axonal changes. These alterations may account for the working memory deficits with normal aging.

Neurotransmitter and Neuromodulator Abnormalities

A neurotransmitter is a chemical messenger that is released by one neuron, travels across a space between two neurons (a synapse), and binds to the second neuron. In this way, information is passed between neurons. A neuromodulator is a chemical that is not itself a transmitter, but affects the release of neurotransmitters.

Dopamine

Age-related changes in the dopaminergic system are well documented in humans, monkeys, and rodents. Levels of dopamine and tyrosine hydroxylase (an enzyme important for the production of dopamine) decrease with normal aging, and these reductions are particularly pronounced in the frontal lobes and basal ganglia. Postsynaptic alterations are also reported to occur with aging, including reductions in D2 dopamine receptors and some increases in D1 receptors.

Age-related reductions in dopamine levels may contribute to age-related working memory impairments. Dopamine depletion in the frontal lobes impairs performance on working memory tasks and dopamine may be particularly important for inhibitory ability. Prefrontal cortex must sort out task-relevant information, and maintain that information in the face of other distractors. Dopaminergic systems may provide the basis

for that allocation of attention. Dopamine may potentiate synapses associated with a reward (e.g. correct recall), thereby intensifying links between task-relevant computations, and weakening others.

Acetylcholine

Considerable evidence links acetylcholine to learning and memory. Acetylcholine is released when animals perform spatial memory tasks, and injection of cholinergic antagonists such as hyoscine (scopolamine) impairs memory acquisition in humans and nonhuman primates.

In aged animals, memory loss is correlated with hypoactive cholinergic neurons. For example, older rats show reduced excitatory postsynaptic potential amplitudes resulting from stimulation of the CA1 region of the hippocampus, suggesting that cholinergic neurons are less responsive in older animals. Older animals also show reductions in cholinergic receptor density that are particularly pronounced in the medial and caudal parts of the striatum, and in the frontal lobes.

Adrenal glucocorticoids

Stress hormones, too, are linked to the neural loss and dysfunction associated with normal aging. The adrenal cortex (in the adrenal glands, located near the kidneys) secretes glucocorticoids, which underlie our physical responses to threatening stimuli. In the short term, glucocorticoids are essential to our survival because under stressful conditions they increase the availability of energy substrates (blood glucose). Prolonged exposure to elevated glucocorticoid levels, however, can be detrimental, suppressing anabolic processes and depleting existing energy stores. With age, the stress response is not terminated as efficiently, causing glucocorticoid levels to remain elevated for significantly longer following stress.

The hippocampus, one of the main target sites for glucocorticoids, seems to be hardest hit by prolonged glucocorticoid exposure. When rats underwent experimental removal of the adrenal glands, disrupting glucocorticoid production, aged rats showed little or no evidence of hippocampal neuron loss as compared with control rats. These results link the production of glucocorticoids to the hippocampal atrophy that occurs with aging. Further evidence for this hypothesis comes from studies in Sapolsky's laboratory, showing that young rats treated with corticosterone show patterns of hippocampal cell loss similar to that in aged rats. Sapolsky and colleagues suggest that the effect of glucocorticoids on hippocampal neurons is probably related to metabolic changes stemming from the fact that glucocorticoids inhibit glucose uptake.

Rate of Decline

As discussed above, different cognitive processes decline at differing phases of the aging process. These differences are probably related to the times that neuropathological abnormalities appear in different brain regions. Cerebellar atrophy, thought to cause changes in the acquisition of a conditioned response, may start at an earlier age than most other brain changes, with significant atrophy present by the fifth decade of life. Other regions such as the medial temporal lobe or frontal lobe may not be altered until the seventh or eighth decades. Similarly, neurotransmitter changes, such as dopaminergic reductions, are thought to start around the seventh decade of life and to continue throughout the remaining adult years.

CONCLUSION

Aging does not affect all aspects of cognition uniformly. It does, however, affect a range of cognitive capacities. These changes are not static, but rather continue to intensify. Cognitive alterations are intimately linked to age-related changes in the neurotransmitter systems and in the structure and function of the brain.

CONTENTS

Alzheimer disease is the leading cause of dementia among older adults. It results in neurochemical and neuroanatomical brain changes that cause increasing cognitive dysfunction.

INTRODUCTION

Alzheimer disease (AD) was first described by Alois Alzheimer in 1907. A German neuropathologist working in Emil Kraepelin's laboratory in Heidelberg, Alzheimer reported a case study of a 51-year-old woman who had psychiatric symptoms and memory problems. Upon her death, Alzheimer noted an abundance of neuritic plaques and neurofibrillary tangles in her brain. Although neuritic plaques had been described previously, Alzheimer was the first to recognize that their presence in large numbers was abnormal, and that the coexistence of the plaques and tangles signaled a previously unidentified disease of the cerebral cortex. This combination of neuritic ('senile') plaques and neurofibrillary tangles is now recognized as the neuropathologic signature of AD.

Alzheimer disease is the most common cause of dementia, accounting for approximately two-thirds of all cases. It is estimated that over 4 million people in the USA have AD, and by the eighth decade of life as many as one in two adults will develop the disease, which is characterized by neuronal changes, neurotransmitter abnormalities and decreased brain volume. These changes underlie cognitive deficits including memory loss, language dysfunction, and visuospatial and temporal disorientation.

DIAGNOSIS

Dementia is defined as an overall loss of intellectual function severe enough to impede daily activities. It consists of a group of behavioral symptoms that must occur together; these symptoms can have various etiologies. Alzheimer disease is defined as the presence of memory impairment plus one other area of cognitive dysfunction: language, motor, attention, executive function, personality, or object recognition, according to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The deficits must have a gradual onset, and a continuous (and irreversible) progression. A definitive diagnosis of AD can be made only at postmortem examination by observing the hallmark neuritic plaques and neurofibrillary tangles. Antemortem, the diagnosis of 'probable' AD is given when an individual meets the criteria of the DSM-IV, the National Institute of Neurological Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINDS-ADRDA), and when all other causes of dementia have been eliminated. When made by a trained clinician, this exclusionary diagnosis is accurate in 80–90% of cases.

INCIDENCE AND PREVALENCE

The incidence of AD increases exponentially with advancing age. At age 70–75 years the incidence of AD is approximately 1% per year, but at age 80–85 years the annual incidence is over 6% per year (e.g. Hebert *et al*., 1995). Overall, women remain at greater risk of developing AD than men. The prevalence of AD also increases with age (e.g. Fratiglioni *et al*., 1991), with 30–50% of adults aged 70 years and above having a diagnosis of probable AD.

NEURONAL CHANGES

Alzheimer disease results in a range of neuronal changes, including cellular dysfunction and death.

Eventually, AD affects nearly all brain structures. Early in the disease, however, some brain regions (e.g. limbic structures) are affected to a much greater extent than others (e.g. the primary sensory cortices).

Neuropathologic Changes

The hallmarks of AD are neurofibrillary tangles (intracellular) and neuritic plaques (extracellular). These changes reduce the efficiency of neural communication. While normal aging is associated with these neuropathological changes as well, the number of plaques and tangles seen in the AD brain is far greater than in nondemented individuals.

Neurofibrillary tangles

Neurofibrillary tangles consist of small, paired, helical filaments (i.e. two fiber strands that are twisted around one another). They are found in the cell body and dendrites of neurons, and often appear flame-shaped, with a rounded cell body and a threadlike apical dendrite. They can also have a more spherical shape. Neurofibrillary tangles are composed of hyperphosphorylated tau protein. Typically, tau protein is a soluble component of the cell. When tau is overphosphorylated, however, it becomes insoluble and forms tangles. Because neurofibrils are frequently used for the transport of chemicals that will be made into neurotransmitters, the tangling of these fibrils renders them useless and can prevent neurotransmitter synthesis. Neurofibrillary tangles are not specific to AD, but also appear in other neurological disorders including Parkinson disease, Down syndrome, progressive supranuclear palsy and other forms of dementia.

Neuritic plaques

Neuritic plaques are dense deposits found outside the brain's nerve cells (extracellularly). They are spherical structures with a dense core of amyloid-β protein surrounded by a halo and a ring of abnormal (dystrophic) neurites. The halo component consists of other types of brain cells (astrocytes) and inflammatory cells (microglia). The dystrophic neurites represent dying nerve terminals and are small, threadlike structures consisting of abnormal neuronal dendrites. In addition to these 'typical' plaques, AD brains may also show 'diffuse' plaques, which have a loose accumulation of amyloid-β rather than a dense core, and no surrounding dystrophic neurites.

Patterns of deposition

Neurofibrillary tangles and neuritic plaques show different patterns of accumulation. Early in the course of AD, neurofibrillary tangles are confined primarily within the limbic structures. Neuritic plaques, however, appear throughout the cortex, even early in AD (Arriagada *et al*., 1992).

Relation between neuropathology and disease

It is unknown whether these neuropathological changes cause AD, or whether they are epiphenomenal. Nonetheless, there does appear to be a link between the amount of tangles in the brain and the severity of AD. Researchers are now working on therapeutic approaches to reduce the formation of tangles and plaques in the brain, hoping that this reduction will halt, or reverse, disease progression.

Brain Atrophy

One of the most prominent features of AD is atrophy (shrinkage) of the medial temporal lobe. The entorhinal cortex (a gateway for information into the hippocampus) and the hippocampus are among the first regions affected. These regions lose about 50% of their neurons, a finding that accounts for the shrunken brain tissue. The volume of these regions, measured by neuroimaging techniques, can be used to identify people with early AD, and may even identify individuals with memory impairments who will later develop AD (e.g. Jack *et al*., 1999). Another region of the brain that shows substantial cell loss early in AD is the nucleus basalis. This region of the ventral forebrain contains many of the brain's cholinergic neurons. Damage to this region reduces neurotransmission in pathways using the neurotransmitter acetylcholine.

As AD progresses the brain changes become more widespread. The ventricles of the brain expand as the surrounding tissue deteriorates. Sulci (the 'valleys' between the brain's folds) widen. Neocortical areas, including temporal and parietal neocortex, show increased atrophy. Eventually nearly all of the brain, including secondary and even primary sensory areas, is affected.

Neurotransmitter Abnormalities

The damage to the nucleus basalis results in reduced levels of choline acetyltransferase, the enzyme needed for acetylcholine formation. These reductions occur relatively early in the disease, but not all cholinergic pathways are affected equally:

the long-axon cholinergic neurons (e.g. those connecting the nucleus basalis and the cerebral cortex) are particularly vulnerable. Because of the dramatic reduction in cholinergic transmission, the first approved therapies for AD were aimed at increasing the amount of acetylcholine in the brain. Current treatment for AD is administration of acetylcholine esterase inhibitors. Acetylcholine esterase is the enzyme that breaks down acetylcholine into its constituent parts. Acetylcholine esterase inhibitors, therefore, enhance cholinergic neurotransmission by blocking the breakdown of the neurotransmitter. Acetylcholine levels remain higher and can have a longer-lasting effect before being broken down. This therapy, however, provides only a transient increase in memory performance, if any, and has no effect on disease progression.

The minimal effectiveness of acetylcholine esterase inhibitors suggests that acetylcholine deficiency is not the only cause of the cognitive dysfunction in AD. In fact, as the disease progresses, nearly all neurotransmitter systems become depleted. There appears to be much individual variation in the neurotransmitters most affected by AD and the absolute reductions. Estimates, however, suggest that levels of neurotransmitters including noradrenaline (norepinephrine), dopamine and serotonin can show reductions of up to 50% in the late stages of AD.

GENETICS

Alzheimer disease can be divided into two types: familial (inherited) and sporadic. Familial AD is relatively rare, representing less than 5% of total cases, and typically affects individuals at a younger age than sporadic AD (often before age 50 years, with cases reported of people developing the disease in their mid-20s). Sporadic AD usually has a later age at onset (after age 65 years). Some research suggests that familial and sporadic AD differ not only in terms of age at onset, but also in their cognitive profile. Familial AD may be associated with a more rapid cognitive decline and shorter time to death. It also may be linked to more verbal deficits and fewer visuospatial deficits than sporadic AD (Filley *et al.*, 1986).

Familial or Early-onset AD

Familial AD is linked to mutations in three genes: those coding for presenilin 1 (PS-1) on chromosome 14, presenilin 2 (PS-2) on chromosome 1, and amyloid precursor protein (APP) on chromosome 21 (Table 1). These mutations are causative: a person who has one of these genetic mutations will develop AD. Familial AD is inherited following an autosomal dominant pattern. This pattern means that if one parent has this form of AD, each offspring has a 50% chance of developing AD. Interestingly, all of these mutations appear to have a common effect: increased production of amyloid-β peptide (Aβ) 42, the main constituent of the amyloid plaques in the AD brain. The peptide is part of a larger precursor protein (APP), which can be cleaved (cut apart) in two different places, leading to the formation of two types of amyloid-β, one with 42 amino acids (Aβ42) and one with 40 (Aβ40). The first type appears to be more likely to form plaques in the brain than Aβ40; it may also be the more toxic form, and its presence may lead to neuronal death. Researchers are now working on ways to reduce the amount of Aβ42 formed from APP, in the hopes of stopping the formation of amyloid plaques, and perhaps also preventing further clinical decline.

Table 1. Molecular genetics of Alzheimer disease

AD Group	*Chromosome*	*Gene*	*Protein*
Familial AD, onset 50s	21	*APP*	Amyloid
Familial AD, onset 40s	14	*PS1*	Presenilin 1
Familial AD	1	*PS2*	Presenilin 2
Late-onset AD	19	*APOE*	ApoE ε2, ε3, ε4

AD, Alzheimer disease.

Sporadic or Late-onset AD

Sporadic AD probably has a multifactorial basis, including possible genetic and environmental influences. Although there are no causative mutations, there is a major genetic susceptibility factor. A gene that encodes apolipoprotein E (ApoE) is found on chromosome 19 (see Table 1). Everyone has this gene: it is essential for carrying cholesterol in our bloodstream. The gene has many alleles (or forms); the most common ones produce the ApoE variants ε2, ε3 and ε4. One allele is inherited from each parent. Being homozygous for the ε4 allele (i.e. having two ε4 alleles) is associated with an increased risk of developing AD (Saunders *et al.*, 1993). Being homozygous for the ε2 allele, in contrast, is associated with a reduced likelihood of developing AD. The allele is not predictive of AD, however; individuals without an ε4 allele can develop AD, and those who are homozygous for the ε4 allele can remain unaffected by AD. The ApoE

alleles are thought to influence the development of late-onset AD in about one-third of the population. Dozens of other genetic risk factors have been suggested, but their roles have been researched less thoroughly than the role of ApoE.

Sporadic AD is also associated with other, nongenetic risk factors. The greatest risk factor is advanced age. One well-researched correlation is with decreased estrogen levels (e.g. Paganini-Hill and Henderson, 1994). It is believed that the reason women are at greater risk of developing AD than men is because of the postmenopausal drop in estrogen levels. Taking estrogen after menopause appears to decrease the likelihood of developing AD, though it does not seem to alter its progression in those who already have the disease. Head injury is another risk factor for AD. Particularly when unconsciousness has occurred, it increases the likelihood of developing AD, and more severe injury is associated with greater risk (e.g. Guo *et al.*, 2000). Head injury as far back as early childhood appears to influence the rate of AD development later in life.

ANIMAL MODELS

Animal models of AD can provide insight into the genetics, pathological progression and treatment of AD. Several transgenic mouse models have been created with the objective of clarifying the role of genetic factors. Researchers have engineered mice that express genes implicated in AD, such as those coding for APP, the presenilins and tau; for reviews see Janus and Westaway (2001), van Leuven (2000) and Duff and Rao (2001). The characteristic pathologic findings in these mice differ depending on the genetic alterations. Transgenic mice created by introduction of APP develop neuritic plaques, and show deficits in learning and memory; however, they do not develop neurofibrillary tangles, which are the other neuropathological hallmark of AD. Transgenic mice created by inserting human tau genes develop abnormal clumping of tau filaments (neurofibrillary tangles), as well as neuronal degeneration, but do not develop neuritic plaques. Mice engineered to express PS-1, in contrast, do not display abnormal pathology or cognitive impairment, but do show elevated levels of Aβ42 (the peptide associated with plaque formation). These models, therefore, provide insights into the contributions of genes implicated in the development of familial AD. Transgenic mice can also be used to examine whether and how genetic risk factors (e.g. expression of ApoE ε4) influence disease progression.

In addition, animal models can provide clues about the pathological progression of AD. Because AD appears to occur naturally only in humans, it has not been possible to examine the neuropathological changes in the brain at various stages of the disease. Rather, the samples available have by necessity come at the time of death. While much information can be garnered from analysis of endpoint data, animal models provide a means for systematic tracking of pathological changes. Hybridizing mice genetically altered to develop neuritic plaques with those engineered to manifest neurofibrillary tangles, has resulted in a strain of mice showing both of the neuropathological hallmarks of AD. This animal model may be particularly important in contributing to our understanding of how these two neuropathological features relate. Researchers are optimistic that use of such animal models will provide information about the relation between amyloid deposits and tau-containing tangles, and about the role they play in the development and progression of AD.

Animal models will also be important in testing potential treatments for AD. Once researchers have established an animal model that closely approximates the pathological and cognitive characteristics of AD, it will be possible to test the efficacy of treatments on these animals.

COGNITIVE FUNCTION

The signs of AD develop slowly, and it is often difficult to pinpoint the time of disease onset. Initial symptoms are mild, and can include forgetfulness, passivity, decreased work productivity, word-finding difficulties, and disorientation. As the disease progresses, nearly all aspects of function are affected, including memory, language, attention, vision, audition, and motor control.

Impaired Capacities

Episodic memory

Impairment of episodic memory – the recollection of events that occupy a specific spatial and temporal context – is typically the earliest and most prominent deficit in AD. Patients have difficulty forming new episodic memories (anterograde amnesia), and this impairment worsens with disease progression. Deficits in episodic memory, including delayed recall of verbal and nonverbal material, are the best way of distinguishing people with AD from healthy older adults (e.g. Locascio *et al.*, 1995). In contrast, however, people with AD remain capable of retrieving some long-term episodic memories. While remote memory is impaired, it

does not show the pronounced decrements seen in the formation of new episodic memories. The loss of retrograde memory (retrograde amnesia) also appears to be temporally graded, with recent memories showing more degradation than remote memories. In fact, the capacity to recollect events from the remote past is often quite resilient in AD. Patients can even become preoccupied with the past, and can confuse their current environment with that of their youth. The degrees of anterograde and retrograde memory deficits are not significantly correlated (e.g. Greene and Hodges, 1996).

The episodic memory deficit is consistent with the neural changes early in AD: brain structures that support long-term memory (medial temporal lobe regions, including the hippocampus) are compromised in early AD, while other regions of the brain are less affected.

Emotional memory

Individuals are often better at remembering emotional compared with neutral information. This emotional memory enhancement effect appears to result from interactions between the amygdala and other regions of the medial temporal lobe, including the hippocampus. Alzheimer disease results in a substantial volumetric reduction in the amygdala, and this amygdaloid atrophy appears to reduce the emotional enhancement effect: people with AD do not show better memory for emotional information than for neutral information (Kensinger *et al*., 2002) and their ability to remember emotional stimuli appears to correlate with amygdaloid volume.

Semantic memory

Semantic memory – general knowledge about the world – is relatively spared early in AD, but as the disease progresses significant deficits arise. Deficits occur on tasks requiring general knowledge retrieval, word definitions, word–picture matching, or picture naming. It is unclear whether the semantic deficit is related to a breakdown in the structure of semantic memory, to impaired access of semantic information, or to a combined deficit in structure and access.

The extent of the language deficits is useful for assessing the severity of AD (Locascio *et al*., 1995). Initial deficits include increased 'tip of the tongue' effects, reduced fluency scores, and a difficulty with tests requiring confrontation naming. In later stages of the disease, deficits can include forgetting the names of spouse or children, and the inability to recall names of common objects. The progression of semantic memory deficits is associated with the expanding pathological changes of advancing AD: as perisylvian areas become affected, semantic memory deficits increase.

Visuospatial function

While early AD is associated with some disorientation, visuospatial dysfunction increases with disease progression. In the middle stages of the disease, it is common for patients to become lost while driving their car or on a walk, even when following a route that they have taken on many occasions.

Executive functions

People with AD show deficits in short-term memory and in on-line processing of information (Corkin, 1982). At least some of these deficits may be due to deficits in the 'central executive' in Baddeley's model of working memory. Becker (1988) suggested that AD might have two main deficits: one paralleling that of amnesia, and the other in the central executive. In support of the central executive hypothesis, people with AD have frequently been found to have poor dual-task performance while being capable of performing each component task at a normal level. Baddeley and colleagues also found that dual-task performance declined with disease progression, while single-task performance remained stable.

Classical conditioning

Most forms of nondeclarative memory are spared in AD. One notable exception, however, is seen with delay conditioning, in which the unconditioned stimulus occurs just before the offset of the conditioned stimulus. People with AD are impaired at acquiring a conditioned response (such as an eyeblink in response to a tone). They require more trials to learn this type of relation (e.g. Woodruff-Pak *et al*., 1996). This deficit is probably not related to damage to the medial temporal lobe because amnesic patients with damage to these structures are capable of acquiring a conditioned response. The deficit is more likely to be related to cholinergic or cerebellar dysfunction.

Vision

Alzheimer disease results in changes in basic sensory and perceptual capabilities. People with AD often have more difficulty perceiving visual stimuli than do nondemented older adults. A significant correlation exists between the severity of perceptual deficits and the extent of cognitive dysfunction (e.g. Cronin-Golomb *et al*., 1995). It is unclear whether this correlation is causal (e.g. visual deficits could cause poorer performance on a task of

visual memory) or associative (e.g. patients with greater brain atrophy are likely to have both sensory deficits and memory dysfunction). The visual deficits are related to reductions in contrast sensitivity, color perception and discrimination, and visual acuity. The visual dysfunction is probably related to neuropathological changes in primary visual cortices and visual association areas because AD does not appear to affect the retina or optic nerve.

Preserved Capacities

Despite the range of capacities affected in AD, some domains remain relatively preserved until late in the course of the disease. Most prominently, many types of nondeclarative (implicit) memory are unaffected by early to moderate AD.

Priming

Priming can be broadly broken down into two subsets: conceptual and perceptual priming. People with AD show a dissociation in performance on these priming tasks: their performance on conceptual priming tasks is impaired, whereas their perceptual priming is normal. This dissociation probably reflects a disproportionate reliance on temporoparietal regions in conceptual priming. Conversely, perceptual priming appears to rely predominantly on occipital lobe regions that are less affected by AD.

Skill learning

Until the late stages of AD, patients are capable of learning new skills, ranging from motor learning to visual adaptation. The preservation of such learning is likely to be related to the relative preservation of brain regions important for nondeclarative learning, including the basal ganglia and frontal lobe.

TREATMENT

The treatment of AD consists predominantly of three types of approaches: (a) mitigating noncognitive disorders (psychiatric symptoms such as anxiety or paranoia, sleep disturbance), (b) restoring neurotransmitter function, and (c) protecting neurons from further death. The majority of drugs prescribed to restore neurotransmitter function have been cholinesterase inhibitors. These drugs, however, have had only minimal effectiveness in slowing the disease progression and have not been able to halt or reverse the disease's effects. There is some evidence that antioxidants (vitamin E), antiinflammatory drugs (ibuprofen), estrogen, and lipid-lowering agents (statins) may be neuroprotective, in as much as they slow the progression of AD. To date, however, there is no evidence that these treatments can slow disease progression in individuals already affected.

SIGNIFICANCE OF RESEARCH FOR UNDERSTANDING BRAIN FUNCTION

Research into AD has improved our understanding not only of the neurologic disorder but also of brain function. By observing the pattern of spared and impaired functions, researchers have learned that some types of memory (e.g. declarative) are affected by diffuse damage to the medial temporal lobe, while other types of memory (i.e. nondeclarative) remain relatively unaffected. Similar dissociations, such as between preserved perceptual priming and impaired conceptual priming, or between impaired anterograde memory and only moderately affected retrograde memory, have helped to uncover the dissociable neural mechanisms responsible for these cognitive functions. Similarly, the finding of reduced cholinergic function in AD sparked interest in the role of acetylcholine in long-term memory formation. Further research has demonstrated the necessity of the cholinergic system for successful episodic encoding.

By comparing performance in AD and amnesia, researchers have also been able to determine what memory dysfunction in AD is caused specifically by damage to the medial temporal lobe system, and what deficits may be related to neocortical damage (Corkin, 1982). This complementary interaction between neurology, neuropsychology, and neuroscience has allowed simultaneous advancements in the diagnosis and treatment of AD, and in our understanding of brain–behavior relations.

Amnesia

Intermediate article

AR Mayes, University of Liverpool, Liverpool, UK
NM Hunkin, University of Sheffield, Sheffield, UK

CONTENTS

Amnesia means loss of memory; more specifically, the term refers to the amnesic syndrome. In this syndrome, usually caused by regional brain damage, there is impaired recall and recognition of facts and episodes encountered both before and after the onset of the disorder, although intelligence and short-term or immediate memory are preserved.

INTRODUCTION

The term 'amnesia' is used in a general sense to mean any kind of loss of memory. The term also has a technical sense in which it refers to the amnesic syndrome. This memory disorder syndrome has four main features. The first is an impairment in the ability to recall or recognize facts or personally experienced episodes encountered following the brain injury; this is known as anterograde amnesia. The second feature is an impairment in the ability to recall or recognize facts and personally experienced episodes that were encountered and put into memory premorbidly; this is known as retrograde amnesia. In patients, the severity of anterograde amnesia is only weakly correlated with the severity of retrograde amnesia, and these disorders are often accompanied by two further features: preserved intelligence, and preserved short-term memory. Research has confirmed earlier, more informal observations, the first of which was made by Claparède in 1911, that people with amnesia can show good memory although they have no recall or recognition of how they acquired such memory. These 'implicit' memories are only shown by changed behavior, because patients are not aware that they are remembering.

Amnesia in the technical sense is, therefore, far from being a general disorder of all kinds of memory. It is referred to as a syndrome because some of its component symptoms probably have different causes, although it remains unclear to what extent the cause or causes of anterograde and retrograde amnesia differ. Most often these memory disorders are caused by damage to any one of several different brain regions, each of which plays a key role in certain kinds of memory (organic amnesia); but it is also known that amnesic symptoms can result from psychiatric causes that are not necessarily triggered by brain damage, and which typically only affect premorbid autobiographical memories (psychogenic amnesia).

Although Lawson was one of the first to describe a relatively selective memory disorder associated with chronic alcoholism in 1878, it was the Russian physician Korsakoff who, between 1887 and 1891, gave the classic description of the amnesic syndrome. Most of the cases he described were of chronic alcoholism, but he also described patients with neoplasm, carbon monoxide poisoning, diabetes and persistent vomiting. Korsakoff syndrome, the variant of amnesic syndrome that bears his name, is believed to be caused by thiamin deficiency. Most often thiamin deficiency is caused by chronic alcoholism, but in the twentieth century it became clear that other forms of nutritional disorder such as anorexia nervosa or persistent vomiting may cause thiamin deficiency and amnesia. Korsakoff also noted that patients with his syndrome usually showed lack of insight into their condition and often falsely recollected information (confabulated). These symptoms have subsequently been found not to be universal, or even particularly common, features of other kinds of amnesia.

Later work clearly showed that the amnesic syndrome could arise from a wide range of other causes including several kinds of vascular incident (such as infarctions of the posterior cerebral artery, and rupture and repair of anterior communicating artery aneurysms), herpes simplex encephalitis and some kinds of meningitis, as well as surgical

treatment of temporal lobe epilepsy involving bilateral removal of the medial temporal lobes. The most famous amnesic patient, known by his initials as HM, had such an operation in 1953, and nearly fifty years later still showed a very severe anterograde amnesia and a less severe retrograde amnesia mainly affecting memories acquired in the years immediately preceding his surgery. It was first suggested by Ribot in 1882 that memories acquired further in the past before brain damage occurred are more resistant to impairment. In other words, he predicted that retrograde amnesia should be temporally graded such that older memories are less impaired.

The history of research on amnesia may be broken into three overlapping stages. The first stage, which began with Lawson, Korsakoff and Ribot, involved systematic clinical observation of patients. The second stage, which began after the Second World War, involved the application to amnesic patients of more formal experimental procedures drawn from mainstream cognitive psychology. In the third stage, modern *in vivo* brain imaging technologies made it possible to determine exactly what brain lesions cause which kinds of memory deficits. This work is complemented by the exploration of which brain regions are activated when normal people use the memory processes that are impaired in amnesic patients. For decades, work on human amnesic patients has been complemented by research on animal models of amnesia in which it is possible to localize damage more focally.

FORMS OF AMNESIA

Amnesia is divisible into organic and psychogenic forms. Psychogenic or functional amnesia, which includes fugue states and multiple personality disorders, typically has no apparent physical cause and is believed to have a psychiatric origin. People with psychogenic amnesia are believed to be neither merely pretending to be unable to remember, nor consciously trying not to remember or create new memories, although it is often possible to identify emotional benefits arising from such patients being unable to remember. This contrasts them with malingerers, who are pretending or consciously trying not to remember.

Fugue states consist of a sudden loss of all autobiographical memory together with the loss of personal identity. Typically, these states are short-lived, lasting only a few hours or days, although there are reports of fugues being maintained over long periods. Fugues tend to be precipitated by a traumatic event such as bereavement or marital strife, and the memory loss may be interpreted as a form of adaptive response in which patients dissociate themselves from their own identity as a means of escaping from the traumatic experience. In multiple personality disorder, a patient appears to have at least two different personalities, and sometimes as many as 20. The different personalities are used to compartmentalize the patient's experiences, and a particular personality needs to be active for particular experiences to be recalled. In addition to fugues and multiple personality states, there are cases when loss of autobiographical memory for the premorbid past is less complete. In these cases the person usually has a retrograde amnesia that is selective for autobiographical memory, but with no impairment of the ability to acquire new autobiographical memories. The ability to acquire new memories is only rarely disrupted in cases of psychogenic amnesia.

Organic and psychogenic amnesias can usually be distinguished from each other by examining the patient's medical history. If the patient has suffered a brain injury, and there is damage to brain areas known to be involved in memory functioning, an organic basis to the memory disorder is likely. In contrast, if there has been no brain trauma or evidence of brain disease, it is more likely that the memory disorder has a psychogenic basis. Some cases are more difficult to interpret; in these, there is evidence of brain damage that is either inconsistent with the pattern of memory impairment observed or does not seem extensive enough to explain the severity of the observed memory impairment. In such cases psychogenic factors may overlie an organic disorder or, conversely, organic factors such as epilepsy may exacerbate an underlying psychogenic disorder.

Like psychogenic amnesia, organic amnesia may be transient, although more often it is permanent. Transient organic amnesia may occur following electroconvulsive therapy and epileptic seizures. It also occurs in post-traumatic amnesia, during the early period following head injury, or emergence from coma in severely injured patients when patients have difficulty in storing and/or retrieving new information. Finally, best known is transient global amnesia, in which there is an abrupt onset of severe anterograde amnesia and a more variable, temporally graded retrograde amnesia. The attack typically lasts for a number of hours and then gradually resolves, leaving the patient with a dense loss of memory covering the period of the attack and a few hours preceding it, but with a more or less restored ability to lay down

new memories. It has been shown that blood flow to the medial temporal lobes and sometimes the thalamic region is temporarily reduced during attacks. The cause of this reversible dysfunction of memory-related regions (see next section) is unknown, but is sometimes associated with migraine.

The severity of the memory deficits in permanent organic amnesia usually remains stable, although there may be some recovery following the initial brain injury. However, amnesia is also typically the major characteristic of the early stages of Alzheimer disease: in this neurodegenerative disease not only does the amnesia became worse as the disease progresses, but other cognitive and memory deficits also appear.

Psychogenic amnesia typically involves a retrograde amnesia for personal episodes and no anterograde amnesia. It is interesting, therefore, that it has recently been claimed that brain damage can also cause a retrograde amnesia in the context of minimal anterograde amnesia. Cases of such focal retrograde amnesia have been used to identify which brain structures are involved in remote memory function. However, such research is controversial because (a) it is difficult to explain how a patient can fail to recall a premorbidly formed memory while being able to store and retrieve new memories fairly normally, and (b) it is difficult to exclude the possibility that the amnesia has a psychogenic explanation.

NEUROANATOMY OF AMNESIA

Damage to any one of several distinct brain regions, which include the medial temporal lobes, the midline diencephalon, the basal forebrain and possibly parts of the prefrontal neocortex, is sufficient to cause the amnesic syndrome. Although these regions comprise distinct gray matter structures, they are all interconnected and there is evidence that damage to the fibre tracts, such as the fornix, which link the different regions can also cause the syndrome, or at least some of its characteristic memory impairments (Tranel and Damasio, 1995).

The medial temporal lobes include the perirhinal and parahippocampal cortices, which receive processed information from the posterior and anterior association neocortices. They provide nearly two-thirds of the cortical input to the hippocampus via an intermediate projection to the entorhinal cortex (Figure 1). The hippocampus, therefore, receives inputs of processed modality-specific and polysensory information, semantic information and possibly other kinds of information related to planning and movement activities from the association

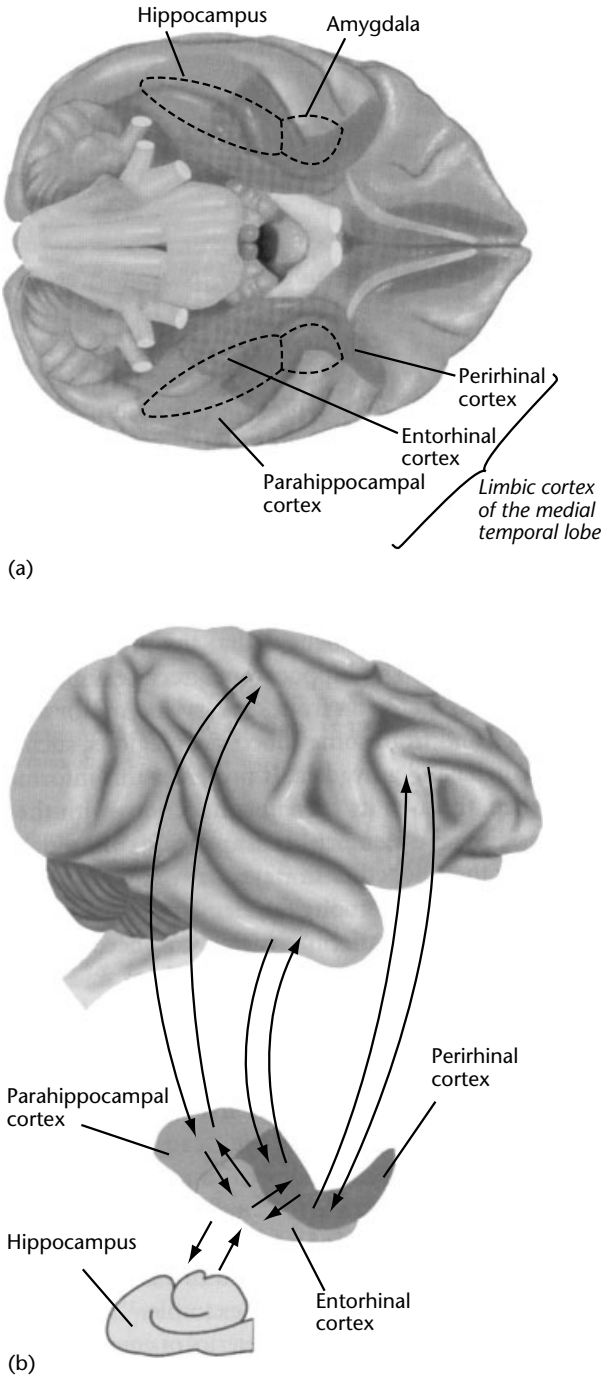

Figure 1. (a) Ventral view of a typical nonhuman primate (monkey) brain which illustrates the position of the medial temporal lobe cortices and the hippocampus and amygdala (which lie just above them). (b) Sagittal view of the same structure, that illustrates the two way connections which exist between the hippocampus and entorhinal cortex; the entorhinal, parahippocampal, and perirhinal cortices; and the parahippocampal and perirhinal cortices, and overlying neocortical structures.

cortices. Combined damage to all medial temporal lobe regions produces severe anterograde and retrograde amnesia in humans and monkeys (Zola-Morgan and Squire, 1993). Research with monkeys has shown that perirhinal cortex lesions alone cause severe anterograde amnesia with badly impaired recognition, whereas parahippocampal cortex lesions may primarily disrupt some kinds of spatial memory. Hippocampal lesions are known to produce mild anterograde and retrograde amnesia, although there is controversy about the nature of this impairment. In humans, this is because selective hippocampal damage is rare, and some of the patients reported have shown equivalent recognition and recall deficits, whereas others have shown moderately severe recall deficits but mild or undetectable recognition deficits. These selectively impaired patients show milder retrograde amnesias than are found in patients with large medial temporal lobe lesions. There is also evidence that severe (and perhaps focal) retrograde amnesia may depend on damage that includes parts of the anterior temporal neocortex and possibly parts of the prefrontal neocortex. The medial temporal lobes contain the amygdala, which is interconnected with the hippocampus and lies above the perirhinal cortex. Although studies with monkeys indicate that amygdala lesions do not usually impair recognition, there is growing evidence that this structure is essential to some aspects of emotional memory and that damage to it reduces the memory advantage of 'emotional' stimuli over neutral ones (Phelps *et al*, 1998).

Evidence from both animals and humans indicates that damage to either the mamillary bodies or the nuclei and fibre tracts in the midline thalamus also causes amnesia. It is not agreed, however, precisely which thalamic regions are implicated in amnesia, although there is good evidence that damage to either the anterior thalamic or the dorsomedial thalamic nuclei causes memory impairments. The memory disorder in Korsakoff syndrome is particularly associated with lesions of the mamillary bodies, and of the anterior and dorsomedial thalamic nuclei.

Structures in the basal forebrain modulate neocortical and medial temporal cortex activity, so it is not surprising that damage to these structures can produce amnesia. The septum and diagonal band of Broca project to the hippocampus via the fornix, and lesions to these basal forebrain structures have been found to cause amnesia. The same has also been claimed for lesions of the nucleus accumbens, a structure that also has hippocampal and other limbic system connections.

The prefrontal neocortex is a large region, and although lesions to some parts of it (e.g. the dorsolateral prefrontal cortex) have been found to disrupt particular kinds of memory in humans and animals, it is often argued that, in contrast to organic amnesia, these deficits are usually mild and are secondary to failures of planning that impair encoding and retrieval of complex information, and hence disrupt memory. It remains possible, however, that damage to those frontal regions, such as the orbitofrontal cortex, which receive the heaviest projections from relevant thalamic nuclei and the medial temporal lobes (Tranel and Damasio, 1995), causes a memory disturbance that is more similar to the amnesic syndrome.

Damage to the fornix, which connects the hippocampus directly (and indirectly via the mamillary bodies) to the anterior thalamus, has been shown to cause a mild amnesia. This includes a mild retrograde amnesia, although – as with hippocampal lesions – it is disputed to what extent the anterograde amnesia caused by the lesion involves recognition as well as recall. A similar disagreement extends to the mamillary bodies and the anterior thalamus.

The extent to which all the structures discussed above function as a unitary and integrated system subserving memory for facts and episodes, and to what degree damage to the different structures impairs these forms of memory in subtly different ways, is not yet clear. Figure 2 illustrates some of the connections between the structures implicated in amnesia. These connections may provide clues about the kinds of processing that may underlie fact and episode memory.

IMPLICIT AND EXPLICIT MEMORY

The terms 'explicit memory' and 'implicit memory' were introduced by Graf and Schacter (1985). Explicit memory is the form of memory required when people know that they are remembering (often a particular episode). It is believed to be essential for performing tasks involving free recall, cued recall or recognition of previously presented information. In contrast, implicit memory is the form of memory required to mediate performance on tasks in which memory is indicated by some behavioral change without the person being aware of remembering something. Implicit memory is functionally heterogeneous and includes skill learning, various forms of simple conditioning, and perceptual learning. It also includes an information-specific kind of implicit memory called priming, which mediates performance on tasks

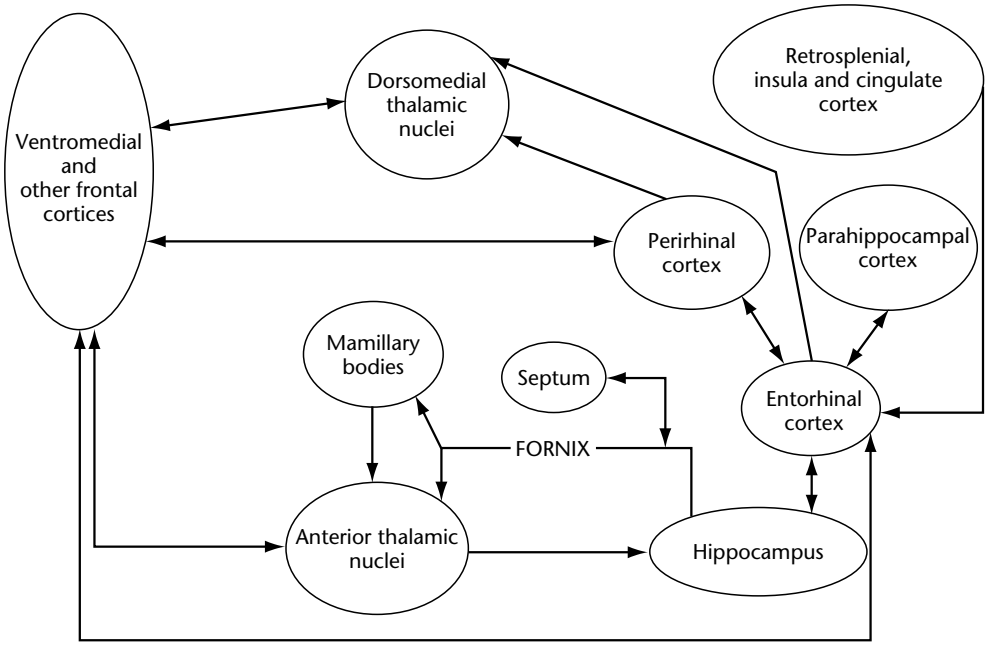

Figure 2. Flow chart illustrating the connections which exist in the primate brain between the components of the medial temporal lobes, the midline diencephalon, and the prefrontal neocortex. Damage to any of these structures is believed to cause at least some of the memory symptoms of the amnesic syndrome. The connections between the structures may provide a useful constraint on theories about what functional deficits underlie the amnesic syndrome.

such as fragment completion, perceptual identification and speeded reading. In experimental investigation into these tasks, participants first study specific information (e.g. words or pictures) and then, after a delay, are required to perform some operation related to that information (such as identifying a briefly displayed studied word). Techniques are used to minimize the degree to which participants use explicit memory to influence their performance. Priming is indicated to the extent that study influences subsequent behavior (e.g. identification) towards the studied information when the behavior is not affected by explicit memory. For example, the speed of reading studied words, compared with similar unstudied words, may be greater; or briefly displayed studied words may be better identified, even when the words are not recognized as having been studied.

Although people with organic amnesia are typically impaired at all tasks involving explicit memory, it has been suspected since the time of Claparède that implicit memory may be preserved. There is good evidence that such patients are relatively unimpaired at acquisition and retention of motor, perceptual and even cognitive skills. Impairments have only become apparent when normal participants' performance, unlike that of the amnesic patients, has been enhanced by their ability to use explicitly remembered strategies. Lacking explicit memory of the learning experiences, amnesic patients are often surprised by their own skills. Similar preservation of simple kinds of classical conditioning has been found. There is some evidence that patients show impaired conditioning when there is a short delay between the end of the conditioned stimulus and the start of the unconditioned stimulus, but it has been argued that this occurs because trace conditioning depends on explicit memory for the relationship between the stimuli. Patients also show preservation of several kinds of perceptual learning and memory.

Evidence about whether people with organic amnesia show preserved priming for all kinds of information is more conflicting. Most but not all researchers believe that patients show preserved priming when the studied information – whether perceptual or semantic in nature – is already familiar and in memory prior to study (e.g. words or famous faces). However, a meta-analysis by Gooding *et al* (2000) indicates that although this is true, amnesic patients' priming of novel items and novel associations is impaired. It might be argued that people with amnesia only show impairments on priming tasks when performance in normal people is facilitated by their superior explicit memory; but this explanation is somewhat implausible because the meta-analysis deliberately compared priming of similar kinds of familiar and

novel information on which participants performed similar priming operations at test (for example, made word or non-word judgments as quickly as possible). Also, it cannot explain why priming of novel associations is impaired even when normal participants have no recognition of studied stimuli. There has been no study of whether people with amnesia show preservation of priming for premorbidly acquired memories, so it is unknown whether such priming might differentiate between organic and psychogenic amnesia. However, when both priming and explicit memory for the same information are impaired it is likely that the information never has been or is no longer in long-term storage.

WHAT CAUSES AMNESIA?

Theories about the causes of amnesia must specify what processes break down to cause the syndrome, what lesions are responsible for this, and why. Initially, theorists treated amnesia as a unitary deficit in which only one functional process was disrupted, and all the lesions that produce amnesia disrupted this process although perhaps to differing degrees. Most researchers now believe that the syndrome comprises several distinct functional deficits, each caused by a different lesion (or, more probably, set of lesions), because it is also believed that processes are mediated by systems of structures rather than individual structures.

Theories may differ with respect to: (a) whether encoding, storage or retrieval processes are disrupted in amnesia; (b) what kinds of fact and episode information the impaired processes directly affect; and (c) what specific structures are thought to be critically damaged and, thus, necessary for the execution of the process in question. It has been proposed that defective encoding (processing and representing) of semantic information causes amnesia, or at least the amnesia of Korsakoff syndrome (Butters and Cermak, 1980). The patients' relatively normal intelligence and ability to show normal memory benefits from directed semantic encoding argue against this view. Also, people with amnesia can answer questions normally about semantic (and some other kinds of) information when the questions are asked immediately following presentation. Amnesia is, therefore, unlikely to be caused by a semantic encoding deficit. However, some evidence suggests that perirhinal cortex lesions may impair integrative encoding of high-level sensory information. This possible visual object encoding deficit remains to be systematically tested in humans.

There have been few retrieval deficit theories of amnesia. The most popular such account suggests that people with amnesia may suffer excessively from interference during retrieval and so should show abnormal numbers of intrusion errors, and benefit abnormally from cues restricting the number of possible responses (Warrington and Weiskrantz, 1974). The evidence favoring these predictions is not good, and the theory also leaves unexplained why people with amnesia have this retrieval problem unless it is a secondary effect of a storage defect. Such a defect could cause a secondary problem with interference during retrieval if contextual associations to studied information were not stored. In such a case, contextual markers would not be available to identify which of several competing alternatives was the appropriate memory in a given situation, with the result that intrusion errors would be made unless appropriately restrictive cues were provided. In general, however, retrieval theories imply that people with amnesia store information normally (in anterograde amnesia) or retain it normally (in retrograde amnesia). This possibility is hard to refute decisively so it still needs to be proved convincingly that amnesic patients do not store fact and episode information normally. If such patients do store this information normally, then they should show preserved priming for the same fact or episode information for which their explicit memory is impaired.

Most theories have suggested that amnesia is caused by a failure of the consolidation processes that put all fact and episode information into long-term storage. More specifically, a failure to put the associations linking together the components of facts and episodes normally into memory storage in the minutes or hours following exposure is postulated to cause anterograde amnesia. Retrograde amnesia is explained in terms of a retention failure for the same kinds of association. However, many researchers believe that anterograde and retrograde amnesia are closely linked deficits because there is a slow consolidation process, perhaps involving rehearsal and repetition, through which long-term storage of memories is eventually achieved in the neocortex (Squire and Alvarez, 1995). If they are correct, then memories acquired closer in time to the brain injury should be more disrupted than memories acquired earlier. The alternative view proposes that such temporally graded retrograde amnesia does not occur because memories about episodic incidents (although perhaps not facts) continue to depend on the medial temporal lobes and perhaps other structures

implicated in amnesia for as long as they last (Nadel and Moscovitch, 1997). The evidence is conflicting.

Aggleton and Brown (1999) have proposed one of the currently most influential theories. Their theory states that amnesia is functionally heterogeneous. They argue that lesions of the hippocampus, fornix, mamillary bodies or anterior thalamus disrupt rapid associative memory consolidation such that recall memory is greatly impaired, but item recognition – except when it relies heavily on recollection – is relatively intact. Another version of this view is that these lesions selectively impair recall because they impair the consolidation of contextual associations such as those involving spatial and temporal relations. In contrast, the theory postulates that lesions to the perirhinal cortex or some of its projections disrupt 'true recognition' or familiarity. Perirhinal cortex lesions also disrupt recollection because they prevent critical inputs reaching the hippocampus. This theory is controversial, as is the view that anterior temporal neocortex lesions disrupt long-term storage of facts and episodes so perhaps causing focal retrograde amnesia (see Kapur, 1992). However, both theories illustrate the increasing belief that the amnesic syndrome is functionally heterogeneous.

TREATMENT OR REMEDIATION

Organic amnesia is permanent and stable when it is caused by destruction of memory-relevant brain regions. In the future, the condition might possibly be treated effectively by transplantation of stem cells to replace some of the lost neurons and form appropriate connections; at present, however, only remediation using strategies to compensate for the permanently impaired memory processes is feasible. Psychogenic amnesia is typically transient, but when it is long-lasting it may be treated by hypnosis or by drugs such as amobarbital, both of which therapies can reduce patients' resistance to retrieving memories.

Remediation of permanent organic amnesia is important because severe memory impairment typically means that patients will be easily disoriented, have only a hazy sense of their past, cannot work, and may require careful supervision in the home. They may also be bored because social interactions and interesting pastimes that depend on memory, such as reading and watching television, can no longer be pursued.

Recent research has focused on alleviating the consequences of having a deficient memory rather than attempting to improve the impaired underlying memory processes. Four kinds of technique have been moderately successful. First, the use of cognitive strategies (such as imagery in teaching the name of a new acquaintance) has been effective, although patients rarely use these strategies unless specifically instructed to do so.

Second, Baddeley and Wilson (1994) have developed an 'errorless learning' technique, in which the possibility of making errors during training is eliminated by repeatedly providing the information to be learned and thereby preventing guessing. For example, patients learn a series of face–name associations by being repeatedly shown a picture of a face immediately followed by its name, which has to be read or copied. This method has been used successfully to teach a range of information. It is uncertain whether it relies on the patients' use of implicit memory or priming, or their residual explicit memory.

Third, Glisky and Schacter (1987) developed the method of 'vanishing cues' for teaching specific factual information to facilitate activities in a particular domain. They taught an amnesic patient a set of computer terms and procedures by gradually reducing the strength of cues given. The patient was able to return to employment where this knowledge could be used. Like the errorless learning technique, this method leads to very few errors being made, and evidence that the memory it produces is dependent on the cues matching those used during learning suggests that it may depend on priming.

Fourth, the ability of people with amnesia to cope may be improved by modifying their immediate environment – for example, by keeping to a regular routine or encouraging the use of a diary. The repetition produced by regularizing the local environment in this way may help patients by allowing them to form important long-term memories using their relatively intact, but slow to consolidate, neocortical storage sites. Like the methods of errorless learning and vanishing cues, the approach could also be effective because the patients' relatively good memory for local (and other) information may depend to a greater extent than does the memory of normal people on implicit memory or priming. There is evidence that this form of memory is much more sensitive than explicit memory to the effects of interference (see Mayes *et al*, 1987), so that the generation of errors would be much more likely to impede appropriate learning in people with amnesia than it would in normal people. Thus, the prevention of errors by making the local environment more regular and repetitive

might facilitate learning in amnesic individuals as well as providing them with a less memory-demanding set of surroundings.

Amygdala

Intermediate article

Ralph Adolphs, University of Iowa, Iowa City, Iowa, USA

CONTENTS

The amygdala is a collection of nuclei in the telencephalon that connect with the sensory neocortex, frontal cortex and a variety of structures that regulate physiological responses. The amygdala participates in the regulation of emotion, attention, memory, and decision-making.

INTRODUCTION

The amygdala is an almond-shaped collection of nuclei which connect with disparate brain structures. In mammals, it is located in the anterior medial temporal lobe, just rostral to the hippocampal formation. The amygdala has a role in motivational, emotional, and cognitive processes that involve information of biological value to the organism. This function has been dissected at the finest grain in animal studies, whereas studies in humans have typically focused on the amygdala's contribution to social cognition.

NEUROANATOMY AND CONNECTIVITY

The amygdala's connections with other brain structures are enormously diverse: it connects with sensory and association neocortex, with hypothalamus, brainstem nuclei, basal forebrain, ventral striatum, thalamus, and hippocampus, and with other structures (Amaral *et al*., 1992). This broad architecture permits the amygdala to link sensory representations of stimuli (in sensory and association neocortex) with modulation of both body state (via hypothalamus and brainstem) and cognition (via frontal cortex, basal forebrain, hippocampus, and other structures). The amygdala's complex connectivity with other brain regions is complemented by an equally complex internal connectivity among its various component nuclei.

Sensory Input to the Amygdala

The amygdala receives sensory information from all sensory modalities. Signals directly from the olfactory bulb are a prominent form of input in mammals other than primates. Projections from brainstem nuclei and insular cortex provide somatic visceral information, and projections from thalamus and temporal cortex provide auditory and visual information.

In primates, the visual inputs to the amygdala have been best studied. Visually responsive high-level neocortices in the anterior temporal lobe project to the lateral amygdala, and provide highly processed visual information. The amygdala in turn projects back to all those regions from which it receives inputs (via its basal nucleus), and also projects back to some earlier sensory cortices from which it does not receive direct inputs. In fact, the amygdala provides nonreciprocal feedback to all earlier stages of visual processing in the ventral visual stream (which subserves object recognition), including the striate cortex (Figure 1). The feedback from the amygdala terminates in layers 1 and 2 of the cortex and provides an interesting architecture by which the amygdala could, in principle, modulate perception even at the earliest stages of processing.

Connectivity with Brainstem and Hypothalamus

The amygdala connects with nuclei in the brainstem and hypothalamus via its central nucleus. These targets permit the amygdala to modulate the organism's somatic state, a function that constitutes an important component of emotion. For instance, emotionally arousing stimuli are known to trigger increases in sympathetic autonomic tone. The amygdala participates in such triggering via its projections to the paraventricular hypothalamus and periaqueductal gray matter, structures that in turn contain neurons that project to the intermediolateral cell column in the spinal cord, constituting the preganglionic sympathetic neurons. It is thus possible in many cases to trace a causal chain from

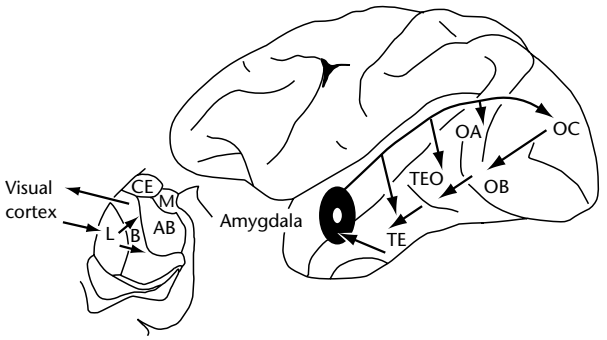

Figure 1. Connections of the amygdala with sensory neocortex. In the monkey, visual inputs to the amygdala originate in high-level visual cortices in the anterior temporal lobe. Feedback from the amygdala is both reciprocal and nonreciprocal, providing projections to all levels of visual processing, including V1. This architecture in principle permits the amygdala to participate in perceptual processing at even the earliest cortical stages. Inputs to, and outputs from, the amygdala rely on the lateral and the basal nucleus, respectively (inset at left). Reproduced with permission from Amaral *et al*. (1992), copyright John Wiley. **Key**: AB, accessory basal; B, basal; CE, central; L, lateral; M, medial; OA, OB, OC, sectors of occipital cortex; TE, TEO, sectors of temporal cortex.

the central nucleus of the amygdala to various effector structures in the brainstem and hypothalamus, all of which regulate autonomic, visceral, and endocrine states (Figure 2).

As with the sensory information, the amygdala's effector communications are not one-way. The amygdala receives information about the somatic changes it effects, via multiple channels. In addition to receiving visceral somatic information from the insular cortex, it also receives more direct information from brainstem nuclei such as the parabrachial nucleus and the nucleus of the solitary tract, as well as direct input from the spinal cord. The vagus nerve is an important route by which body-state information is conveyed to the brainstem and then to the amygdala.

Connectivity with Structures Mediating Cognitive Processes

The above two sets of connections – with sensory cortices on the one hand, and with autonomic and visceral effector structures on the other – would suffice to permit the amygdala to trigger emotional body-state changes in response to sensory stimuli. While this is certainly one function of the amygdala, it is only a small part of the whole story. Perception of emotionally salient stimuli triggers changes not only in the functioning of an animal's body, but also in the animal's cognition. Attention, memory, decision-making and other processes are all prominently modulated by emotion and motivation, and all involve the amygdala.

The amygdala's participation is by virtue of its connections with many other brain regions. For instance, the amygdala projects to cholinergic nuclei in the basal forebrain, which modulate attention; to the hippocampal formation, which is involved in memory; and to the prefrontal cortex, which is involved in planning, reasoning, and decision-making. All these structures, and all the cognitive processes they mediate, can be influenced by the amygdala. As a consequence, emotionally salient information from a sensory stimulus will lead to changes not only in an animal's body, but also in the way that its brain processes that information.

To put the amygdala's role in full perspective, we need to add yet another consideration. The amygdala links sensory percepts with both bodily and cognitive changes, but it does not do so on its own. Rather, it does so in conjunction with other structures that have similar roles. In particular, the amygdala functions in tandem with the orbitofrontal cortex and the ventral striatum, both of which are intimately involved in motivation and emotion.

Intrinsic Processing of the Amygdala

Inputs to the amygdala from the sensory neocortex terminate in the lateral nucleus. Outputs from the amygdala to brainstem and hypothalamus originate in the central nucleus, and outputs to many other structures, such as ventral striatum, cingulate cortex and orbitofrontal cortex, issue from the lateral and basal nuclei, among others. Connections between the lateral nucleus and the basal, central and other nuclei mediate considerable internal information processing (Pitkanen *et al*., 1997). Put simply, there is a flow of information from the lateral to the central parts of the amygdala, either directly or via intermediate nuclei. Lesions of the lateral nucleus can therefore impair all aspects of an animal's conditioned response to a stimulus, whereas damage to other nuclei impairs only specific components of such a conditioned response (Amorapanth *et al*., 2000).

AMYGDALA FUNCTION IN ANIMALS

The amygdala has been studied extensively in rats, cats and primates, with some convergent findings. Ever since the classical studies of Klüver and Bucy in the 1930s, the amygdala has been implicated in emotional and social behavior. This rather vague function has now been dissected by studies

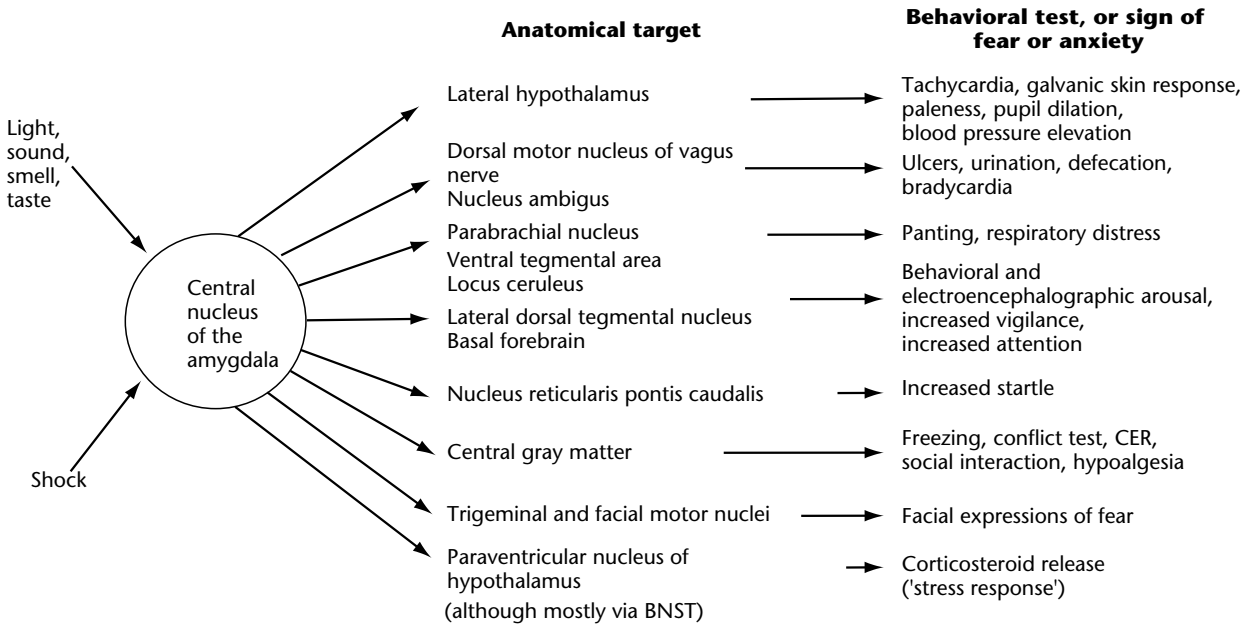

Figure 2. Outputs of the amygdala that mediate fear conditioning. Conditioned and unconditioned stimuli are associated in the lateral amygdala, which in turn projects to the central nucleus of the amygdala. The central nucleus can effect autonomic, endocrine, and visceromotor fear responses by virtue of its connections with structures in brainstem and hypothalamus. Reproduced with permission from Davis (1992), copyright John Wiley.

demonstrating a more specific role in associating sensory stimuli with their rewarding or punishing contingencies. Different nuclei within the amygdala contribute to different aspects of this function. It remains an open question whether the amygdala's basic function is related to reward and punishment in general, or whether it is more specifically related to processing the significance of social stimuli, although findings in animals are more consistent with the former possibility than with the latter.

Regulation of Physiological Responses

Consistent with its connections to hypothalamus and brainstem nuclei, the amygdala participates in regulating a wide array of physiological responses (Figure 2). Direct evidence for this role comes from experiments in which electrical stimulation of the amygdala by implanted electrodes produced changes in physiological measures such as blood pressure and heart rate, corroborating the amygdala's role as an autonomic control structure, and consistent with its known connectivity.

Fear Conditioning

The topic that has seen the most intense research in animal studies is fear conditioning. In fear conditioning an animal is presented with two different kinds of stimuli: an unconditioned stimulus (US) that is highly aversive, such as an electric shock, and a conditioned stimulus (CS) that is neutral to begin with, such as a light. At the beginning of the experiment the animal shows a physiological reaction to the electric shock, but not to the light. During the conditioning experiment, the electric shock is paired with the light stimulus. After several such CS–US pairings the animal learns that the light predicts the shock, a form of associative emotional memory. The final stage of the experiment is to present the CS without the US. The fear-conditioned animal will behave as though it is afraid of the light, a conditioned response that can be measured in a number of ways as indicated in the right-hand column in Figure 2. (*See* **Conditioning**)

Conditioned fear responses critically depend on the amygdala, and cells within the lateral amygdala increase their firing rates and the synchrony of their discharges following the CS. Importantly, the dependency of the acquisition and expression of fear-conditioned responses on the basolateral amygdala is not attributable solely to the amygdala's role in the behaviors used to assess fear conditioning, such as 'freezing' (Maren, 1999).

Current debates

Despite the popularity of the fear-conditioning paradigm, there are many issues still to resolve. Is

the amygdala essential for all components of fear conditioning? Is the memory of the US–CS association actually stored in the amygdala? Affirmative answers to these questions have been given by some, but contested by others. One general issue is whether the amygdala is essential to the acquisition of fear-conditioned responses, or whether its function is better thought of as modulatory and important rather than essential (e.g. Wilensky *et al*., 2000). Another issue concerns the role of fear conditioning during development, and its relation to emotional and social development. Fear conditioning is not seen at birth in all species; possibly its absence early in life permits an animal to form an attachment to its parent regardless of the circumstances (that is, even when the presence of the parent occurs together with aversive events).

Reconsolidation

If the amygdala is indeed the repository for the associations between conditioned and unconditioned stimuli in fear-conditioning experiments, it remains an open question precisely how such storage is implemented. One possibility is that a relatively permanent association is stored in a way that is insensitive to future perturbations. This appears unlikely at first, because it is known that fear-conditioned responses can be extinguished if the CS is presented for many times without the US. However, this extinction appears to rely not on an erasure of the memory trace within the amygdala, but rather on active inhibition of the amygdala's fear memory by the prefrontal cortex. It thus appears that some components of the fear memory may indeed be stored in the amygdala permanently, an aspect that may have implications for indelible fear responses in humans, for instance in posttraumatic stress disorder and phobias.

Although the memory of the fear conditioning in the amygdala may be relatively permanent, it is not static. Experimenters have found that reactivating the fear memory by presenting the CS rendered the memory trace plastic and susceptible to alteration. After reactivation of the memory, there was a period of 'reconsolidation' during which the memory could indeed be erased. Injections of drugs that inhibited protein synthesis, such as anisomycin, were found to erase the fear-conditioned memory, but only when given during such a period of reconsolidation (Nader *et al*., 2000). This finding may have broad applicability to memory in general, including memory in humans, and emphasizes the dynamic nature of memory representations in the brain. (*See* **Memory Consolidation**)

Molecular mechanisms

What are the molecular mechanisms whereby the amygdala stores the associations learned during fear conditioning? There is evidence that such associative memory may rely on long-term potentiation (LTP) within the amygdala. The acquisition of fear-conditioned responses requires within the amygdala some of the molecular machinery known to be involved in the induction and maintenance of LTP, such as protein kinase A, protein synthesis, and perhaps even NMDA (*N*-methyl-D-aspastate) receptors (although this has not been conclusively shown). It thus appears likely that at least some components of the amygdala's role in associative memory are similar at the molecular level to those required for memory consolidation in the hippocampus.

Other Forms of Conditioning

The amygdala has also been implicated in other forms of conditioning besides the classical (Pavlovian) fear response. Conditioning to stimuli that are rewarding rather than aversive does not appear to rely on the amygdala to the same extent that conditioning to aversive stimuli does. However, the amygdala has been found to be important in reinforcer devaluation effects, in which the value of a rewarding US is changed: for instance, by using food reward as the US and then later feeding the animal to satiation on that food so that the US no longer has the same motivational value that it did at the time of conditioning. Normal animals are sensitive to such manipulations, but animals with amygdala damage are not. These studies suggest that a comprehensive function of the amygdala in associative emotional memory is the provision of access to current values of reinforcing stimuli, a function in which it participates intimately with the orbitofrontal cortex (Baxter *et al*., 2000).

Modulation of Motivated Learning

Aversively motivated learning can be modulated by various neurotransmitter systems acting within the amygdala (Cahill and McGaugh, 1996; McGaugh, 2000). For instance, injection into the amygdala of one of a variety of drugs that modulate neurotransmission mediated by γ-aminobutyric acid (GABA), noradrenaline, or opiates immediately after training influences long-term memory for stimulus avoidance. Research suggests that the amygdala can influence such memory by modulating consolidation that actually takes place within other brain structures, such as the hippocampus and basal ganglia.

The amygdala thus participates in at least two distinct types of memory function: associative emotional memory (such as fear conditioning), which may be stored within the amygdala, and modulation of memory (including declarative memory in humans) that is itself dependent on other brain structures.

Influences on Attention

The amygdala's role in attentional processes has been investigated in a number of experiments (Holland and Gallagher, 1999). One component of attention, orienting behavior towards cues that have become associated with rewarding contingencies, has been found to rely on a circuit involving the central nucleus of the amygdala and its connections with the substantia nigra and the dorsal striatum. Another important component of attention, increased allocation of processing resources toward novel or surprising situations, appears to depend on the integrity of the central nucleus of the amygdala and its connections with cholinergic neurons in the substantia innominata and nucleus basalis, structures in the basal forebrain. Thus, the amygdala could modulate cholinergic neuromodulatory functions of the basal forebrain nuclei, and consequently modulate attention, vigilance, signal-to-noise and other aspects of information processing that depend on cholinergic modulation of cognition. Through circuits including components of amygdala, striatum, and basal forebrain, emotion may thus help to select particular aspects of the stimulus environment for disproportionate allocation of cognitive processing resources; in other words, the organism preferentially processes information about its environment that is most salient to its immediate survival and wellbeing. Recent studies in humans have demonstrated such a role (Anderson and Phelps, 2001).

Social Behavior

Although early experiments concerning the effects of amygdala lesions highlighted impairments in social behavior, this issue has received scant attention. In general, the findings of the effects of focal amygdala lesions have corroborated impairments in social behavior – typically an increase in tameness and placidity towards others (Weiskrantz, 1956; Emery *et al*., 2001). However, how such an impairment plays out in a group of animals depends on the species and on the environmental circumstances in which the social behavior is assessed: monkeys whose amygdala has been removed can be the subjects of either increased affiliative or increased aggressive behavior from other monkeys in the troop. It remains an open question to what extent the deficits in social behavior that are seen following amygdala damage could be understood in terms of (or could be reducible to) impairments in more basic processing of reward and punishment.

AMYGDALA FUNCTION IN HUMANS

In contrast to animal studies, which implicate the amygdala in processing reward and punishment in a general sense, studies with humans point to a more restricted function in processing socially relevant stimuli. Furthermore, findings in humans indicate a role of disproportionate importance in processing stimuli related to negatively valenced stimuli that signal threat, ambiguity or distress. However, the apparent differences between animals and humans may be due more to the kinds of tasks and stimuli employed than to actual differences in amygdala function.

Conditioning

Damage to the human amygdala impairs the ability to acquire conditioned fear responses. One study showed that a patient with bilateral damage to the amygdala, but with an intact hippocampal memory system, was unable to acquire conditioned autonomic responses, but was nonetheless able to acquire declarative memory about the CS–US pairings: in essence, the patient could tell the experimenter that the light had been paired with the shock – so the patient knew, as a declarative fact, that light predicted shock – even though there was no fear conditioning (Bechara *et al*., 1995). Functional imaging studies have likewise found evidence that the amygdala is activated in normal people during fear conditioning.

Recognition of Emotion

Both lesion and functional imaging studies of the brain have confirmed a role for the amygdala in perception and recognition of emotional stimuli. The evidence is strongest in the case of recognition of emotions from facial expressions, although there is some evidence for emotion perception from auditory, olfactory, and gustatory stimuli as well. A rare patient with bilateral amygdala lesions was found to have an impaired ability to recognize fear from faces, a finding subsequently replicated in several other studies, and corroborated by the finding that

viewing faces showing expressions of fear activates the amygdala in normal people.

Despite these studies, it remains unclear precisely which emotions the amygdala is most involved in processing. While fear recognition is notably impaired in some people with amygdala damage, this is not always the case, and others with similar brain lesions are more impaired on recognition of anger, sadness or disgust (Adolphs *et al*., 1999). Functional brain imaging of psychiatric patients has shown that some people with phobias or similar disorders have abnormal activation of the amygdala (for example, an abnormally high activation of the amygdala occurs in response to 'neutral' faces, in patients who are socially phobic). All these findings have led to proposals that the amygdala processes predominantly information about threat, about ambiguity or about distress. At this stage, all we can say for sure is that the amygdala participates in processing knowledge of emotion from a variety of social stimuli, such as facial expressions – but whether there is specificity regarding particular emotions, and what that specificity consists of, are issues requiring further research. Some functional imaging studies have found activation of the amygdala by pleasant stimuli also.

Another important point is that the amygdala does not appear essential for all knowledge regarding emotions. In particular, knowledge of emotions from explicit lexical stimuli is unaffected by amygdala damage. People with bilateral amygdala damage are quite able to use words such as 'fear' appropriately in conversation, and possess considerable knowledge about the kinds of situation that would normally make people feel afraid, or the kinds of behavior elicited by fear. However, the concept of fear that people with bilateral amygdala damage have is not entirely normal: it has gaps. It seems likely that those gaps are most prominent for emotional knowledge that cannot be explicitly encoded into language – such as knowing what a fearful face looks like.

Functional imaging studies have confirmed that the amygdala is activated by emotional facial expressions, especially ones showing fear. Such activation has been observed even when the face stimuli were presented so briefly that they could not be consciously recognized (Whalen *et al*., 1998) There is evidence to suggest a differential role for the right amygdala in processing emotional visual stimuli below the level of conscious awareness, and for the left amygdala in processing emotional stimuli that are consciously perceived (Morris *et al*., 1999).

It is less clear to what extent the amygdala is involved in recognition of emotional auditory stimuli; some lesion and functional imaging studies have suggested such a role, whereas others have not. The most robust activation of the amygdala to sensory input with emotional significance has been observed with olfactory stimuli, where unpleasant smells reliably activate the amygdala (Royet *et al*., 2000).

Emotional Memory

As in animals, the amygdala in humans modulates memory for emotionally arousing stimuli. In humans, this has been studied in regard to declarative memory. When normal people are shown emotionally arousing pictures or film, they remember best those stimuli that they found the most emotionally arousing. Functional imaging studies have shown that activation of the amygdala at the time of encoding (when the stimuli were shown, while the subject was in the scanner) correlated with how well the person later remembered those same stimuli when questioned several weeks later (Canli *et al*., 2000). Consonant with these findings, people with bilateral amygdala damage were less able to remember emotionally arousing pictures – they remembered them only as well as neutral pictures. Electrical stimulation of the vagus nerve – which provides visceral body-state information to brainstem nuclei and the amygdala – has been shown to enhance memory, consistent with the idea that emotional body states can modulate cognitive processes such as memory, at least in part via the amygdala.

Social Cognition

The human amygdala plays a more general role in social cognition as well. In one study, participants were asked to judge how trustworthy or approachable they found other people; those with bilateral amygdala damage gave abnormally positive ratings (Adolphs *et al*., 1998). Other studies have found activation of the amygdala in response to viewing faces of people of another race: the amygdala habituated more rapidly when viewing faces of one's own race than of another race, and amygdala activation to unfamiliar faces of a different race correlated with implicit measures of race evaluation (Phelps *et al*., 2000). Such racial outgroup responses may fit into the general scheme of threat detection and vigilance by the amygdala. Finally, there is evidence linking amygdala pathology to autism (Baron-Cohen *et al*., 2000): some

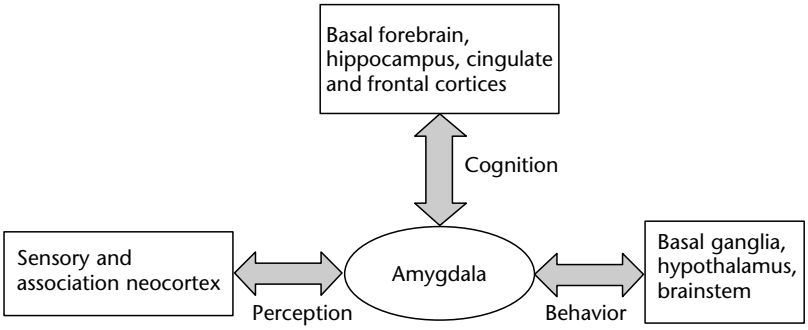

Figure 3. Connectivity of the amygdala at the system level. The amygdala's participation in multiple effector mechanisms permits mediation of a concerted, integrated emotional response in both body and brain.

structural and functional imaging studies suggest such a link, and people with autism are impaired on some of the same tasks as people with bilateral amygdala damage. Clearly, the amygdala is important in social cognition.

A SYSTEMS-LEVEL VIEW OF THE AMYGDALA

While it is clear that the amygdala broadly participates in emotion and social behavior, the mechanisms that underlie this function remain poorly understood. In general terms, the amygdala can participate in emotion in three different ways (Figure 3). First, it can link perception of stimuli to an emotional response, by virtue of its inputs from sensory cortices and its outputs to control structures such as the hypothalamus, brainstem nuclei, and periaqueductal gray matter; second, it can link perception of stimuli to modulation of cognition, by virtue of its connections with structures involved in decision-making, memory, and attention; and third, it can link early perceptual processing of stimuli with modulation of such perception via direct feedback. The amygdala's participation in all three of these mechanisms enables it to contribute globally to affective processing in a concerted manner, by modulating numerous processes simultaneously.

To which aspects of emotion could such mechanisms contribute? Certainly, the amygdala contributes to emotional responses to stimuli. It also contributes to the recognition of emotions, but this function is likely to be indirect: possibly the amygdala's modulation of perception by feedback, or its elicitation of components of an emotional response, can contribute to the brain's ability to reconstruct knowledge about the emotion signaled by a stimulus. Finally, the amygdala's role in feeling an emotion (in the conscious experience of emotion) is unclear, and may well be inessential.

Anosognosia

Introductory article

Alfred W Kaszniak, University of Arizona, Tucson, Arizona, USA

CONTENTS

Anosognosia is a clinical syndrome in which a patient with brain dysfunction appears unaware of a neurological or neuropsychological impairment, such as paralysis or amnesia.

INTRODUCTION

In 1914, Joseph Babinksi described several patients who were paralyzed on the left side of their body due to damage in the right hemisphere of the brain. Most startling was his observation that these patients appeared to have no awareness of their paralysis and never complained about their impairment. Although others had made similar observations in the late 1800s and early 1900s, it was Babinski who coined the term 'anosognosia' to describe this syndrome. Subsequently, the term has been extended to encompass similar unawareness of deficit phenomena in persons suffering from a variety of neurological impairments. Anosognosia has been documented for deficits as diverse as blindness, impaired recognition of familiar faces, hemiplegia (paralysis of one side of the body), and aphasia (acquired disorder of language comprehension and expression).

Historically, there has been debate about how best to conceptualize anosognosia. In their influential book entitled *Denial of Illness*, published in 1955, neurologist Edwin Weinstein and psychologist Robert Kahn argued that anosognosia is a motivated unawareness, reflecting the operation of psychodynamic defense mechanisms that block symptoms or deficits from awareness. Although this conceptualization is intuitively appealing, neurologist and neuroscientist V. S. Ramachandran has recently noted that the psychodynamic interpretation does not account for two important aspects of anosognosia. First, anosognosia typically occurs only when there is damage to particular brain structures. These structures include lower portions of the parietal cortex, frontal lobes, and the subcortical structures connecting to these structures, and anosognosia is seen predominantly following right, rather than in left hemisphere brain damage. Anosognosia is typically not observed when peripheral, spinal, lower brain stem, or cortical primary sensory or motor areas alone are affected. Second, the unawareness is often quite specific. For example, a patient may deny his/her hemiplegia but readily admit to other disabling or distressing symptoms. Occasionally, persons with hemiplegia of both their upper and lower extremities may admit that their leg is paralyzed but insist that their arm is not. In contrast to earlier psychodynamic conceptualizations, most current theories of anosognosia adopt a neuropsychological explanation, attributing the impaired awareness of deficit to dysfunction in brain circuits important for self-monitoring. In a frequently cited review paper published in 1989, neuropsychologists Susan McGlynn and Daniel Schacter emphasized the specificity and dissociations (i.e. intact awareness for some impairments and impaired awareness for other impairments) found in different forms of anosognosia in individuals with focal neurological damage. Based on their review of clinical-pathological correlation studies, they concluded that damage to right parietal and/or frontal brain regions is of particular importance in causing anosognosia.

CLINICAL STUDIES OF ANOSOGNOSIA FOR AMNESIA AND DEMENTIA

Some of the most informative recent research for understanding the neuropsychology of anosognosia comes from studies of amnesia and dementia. Amnesia refers to an acquired loss of memory. Although amnesia may be due to psychological factors, such as intensely frightening personal experiences, it is most often due to neurological causes. In 1889, the physician S. S. Korsakoff described the amnesic disorder that is now called Korsakoff's syndrome and observed that most of his patients had little apparent awareness of their

memory deficits. Korsakoff's syndrome most typically occurs in persons with a history of chronic alcohol abuse and thiamine deficiency, with postmortem examinations of the brain revealing damage in the dorsomedial nuclei of the thalamus, the mammillary bodies, and other nearby brain structures. Computerized tomographic (CT) and magnetic resonance imaging (MRI) studies have confirmed the presence of thalamus and mamillary body damage in persons with Korsakoff's syndrome and have also revealed damage to the orbitofrontal and mediotemporal areas of the cerebral cortex. In addition to severely impaired memory (thought to be associated with the thalamic, mamillary body, and mediotemporal cortex damage), persons with Korsakoff's syndrome also show other cognitive deficits, such as impairments in shifting and dividing attention, in performing tasks requiring hypothesis generation, testing, and problem solving, and in preserving the temporal order of information. These deficits appear to be associated with the frontal cortical damage.

In contrast to persons with Korsakoff's syndrome, individuals with equally severe memory impairment, due to restricted medial temporal (particularly hippocampus) damage, do not show frontally related cognitive dysfunction and are generally well aware of their memory deficits. Persons with amnesia due to medial temporal damage may spontaneously comment about their memory difficulty and rely upon mnemonic aids such as reminder notes and schedule books. Thus, amnesic patients without frontal lobe damage appear to have intact awareness of their memory deficits, while those with frontal damage (i.e. those with Korsakoff's syndrome) are anosognosic for their amnesia.

The study of persons with missile wound brain injuries has supported the association of impaired awareness of memory deficit with frontal lobe damage. Those who lack awareness of their memory impairment have been found to have damage involving both frontal lobes (among other areas), whereas those with intact awareness of their memory deficits show no evidence of frontal lobe damage. Other persons with amnesic syndromes due to brain damage that includes the frontal lobes (e.g. anterior communicating artery aneurysm rupture, closed head injury) have also been found to be anosognosic for their memory deficits.

Dementia refers to progressive impairment of multiple cognitive functions (including memory) due to acquired brain disease. Clinical accounts of anosognosia in dementia syndromes began appearing in the early 1980s. The most prevalent cause of dementia is Alzheimer disease (AD), a neurodegenerative disorder with neuron loss and other microscopic brain changes that are most prominent in the medial temporal, posterior temporal, parietal, and frontal brain regions. Persons with AD show relatively severe memory impairment early in the course of their dementia, along with milder deficits in other cognitive functions (e.g. perception, language, judgment). These other cognitive functions become increasingly impaired with disease progression. The memory and other cognitive impairments correlate with the pattern of observed neuropathological changes, particularly involving medial temporal and frontal brain regions. Many persons with AD, particularly as their illness progresses, show impaired awareness of their memory and other cognitive deficits.

Impaired awareness of deficits has also been noted in clinical descriptions of other types of dementia besides AD. These include vascular dementia (typically associated with multiple and bilaterally distributed small cerebral strokes), frontotemporal dementia (presenting with impaired impulse control, poor social judgment, and cognitive deficit, and typically involving severe atrophy of frontal and temporal cortices), and Huntington's disease (an autosomal dominant genetic neurodegenerative disorder characterized by motor, cognitive, and emotional dysfunctions associated with caudate nucleus atrophy and frontal lobe changes).

AD and other dementia types involve impairments in a wide range of cognitive, behavioral, emotional, and functional areas. Thus, the study of deficit awareness in dementia provides an opportunity for examining the degree to which impaired awareness is general or limited to particular deficits. Clinical observations have suggested that awareness of deficit can be selective in dementia. For example among persons with AD some deny all cognitive deficits, while others claim that their memory is good but admit to difficulty in finding words, and still others deny memory impairment but admit to reading difficulties.

Some clinical observers have suggested that loss of awareness of deficits occurs earlier in the course of illness for frontotemporal dementia than for AD. Both of these progressive dementia types are typically associated with signs of frontal lobe pathology, but frontal damage is generally more severe in the early stages of frontotemporal dementia than AD. This is consistent with the association between frontal lobe pathology and impaired awareness of deficit that has been observed in amnesic syndromes.

Studies of the neuropsychological correlates of anosognosia for dementia in AD have also supported a relationship to frontal lobe damage. For example, an association has been demonstrated between decreased fluency of speech (as measured in tests requiring the generation of words within particular categories or beginning with particular letters) that is typically seen following left or bilateral frontal cortex damage, and clinical ratings of anosognosia for memory deficit in persons with AD. Similarly, anosognosia for dementia in AD has been shown to be associated with both lower general mental status test performance and specific impairment on measures of 'executive functions' (involving the capacity to plan and carry out complex, goal-oriented behavior) that are sensitive to frontal lobe dysfunction. More direct evidence of a relationship to frontal brain dysfunction is provided by research showing that clinical ratings of anosognosia for memory loss in persons with AD are associated with decreased blood flow (as measured by single photon emission computed tomography) in the right dorsolateral frontal brain region. (*See* **Alzheimer Disease**; **Amnesia**; **Huntington Disease**)

LABORATORY STUDIES OF ANOSOGNOSIA FOR AMNESIA AND DEMENTIA

Although important, clinical observations alone allow for only limited and tentative conclusions concerning both the neurobiological correlates and nature of anosognosia. There are several reasons for the inferential limitations of clinical observations. First, the methods employed in making clinical observations of impaired awareness (e.g. clinical rating scales, patients' responses to interview questions) are generally unsystematic and have varied across investigators. This creates problems for any attempt to compare findings across studies. Further, clinical observations alone do not allow for the development of any articulated theory of anosognisia. One goal of research on anosognosia is to make theoretical inferences concerning human metamemory functions. The term 'metamemory' refers to those processes involved in the conscious monitoring and control of, as well as beliefs about, one's own memory functioning. Theoretically important questions such as whether anosognosia represents inaccurate self-efficacy beliefs (e.g. a person's beliefs about how well their memory generally functions), poor self-monitoring, or some combination of these or other factors, cannot be adequately addressed by purely clinical observations. Recently, systematic laboratory studies have become available, allowing quantitative measurement of different aspects of awareness in amnesia and dementia. Most of these laboratory studies have focused on awareness of deficits in Korsakoff's and other amnesic syndromes or AD.

Laboratory approaches have typically used one of three different methods to study awareness of memory deficit: comparisons of patient self-report and others' ratings of patient disability; evaluation of the accuracy of patients' predictions for their performance on specific cognitive tasks; or feeling-of-knowing paradigms (e.g. confidence ratings or rankings regarding the likelihood that recently learned information or long-term knowledge which the individual failed to recall would later correctly be recognized from among multiple alternatives). These different methods provide information relevant to theoretical formulations concerning the nature of metamemory impairment. Psychologists Christopher Hertzog and Roger Dixon, reviewing metamemory research involving healthy adult participants, have distinguished three aspects of metamemory: (1) knowledge about how memory functions and the utility of different strategies in memory tasks; (2) memory self-monitoring, defined as awareness of the current state of one's own memory system; and (3) self-referent beliefs about memory (memory self-efficacy beliefs). In general, the first two methods described above (patient self-report versus others' ratings; performance prediction accuracy) have provided information relevant primarily to those aspects of metamemory concerning knowledge of how memory functions and memory self-efficacy beliefs. The third method (feeling-of-knowing paradigms) provides information that can be interpreted as more specifically relevant to questions about memory self-monitoring.

Results of studies using these different methods are consistent with the conclusion that anosognosia for amnesia occurs in memory-impaired persons who also have frontal lobe dysfunction. Further, evidence suggests that it is the memory self-monitoring aspect, rather than knowledge of how memory operates, that breaks down in disorders such as Korsakoff's syndrome and AD. However, the question of whether at least some of the relevant research findings may reflect a failure to update self-efficacy beliefs (due to the memory impairment itself), rather than impaired self-monitoring, awaits an answer from future research.

Prospective studies are needed to determine whether premorbid patient characteristics may be related to anosognosia. Further research is also needed to simultaneously compare different

methods of assessing anosognosia, particularly contrasting those approaches relevant to theoretically distinct aspects of metamemory (e.g. memory self-monitoring versus memory self-efficacy beliefs). Finally, there is a need for additional studies concerning the practical implications of anosognosia for amnesia and dementia: for example relationships may exist between anosognosia for dementia and the tendency to engage in potentially risky behavior such as driving. It has been hypothesized that impairment in the ability to recognize cognitive and behavioral limitations may play a role in both driving and other risky behavior among persons with AD. Given the practical implications, research designed to systematically test this hypothesis is of high priority.

Aphasia

Intermediate article

Argye Elizabeth Hillis, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA
Alfonso Caramazza, Harvard University, Cambridge, Massachusetts, USA

CONTENTS

Aphasia is impairment of language caused by brain damage. The term may be restricted to acquired disorders of language caused by focal brain lesions such as stroke, or more broadly applied to developmental language disorders or impairments due to diffuse brain damage such as head trauma or dementia.

INTRODUCTION

The study of language disturbance resulting from brain lesions has fascinated researchers over the years. In 1836, Dax reported one of the first cases of aphasia and proposed that the disorder reflected damage to a language center in the left frontal lobe. Nearly thirty years later, Paul Broca made a similar proposal on the basis of several patients with minimal speech output who were found to have lesions in the left, posterior frontal lobe at autopsy. That report, published in 1861, set the stage in the following decades for the theories of Wernicke and Lichtheim, which postulated the existence of various 'brain centers' that were critical for separate aspects of language. However, over subsequent decades the Wernicke–Lichtheim proposal of aphasia classification based on damage to specific brain centers was severely criticized by Freud, Marie, Goldstein, Luria and others. At the same time, competing classification schemes were being proposed (Table 1). The resulting confusion concerning the relationship between brain damage and aphasia led to a virtual abandonment of aphasia research until 1965, when Norman Geschwind revived and expanded the Wernicke–Lichtheim theory. In this scheme, three distinct domains of language were said to be mediated by specific regions of the left cortex: fluency of speech production mediated by Broca's area (posterior-inferior frontal lobe); comprehension of language mediated by Wernicke's area (posterior superior temporal gyrus); and repetition mediated by the arcuate fasciculus – a white-matter tract between Broca's area and Wernicke's area. The relative sparing or impairment of these domains formed the basis of the 'classical aphasia' syndromes: Wernicke, Broca, conduction, transcortical sensory, transcortical motor, and mixed transcortical aphasias. (Note that a similar effort to revive this same classification scheme had been made by Nielsen in 1936, but with far less impact.) These aphasia syndromes, identified in chronic stroke patients, roughly coincide with distinct cortical lesions on radionuclide brain scans or computed tomographic head scans. Perhaps because of these early claims of a correspondence between the site of brain damage and the resulting clinical aphasia syndrome, Geschwind's proposal gained credibility. It has since formed the basis for much of the current conceptualizations of aphasia in neurology, speech–language pathology and neuropsychology. Although it is not evident that Geschwind's classification scheme is any more valid than other proposed classification schemes, it merits description because of its historical influence.

CLASSICAL APHASIA SYNDROMES

Wernicke Aphasia

Wernicke aphasia is characterized by prominent impairment in the understanding of spoken words and sentences, and effortless production of utterances with the basic structure and melody of sentences but mostly devoid of clear meaning. Speech

Table 1. Proposed aphasia classifications: syndrome clusters comparable to Geschwind's 1965 classification

Other classification systems (year)	*Geschwind classification*							
	Broca aphasia	*Wernicke aphasia*	*Conduction aphasia*	*Global aphasia*	*TCM*	*TCS*	*MTC*	*Anomic aphasia*
Broca (1865)	Aphemia	Verbal						Amnesia
Wernicke (1881)	Cortical	Cortical	Conduction	Total	TCM	TCS		
Lichtheim (1885)	Motor	Sensory						
Head (1926)	Verbal	Syntactic				Nominal		Semantic
Pick (1931)	Expressive	Impressive		Total				Amnestic
Weisenberg and McBride (1935)	Expressive	Receptive		Expressive/ receptive				Amnestic
Kleist (1934)	Word muteness	Word deafness	Repetition					Amnestic
Neilsen (1936)	Broca	Wernicke	Conduction	Global	TCM	TCS		Amnestic
Wepman (1964)	Syntactic	Jargon				Pragmatic		Semantic
Luria (1966)	Efferent motor	Sensory	Afferent motor		Dynamic	Acoustic		Semantic

MTC, mixed transcortical; TCM, transcortical motor; TCS, transcortical sensory.

in Wernicke aphasia is described as 'empty', consisting of strings of real words in apparently meaningless combinations ('yeah, that was the pumpkin furthest from my thanks') or phrases replete with word-like neologisms ('the scroolish prastimer ate my spanstakes'). Repetition resembles spoken output – mostly fluent jargon. Naming is generally poor. The syndrome has been ascribed to lesions of the posterior-superior temporal cortex (Wernicke's area), often along with the nearby parietal cortex.

Broca Aphasia

The hallmark of Broca aphasia is nonfluent, 'agrammatic' speech output with relatively preserved comprehension ability. Spoken output is characterized by the omission of grammatical morphemes, such as prepositions, conjunctions and verb inflections. To illustrate, a patient with Broca aphasia described her recent onset of neurological impairments in this way: 'Stroke…Sunday…arm, talking – bad.' Often there is concomitant effortful production of words with distorted articulation. Repetition of sentences mirrors spontaneous speech – it is effortful and telegraphic, but the gist of the sentence is mostly retained. Naming is generally impaired, with verbs named more poorly than nouns. Comprehension of single words is mostly spared, but comprehension of syntactically complex sentences is often impaired (Caramazza and Zurif, 1976). The full syndrome is typically ascribed to damage to Broca's area, along with adjacent frontal fields, and the underlying white matter and basal ganglia. Damage to Broca's area, or the underlying white matter, alone causes selective impairment in planning and executing the complex movements to articulate words, a disorder known as 'aphemia'. Often, cases of Broca aphasia evolve from an initial global aphasia, with severely impaired comprehension as well as speech production. In at least some cases, this 'evolution' may be due to initial poor blood flow to Wernicke's area posterior to the stroke, causing impaired comprehension. If blood flow is restored to that area, comprehension improves (Figure 1).

Global Aphasia

The combination of severely impaired comprehension of language and extremely limited speech output is known as global aphasia. Spontaneous speech and repetition are limited to a few perseverative words or nonword utterances (e.g. 'dee dee dee'). Cursing or the production of frequently used phrases, such as 'I don't know' or 'How do you do?', may be spared in this and other aphasia types. Global aphasia is usually ascribed to large lesions involving both Broca's and Wernicke's areas, and the basal ganglia, but can also result from two lesions – one anterior and one posterior.

Transcortical Aphasia

In transcortical aphasias the fluency and content of sentence repetition far exceed those of spontaneous speech. In transcortical sensory aphasia, comprehension of language and content of speech are markedly impaired (as in Wernicke aphasia) but sentence repetition is relatively accurate. A lesion posterior to Wernicke's area, near the temporooccipital junction, is frequently implicated. In transcortical motor aphasia, comprehension and content of

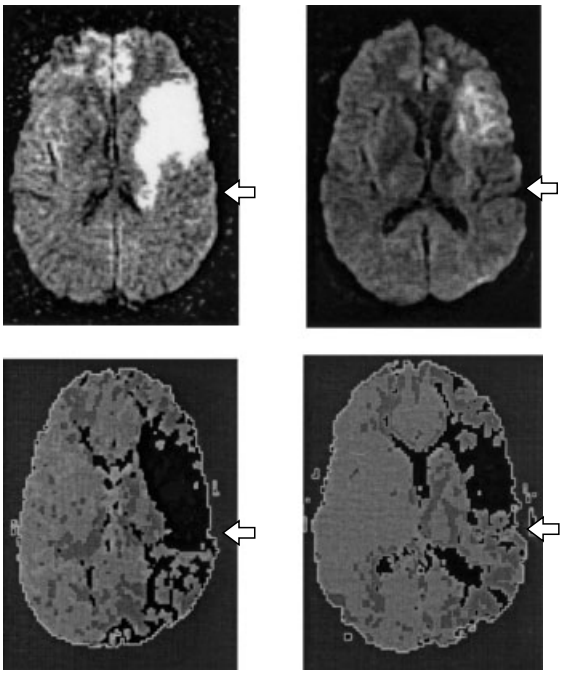

Figure 1. (a) Magnetic resonance diffusion-weighted (top) and perfusion-weighted imaging showing acute stroke involving Broca's area (and other frontal regions, and caudate), with hypoperfusion of Wernicke's area (arrow) in a patient with early global aphasia. Darker areas are regions of poor perfusion. (b) The same patient, after partial reperfusion of Wernicke's area and concomitant resolution of the comprehension deficit.

speech are relatively intact, while fluency and articulation are impaired in spontaneous speech but not in sentence repetition. Stroke or poor blood flow to the left dorsolateral frontal lobe, anterior and superior to Broca's area, has been associated with this form of aphasia. Finally, in mixed transcortical aphasia, also known as 'isolation syndrome', all language functions are impaired except repetition. Such patients can repeat sentences verbatim, with no evidence of comprehending them. A combination of lesions causing transcortical motor and transcortical sensory aphasia has been postulated as the cause of mixed transcortical aphasia.

Conduction Aphasia

In contrast to the transcortical aphasias, conduction aphasia is associated with disproportionately impaired sentence repetition. Speech is fluent and grammatical, although phonemic paraphasias are often present. The frequently observed phenomenon of progressive self-correction of speech errors, such as 'tormano, tornano, tornado', has been called '*conduit d'approche*'. In at least some cases the impaired repetition has been shown to be due to severely limited auditory short-term memory, such that the patient is unable to retain the entire sentence in short-term memory while articulating it (Warrington and Shallice, 1969). Conduction aphasia was initially claimed to result from lesions of the arcuate fasciculus (resulting in a putative disconnection between Wernicke's area and Broca's area), but there is little evidence for this particular lesion–deficit association. More recently, conduction aphasia has been ascribed to lesions of the left supramarginal gyrus and/or the insula or Wernicke's area.

Reading and Writing Disorders

In all of the above aphasia syndromes, reading comprehension is generally impaired at least to the degree of auditory comprehension, and written output is typically impaired at least as much as spoken output, often mirroring the content of speech. However, there are cases of pure (auditory) word deafness, in which comprehension of spoken language is severely impaired, but comprehension of written language is intact (Denes and Semenza, 1975). There have also been reported cases in which written naming accuracy far exceeds spoken naming accuracy. There are also a variety of patterns of pure reading impairment (alexia), writing impairment (agraphia) or both (alexia with agraphia), associated with different lesion sites.

Anomic Aphasia

In anomic aphasia the predominant problem is in naming, or word retrieval. Occasionally, naming is selectively impaired for certain categories, such as proper names, verbs or nouns (Goodglass *et al.*, 1966). More often in category-specific aphasias, both naming and comprehension are impaired or spared in selective semantic categories, such as that of living things (Warrington and Shallice, 1984). In pure anomic aphasia, words are understood but poorly retrieved. Anomic aphasia was initially considered to be nonlocalizing and to be the residual state of other aphasic syndromes, or broadly overlapping with Wernicke aphasia. However, one type of naming disorder that has a well-documented association with lesion site is that of optic aphasia, in which naming of pictures and other visual stimuli is severely disrupted, but naming in response to definitions and naming of stimuli presented in auditory or tactile form are spared. The patient appears to recognize the visual stimulus, and will

often mime how to use the object (Lhermitte and Beauvois, 1973). This clinical syndrome was initially described in 1881 by Dejerine, who proposed that optic aphasia occurred when there were two lesions: one in the left occipital lobe causing right homonymous hemianopia, such that all visual processing takes place in the right occipital lobe; and a second lesion in the splenium of the corpus callosum causing a disconnection of the right occipital lobe from the left hemisphere language areas (Figure 2). Thus, objects can be seen and recognized (in the right hemisphere) but not named (because of the disconnection to the left perisylvian region).

This classification scheme is summarized in Figure 3. It is important to note, however, that this 'syndrome' approach advocated by Geschwind and his colleagues is a clinical nosology, based on frequently co-occurring deficits in individuals who have sustained strokes. It is not based on any defensible theory of language: that is, it has not been proposed that there is a single underlying deficit that gives rise to all of the symptoms observed in a single aphasia syndrome. For example, Broca aphasia refers to the co-occurrence of nonfluent, agrammatic speech, difficulty in comprehending syntactically complex sentences, and effortful articulation. Although it has been postulated that damage to a 'central syntactic processor' might give rise to both the agrammatic speech and the impaired comprehension of syntactically complex sentences, such a proposal does not account for impaired speech articulation. Rather, it is likely that the frequent co-occurrence of these various symptoms reflects the fact that large, consistent regions of the brain are typically supplied by distinct cerebral arteries, the occlusion of which results in stroke. Suppose the large area supplied by a vessel such as the superior division of the left middle cerebral artery (MCA) consists of a number of smaller regions each responsible for a specific language function (e.g. grammatical sentence formulation, computation of syntactic relations, and articulation); occlusion of this vessel would typically result in impairment of all three functions. According to this hypothesis, occlusion of a different cerebral artery would spare these functions and

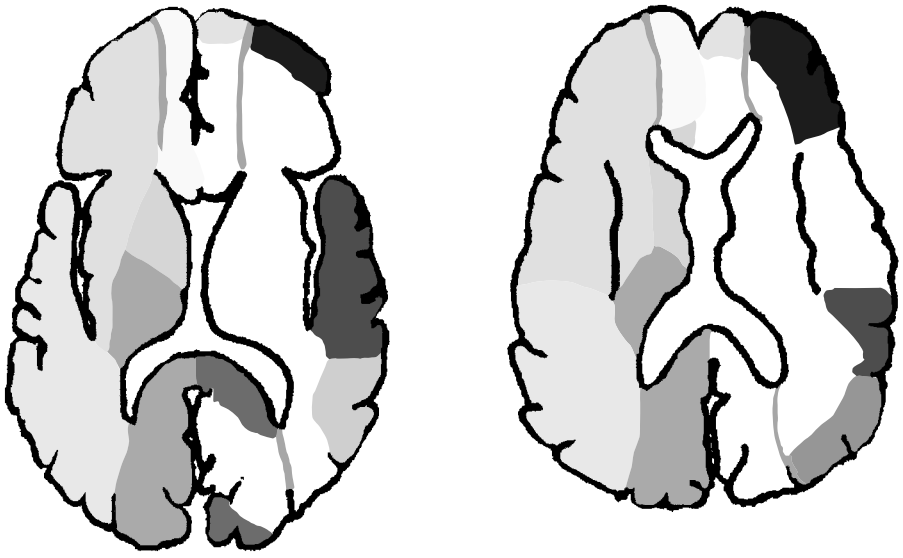

Figure 2. [*Figure is also reproduced in color section*.] Approximate vascular distributions of major arteries supplying language cortex are shown on the left side of each brain cut (the right hemisphere on computed tomographic and magnetic resonance imaging). Pale yellow, anterior cerebral artery (ACA); beige, anterior choroidal branch of internal carotid artery; light blue, superior division of the middle cerebral artery (MCA); pink, inferior division of the MCA; lavender, posterior cerebral artery (PCA); gray, border of ACA/MCA and MCA/PCA (potential 'watershed' areas). Regions of the cortex implicated in classical aphasia syndromes are shown on the right side of each brain cut (the left hemisphere). Bright yellow, Brodmann's area (BA) 10, associated with some cases of transcortical motor aphasia; dark blue, BA 44 and 45, Broca's area; red, BA 22, Wernicke's area; dark green, BA 39, the angular gyrus; light green, BA 37, the posterior middle temporal gyrus; purple, BA 31, the splenium of the corpus callosum and BA 18, visual cortex (areas associated with optic aphasia); gray, 'watershed' areas associated with the transcortical aphasias (the width of this territory depends on the degree of diminished flow in the ACA/MCA or MCA/PCA). Adapted from Damasio and Damasio (1989).

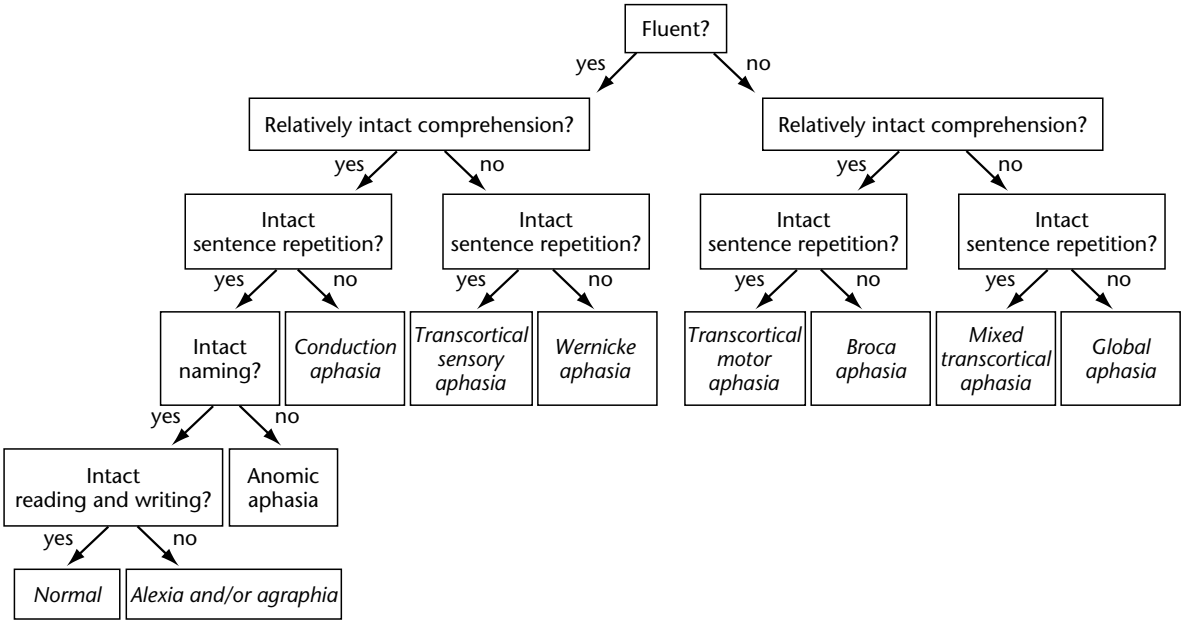

Figure 3. A decision tree for classifying aphasia according to Geschwind's 1965 scheme.

damage other functions. Thus, the clinical syndromes might serve to localize the region of the brain affected by the lesion, and identify the artery involved.

ANATOMICAL CORRELATES OF APHASIA SYNDROMES: VASCULAR DISTRIBUTIONS

There is a wealth of data consistent with the hypothesis that the syndromes described above are manifestations of occlusion of specific arteries. There is evidence that Broca aphasia reflects a blockage of the superior division of the left MCA which supplies the left posterior, inferior frontal lobe and much of the basal ganglia (Figure 2). Because this branch also serves the cortex responsible for motor function of the face and arm on the contralateral side, most patients with Broca aphasia have right face and arm weakness. In contrast, Wernicke aphasia is thought to reflect blockage of the inferior division of the left MCA, resulting in stroke in the left posterior temporoparietal area. This branch also supplies the optic tract (visual pathway), so that patients with Wernicke aphasia often have a contralateral visual field cut. Global aphasia typically reflects occlusion of the left proximal MCA before it divides, resulting in a large stroke involving the left frontotemporoparietal cortex and subcortical structures. Transcortical motor aphasia has most often been attributed to left anterior cerebral artery strokes, involving the left medial frontal lobe, but in other cases has been attributed to strokes in the watershed distribution on the border between the left anterior cerebral artery (ACA) and left MCA (see Figure 2). In these cases, blood flow in both the ACA and MCA is so diminished that it does not reach the borders of the normal territories. Similarly, the collection of symptoms that characterize transcortical sensory aphasia are frequently caused by watershed strokes between the left MCA and left posterior cerebral artery (PCA). Not surprisingly, mixed transcortical aphasia results from strokes involving both watershed regions (ACA–MCA and MCA–PCA), which can occur in the presence of low blood pressure resulting in poor blood flow through all of these vessels. Of course, there can be strokes involving only a portion of the territory of any of these vessels, which would plausibly result in only a subset of the symptoms that form a clinical syndrome. Thus, cases of anomia might be due to damage to a portion of the inferior division of the MCA territory, causing only part of the clinical syndrome of Wernicke aphasia. Anomia can also be caused by lesions involving only portions of the brain regions responsible for other aphasic syndromes, since it can be present in every aphasia type.

WEAKNESSES OF THE LESION–SYNDROME APPROACH

If the above clinical syndromes reflect the relative consistency of vascular beds, such that strokes

generally affect a typical collection of brain regions that may each be crucial for different language functions, it follows that brain damage caused by nonvascular lesions, such as tumor or trauma, would be likely to affect different brain areas and, consequently, different sets of language functions. In other words, profiles of language disturbance would not be expected to correspond with the classical aphasia syndromes. Indeed, tumor (primary or metastases), trauma, abscesses and other infections can all cause aphasia, but the patterns of impairment frequently do not fit the classification scheme outlined above. For example, herpes encephalitis tends to affect the mesial temporal and frontal lobes. When the encephalitis predominantly occurs in the left temporal lobe, a selective impairment in naming and comprehending animals and other living things is frequent. This type of category-specific language deficit has also been reported after closed head trauma, which preferentially affects the temporal lobes, and in the temporal variant of frontotemporal dementia (also called semantic dementia). Patients with frontotemporal dementia may have a primary progressive aphasia with deterioration in language functions before other cognitive abilities. In the temporal variant speech is often fluent, but progressively devoid of content or meaning. In contrast, the frontal variant of frontotemporal dementia is often heralded by a nonfluent, primary progressive aphasia, characterized by increasingly halting, telegraphic speech, with relatively spared comprehension. Tumors and abscesses cause widely disparate language disturbances, depending on both the location of the lesion and the rate of growth. Slow-growing lesions may cause no neurologic dysfunction until late in the disease, when associated brain swelling may acutely compress a ventricle or crucial structure. Even in stroke, there are notable variations in the human vasculature, such that the territory of a given vessel is somewhat different between individuals and may be markedly so in a few. This fact may account for the observation that in the best of circumstances, only about 50% of patients with aphasia due to stroke can be easily classified into one of the classical syndromes.

Furthermore, despite early reports documenting a close relationship between aphasia classification and site of lesion in chronic stroke, the correlation of aphasia type with location of lesion has not withstood recent attempts at replication. In the early studies, exclusion of patients with lesions but without aphasia, or patients with short-lived aphasia, may have resulted in overestimation of the value of lesion location for positively predicting aphasia. Another potential reason for the conflicting results is that early studies may have included only the 'best' or 'cleanest' cases of each syndrome type, whereas other studies may have included cases that were not as easily classifiable. Nevertheless, large-scale studies that have used similar measures to classify patients, and have included a category of 'others' for patients who do not fit well into any of the syndromes, have not provided evidence for a strong localization of these aphasia types (Kreisler *et al*., 2000). Kreisler and colleagues found that the most common site of lesion in patients with Wernicke aphasia and those with Broca aphasia was the insula-external capsule region in both groups. Only 60% of patients with Broca aphasia had strokes involving the inferior frontal gyrus (Broca's area), and only 70% of patients with Wernicke aphasia had strokes involving the left posterior temporal gyrus (Wernicke's area). However, stronger associations were found between impairment of specific language tasks (naming, repetition) or speech characteristics (fluency) and the site of lesion. For instance, 92% of patients with poor auditory comprehension had lesions involving the posterior superior and middle temporal gyri. This study indicates that there may be stronger localization of impairment for specific language tasks than for aphasia syndromes.

However, even the separation of impairments to different tasks may be too gross a characterization of language disorders to identify the neuroanatomical substrates. Kreisler *et al*. (2000) found, for example, that damage to any one of several regions of the brain results in impaired naming. The presence of damage to any one of five areas – the insula–external capsule plus the white matter underlying temporoparietal cortex, the medial temporal gyrus, superior frontal gyrus, middle frontal gyrus, or the thalamus – was associated with impaired picture naming. These observations probably reflect the fact that naming is a complex process, consisting of a number of cognitive processes that may take place in different brain regions. Naming a picture involves, at the very least, early visual processing resulting in recognition of the picture as something familiar; accessing the semantic representation of the object (the collection of features that define how that object is distinguished from other objects with different names); accessing the phonological form of the word (the lexical representation, or stored pronunciation of the

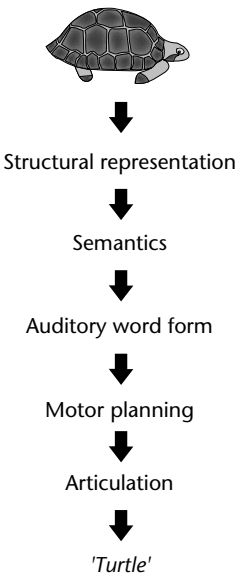

Figure 4. The cognitive processes underlying naming.

word); programming the movements of the lips, tongue, jaw and palate to produce the name; and finally, articulating the word by implementing the planned movements (Figure 4). It is plausible that these components of the naming task are carried out by separate regions of the brain. In this case, damage to any one of the regions would disrupt the person's ability to name an object, although the mechanism would be different across cases.

LOCALIZATION OF SPECIFIC LEXICAL PROCESSES AND REPRESENTATIONS

Studies using advanced neuroimaging of function or dysfunction have indicated that there may be more reliable localizations of each of these component processes (e.g. access to semantic information) than of broader language tasks (e.g. naming).

Structural Representations for Object Recognition

Evidence from surgical ablation studies in primates and functional activation imaging in humans indicate that visual object recognition entails a neural network consisting of retinotopic visual representations in primary visual cortex; visual feature perception, such as perception of color and movement in visual association cortex; unimodal visual/structural descriptions of the shape, color and motion of familiar objects in the medial superior temporal, lateral intraparietal, and the posterior and anterior inferior temporal cortices; and a polymodal representation of familiar objects in the midtemporal cortex.

Semantic Representations

Some lesion studies indicate that impairments of semantic representations (word meaning) are associated with lesions in Wernicke's area and the left middle temporal gyrus. Likewise, electrical stimulation of Wernicke's area interferes with lexical-semantic processing. Positron emission tomography (PET) studies, which show areas of 'activation' or increased regional blood flow (rCBF) associated with increased metabolism, also show activation of Wernicke's area and the left midtemporal cortex in semantic processing. Similar results are found with another method of functional imaging, perfusion-weighted imaging (PWI), which shows regions of poor perfusion, or blood flow, resulting in tissue dysfunction in the setting of cerebrovascular disease. Studies confirm a strong correlation between impaired access to semantics and poor perfusion of Wernicke's area (Hillis *et al*., 2001). Furthermore, when blood flow was restored to Wernicke's area in a subset of these patients, access to semantics was restored, indicating that this region is involved in semantic processing (see Figure 1).

Such findings do not allow the conclusion that Wernicke's area (or any other brain region) is alone responsible for a given cognitive process. For example, although Wernicke's area appears to be important for the understanding of words, it is unclear what – if any – semantic information is represented in this area. It is more likely that semantic representation is distributed across a variety of temporal and parietal brain regions and that the role of Wernicke's area is in linking phonological (spoken) word forms to meanings. Although it is often difficult to establish that patients with damage to Wernicke's area are impaired in mapping words to their meanings, rather than impaired at the level of meanings themselves, rare cases of dissociation between these two functions have been reported in patients with extraordinarily small lesions. For example, Hillis *et al*. (1999) described a patient, J. B. N., who spoke in fluent jargon and failed to comprehend spoken words or sentences, despite normal hearing and 'early' auditory processing. Nevertheless, J. B. N. had intact writing and comprehension of written language. Thus, this patient did not have impaired semantics, or word meanings, but was impaired in linking spoken

words to their meanings and vice versa, owing to poor blood flow in the sylvian branch of the anterior temporal artery, supplying Wernicke's area. Interestingly, this proposal about the role of Wernicke's area in linking words to their meanings was first put forward by Carl Wernicke himself in the 1870s.

Auditory Word Forms

Most functional imaging studies fail to distinguish between access to auditory word forms and mapping auditory word forms to semantics, since recognizing or saying a word is likely to 'automatically' activate its meaning. Hence, not surprisingly, PET studies show increased blood flow in Wernicke's area during tasks of auditory word-form processing. As discussed above, this region may be where auditory word forms are linked to semantics, not where auditory word forms are represented. Evidence from PWI in acute stroke patients indicates that impaired naming without impaired comprehension occurs with hypoperfusion (poor blood flow) just posterior and inferior to Wernicke's area. To illustrate, the patient whose scans are shown in Figure 5 had selective impairment in accessing auditory word forms for oral naming and oral reading when the posterior middle temporal gyrus was hypoperfused (receiving poor blood flow), but this impairment resolved when this region was reperfused the following day. Such studies indicate that the posterior middle temporal gyrus was crucial for access to auditory word forms for output, but not for semantics, in this patient.

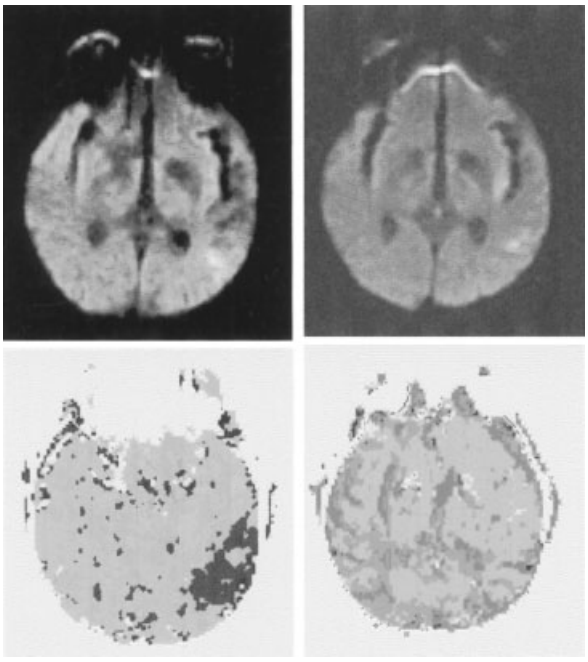

Figure 5. [*Figure is also reproduced in color section.*] (a) Magnetic resonance diffusion-weighted imaging (top) and perfusion-weighted imaging (bottom) showing hypoperfusion of the posterior middle temporal gyrus on day 1 in a patient with impaired access to auditory word forms for output, causing poor oral naming and oral reading, but intact semantics. (b) Day 2, showing reperfusion of the posterior middle temporal gyrus when naming and oral reading abilities had recovered.

Motor Speech

Studies of stroke patients indicate that Broca's area and the medial third of periventricular white matter are critical for motor speech. Similarly, intraoperative cortical stimulation, causing temporary, focal dysfunction of regions within Broca's area, disrupts motor speech.

WEAKNESSES OF THE LESION–DEFICIT APPROACH

We have discussed the role of various cortical regions that seem to be involved in specific components of the naming process. However, subcortical structures may also play a role in carrying out these processes, since subcortical stroke can cause aphasia. Studies of dysfunctional tissue, using PET, single photon emission computed tomography or PWI, have shown that at least some cases of aphasia associated with lesions restricted to subcortical structures show perfusion abnormalities in the temporoparietal cortex (Figure 6). These studies indicate that language deficits in such cases might be due to low blood flow to the cortex, rather than to the subcortical lesion itself.

Most lesion–deficit studies are complicated by the fact that the neural substrates of a given function may change after stroke. Reorganization of motor and sensory (and perhaps language) 'maps' shift over the course of days to months after brain injury or peripheral lesions. Therefore, the neural regions responsible for any given language process are probably identified best by experimental temporary lesions (such as those produced by transcranial magnetic stimulation) or by imaging stroke and dysfunctional tissue in the first day of stroke symptoms before significant reorganization occurs. Investigations of the correlation between language deficits in the first day of stroke and concurrent

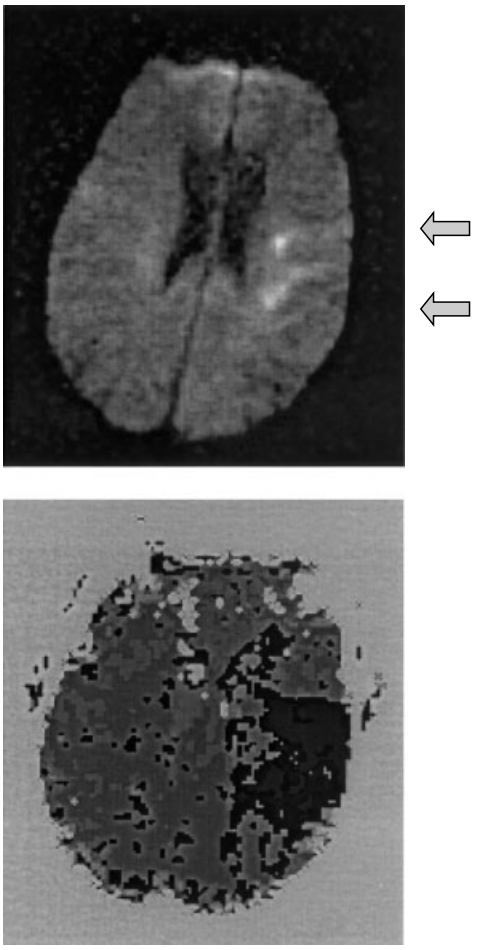

Figure 6. Diffusion-weighted imaging (top) showing tiny subcortical strokes (arrows), and perfusion-weighted imaging done at the same time, showing cortical hypoperfusion of the left temporal lobe, in a patient with global aphasia. Darker areas show regions of poor perfusion.

regions of abnormality defined by diffusion-weighted imaging (DWI), which shows areas of acute stroke within minutes of onset, and PWI are likely to be less contaminated by varying degrees of reorganization or recovery than traditional studies of chronic deficits and lesions. Preliminary studies using these advanced imaging techniques have revealed some strong associations between areas of dysfunction (due to hypoperfusion) and impairments of specific lexical functions in acute stroke before reorganization. These data converge with results from activation studies (using functional magnetic resonance imaging and PET) in support of the hypothesis that language tasks such as naming involve a network of brain regions that are each responsible for relatively discrete types of language representations or processes.

CONCLUSION

A profusion of reports spanning the last century and a half of brain lesions associated with patterns of language disturbance has shown that occlusion of a given cerebral artery or branch often results in a particular aphasia syndrome – a set of frequently co-occurring language deficits. More recent studies, using advanced functional imaging to show areas of activation in normal people engaged in a particular task or to show regions of dysfunctional brain tissue at the time of onset of specific language deficits, have demonstrated that distinct processing components of any language task, such as naming, are subserved by separate brain areas. These findings are consistent with research in cognitive neuropsychology and other branches of cognitive science, showing that each language task entails numerous levels of representation and processing which can be differentially impaired by brain damage. However, we are still far from defining a theory of the neural substrates for language processing that goes much beyond a coarse taxonomy of the major components of language: semantics, auditory (phonological) word forms and the like. This is in contrast to the rich data that aphasia provides for inferring the structure of normal language processing. For example, there are many reports of exquisitely fine-grained dissociations involving selective damage or sparing of spoken but not written word retrieval, nouns relative to verbs, content words (nouns and verbs) relative to function words, inflectional (e.g. number and tense) relative to derivational morphology (such as the '-er' rule of noun formation from verbs, e.g. 'hunter'), consonants relative to vowels, and so on. Dissociations such as these impose biologically motivated constraints on the theories of lexical processing. However, we still do not have an equally fine-grained analysis of the neural mechanisms corresponding to the functional units of language processing revealed through the detailed analysis of language deficits in aphasia.

Apraxia

Intermediate article

Michael Peters, University of Guelph, Guelph, Ontario, Canada

CONTENTS

Apraxias are movement disorders that cannot be attributed to primary motor problems such as paralysis or weakness, or to mental incompetence. Apraxias manifest in the failure to perform, accurately and smoothly, simple or complex movements. In studying apraxias we learn much about purposive motor behavior in general.

INTRODUCTION

In the absence of a generally agreed definition, apraxia is identified here as a higher-order movement disturbance that involves many facets of motor behavior (Freund, 1992). However, more restrictive definitions are often used in clinical applications. A widely used definition states that apraxia is 'a disorder of skilled movement that is not caused by weakness, akinesia, deafferentation, abnormal tone or posture, movement disorders – such as tremors or chorea – intellectual deterioration, poor comprehension, or uncooperativeness' (Heilman and Rothi, 1993). It manifests itself in the failure to perform, accurately and smoothly, simple or complex movements by imitation, or in response to verbal command.

In approaching the problem of apraxia, we can subdivide the production of skilled movement into several stages. First, there is the general idea of an action plan. For instance, we may decide to peel an apple. Second, there is the translation of the general 'I want to …' idea into a specific plan of action. In this case, we need to find a suitable knife, and then the apple. Once we have the knife and the apple, we can execute the action plan 'peel the apple'. There are two different aspects to execution. First, we need to have a clear idea as to how we peel an apple. One hand will have to hold the apple and this hand will have to position the apple so that the knife can act on it. This requires us to monitor the orientation of the apple in space, with constant adjustments of the position as the act of peeling progresses. Simple as the act of peeling is, it requires us to orient the apple so that the peeling strokes are not wasted. We do not wish to peel the same area twice, or rotate the apple so that bits of peel are missed. The second aspect of execution lies in the actual motor aspects of the peeling action. That is, we know what we want to do, but now we must do it as well as we can. The angle of the knife must be appropriate and the strokes must be such that they remove as little of the apple flesh and as much of the skin as possible. In addition, the actions of the two hands have to be coordinated so that the knife stroke does not begin before the apple is oriented properly. This example illustrates the very simple case where an action is implemented out of the person's own volition. When a person is asked to demonstrate an action, for example how to use a hammer, there is the important element of memory which is implicated both in the association of the object with hammering as a concept as well as the association of the object with a specific type of action. Here, access to motor planning areas through visual or auditory or even tactile avenues becomes an important component of performance.

Considering the number of variables involved, it is easy to see that problems in carrying out this task can be affected by disturbances at different levels, from the initial development of an action plan to the technical aspects of carrying out the movement. By consensus, the definition of apraxia excludes problems that arise in the actual implementation of movement, or what might be called the very last stage of producing skilled movement. In addition, the definition also excludes problems at the 'top end' of the process, so that difficulties in carrying out skilled movement due to general intellectual deterioration, an inability to understand, or a lack of willingness to cooperate, are also excluded from the definition of apraxia.

The definition places the problem of apraxia somewhere between actual motor implementation at one extreme and general mental competence at the other. The variety of factors that can produce

apraxia of skilled movement, once these two end points are excluded, is still dauntingly large. Indeed, because the causes of the disturbance can be so varied, investigators have attempted to provide a classification of apraxia in terms of both the body parts affected, and the particular level at which the disturbance occurs. There is no ideal or compelling classification of apraxia, but in the following we shall discuss the major categories of apraxia that have been recognized. In particular, we shall see that it is not always possible to separate general mental state and the state of the motor system from intervening variables that are thought to cause apraxia.

VARIETIES OF APRAXIA

Ideomotor Apraxia

By far the best-researched and understood type of apraxia is ideomotor apraxia, especially that involving the upper limbs. For this reason, we will consider some of the general aspects of how to test for apraxia, and the principal categories of disturbances, within the framework of this form of apraxia.

Testing for apraxia

Recognition of the different kinds of apraxia depends on clinical examination and experimental measurement of motor behavior. Although there is no standardized methodology, certain approaches are common to many investigations. In examining motor performance, individuals can be asked verbally to perform a task, or they can be asked to imitate a movement that is demonstrated for them. Investigators distinguish between transitive movements, where the individual acts on an object or operates a tool, and intransitive movements where no object is acted on. Examples of intransitive movements would be saluting, taking up the stance of a boxer, or waving goodbye. A further distinction is occasionally made between movements that are representational and those that are not.

Part of testing for ideomotor apraxia involves an assessment of actual motor performance, to evaluate the possible role of 'lower level' causes such as tremor or weakness. In the past, data were mostly collected by recording observations of the performance of the patients, and subtle deficits in motor execution were often missed or ignored. More recently, precise recording of movement in space and time has become possible, and studies in which precise measurement of movement supplements clinical observation are becoming more widespread.

General disturbances in apraxia

Because of the complex neurological machinery that underlies skilled motor behavior, one can expect that lesions in different areas will produce different kinds of problems. Such disturbances can manifest themselves in whatever motor systems are involved (such as movements of the speech musculature, the body axis, or limbs). For the limbs, the following problems have been noted.

Problems in spatial function

Current consensus holds that much of motor planning – which by definition includes spatial factors because movement implies movement in space – relies on regions in the parietal lobe of the cortex. We can expect that lesions in this region will lead to problems both in the planning and execution of movement, and in spatial problems. A distinction is made between personal and extrapersonal space, the former referring to the spatial relations of parts of the body to each other, while the latter refers to external objects and their spatial relations to each other and the body of the observer. Common problems in personal space would involve the incorrect positioning of a tool: thus, if asked to pantomime cutting a loaf of bread, an individual might position the hand and imaginary knife in the horizontal rather than the vertical plane. An incorrect coordination of joints will also lead to spatial errors during movement. Spatial errors also result when there is a faulty integration of proximal and distal parts of the limb: for instance, an individual might position the arm correctly for a salute while assuming an unrelated posture of the hand.

Apraxic patients may show problems not only in the execution of movement in space but also in imagining movement. Interestingly, such difficulties can be quite specific to imagined movement, leaving spatial imagery involving objects intact (Ochipa *et al.*, 1997).

Problems in timing, sequencing and initiation of movement

Timing is often confounded with sequencing because in sequencing of movement the timing of the initiation and cessation of component movements determines successful 'running off' of a sequence. It may be helpful to distinguish between

two kinds of sequencing. First, there is the rapid sequencing of progressive movements, such as in those involving several joints. Much of the timing is automatic, and may be considered 'process' timing. There is also the sequencing of separate functional components in the gain of a goal-oriented action. For example, in preparing an envelope for mailing, the separate components involve inserting the letter, sealing the envelope, attaching the stamp and writing the address. Problems in timing and sequencing in ideomotor apraxia can be observed following parietal or frontal damage, with different causation of timing errors for each location. Modern techniques allow a clear visual presentation of apraxic sequencing problems in three-dimensional space (Poizner *et al*., 1990). Timing anomalies are also of great importance in the documentation of apraxia of speech. Clinical observations suggest that not only is the sequencing of movements across joints in the same limb affected by apraxia, but that sequencing of movement between hands (bimanual movements) is often the most conspicuously impaired activity in apraxic patients, to the point that bimanually coordinated movements may not just be poor but impossible to perform.

Simple movements

The study of simple movements is important for methodological reasons, because such movements can be measured with some precision. The many regions in the brain that are responsible for the production of skilled movement add to the controversy about the execution of 'simple' movements. For instance, rapid finger-tapping has been said to be affected in apraxia by some, while others fail to find an effect (Heilman, 1975; Haaland *et al*., 1980). The initiation of movement as such may also be affected in apraxia, but here too the evidence is not clear. It is in the study of simple movements where the dividing line between apraxia and problems in motor execution becomes difficult to define. We may draw a parallel to agnosia, where individuals have difficulties with the recognition of objects. While it is felt that such difficulties cannot be attributed to problems in sensory processing as such, it is extremely rare to encounter an agnosia without some degree of sensory impairment. Similarly, it is rare indeed to encounter a person with apraxia who does not have some degree of motor impairment, however subtle. Nevertheless, because impairments in motor execution do not lead to apraxia in themselves, it is felt that impairment in movement execution may coexist with, but does not cause apraxia.

Ideational Apraxia

Ideational apraxia is rare but striking, and involves problems in sequencing the separate acts that lead to goal-directed behavior. For instance, when asked to prepare a cup of tea, the difficulties would not lie so much in the execution of the individual acts – such as reaching for and filling a kettle, placing tea in the teapot, letting it steep, and then pouring the tea – as in the correct sequencing of the component acts. We note here that the component acts are in themselves complex, and they may be performed quite well in isolation. For instance, the individual might place the teabag reasonably well – but in the kettle, not in the teapot. It is true that ideational apraxia is rarely seen without ideomotor apraxia, but they vary in severity independently from each other. Ideational apraxia affects normally occurring activities while ideomotor apraxia is more often observed in precisely the opposite setting, when movements are to be performed out of context. Some see ideational apraxia as part of a disconnection syndrome, where the motor planning substrate has impaired or no access to the motor execution machinery. The specificity of ideational apraxia to sequencing of motor acts has been illustrated by showing that patients will not be able to arrange in sequence a number of pictures that show progressive phases of actions with given objects, but are nevertheless able to correctly sequence pictures that show a chain of events that did not involve a sequence of movements (Lehmkuhl and Poeck, 1981).

Conceptual Apraxia

Conceptual apraxia and ideational apraxia are often considered to be synonymous. However, it is reasonable to distinguish between a sequencing problem for a succession of movements, and a problem that involves the proper selection of a specific movement. Heilman and Rothi (1993) emphasize that conceptual apraxia often involves the conceptual aspects of tool use, such as impairment in performing the appropriate motion with a given tool, not being able to pair a tool with the object that the tool would normally act on, choosing substitute tools that do not possess the essential features needed for a given application, or the ability to fashion a tool. As in the case of ideational apraxia,

conceptional apraxia is often seen together with ideomotor apraxia, but not necessarily so. The converse, ideomotor apraxia without conceptual apraxia, is quite common.

Apraxia of Speech

Apraxia of speech, also referred to as 'anarthria', has been controversial because it is difficult to disentangle anarthria from Broca aphasia, where patients have difficulties in producing fluent speech, or dysarthria, where the final elements of speech articulation are affected. In speech apraxia, problems arise regardless of the context in which speech is produced. This contrasts with Broca aphasia, where it does matter under what conditions vocalizations are produced. For instance, in Broca aphasia singing may be relatively much less affected than spontaneous speech, while in speech apraxia the patient will show no such difference. If the person with limb apraxia has difficulties in accessing skilled movements and postures of the limbs, the person with speech apraxia has difficulties in accessing and organizing the 'postures' and movements necessary in speech production. The problem lies at a level one step removed from the actual production of speech sounds. This can be demonstrated in patients who have buccofacial apraxia (problems in assuming tongue and mouth postures) without speech apraxia. However, more often than not speech apraxia is accompanied by such problems (Martin, 1974). As might be expected, speech apraxia is sensitive to the length of utterances.

Apraxia in Dementia and Other Brain Disorders

Apraxias are part of the defining clinical symptoms of dementias and of Alzheimer disease in particular. Strictly speaking, because such apraxias are part of a disease that involves general intellectual deterioration, they do not fall under the general exclusionary definition. However, because apraxias in Alzheimer disease are an important part of the clinical picture, they are considered under this label. It is not surprising, considering the widespread neurological changes in Alzheimer disease, that numerous varieties of apraxia have been described. Conceptual apraxia, ideomotor apraxia, dressing apraxia, constructional apraxia and ideational apraxia have all been described. Systematic work in this area is only now beginning, and some claims have been made that patients with Alzheimer disease are more impaired in performing intransitive than transitive movements, compared with patients with specific left hemisphere brain damage. Contrary claims are also made. While apraxia in Alzheimer disease is common, it also occurs in other dementias and degenerative brain diseases (Leiguarda *et al*., 1997).

Other Varieties of Apraxia

Limb-kinetic apraxia

In limb-kinetic apraxia, we find that the idea of the movement plan is spared but that the execution of even simple and practiced movements is coarse. Limb-kinetic apraxia is found contralateral to the lesion (in contrast to ideomotor limb apraxia, where damage may be ipsilateral or contralateral to the apraxic limb). Because limb-kinetic apraxia is close to the implementation aspect of movement, some have suggested the label 'apraxia of execution' (Freund, 1992). In prototypical patients, it has been claimed that there is no evidence of direct primary defects in motor function and the defect is one of 'the breakdown of fine skillfulness of fingers' in the absence of other types of apraxia (Denes *et al*., 1998).

Apraxia of lid opening

Apraxia of lid opening shares with limb-kinetic apraxia the debate of whether it should be considered a proper apraxia. This apraxia presents itself as inability to close the eyelids voluntarily even though they close or open during reflex blinking (Chapanis and Gropper, 1968; Boghen, 1997; Defazio *et al*., 1998).

Axial apraxia

In axial (or truncal) apraxia neck and trunk movements are affected. Most interesting are cases where aphasia (in this case language comprehension) affects limb movements, while truncal and gait movements can be performed without the patient having any clear comprehension of the verbal command asking for trunk and gait movements. This is probably due to some capacity of the right hemisphere to perform bilateral trunk and gait movements.

Gait apraxia

Whether or not gait apraxia should be considered an apraxia is not clear. Because gait movements have been observed in spite of intact sensation or limb weakness some clinicians feel that a true gait apraxia may exist. However, a predominant aspect of gait apraxia is a lack of initiative to move the legs

and a lack of spontaneity in movement. To the extent that difficulties with gait can be caused by many factors it is likely that cases of true gait apraxia are very rare. The point has been made that the problem with gait apraxia is not so much one of incorrect or inappropriate movements but one of problems with initiation (Brown, 1972).

Dressing apraxia

Dressing apraxia may denote a true apraxia, such that the organization of the learned and skilled movements required for dressing are affected, but the failure to dress properly may also be due to more general problems, such as lateral neglect.

Constructional apraxia

In the clinical demonstration of constructional apraxia, individuals fail to arrange objects such as building blocks according to a visually presented scheme. Such cases, often associated with right hemisphere lesions, are more appropriately considered a secondary outcome of visuospatial processes.

NEUROANATOMY

The Role of the Left Hemisphere

There is little doubt that the left hemisphere has a predominant role in apraxia. Beginning with the earliest descriptions of apraxia, in the vast majority of cases the patients have left hemisphere damage. This supports the general understanding that in right-handed people especially, the conception and generation of movements relies heavily on left hemisphere function. Beginning with Liepmann in 1905, attempts have been made to separate different types of apraxia in terms of cortical lesion location. Thus, Liepmann suggested that lesions associated with limb-kinetic apraxia would be straddling the primary motor and sensory cortex, lesions causing ideomotor apraxia would be posterior to this in the higher-order sensory cortex, and lesions causing ideational apraxia even further posterior, close to the visual cortex.

Subsequent work is less confident of a precise allocation of cortical region for specific apraxias. Three general regions of damage are associated with apraxia. First, there is the parietal region in general and the angular and supermarginal gyri in particular, which are associated with the representation of movement schemes in time and space. Large lesions in this region would lead not only to apraxia, but also to an inability to judge whether a movement demonstrated to the patient is flawed or not. Lesions that leave this region intact but are slightly more anterior (without infringing on premotor regions in the frontal cortex) would lead to apraxia, but affected patients would have the ability to judge whether a movement demonstrated to them is flawed or not. Such lesions would be responsible for 'disconnection' apraxias, where the problem arises from a lack of access from the posterior areas involved in planning and movement image generation to the anterior areas that are more directly involved in implementation. Small lesions that sever the arcuate fasciculus, a tract that connects posterior to anterior cortex, can produce apraxia. This type of disconnection apraxia is probably the only kind where a circumscribed small lesion can cause apraxia (Tanabe *et al*., 1987).

In contrast to posterior lesions, anterior lesions (anterior to the primary motor cortex) are implicated in disturbances of implementation and specific sequencing of consecutive motor acts. The supplementary motor area (SMA) has long been suspected of involvement in apraxia and a number of cases are known where the SMA has been specifically implicated. It is of interest that these cases involve bilateral apraxia; the SMA is known to be involved in bimanual coordination. In addition, the premotor cortex has been identified with limb-kinetic apraxia, also involving both arms.

The Role of the Right Hemisphere

The role of the right hemisphere in apraxia is contested. Soon after the emphasis on left hemisphere lesions in apraxia was pointed out, cases of apraxia after right hemisphere lesions were described (Brun, 1922). Isolated cases are known of right-handed people who are fully apraxic in the right hand after right brain lesions. However, there is a debate about whether in larger series of brain-damaged individuals, some degree of apraxic impairment is seen in those with right hemisphere lesions. It appears that in such series, apraxia after right brain damage is rare. However, a number of researchers show that subtle problems exist. For instance, patients with right-side lesions performed consistently much better than patients with left-side lesions on most tests for apraxia, but they performed worse than control subjects on verbal command when asked to make intransitive movements. In addition, of the 11 patients with right hemisphere lesions, five performed at a level below that of the worst control subject. Other researchers similarly found that while individuals with right-brain damage showed fewer apraxic problems, they performed less well than normal

participants on specific tests (Goldenberg and Hagmann, 1998). It is clear that much of the negative evidence on right hemisphere contributions cannot be considered conclusive because it matters what movements were tested, and to what extent the right hemisphere would be involved in a given movement (Roy *et al*., 1991). An important distinction is between the frequency of apraxic disturbances and the severity; the frequency of apraxia tends to be less after right hemisphere lesions while the severity of apraxia when it does occur is comparable after right and left hemisphere lesions.

The Corpus Callosum

Implicit in the idea that the left hemisphere is predominant in the formulation of movement plans is the assumption that such plans reach the right hemisphere regions responsible for the movements of the left arm via the corpus callosum, from the left hemisphere. 'Pure' lesions in the anterior regions of the corpus callosum that carry motor commands to be implemented by the right hemisphere might therefore lead to apraxia in the left arm – even though the right arm will not be affected. Some cases corresponding to this scheme have been described.

Subcortical Involvement

In general, lesions of subcortical structures that lead to apraxia also involve cortical damage, and it is difficult to disentangle the effects of such multiple lesions. Perhaps the strongest evidence for a distinct subcortical lesion associated with apraxia (usually ideomotor apraxia) comes from apraxic patients with restricted thalamic lesions (Pramstaller and Marsden, 1996). Speculative interpretations implicate part of the thalamus that is intimately connected with a cortical region known to be involved in apraxia. One possible involvement of the basal ganglia in particular may relate to reports of slight difficulties in the initiation of movement in some apraxic patients. Here, it may be suggested that in addition to the cortically derived signs of apraxia, subcortical contributions may be involved. The failure to see slowness in initiation of movement in some apraxic patients may therefore stem from a noncortical source.

APRAXIA AND APHASIA

The association between aphasia and apraxia is well known and documented. In the demonstration of ideomotor apraxia a language problem was implicit in the very first descriptions, because it was the inability to perform in response to verbal commands that defined the disturbance. In addition, even if patients are selected not on the basis of apraxia but on the basis of brain lesions in the left or right hemispheres, patients with left-brain damage will show a strong association of aphasia with ideomotor apraxia. Similarly, in the much rarer cases of ideational apraxia, lesions that tend to produce this apraxia will almost always also produce aphasia. Thus, there are strong links between apraxia and aphasia for different apraxias. However, it is here where individuals with anomalous cerebral lateralization of praxis and language functions provide important information. Despite their rarity, over time a considerable number of patients have been described who have dissociations between aphasia and apraxia. Such patients usually have what is called 'crossed apraxia', where apraxia is caused by right hemisphere lesions. In some of these aphasia is also produced by right hemisphere lesions, but in others there is no aphasia. Of greatest importance here are left-handers who will tend to have language presentation in the left hemisphere. While there is some debate as to whether left-handers show apraxia after right hemisphere lesions, specific and careful testing suggests that this is the case. Careful testing is indicated because left-handers may show less severe apraxia than right-handers and faster recovery after lesions in either hemisphere.

While it is tempting to speculate that the strong general association of aphasia with apraxia is due to higher-order mechanisms that are involved in generation action in either language or body movement, it is more likely that the coincidence of disturbances in both domains is due to lesions that are large enough to affect both substrates involved with language and body movement. Even allowing for the fact that some apraxias often are unrecognized, apraxias are less common after general brain damage than aphasias.

Aphasias therefore appear to be related to apraxias in two ways. First, directly, as in apraxias that emerge when movement to verbal command is tested and when the access from language areas to motor implementation is impaired. Second, there is a general correlation between presence and severity of aphasia and presence and severity of apraxia. Two possible explanations can be considered. First, the regions involved with language comprehension and motor planning in the posterior cortex are coextensive and lesions that affect one function are likely to affect the other. This is slightly

less of a problem in the frontal lobe, but the same principle obtains. For instance, lesions producing Broca aphasia are likely to impinge on regions associated with buccofacial apraxia. Second, it is possible that especially at the top level of motor planning and language preparation, there are higher-order mechanisms that operate at a level above the specific modality and when these are damaged, both apraxia and aphasia ensue because mechanisms common to both are affected.

CONCLUSION

The systematic study of apraxia is in its infancy. If we adopt a broad definition of apraxia, we can see that damage in many parts of the central nervous system can lead to apraxia, and that the causes for the observed 'higher order motor disturbance' are manifold, ranging from relatively low-level problems in the timing and sequencing of unfolding movements to problems in the conceptual plan for movements. Future work will probably focus on an aspect of apraxia that has been relatively neglected by research: the representation of and access to motor memory.

In the course of trying to understand apraxia, we are also trying to understand purposeful motor behavior and its generation by analyzing the stages from conception of a movement plan to the final realization of that plan with a specific set of muscles. This will benefit neural network applications of movement control. Neural network approaches have been extremely successful in simulation of language recognition and the recognition of stimuli in the various sensory modalities. There is little doubt that some of the neural network techniques applied to recognition of incoming information can also be of use in the guidance of robotic movement. For instance, there is no reason why specified motor concepts such as 'reaching' and 'grasping' cannot be used in algorithms that control simple movements. Nevertheless, there is a large gap between neural networks that can implement a concept such as 'reaching' and neural networks that can generate such concepts.

Attention, Neural Basis of

Introductory article

Peter De Weerd, University of Arizona, Tucson, Arizona, USA

CONTENTS

Attention, the ability to selectively process sensory information, is generated by the modulation of sensory processes by frontoparietal neural networks.

INTRODUCTION

The neural basis of attention resides in the ability of structures in the brain representing the behavioral relevance of stimuli to alter sensory processing, so that relevant stimuli are processed effectively and irrelevant ones are ignored. Attention, however, is not a unitary cognitive ability. Attention can alter the sensory processing of stimuli in all sensory systems. In addition, there are different kinds of attention which are related to specific behavioral requirements in different cognitive tasks. Thus, depending on the cognitive task one faces, and the sensory systems involved, different neural networks in the brain will become active during attentional operations.

Definitions of Attention

At the end of the nineteenth century the psychologist William James described attention as a 'concentration of consciousness', with the purpose of 'withdrawing from some things in order to deal effectively with others'. An experimental demonstration of that idea was given by Hermann von Helmholtz in 1894. He filled a large screen with letters, which were spread too widely to be read at once without moving the eyes. During a brief illumination of the screen with a flash of light, which made it impossible to use eye movements to explore the screen, he measured the number of letters that could be read. Only a few letters (up to about five) could be read during each flash. Interestingly, the letters that could be read were not necessarily located at the center of gaze. Letters in any region of the screen away from the center of gaze could be read if the region of interest was selected in advance. This experiment demonstrates several aspects of attention which are still being investigated today: the dissociation of directed attention from eye gaze ('covert' attention), the selective nature of attention, and the limited capacity of attention.

The experiment of Helmholtz indicates that the ability to selectively attend to information is an answer to limitations in sensory information processing. The ability to select information also avoids our behavior being determined by the strength of random stimuli in our environment. Behavior otherwise would inevitably become uncoordinated and chaotic. Hence, the ability to select information is crucial, because it allows us to willfully give precedence to behaviorally relevant information, at the cost of irrelevant information. The 'grabbing' of attention by powerful stimuli is referred to as 'bottom up' (exogenous) attention, and the intentional selection of behaviorally relevant stimuli is referred to as 'top down' (endogenous) attention.

There are different kinds of top-down attention. Selective attention, the main topic discussed here, is the ability to detect or discriminate relevant stimuli (targets) in the presence of competing irrelevant stimuli (distracters). Selective attention is required to find a familiar face in a crowd at a party. A second attentive process is vigilance: the ability to orient attention and respond to randomly occurring, relevant events in the environment over an extended period. A guard who is keeping an eye on the entrance of a building, monitoring for suspicious activity throughout the night, is carrying out a vigilance task. In addition, it has been proposed that there are attentional functions that maintain 'executive control' over goal-directed behavior and thought processes. Executive control functions are especially important when stimuli contain conflicting information. The onset of reading of the word 'green' will be faster when the word is printed in green than when it is printed in red, a phenomenon known as the Stroop effect. Applying

a level of analysis to a stimulus that contains conflicting information, appropriate for the required behavioral response, is a function of executive processes.

Circuits of Selective Attention in the Visual System

The ability to attend to a stimulus is best understood as an emergent property of the functional architecture of sensory systems. This concept will be explored within the context of the visual system (Figure 1).

The primary visual area (V1) receives retinal information through the lateral geniculate nucleus, a relay station in the thalamus. Following lesion and anatomical studies in the monkey, Ungerleider and Mishkin proposed in 1982 that forward projections from V1 give rise to two visual processing streams. One is directed ventrally to the temporal lobe, and is involved in the analysis of objects (ventral pathway, or 'what?' pathway). The other one is directed dorsally to the parietal lobe, and is involved in the analysis of locations of objects relative to each other and relative to the observer (dorsal pathway, or 'where?' pathway). A relative segregation between ventral and dorsal streams is maintained in their projections to the prefrontal cortex in the frontal lobe (Figure 1). Prefrontal cortex is involved in the maintenance and manipulation of information in working memory, response selection and a variety of executive processes.

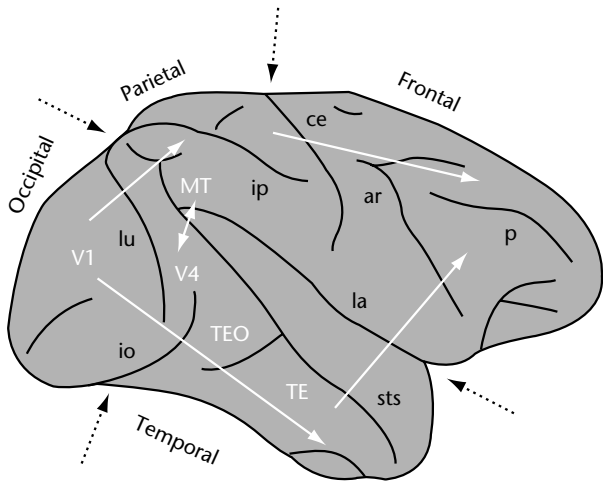

Figure 1. A neural network for attention in the primate brain. Shown is a lateral view of the brain of a rhesus macaque, with the back of the brain towards the left. Dotted arrows correspond to the boundaries between occipital, temporal, parietal, and frontal lobes. White labels indicate visual areas, white arrows indicate anatomical pathways. Visual area V1 gives rise to a ventrally directed pathway which includes V2 (buried in the lunate sulcus), V4, and areas in the temporal lobe (TEO and TE). It also gives rise to a dorsally directed pathway which includes V3 (buried in the lunate sulcus), MT (buried inside the superior temporal sulcus), and areas in the parietal lobe. There is cross-talk between areas belonging to these two visual processing pathways (e.g. double arrow between V4 and MT). Roughly 40 visual areas have been described, and only a few are indicated here. Projections from parietal and temporal lobes towards the prefrontal region of the frontal lobe retain a significant degree of segregation. Forward projections (white arrows) from one to the next area are always returned by backward projections (not shown). ar, arcuate sulcus; ce, central sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus; la, lateral sulcus; lu, lunate sulcus; p, principal sulcus; sts, superior temporal sulcus.

Each of the two processing streams is composed of a number of areas, which are hierarchically organized. Lower-order areas (closer to V1) each contain an orderly retinotopic map of the environment, and are composed of neurons with small receptive fields (RFs), which process simple aspects of the stimulus, such as the orientation of edges. Higher-order areas do not show retinotopy, their neurons have large RFs, and they process complex aspects of the stimulus, such as its shape. Owing to this hierarchical organization, lesions at low levels result in severe sensory deficits, while lesions at intermediate and higher levels leave elementary sensory processes intact and interfere in more subtle ways with visual processing. Lesions at higher levels of the ventral stream induce a disorder in visual object recognition that is referred to as 'agnosia'. Parietal damage causes severe spatial deficits. Because these lesion effects reflect at least in part attention deficits, they are discussed in the following section.

When we look at an object it is automatically perceived as a whole, with a particular location, color, shape, and orientation. Because different aspects of a stimulus are processed in a distributed manner in different cortical regions, this raises the question of how the different features of a stimulus are combined in order to generate a holistic perception. This question is referred to as the 'binding' problem, and the quest for a solution to that problem is intimately related to the quest to understand mechanisms of selective attention. A fundamental insight that will help to resolve both issues is the fact that the separation of the different processing streams is only relative: at various levels in the system, there are anatomical connections between pathways that permit cross-talk. Furthermore, feedforward projections are returned by feedback

projections. Hence, neural activity in a given area can be modulated by activity in other areas or structures to which it is connected. These modulatory influences are a functional property that reflects the structural layout of the system, which is crucial to understanding attention and other cognitive abilities.

PARADIGMS OF ATTENTION IN EXPERIMENTAL PSYCHOLOGY

Before explaining how modulation of activity creates the cognitive ability of attention, it is important to review the different paradigms psychologists have used to investigate attention. These paradigms have led to a precise characterization of attentional behavior, and have become the cornerstone of most experiments on attention in the broad field of cognitive neuroscience (Figure 2).

Spatial Cueing

The spatial cueing paradigm was developed by Posner and colleagues to measure the effects of directed attention (Figure 2(a)). Participants are instructed to keep their eyes on a central fixation cross presented on a computer monitor, and to covertly attend to a location in the left or right half of the screen, indicated by an arrow close to the fixation cross (the cue). The cue is followed in time by a target (e.g., a small square) briefly presented away from fixation. The target can be presented in the cued location (valid cue), or in a minority of cases in a location in the other half of the screen (invalid cue). Participants have to make a button response as soon as they detect the target. On trials in which the target is preceded by a valid cue, response times are shorter (about 250 ms) than on trials in which the target is preceded by an invalid cue (about 300 ms). These results support the idea of a 'focus of attention'. After a valid cue, participants move their focus of attention to the expected location in anticipation of target presentation, and target detection benefits from the presence of attention at the cued location. After an invalid cue, attention moves to the invalid location, and the target is presented outside the focus of attention. The associated cost, an increased reaction time, may be due to the reorienting of the attentional focus to the target.

The reorienting of attention to a location in response to a cue is controlled by the participant, and

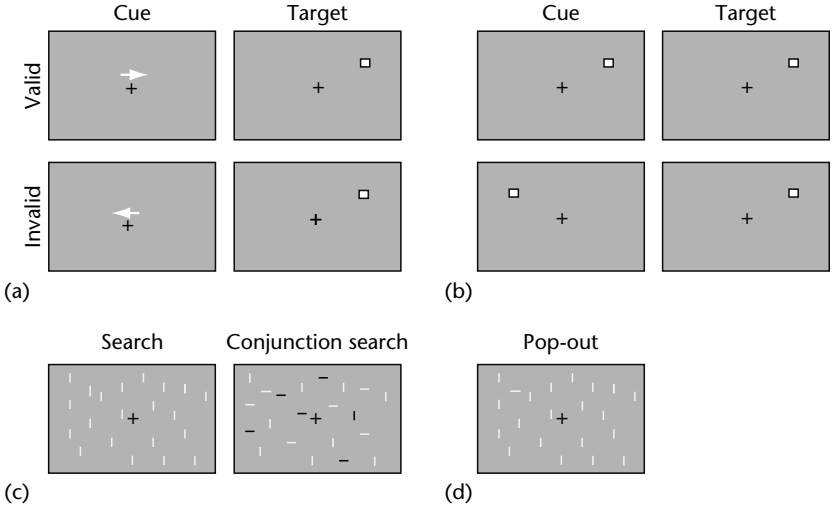

Figure 2. Paradigms in attention research. (a, b) Spatial cueing paradigms. (a) The top two panels show a symbolic cue (arrow) close to a fixation spot (cross) on a computer monitor (gray rectangle) which validly predicts the location of the target (square), presented briefly after offset of the cue. The bottom two panels show target presentation after an invalid cue. When cues are valid on most trials, attention is shifted to the cued location in anticipation of target presentation, and this speeds up responses to the target. (b) Valid (top row) and invalid (bottom row) cueing of attention by a physical stimulus. Even if half of the cues are invalid (rendering the cue unpredictive of target location), the cue has specific attention effects on targets presented in the cued location. (c, d) Search paradigms. (c) Searching for a target among distracters is slow and time-consuming when the target is similar to the distracters (left panel), or if the target is defined by a conjunction of features on more than a single stimulus dimension (right panel). (d) Search is fast and seemingly effortless (pop-out) when the target differs from distracters on a single dimension, and when the difference is large.

this type of cueing is referred to as endogenous cueing ('top down' attention). On the other hand, attention is often automatically oriented to new stimuli. When a student enters class late, it is almost inevitable that everybody turns attention to the latecomer. This exogenous cueing effect ('bottom up' attention) has been investigated in a variation of the spatial cueing paradigm (Figure 2(b)). In this variation, small cues are presented in random locations on the computer screen while the participant fixates a small cross in the middle of the screen. The cue location is unpredictive for the location of the subsequently presented target stimulus. Nevertheless, the cue affects processing of the target if the target happens to be presented in the location of the preceding cue. This effect depends upon the time interval between the cue and target presentation. A target that follows a cue within 250 ms will be responded to with a decreased reaction time, while a target lagging behind the cue by more than about 300 ms will be responded to with an increased reaction time, compared with target presentations not preceded by a cue.

Thus, the mere presentation of a stimulus in a given location can attract attention to that location for a limited time. After that time, attention is disengaged from the stimulus location, and a reorientation of attention to the same location is suppressed. This effect is referred to as 'inhibition of return'. It is important that attention can be attracted easily to unexpected but significant events in the environment, but it is equally important that attention then can be freed from that event to make it available for new, potentially important stimuli. If there were no easy disengagement of attention, attention could get stuck to a stimulus, and new incoming stimuli might go unnoticed. The brief period during which attention is engaged in the processing of a particular stimulus, and during which limited or no attention is available for the processing of new stimuli, is often referred to as the 'attentional blink'.

Search Paradigms

The metaphor of a 'focus of attention' has also been used to explain performance in visual search tasks, a second major paradigm to study attention. In a search task, participants are presented with displays filled with distracter stimuli, which may or may not contain a specific target. Participants are instructed to respond with a button press as soon as they find the target, or to press another button to indicate its absence. Performance is assessed by measuring the time required to find the target as a function of the number of distracters in the display. The resulting plot is referred to as a 'search curve'. A typical experiment suggesting serial search would show an increase in search time by about 30 ms per item.

Search performance becomes dependent on the number of distracters in the display when the target is difficult to distinguish from the distracters (Figure 2(c)). An example of such a search display is one in which the target is a line element slightly tilted away from vertical, surrounded by vertical distracters. Another example is one in which the target is defined by a conjunction of features: the target could be a vertical red line, surrounded by horizontal red, vertical green, and horizontal green lines. The latter task (conjunction search) is difficult because different properties of the objects have to be analyzed and combined before it can be determined whether the object matches the target being searched. The time-consuming nature of these types of search suggests that a focus of attention is continually relocated during search to scan items in the display serially, and in the case of conjunction search also suggests that focal attention plays a role in solving the binding problem.

While search displays have been used to demonstrate serial search, 'pop-out' displays have been used to demonstrate the existence of 'parallel search'. In pop-out displays, the target (e.g. a horizontal line) differs strongly from the surrounding distracters (e.g. vertical lines) and the time required to detect the target appears independent from the number of distracters (Figure 2(d)). The identification of a target in pop-out displays is often considered to occur 'preattentively', or to result from a parallel attentional operation.

A COGNITIVE NEUROSCIENCE APPROACH TO ATTENTION

While the experimental paradigms introduced above characterize important aspects of attentional behavior, they do not address the important question of how modulations of sensory processes produce attentive behavior. Recent neurophysiological findings have brought us closer to an answer.

Findings in the Temporal Lobe

In a series of ground-breaking recording studies, Desimone and colleagues flashed pairs of stimuli inside the RF of single neurons of temporal lobe areas V2, V4, and TE in monkeys trained to identify one of the stimuli and ignore the other.

The neurons' responses were determined by the attended stimulus (target), while the influence from unattended stimuli inside the RF upon the neurons' responses was greatly attenuated (Figure 3). In the period during which the monkeys were waiting for the presentation of each stimulus pair, increased baseline activity was observed compared with the spontaneous firing rate. Depending on the task, increased baseline activity might represent the instruction to the monkey to attend in a particular location, or to expect a stimulus of a given identity, and it might facilitate processing of the target stimulus.

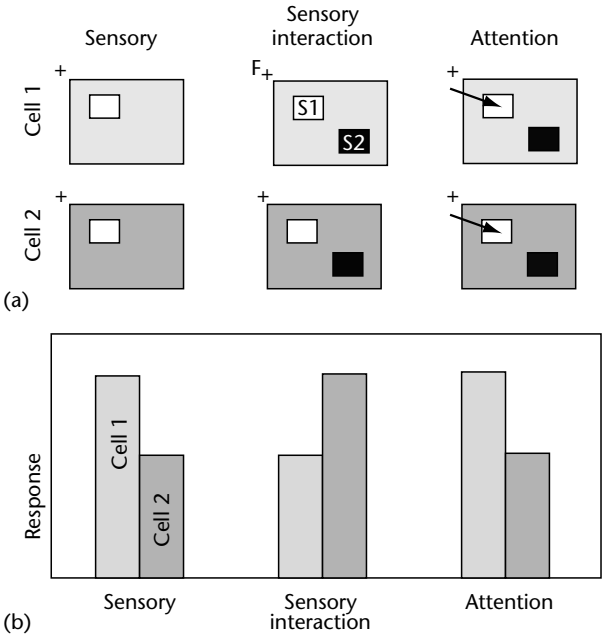

Figure 3. Elimination of sensory interaction (competition) by attention. (a) Different configurations of stimuli and covert attention inside the receptive fields (RF) of two cells (cell 1 and 2). The monkey fixates a cross (F) while covertly attending (arrow) or ignoring stimuli away from fixation placed in the RF of cells 1 or 2, whose activity is recorded. The RFs of cell 1 and 2 are shown as the light and dark gray squares, respectively. Stimuli are symbolized by small white (S1) or black (S2) squares. (b) Pattern of responses illustrating competition and effects of attention. For cell 1, stimulus S1 is more effective than S2 (response to S2 alone not shown). Because stimuli compete for control over the firing rate of the cell, the addition of the less effective stimulus (S2) to the more effective stimulus (S1) drives the response down (sensory interaction). That suppressive effect is eliminated when attention is covertly directed to S1 (arrow in A). Cell 1 now responds as if only S1 were present in its RF, despite the presence of S2 in the RF. Thus, attention eliminates competitive effects caused by behaviorally irrelevant stimuli. In cell 2, stimulus S2 is more effective than S1, and adding S2 to S1 in the RF increases the response compared with the response obtained with S1 alone. Attention to the less effective stimulus S1 will screen out the effect of the more effective stimulus S2, resulting in a decreased response. Thus, whether attention will increase or decrease the activity of a given neuron depends upon the selectivity of the neuron for the stimuli in its RF.

These data provide a neural foundation for the behavioral finding that target stimuli are processed more efficiently than nonattended distracters. In 1995, Duncan and Desimone proposed a 'biased competition' model of attention to account for these findings. In this model, objects presented simultaneously in the visual field compete with each other for control over the firing rate of cells within whose RF they are presented. The competition is decided in favor of stimuli that receive a biasing signal which can be generated 'bottom up' (by a salient stimulus) or 'top down' (by an instruction to identify a particular target among distracters, or to monitor objects in a particular location). The increased spontaneous activity reported during attention tasks may be a correlate of such a biasing signal. Thus, the process of attention is viewed as a biased competition between populations of cells representing different objects or locations (Figure 4).

In agreement with the idea that temporal lobe areas are important for attention, cortical lesions of monkey areas V4 and TEO in the temporal lobe cause an inability to discriminate properties of target objects surrounded by distracters, especially when the target is weak (e.g. smaller or dimmer than the distracters). Without distracters, deficits in discriminating the target are absent or limited. These lesion deficits in the monkey resemble agnosia, a neurological syndrome found after occipitotemporal damage in humans. Humans with agnosia have trouble recognizing visually presented objects embedded in a complex scene, or visually presented complex objects consisting of multiple parts; yet simple stimuli presented by themselves can be discriminated with great accuracy. These general characteristics of agnosia suggest that attention deficits contribute to the syndrome. In the terminology of Duncan and Desimone, agnosia may reflect, at least in part, a failure of biased competition, because of damage to the substrate in which the competition takes place.

Findings in the Parietal Lobe

The description of attention as a process of biased competition leads to the question: where does the

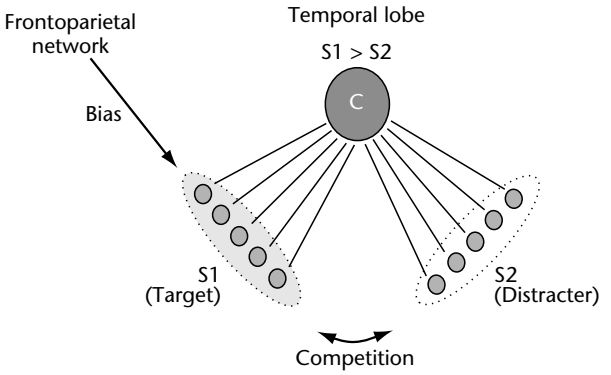

Figure 4. Competition in the temporal lobe is biased by signals generated in a frontoparietal network. Cell C receives input from a population of cells coding S1, and another population of cells coding S2. Each population provides a mixture of excitatory and inhibitory inputs to cell C. The balance of excitatory and inhibitory inputs to C provided by each population determines the size of C's response to S1 and S2 presented alone in C's RF. The response to S1 and S2 presented together in C's RF is determined by the total balance of all excitatory and inhibitory inputs from both populations taken together (competition). When one of these two stimuli (e.g. S1) is made behaviorally relevant (a target), and is therefore attended to, a biasing signal renders inputs from cells coding the target more efficient compared with the distracter. As a result, C's activity will reflect the balance of excitatory and inhibitory inputs provided by S1 alone, rather than the balance of excitatory and inhibitory inputs provided together by the two stimuli in the RF, and S1 wins a competition with S2 for control over the firing rate of cell C (S1 > S2). 'Bottom up' stimulus-driven bias can have effects similar to 'top down' bias generated in a frontoparietal network. This formalization of biased competition theory was first proposed by Reynolds and Desimone in 1999.

bias come from? To answer this question, we turn briefly to a parallel line of work on attention in the parietal cortex. Mountcastle in 1976 and Wurtz in 1982 showed that neurons in parietal cortex of the monkey were more active when the stimulus in their RFs was behaviorally relevant (attended) than when it was not. Several imaging studies in humans have now confirmed that covertly orienting one's attention to a stimulus or location leads to enhanced activity in parietal cortex. Further neurophysiological work in monkeys suggests that the effects of behavioral relevance on parietal activity can depend upon the type of action planned by the monkey towards the target (e.g. an arm versus an eye movement).

Lesions in the parietal cortex induce a complex set of deficits in the representation of space and action. Unilateral parietal damage leads to neglect of the contralateral side of the body, and of stimuli in contralateral extrapersonal space. Neurologists often use the line bisection test to assess neglect: patients with neglect will bisect a horizontal line towards one end of the line, as the other part of the line will become neglected when they look at it. When a strong stimulus is presented on the neglected side, patients can recognize the stimulus perfectly, but when two such stimuli are presented, one in the neglected hemifield and one in the other hemifield, then the stimulus in the neglected hemifield will remain unnoticed, a phenomenon referred to as *extinction*. Extinction and neglect do not always co-occur after parietal damage, indicating that both phenomena may constitute dissociable syndromes after different types of parietal damage.

Using a spatial cueing test, Posner and colleagues found that patients could shift attention to the neglected hemifield when cued correctly, and engage in attentional operations in that hemifield, but had trouble redirecting attention from the ipsilateral to the contralateral (neglected) hemifield. It was therefore postulated that parietal lesions induce a failure of a disengagement operation. Other experiments suggest that the pulvinar nucleus, a thalamic nucleus that provides weak but direct projections to the parietal lobe, plays a part in the shifting and engaging of attention.

Bilateral parietal damage leads to a constellation of symptoms, including optic ataxia (deficit in visually guided reaching), paralysis of gaze, inattention to peripheral stimuli, and sustained hyperattention to single objects or locations (Balint syndrome). Patients with this syndrome do not know where they are, and have no idea of spatial relations between objects. However, once attention is directed to an object, they can identify it perfectly. In pop-out displays, their report of the presence of the target is not influenced by the number of distracters, as in non-afflicted individuals, but they cannot tell where the target is once it has been reported. In conjunction search tasks, people with Balint syndrome require extraordinary amounts of time to find the target (about 1 s per item). In addition, they often make 'illusory conjunctions' (e.g. joining the orientation of a given item with the color of a neighboring item). These illusory conjunctions can also be demonstrated in non-afflicted individuals when the search display is presented very briefly (and followed by a mask). In both situations, there may be not enough attention available to focus accurately on one of the items.

A compelling account of the function of focused attention was given in 1980 by Treisman and Gelade in a model referred to as the 'feature integration' theory. According to this theory, different elementary features in the image (e.g. color, orientation, motion) are analyzed in separate feature maps – an idea at least in part supported by physiological evidence – and the read-out of activity within single maps occurs fast and in parallel. This would explain simple pop-out phenomena. However, when targets have to be identified that are defined by a combination of two or more features, the activity in different feature maps must be combined, which is a lengthy operation requiring focused attention. Hence, the time-consuming nature of conjunction search may reflect a mixture of factors, including the disengagement, orienting, and engagement of attention, as well as the time required to conjoin features. Imaging data support the idea that parietal cortex is involved in the directing of attention to targets, in the shifting of attention in response to both endogenous and exogenous cues, and in conjunction search, but not in feature search or pop-out. Since conjunction search implies shifts of attention and conjoining of features, parietal activity could indicate either or both.

Findings in the Frontal Lobe

An additional line of research that is related to the question where the biasing signal comes from was initiated by Fuster and Alexander in 1971. They found that neurons recorded around the principal sulcus in prefrontal cortex showed enhanced activity during delayed-response tasks, in which the monkey was required to remember a previously cued location that would become the target of a directed action after a delay of a few seconds. Later research has demonstrated that neurons in prefrontal cortex can be activated during tasks that require working memory for both location and object identity.

Many attentional operations require working memory. For example, while a participant looks for a target in a search array, incoming sensory information is matched against a template of the target that is kept on-line in working memory. Many physiological and imaging studies have confirmed that working memory and attention both rely heavily on prefrontal cortex. Limitations on attentional capacity, witnessed by the impossibility of identifying more than a few targets at once, are reminiscent of limitations to hold more than a few stimuli in working memory.

Modulation of Competition in the Occipitotemporal Lobe by a Frontoparietal Biasing Signal

Competition in the occipitotemporal lobe

The term 'competition' refers to the sensory interactions that take place automatically when two stimuli S1 and S2 are placed inside a cell's RF. If this cell (C) receives inputs from a pool of neurons that codes S1, and another pool that codes S2, then the response of the cell will be determined by a mixture of the influences of S1 and S2. Attention biases the efficacy of one set of inputs relative to the other set, such that the activity of the cell will reflect preferentially the attended stimulus (Figure 4). Cells encoding a target could enhance their influence on the activity of cell C by slightly depolarizing their cell membranes. This enhances the probability that these cells will generate action potentials whenever the target is presented in their RFs. Alternatively, the pool of neurons that represents the target may synchronize its spontaneous and stimulus-driven activity. This enhances the probability of coinciding spikes in the pool of neurons coding the target. Because of the summation properties of neurons, rate enhancements and synchronization could both increase the control of the pool of neurons coding the target over the activity of the postsynaptic cell C. The pool of neurons coding the target is thought to include neurons coding various aspects of the stimulus, distributed in temporal lobe areas and other parts of the brain. The synchronization of the activity of neurons coding different properties of an object could be a mechanism for the binding of those object properties, a proposal championed by Singer and colleagues.

A frontoparietal source for the biasing signal

Where does the biasing signal come from? Alternatively, what makes a stimulus behaviorally relevant? A stimulus is behaviorally relevant when there is a requirement to make a saccade to it, to reach and grab it, and to keep it in working memory. It is precisely under those conditions that specific regions in parietal and frontal cortex become active. Thus, to the extent that requirements in an attention task engage frontoparietal regions, activity in those regions could bias activity in ventral stream areas through connections between retinotopically matched regions in ventral and frontoparietal areas.

Evidence suggests that parietal activation during endogenous directing, shifting, and maintenance of

spatial attention may be controlled by the prefrontal cortex, while parietal activity related to exogenous cueing may be controlled by subcortical thalamic input to the parietal cortex. From the perspective of a theory of binding, the bias would be considered part of the representation of the attended object. Indeed, a complete object representation would consist of a synchronized ensemble of neurons distributed in the frontal, parietal, and temporal lobes, representing the object's identity and location, and possible actions towards it. Similarly, the appropriate binding of features (e.g. color and orientation) in conjunction stimuli may be related to the synchronization of activity in neurons coding the color and orientation of those stimuli by a common biasing signal. Thus, selective attention, synchronization, and binding may be intimately related.

Implications for the Serial versus Parallel Search Debate

Attentional bias signals affect sensory processing at the earliest levels of sensory systems. This settles a long debate between 'early selection' proposals (pioneered by Broadbent in 1958) and other proposals advocating 'late selection'. Not unlike feature integration theory, early selection theory predicts that nonattended stimuli are incompletely processed, and that full processing of all aspects of a target stimulus requires focusing of attention, which implies that search must have a serial component. However, strong arguments have been made against the existence of serial search. It has been argued that target search can be mediated by biasing sensory processing towards the target everywhere in the visual field in parallel. Increases in search time as a function of increases in the number of distracters would merely reflect a thinner spread of a limited amount of attention over all items in the display.

Evidence is mounting, however, that performance in search tasks depends on a mixture of serial and parallel operations. For instance, it has been reported that detection of a 'pop-out' target is impaired when an attention-demanding task is carried out at fixation during stimulus presentation. This does not exclude a parallel component in the detection of pop-out, but it does argue against the idea that pop-out is entirely preattentive. Thus, some degree of directed attention may have a role, even in pop-out. Furthermore, performance in spatial cueing tasks, designed to reveal serial relocations of a focus of attention, is influenced by a segmentation of visual space into surfaces and objects, which takes place in parallel across the field. Specifically, experiments by Driver and colleagues show that reorienting attention to a target location, after an invalid positional cue, occurs faster if the invalid cue and target are both presented within the same shape, compared with when the target and cue are presented in different shapes. Although those experiments are set up to equate the distance over which attention has to be reoriented, reorientation takes significantly longer between than within objects. Hence, spatial attention does not operate within unsegmented space.

Findings in patients with neglect due to unilateral parietal damage support this hypothesis. Neglect is often described as a purely spatial imbalance in the distribution of attentional operations between hemifields. However, experiments in a patient with right parietal damage showed that details on the right side of an object placed in the left (neglected) hemifield are perceived more accurately than details on the left side of an object placed in the right (normal) hemifield. The idea that parietal cortex manipulates the distribution of attention in an object-driven way, rather than a purely spatial way, is compatible with the role of parietal cortex in representing potential actions towards target objects.

In sum, processing of a visual scene may begin with a fast quasiautomatic segmentation based on parallel processes that require little attention. Subsequently, attention may be distributed across this roughly segmented scene, in ways that reflect behavioral demands, and which may not be exclusively parallel or serial. When relevant objects are expected in a single location, attentional resources will be focused on that location. When switches of attention between locations are required, this serial redistribution of attention will be influenced by the preceding segmentation of space. Furthermore, when a specific target object is searched for without knowledge of its location, a 'top down' parallel bias may contribute to the identification of potential targets, but does not exclude the possibility that potential targets are serially inspected. Thus, while items in a search display may not be scanned individually, parallel processes (including automatic 'bottom up' segmentation and parallel 'top down' biases) may lead to the determination of likely targets, which may then be inspected serially. The exact distribution of attention in response to task demands is controlled by executive processes. These and similar ideas have led to various mixed parallel–serial models of attention.

CONCLUSION

The combination of behavioral paradigms developed by psychologists and new methodological approaches developed in the field of cognitive neuroscience has greatly enhanced our understanding of attention and of the neural processes that underlie it. Attention can be best understood as a modulation of sensory processes driven by regions in the brain that represent the behavioral relevance of stimuli. These modulations ensure that behaviorally relevant objects (or locations) in the environment are preferentially processed at the cost of irrelevant ones.

Audition, Neural Basis of

Introductory article

Shihab Shamma, Institute for Systems Research, University of Maryland College Park, College Park, Maryland, USA

CONTENTS

Sound is translated into neural signals by the organs of the auditory system. Key to this process is the cochlea, which converts sound pressure waves into spatially ordered patterns of membrane vibrations and then transforms these vibrations into neural patterns in the auditory nerve.

INTRODUCTION

Sounds in the environment are produced when a force excites a structure and causes it to vibrate. Sounds may be sudden and non-repetitive (e.g. a clap or the snapping of a twig), sustained and irregular (e.g. the burbling of water or the whisper of a friend) or sustained and regular (e.g. a singing voice or the rhythm of a drumbeat). In all cases the emitted sound carries information about the exciting force, the vibrating structure, and other physical features, such as the resonating chambers that modify the sound on its way to our ears. Our auditory systems, and those of most other animals, have evolved ingenious ways of extracting all of this information and they use it to detect, locate and identify sound sources of danger, food, courtship and companionship.

THE NATURE OF SOUND CUES

When the driving force causes a structure to vibrate (e.g. a plucked string), or is itself repetitive in nature, the sound produced consists of a succession of almost identical copies of the same emission. The fact that the emissions are so similar is an excellent clue to their common origin, so we might expect organisms to have evolved special mechanisms for recognizing repetition. Furthermore, the time intervals between repetitions are meaningful, as they characterize both the driving force and the vibrating structure of the sound source. When repetitions are slow (less than 50 repetitions per second – or Hz), they are heard as distinct sounds that reflect the dynamics of the driving force. For example, the sequence of notes in a melody or the rhythmic tapping of a drum result from finger movements, and the succession of speech sounds in an utterance reflect movements of the mouth. When the dynamics or frequency of the driving force become faster (50–4000 Hz), we begin to perceive a sustained sound with a distinct pitch that is proportional to the frequency of vibrations. This percept is critical to our appreciation of melody in music, and to the recognition of human voice. Finally, excited structures often exhibit complex patterns of vibrations consisting of numerous simultaneous frequencies that may extend to very high rates (even exceeding the audio range of humans at 20 000 Hz). These complex vibrations evoke distinct sound qualities (or timbres) that reflect the shape of the structure (e.g. a violin versus a cello), its material composition (e.g. wood versus brass) and dynamics (e.g. a muted versus a free string).

COCHLEA FUNCTION

When sound reaches the ears as pressure waves in air or water, it causes the eardrum to vibrate. It in turn transmits the vibrations to the cochlea of the inner ear via an attached chain of three tiny bones located in the middle ear. The cochlea is the key hearing organ. It consists of an elongated fluid-filled cavity with elaborate sensory cells that are embedded within exquisitely sensitive membranes that extend along its entire length. The cochlea has two main functions as illustrated in Figure 1.

First, it converts the sound pressure wave into a spatially ordered pattern of membrane vibrations. Specifically, the mechanics of the cochlear membranes gradually change their electromechanical properties along its length in a manner that causes different places to vibrate best (or be tuned) to

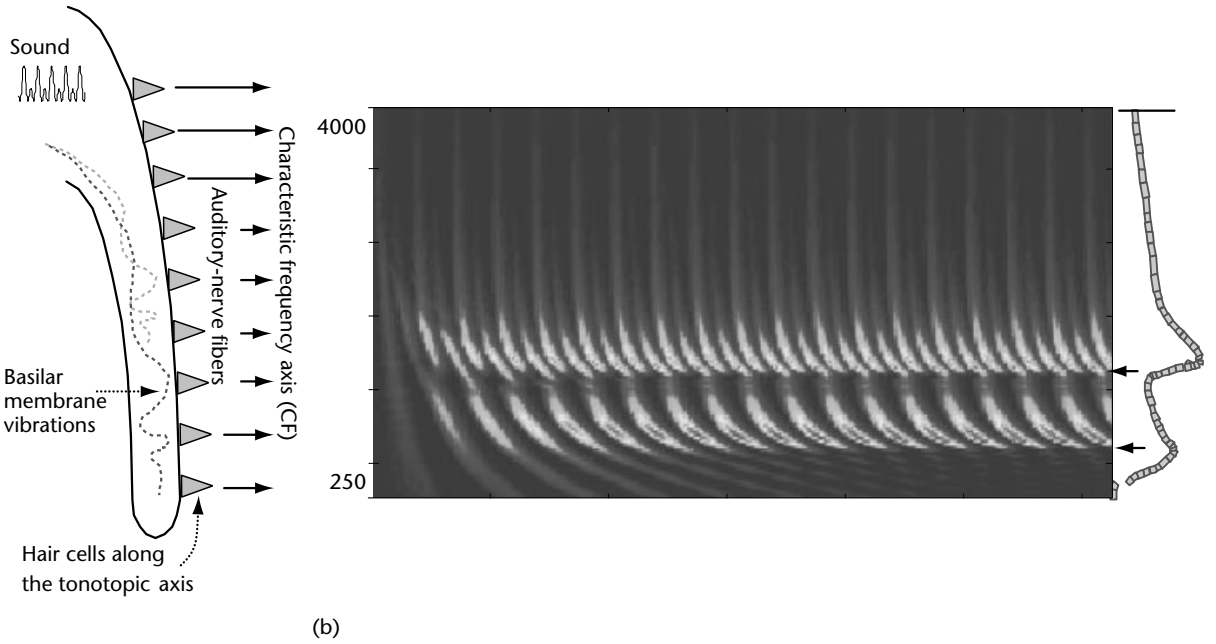

Figure 1. [*Figure is also reproduced in color section*.] Schematic model of the early stages in auditory processing. (a) Cochlear analysis. Sound enters the cochlea via the eardrum and the middle ear, initiating travelling wave displacement patterns on the basilar membrane. Vibrations due to low frequencies propagate and achieve their maximum amplitude further down the cochlea (broken red line) compared to high frequencies (broken green line). This mapping of sound frequency components onto different places along the cochlea creates the tonotopically ordered (spatial) axis of the auditory system. Basilar membrane vibrations are transduced into spatiotemporal responses on the auditory nerve by an array of hair cells distributed along the length of the cochlea. (b) Auditory nerve responses. The spatiotemporal response patterns in the auditory nerve due to a two-tone stimulus (300 and 600 Hz). The ordinate represents the tonotopic axis (labeled by the characteristic frequency axis (CF) at each location). The response at each CF represents the instantaneous probability of firing in the nerve fiber at that CF. Note that each component in the stimulus initiates a localized travelling wave pattern that abruptly ends creating a prominent discontinuity near the appropriate CF (marked by the arrow heads to the right of the panel). The stimulus responses depicted here are at a low sound level, such that it does not saturate the nerve responses. The response amplitudes are therefore strongest near the CFs of the two tones, resulting in clear peaks in the average response curve (red plot to the right).

different frequencies. Consequently, sounds with very high frequencies cause large membrane vibrations near the entrance to the cochlea, whereas those with low frequencies cause maximal vibrations near the end of the cochlea. In this way, the cochlea effectively separates the different components of the sound according to their frequency, sending them off to different places and creating a frequency-organized axis known as the tonotopic axis of the cochlea. Each complex sound therefore creates a unique spatial pattern of strong and weak vibrations along the tonotopic axis that reflects the amplitudes of its different frequency components – or its frequency spectrum.

The second main function of the cochlea is to transform these vibrations into neural patterns on the auditory nerve, to be interpreted by the brain subsequently. This is accomplished by more than 3000 specialized sensory cells (known as the hair cells) that are distributed along the cochlea. Hair cells possess channels that open and close rapidly, modulating the flow of electric current into them. The currents initiate a cascade of electrochemical events, culminating in neural signals on the auditory nerve that faithfully encode the phase (or are phase locked to the time course) of the vibrations at each point up to fairly high frequencies (4000 Hz in some mammals, and 9000 Hz in some birds). Since stronger vibrations also lead to a more vigorous neural response, the auditory nerve in effect encodes the spectrum of the sound both by the level and by the phase-locked structure of the responses along the tonotopic axis.

NEURAL PATHWAYS

The first neural structure beyond the auditory nerve is the cochlear nucleus, which consists of

several anatomically elaborate subdivisions that receive parallel direct projections from the nerve. Multiple pathways emerge from the cochlear nucleus up through the midbrain and thalamus to the auditory cortex, each passing through different neural structures, repeatedly converging on to and diverging from other pathways along the way. This complexity reflects the rich and varied auditory percepts extracted from the sound, the integration of these percepts into a total auditory sensation, and its final fusion with vision and other sensory modalities, and with motor actions.

Although there is still much to be learned about the exact mechanism whereby all of these neural pathways and structures process sound, it is nevertheless clear which signal cues the nervous system must extract in order to give rise to a few important auditory percepts that include loudness, pitch, timbre and sound location.

LOUDNESS, PITCH, AND TIMBRE

Perhaps the most intuitive of these percepts is that of loudness. It is normally associated with increasing the volume (amplitude or intensity) of the sound. However, there is another physical dimension that correlates strongly with loudness, namely the range of frequencies that make up the sound, or its bandwidth. Loudness can therefore be generally viewed as being mediated by the total volume of neural activity in the auditory nerve, and thus increasing the activity (by raising either the sound intensity or the bandwidth) leads to a louder sound.

The sensation of pitch is also a readily understood attribute of sound that is normally associated with musical scales and melodies, or with the low and high voices of men and women, respectively. Pitch is strongly correlated with the repetition rates or frequencies in a sound. However, unlike loudness, the neural basis of pitch is a much more contentious topic, largely because 'pitch' is an imprecise term that is ascribed to multiple sensations which have distinct origins, and most probably different neural mechanisms. For example, the pitch of a pure tone is directly related to its frequency, and is felt over a very broad range of approximately 50 to 20 000 Hz. From a neural perspective, this percept is readily encoded by the location of best tone-evoked response along the tonotopic axis. A second example is so-called rattle pitch, namely a relatively weak sensation that is correlated with the modulation rate of the amplitude of a noise or a tone. This pitch is typically heard only up to a few hundred hertz (< 400 Hz), and is likely mediated by neural responses (in the auditory nerve and beyond) that are explicitly entrained to the modulation rate. The final and most salient sensation of pitch is that of musical instruments and voices. This percept exists over a moderate range of frequencies (< 4000 Hz), and is exclusively associated with harmonic sounds composed of frequencies that are integer multiples of a common fundamental frequency. An interesting fact about this pitch is that its value remains that of the fundamental frequency, even if the fundamental component in the sound is missing (hence the common description of this percept as the 'pitch of the missing fundamental'). That is, the pitch value is derived from the harmonic relationship between the components, and not simply from the fundamental frequency *per se* as illustrated in Figure 2a. The neural basis of this percept remains uncertain. One plausible theory proposes that the brain stores (or learns) harmonic templates of all pitch values, and the percept is derived according to which templates best match the spectrum of the incoming sound (Figure 2b). According to another theory, the pitch is computed directly from the incoming sound without resort to any templates, and as such it does not explicitly distinguish between this percept and the 'rattle' pitch described earlier (Figure 2b). Both of these theories (and many other variations) can account for most relevant psychoacoustical findings. The major missing piece in the pitch puzzle is the lack of firm biological understanding of the mechanisms underlying pitch processing in general.

Timbre is best regarded as the quality of a sound. It is the percept that allows us to distinguish between a violin, an oboe and a piano playing at the same pitch, or to perceive the difference between vowels (or other phonemes) in spoken language. Timbre is a multidimensional percept that is difficult to reduce to a simple scale (e.g. the low-to-high scale of pitch and loudness). Instead, it has been customary to propose several 'descriptive' scales to quantify it, using intuitive notions such as 'sharp to dull' and 'continuant to transient'. However, experimental evidence makes it abundantly clear that the shape and dynamics of a sound spectrum directly influence its timbre. Spectral shape is extracted early in the auditory system, perhaps as early as the cochlear nucleus, where the neural activity of a specific type of neuron has been found to represent faithfully and robustly the acoustic spectrum along its tonotopic axis. Further elaboration of this representation occurs in the midbrain and cortex, where more complex spectral features are selectively detected. The neural correlates of

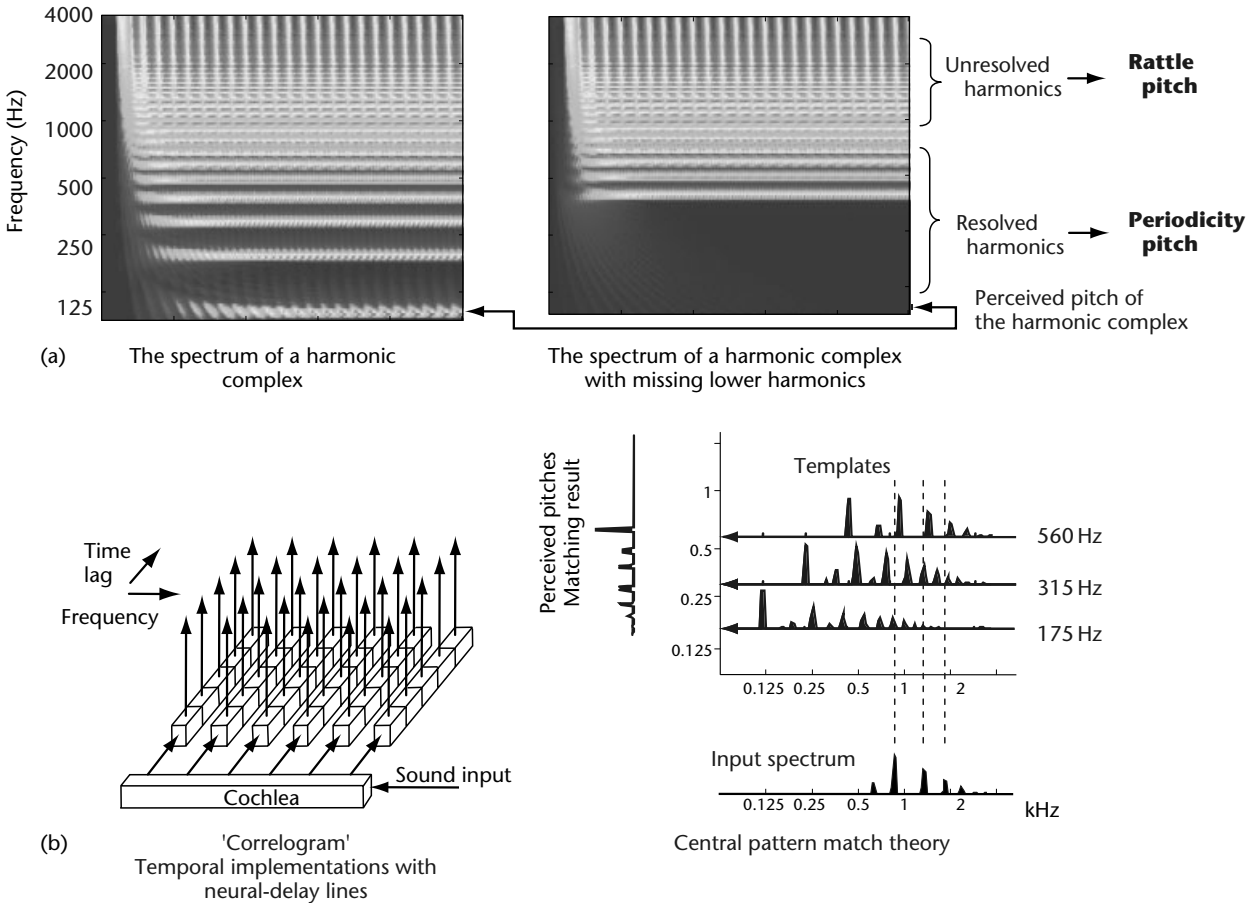

Figure 2. [*Figure is also reproduced in color section*.] Representation and extraction of stimulus periodicity of a harmonic complex. (a) The auditory spectra of two harmonic series of a 125 Hz fundamental. The low-order harmonics are well *resolved* along the tonotopic axis. These harmonics evoke a pitch sensation at the fundamental frequency of the series (i.e. at 125 Hz). The high-order harmonics (> 8th harmonic or 1 kHz) are largely *unresolved* and they instead evoke a pattern that 'beats' at the difference frequency of 125 Hz. These harmonics evoke a weaker pitch (called the 'rattle pitch') at the beating frequency (i.e. 125 Hz in this case). (Left) The harmonic complex here contains all 40 harmonics and evokes a strong pitch at 125 Hz. (Right) The harmonic complex here lacks the lowest three harmonics (125, 250, 375 Hz); nevertheless, it still evokes a strong pitch at the 'missing fundamental' frequency of 125 Hz. (b) Two algorithms for extracting this missing fundamental pitch. (Left) The schematic illustrates an autocorrelogram implementation. It presumes the existence of organized delay lines to compute the autocorrelation of the responses from each auditory nerve channel (or fiber) prior to computing the pitch. (Right) Schematic illustrates a *template-matching idea*. It presumes the existence of harmonic templates in the brain that are matched to incoming spectra so as to measure the pitch.

spectral dynamics also undergo significant transformations in different auditory stages, with faster temporal features (> 50 Hz) mainly being evident in the pre-cortical stages. In the auditory cortex (as in other sensory cortices) the dynamics of the responses explicitly represent the temporal evolution of the sound spectrum over relatively slow rates (< 50 Hz). These timescales are commensurate with the dynamics of the vocal tract in speech, the rate of change in pitch in musical melody, the transient dynamics that differentiate a string that is struck from one that is bowed (e.g. a piano versus a violin), and the rhythms of percussion instruments. Finally, there are other more complex representations of sound combining spectral and dynamic features which have been found to endow cortical cells with elaborate response selectivity. Examples of these include selectivity to downward or upward frequency-swept sounds in bats, to phrases of species-specific calls in primates, to phoneme or phonemic clusters in humans, or even to entire songs in birds. However, it is still unclear what neural mechanisms and architectures give rise to these representations and how, and the

way in which these representations ultimately relate to our perception of timbre.

SPATIAL HEARING

Finally, we consider the perception of sound location in space. This auditory function is critical for survival – for example, in escaping predators, following prey and finding mating partners. Despite the enormous variability in the nature of the cues and mechanisms involved in this task, some principles are common to most species. The first of these is the use of differences in the sound impinging on the two ears, especially differences in time of arrival and in sound intensity. Specifically, when a sound source is centered in front of the head, it reaches the two ears simultaneously. If it moves to the right, the path to the right (relative to the left) ear shortens, and thus the sound reaches the right ear sooner – by a fraction of a thousandth of a second, a detectable difference for many animals (especially those with larger heads). An analogous difference in sound level occurs when a source is closer to one ear, especially for high-frequency sounds where the head shadow is more effective. Most animals have evolved neural mechanisms for detecting, extracting and utilizing these inter-aural differences in order to locate the sound source. For example, there are specialized coincidence cells in all mammals and birds that receive synchronized inputs from the two ears, and which are tuned to detect a particular time-delay between them. In barn owls, such cells are highly organized topographically so as to create an optimum time-delay axis. Another commonly found cell type is tuned to detect specific level differences between the two ears.

The second important localization principle concerns the use of special spectral cues (from one or both ears) to locate the elevation of a sound source or to characterize the acoustic environment. These spectral cues are usually introduced by auxiliary structures such as the pinna (the external ear), the shoulders, and nearby walls and floors. In the case of the pinna, its highly convoluted cavities function as mini-resonators that absorb or amplify certain sound frequencies depending on the direction of arrival of sound. This is extremely useful because, when a source is located on the midline, the two paths to the ears are equal regardless of the source elevation, and thus the only way to localize it is based on pinna-originated spectral cues. In mammals, there is some evidence that specialized neural pathways have evolved as early as the cochlear nucleus to detect these unique cues and process them in conjunction with the binaural cues. Another useful function of certain spectral cues is to convey information about the reverberant qualities of a room, and hence (indirectly) about its size and material structure. This issue is extremely important with regard to both the architectural design of music halls and auditoriums and the assessment of the quality of communication channels and equipment.

CONCLUSION

There are many other auditory attributes and tasks in the animal world that we have not touched upon, and that are as important to these animals as the perception of sound timbre, pitch and location is to us. Examples include the ultrasonic echolocation in bats and dolphins that enables them to locate prey and avoid obstacles in cluttered environments, the infrasonic (very-low-frequency) communication signals among many terrestrial animals (e.g. elephants), and the unique auditory adaptations of many animals that help them to deal with the limitations of their small size (e.g. insects) or their aquatic environments (e.g. fish). Finally, we have not considered a number of key questions. For example, how does the auditory system assemble all of these disparate percepts into an integrated whole that identifies the sound source as an entity amidst the clutter of other simultaneous sound sources in the environment? And how do auditory percepts become integrated with visual, motor and other neural processes of attention and memory so as to give rise to the typical active auditory behaviors that we normally associate with this amazing modality? The answers to these and countless other auditory mysteries lie in the findings of future exciting research.

CONTENTS

The autonomic nervous system has been viewed as a reflexive system for maintaining internal homeostasis. It is now clear, however, that the autonomic nervous system has reciprocal interactions with higher neurobehavioral substrates, influencing both autonomic control and cognitive/behavioral processes.

INTRODUCTION

The autonomic nervous system (ANS) is the designation applied by John Langley to a complex network of peripheral nerves and ganglia, together with associated regulatory systems of the brain and spinal cord, which serve to control smooth muscles and glands of the viscera (Langley, 1921). Implicit in the term 'autonomic' is the view that the ANS is rigidly regulated, and not subject to the vagaries of 'volitional' control like the somatic nervous system. This was even more strongly implied by an earlier name: the involuntary nervous system.

The influential physiologist Walter Cannon argued that the ANS was specialized for what he termed 'homeostasis', or the maintenance of stability of the internal fluid matrix, necessary to sustain life (Cannon, 1939). This function was suggested to be implemented by an array of feedback-regulated autonomic reflexes responding to perturbations in visceral states with compensatory adjustments to restore homeostatic balance. An example is the baroreceptor reflexes, whereby an increase in blood pressure, signaled by baroreceptor afferent activity, triggers reflex responses including relaxation of vascular smooth muscle, as well as decreases in heart rate and myocardial contractility that reduce cardiac output. Together, these responses serve to decrease blood pressure and compensate for the initiating perturbation (Figure 1).

Early research focused on the plethora of autonomic reflexes organized at lower brainstem and spinal cord levels. An important historical development, however, was an emerging recognition that central regulatory systems extended well above these lower levels of the neuraxis. Although many aspects of ANS regulation may be based on simple reflexes, autonomic adjustments are also closely linked to cognitive and behavioral processes that arise from higher neurobehavioral substrates, including the limbic system and cerebral cortex. Another important recognition is the fact that the ANS is as much a sensory system as a motor system. In addition to contributing to lower-level reflexive regulation, visceral afferent information now appears to bias processing in higher neural systems.

ANATOMY AND PHYSIOLOGY

Peripheral Components

In addition to the intrinsic enteric system that is sometimes considered to be part of the ANS, the ANS consists of two major peripheral divisions, the sympathetic and parasympathetic branches. These two branches have distinct central origins, and differ in their peripheral anatomy and physiology. The sympathetic nervous system has its central origins in the intermediolateral cell column of the thoracic and lumbar divisions of the spinal cord (Figure 1), and so has also been termed the thoracolumbar division. Spinal sympathetic motor neurons give rise to preganglionic efferents which exit the spinal cord in the ventral roots and enter an interconnected set of sympathetic chain ganglia which lie along each side of the cord. On entering the chain ganglia, preganglionic fibers may ascend or descend before terminating on sympathetic

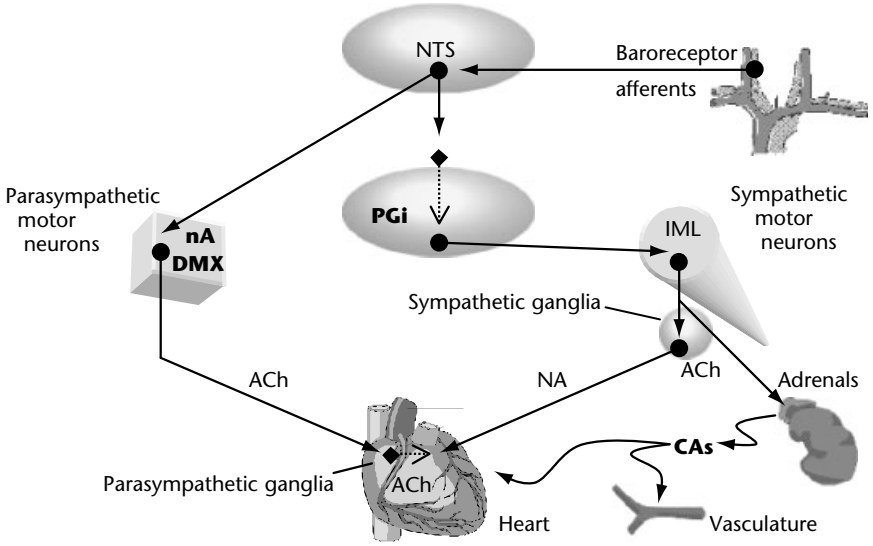

Figure 1. Some features of the baroreflex circuits and peripheral organization of the autonomic nervous system. Baroreceptor afferents project to the nucleus of the tractus solitarius (NTS), by which baroreceptor activity leads to activation of parasympathetic motor neurons in the nucleus ambiguus (nA) and dorsal motor nucleus of the vagus (DMX). The NTS also indirectly inhibits the nucleus paragigantocellularis (PGi) within the rostral ventrolateral medulla, leading to a withdrawal of excitatory drive on the sympathetic motor neurons in the intermediolateral cell column of the cord (IML). ACh, acetylcholine; CAs, catecholamines; NA, noradrenaline (norepinephrine). (Adapted from Cacioppo JT, Tassinary LG and Berntson GG (2000) *Handbook of Psychophysiology*, p. 465, with permission from Cambridge University Press.)

ganglion cells, which give rise to postganglionic axons that in turn project to visceral organs. Because of the extensive ganglionic interconnections within the sympathetic nervous system, this division was often considered to discharge as a whole (i.e., in sympathy). We now know, however, that the sympathetic system can exert much more precise and organ-specific actions. The primary neurotransmitter at the ganglionic synapse is acetylcholine (ACh), whereas the postganglionic synapse employs the catecholamine neurotransmitter noradrenaline (norepinephrine). There are some deviations from this general anatomical plan, as preganglionic fibers innervate the adrenal medulla directly, without synaptic interruption in the chain ganglia. Hence, sympathetic synapses onto the adrenal medulla release ACh, and the adrenal secretory cells release the catecholamines noradrenal and adrenaline (epinephrine). In contrast to postganglionic sympathetic innervation, however, these adrenomedullary catecholamines are released into the general circulation where they can act humorally on many organ systems, including some that do not receive direct innervation. Because many of the peripheral actions of the sympathetic system are activational and promote energetic metabolism, this division has been considered to be a mobilization system involved in responding to adaptive challenges.

The other branch of the ANS, the parasympathetic division, differs from the sympathetic in its central origin, peripheral anatomy, neuropharmacology, and functions. The lower central motor neurons of the parasympathetic division lie in the intermediolateral column of the sacral spinal cord, and in numerous nuclei within the brainstem (e.g. the nucleus ambiguus, dorsal motor nucleus of the vagus, and salivatory nuclei; see Figure 1). Because of this anatomy, the parasympathetic division has been termed the craniosacral branch, and is also sometimes referred to as the 'vagal' branch, after the vagus nerve (10th cranial nerve) that carries parasympathetic efferents. Strictly, however, the latter term applies only to the vagal component of the parasympathetic branch. Like the sympathetic division, the parasympathetic system includes peripheral ganglia, but these are not collected into coherent ganglionic chains, but rather are generally located in or near the visceral organs innervated. Because of this anatomical difference the parasympathetic system has been thought to be capable of more localized action, although considerable regional specificity can also be demonstrated for the sympathetic branch. As in the sympathetic system,

the preganglionic axons of the parasympathetic branch employ ACh as a neurotransmitter (both divisions acting primarily via nicotinic cholinergic synapses on the ganglia); but in contrast to the sympathetic division, postganglionic axons of the parasympathetic system also employ ACh (generally acting via muscarinic cholinergic receptors). This simple distinction in neurochemical coding among the peripheral autonomic branches belies the tremendous complexity of neurotransmitter, neuromodulatory, and neurohormonal interactions within the peripheral ANS.

Opposing versus Synergistic Actions and Modes of Autonomic Control

Many visceral organs are dually innervated by both autonomic branches, and the two divisions are often opposing in their actions. For example, the sympathetic cardiac innervation increases heart rate via β adrenergic receptors that speed the depolarization of the sinoatrial pacemaker potential. In contrast, the parasympathetic innervation slows the beat of the heart via ACh, acting at muscarinic receptors on the sinoatrial node, which increases potassium conductance and slows the rate of pacemaker depolarization. More generally, in contrast to the mobilizing functions of the sympathetic branch, the parasympathetic system has been viewed as a conservation system that functions to promote energy intake, reduce energy expenditure, and preserve energy reserves. Historically, the autonomic branches sometimes have been considered to be subject to reciprocal central control, with increased activity of one division associated with decreased activity of the other (Berntson *et al*., 1991). Indeed, to the extent to which branches are functionally opposed, the reciprocal mode of regulation would yield the widest dynamic range of autonomic control over target organs (Berntson *et al.*, 1991).

All organs are not dually innervated, however, and it is often the case that actions of the two branches on a given organ are not precisely opposite. Major arterioles, for example, receive only sympathetic innervation, and both sympathetic and parasympathetic activity can stimulate salivary secretion. Even when generally opposing in their actions, as in the control of heart rate, the two branches may operate by different cellular mechanisms with distinct features and temporal dynamics. These differences can lead to distinct functional states, with differing levels of activity of the two branches, which cannot be duplicated by simple variations along a reciprocal bipolar continuum extending from maximal sympathetic to maximal parasympathetic activity. Penile erection and ejaculation, for example, require the coactivation of both autonomic branches.

Higher Central Controls and Neurobehavioral Systems

Many basic autonomic homeostatic reflexes, such as baroreceptor reflexes, do display a reciprocal pattern of control over the autonomic branches. However, the ANS is far from being a simple homoeostatic mechanism controlled by reflex systems of the lower brainstem. Indeed, it is now apparent that autonomic outflow is regulated by neurobehavioral systems at the highest levels of the neuraxis, including the cerebral cortex. Rostral brain systems not only modulate lower reflex mechanisms, but issue descending projections that terminate directly on autonomic source nuclei in the brainstem and spinal cord. In accord with the general increase in flexibility and integrative capacity of higher neural systems, rostral neurobehavioral mechanisms appear to exert more variable and flexible control over autonomic outflows. Consequently, in addition to the reciprocal mode of control often seen in reflex regulation, a wider range of control modes can be observed in behavioral contexts, including independent changes in the autonomic branches as well as coactivation or coinhibition of both divisions.

Autonomic Afferents and Ascending Central Pathways

An important aspect of the autonomic nervous system is its sensory function (Dworkin, 2000). In fact, over 75% of the fibers in the largest autonomic nerve, the vagus, are afferents. Visceral afferents carry a range of information concerning the internal state of the body, from baroreceptors, chemoreceptors, and other interoceptors. Some visceral afferents enter the spinal cord via the dorsal root (along with somatic afferents) and terminate in the dorsal horn, where second- and higher-order neurons may participate in local autonomic reflexes, or relay visceral information to higher central structures. One such structure is the nucleus of the tractus solitarius (NTS), a major visceral relay station in the brainstem (Figure 1). Additional visceral afferents, such as those carried by the vagus and other cranial nerves, terminate directly in the NTS. The NTS is a key structure in brainstem autonomic reflexes and serves as an important relay in

ascending pathways to higher levels of the neuraxis where they can modulate the processing of rostral neural systems. Although the functional contributions of this ascending visceral information have not been fully elucidated, it has been shown, for example, that baroreceptor activation can reduce cortical arousal, suppress spinal reflexes, and attenuate pain transmission (Dworkin, 2000). The impact of this ascending information on rostral neurobehavioral mechanisms, and its role in cognitive and behavioral processes, has become an active area of research.

FUNCTIONS OF THE ANS: HOMEOSTASIS AND ALLOSTASIS

A historically recognized role of the ANS is in the maintenance of internal homeostasis. Central and ganglionic autonomic reflex circuits react to perturbations in internal states and generate responses that compensate for these perturbations and restore internal conditions. On standing up from a sitting position, for example, gravitational forces result in a pooling of blood in the legs, which could lead to a dangerous drop in blood pressure and circulatory compromise. This orthostatic challenge becomes a serious problem in autonomic failure and other conditions of impaired autonomic function, where it may lead to syncope (fainting). In healthy individuals, however, this postural maneuver results in the unloading of the carotid baroreceptors and an associated decrease in baroreceptor afferent activity. Baroreceptor reflexes then trigger a compensatory increase in sympathetic outflow and a reciprocal decrease in parasympathetic activity. The resulting increase in heart rate and cardiac output, together with sympathetically mediated vasoconstriction, serves to restore normal blood pressure. This illustrates a classical feedback-regulated (servocontrolled) homeostatic reflex. However, the homeostatic model of autonomic function is overly restrictive, and does not adequately reflect the adaptability and flexibility of autonomic regulation.Feedback-regulated systems, for example, can respond only after a disturbance has taken place, and hence do not effectively prevent these disturbances. Fortunately, central autonomic control systems provide for a broader range of regulatory adjustments, including anticipatory responses.

The early work of Pavlov, demonstrating the conditioning of autonomic responses, foreshadowed current models of autonomic regulation that extend well beyond simple feedback-regulated control mechanisms. Through central associative processes, both exteroceptive and interoceptive stimuli can come to control ANS activity in an anticipatory fashion, and can effectively prevent or minimize perturbations prior to their occurrence (Dworkin, 2000). Conditioned anticipatory autonomic responses, for example, contribute to cardiovascular adjustments to orthostatic stress prior to severe blood pressure perturbations, and trigger anticipatory insulin release prior to the onset of a meal. Specific associations between an innocuous stimulus (conditioned stimulus, CS) that is paired with an aversive event (unconditioned stimulus, US) can result in conditioned fear reactions to the CS in which preparatory somatic and autonomic responses can be emitted in anticipation of the aversive stimulus or event (Ohman *et al.*, 2000). Similarly, the exaggerated affective and autonomic reactions to a wider (and sometimes poorly defined) range of stimuli and contexts in anxiety states probably reflects a pattern of hyperattentional processing of threat-related stimuli based on a broader and less specific associative structure (Berntson *et al.*, 1998).

Moreover, although central autonomic regulatory systems do contribute to homeostasis, steady state conditions are not always optimal, and central regulatory systems may also promote explicit deviations from homeostasis. Psychological stress, for example, can lead to an inhibition of the baroreceptor heart rate reflex, allowing an increase in both heart rate and blood pressure that might contribute to an adaptive response (see Berntson and Cacioppo, 2000). This is indicative of what has been termed 'allostasis' (McEwen, 1999), rather than homeostasis, and represents a class of autonomic control by which central mechanisms can actively adjust internal states in accord with adaptive demands (see McEwen, 1999; Berntson and Cacioppo, 2000). This is important, as it is not always optimal to maintain homeostatic, steady state conditions. During physical exercise or in the face of a survival threat, for example, there would be considerable adaptive advantage to increasing cardiac output and blood pressure, to enhance blood perfusion of muscles. In such instances, integrative neural systems shift the regulatory set point to a new level (allostasis), rather than maintaining a single homeostatic state. In fact, regulation of autonomic activity is often more dynamic than static, especially in behavioral contexts, so central neurobehavioral systems could more appropriately be considered to exert a pattern of allodynamic regulation over autonomic states (Berntson and Cacioppo, 2000). The construct of allodynamic regulation more appropriately encompasses the

complexity and flexibility of central autonomic control and its integration with neurobehavioral function.

EMOTION, ANXIETY, AND ANS ACTIVITY

Autonomic reactions have long been recognized as integral aspects of emotional states such as fear and anxiety, and it is now apparent that there is no clear distinction between higher neural systems underlying behavioral, autonomic, and neuroendocrine regulation. Increasingly, a close integration of these diverse response domains is apparent, so that behavioral responses, for example, are accompanied by the requisite autonomic, and neuroendocrine support. An illustration of this comes from the broad actions of corticotrophin releasing hormone systems at many levels of the neuraxis, which appear to coordinate and integrate the affective, behavioral, autonomic, and neuroendocrine states underlying stress reactions.

In addition, cerebral cortical areas, including the medial prefrontal cortex, have been implicated in the cognitive aspects of affective states, and have been shown to have relatively direct projections to lower autonomic mechanisms (Berntson *et al.*, 1998). These descending pathways (Figure 2) represent important routes by which rostral neural systems can modulate and regulate ANS activity. Indeed, autonomic adjustments are ubiquitous in cognitive and behavioral contexts, and these adjustments frequently do not adhere to expectations based on simple metabolic demands. Rather, these autonomic adjustments are likely to reflect an integrated pattern of central control over cognitive, behavioral, and autonomic functions. Consequently, it is not surprising that psychological dysfunctions are often associated with altered autonomic control.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) published by the American Psychiatric Association recognizes altered autonomic activity as a frequent feature of anxiety disorders. However, there is no single autonomic feature that uniformly characterizes anxiety states; indeed, there appear to be considerable differences between the anxiety disorders, and even between individuals within a given diagnostic category (Berntson *et al.*, 1998). This variability attests to the flexibility of autonomic control by higher neural substrates. It remains the case that altered autonomic function is a common accompaniment of anxiety disorders, and may reflect both cause and consequence of these conditions.

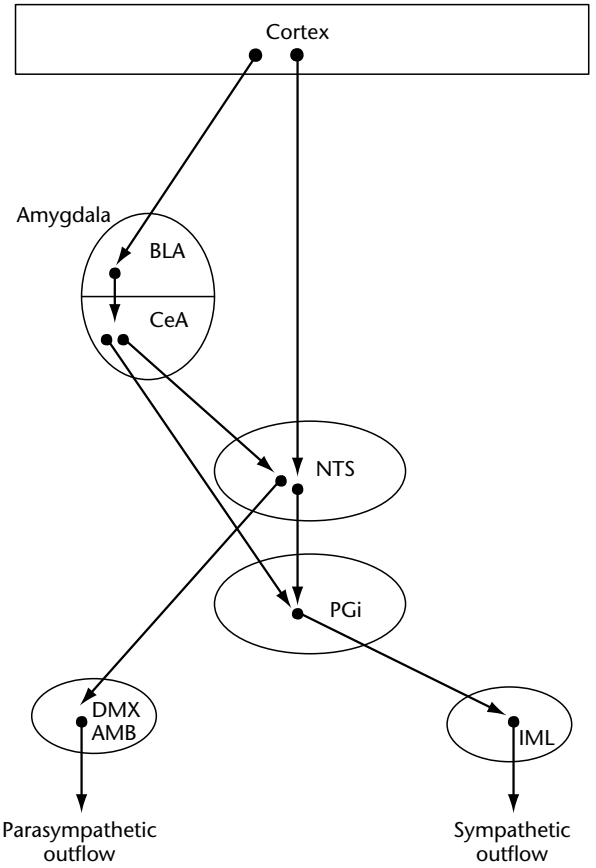

Figure 2. Descending neural systems that affect fear, anxiety, and autonomic control. AMB, nucleus ambiguus; BLA, basolateral amygdala; CeA, central nucleus of the amygdala; DMX, dorsal motor nucleus of the vagus; IML, intermediolateral cell column of the cord; NTS, nucleus of the tractus solitarius; PGi, nucleus paragigantocellularis.

The pathways considered above (Figure 2) provide ample routes by which cognitive and behavioral processes can influence autonomic states. Autonomic and neuroendocrine activation in response to stressors serves to mobilize visceral resources in support of the requirements of 'fight or flight', and of the attentional and cognitive demands of adaptive challenges. The stressors of contemporary society, however, do not require – or even allow – a behavioral response of fight or flight, and hence this visceral mobilization may not be readily resolved. Indeed, the metabolic demand for somatic activation imposed by chronic stressors has diminished at the very time that the requirement for visceral support of attentional, cognitive, and behavioral adaptation strategies has increased. Thus, the physiological response to stress that worked well in human evolution may have

maladaptive aspects, which become more evident as urban societies develop and life expectancy increases well beyond the reproductive years. Because the somatovisceral mobilizing functions of the autonomic nervous system appear to have evolved to deal with transient challenges (Dworkin, 2000), the prolonged somatovisceral activation associated with chronic psychological stressors in today's society may have long-term health costs (McEwen, 1999). Consequently, the cortical and cognitive processes that underlie this chronic activation are especially important to understand.

COGNITIVE INTERACTIONS WITH ANS ACTIVITY

The descending pathways of Figure 2 represent important substrates for 'top down' regulation of the ANS, whereby cognitive and behavioral states can affect autonomic function. Indeed, cognitive imagery alone is sufficient to trigger autonomic responses. Because cognitive and attentional biases lie at the core of anxiety disorders such as posttraumatic stress disorder and generalized anxiety disorders, these descending pathways probably contribute to the altered autonomic function in anxiety states. The interactions between cognitive and autonomic functions are not one-way, however, and the sensory functions of the ANS may allow autonomic states to bias cognitive processing.

The nineteenth-century psychologist William James proposed that sensory feedback from physiological responses might constitute emotional experience (see Cacioppo *et al.*, 1992). Although it now appears that somatovisceral feedback is not essential for emotional reactivity, this feedback may importantly bias cognitive and emotional processing (see Berntson *et al.*, 1998). Thus, visceral afference, carried by vagal afferents with a relay in the NTS, has been shown to enhance emotional memory in animals (McGaugh *et al.*, 2000), and feedback from autonomic responses may be sufficient to trigger panic attacks in people with panic disorder. More generally, somatovisceral and environmental feedback may have a crucial role in organizing and regulating broad aspects of behavior, affect, and cognition (see, for example, Bechara *et al.*, 2000).

One anatomical route by which this type of 'bottom up' priming may be effected is suggested by work on the nucleus paragigantocellularis (PGi) and the locus ceruleus (LC) in the brainstem (Aston-Jones *et al.*, 1996). These structures could be considered as parts of an ascending visceral afferent system. The PGi receives direct input from the NTS, and modulates sympathetic outflow via descending projections and LC activity via ascending projections (Figure 3). Thus, activity of LC neurons would be expected to be highly responsive to the state of activity of the sympathetic branch. Noradrenergic neurons of the LC in turn issue excitatory projections to the basal forebrain cortical cholinergic system, as well as to the cortex directly.

The ascending pathways of Figure 3 represent a potentially important route by which autonomic activity and associated visceral afference might modulate cognitive and emotional processing. In addition to the known descending projections from rostral neurobehavioral systems, this ascending pathway suggests an additional class of interactions between autonomic activity and cortical/cognitive processes. Moreover, the potential for both 'top down' (Figure 2) and 'bottom up' (Figure 3) influences may represent the substrate for a vicious circle of reciprocal

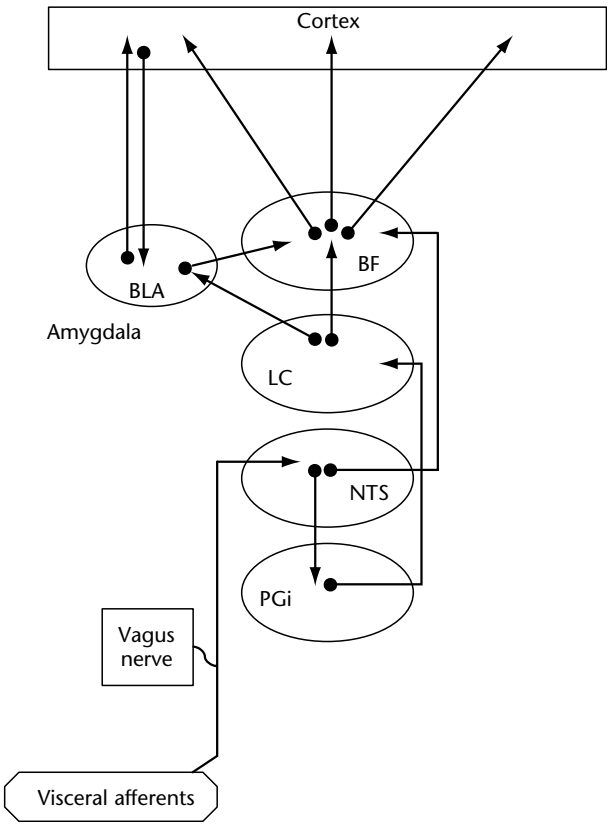

Figure 3. Ascending neural systems that may affect cognitive and emotional processing. BF, basal forebrain; BLA, basolateral amygdala; LC, locus ceruleus; NTS, nucleus of the tractus solitarius; PGi, nucleus paragigantocellularis.

cognitive/autonomic priming that might account for the apparent irrationality and exaggerated hyperattentional processing in anxiety states.

Anxiety, Anxiolytics, and the Basal Forebrain Cortical Cholinergic System

Because cognitive processes appear to contribute substantially to the clinical features of anxiety, including the hyperattentional processing of threat-related stimuli, it is not surprising that cortical systems have been implicated in anxiety disorders. An illustration comes from studies on anxiety and the basal forebrain cholinergic system (Berntson *et al.*, 1998). The widespread corticopetal projections of the basal forebrain provide the primary source of cortical ACh, and ACh appears to enhance cortical processing generally (Sarter and Bruno, 2000). This is illustrated by the global dementia of Alzheimer disease, which is associated with degeneration of the basal forebrain cholinergic system. In view of these considerations, cortical cholinergic activity would be expected to exaggerate the cognitive processing underlying anxiety. This is consistent with the finding that selective immunotoxic lesions of the cholinergic neurons of the basal forebrain in the rat attenuate the exaggerated behavioral and autonomic reactions in anxiogenic contexts (Berntson *et al.*, 1998).

Additional evidence supports this view and explains the antianxiety actions of benzodiazepine receptor agonists such as chlordiazepoxide and diazepam (for a review, see Berntson *et al.*, 1998). The activity of basal forebrain cholinergic neurons is regulated in part by an inhibitory input mediated by γ-aminobutyric acid (GABA), which in turn is bidirectionally modulated through a benzodiazepine binding site on the GABA receptor complex. The anxiolytic benzodiazepine receptor agonists enhance GABA-mediated inhibition and reduce basal forebrain cholinergic activity. Conversely, benzodiazepine receptor inverse or partial inverse agonists, which decrease GABA-mediated inhibition and enhance basal forebrain cholinergic activity, have notable anxiogenic properties (see Berntson *et al.*, 1998). Especially relevant in the link between anxiety and autonomic function may be the medial prefrontal cortex, an area that has been repeatedly implicated in both affect and autonomic control. Selective immunotoxic lesions of the basal forebrain cholinergic projections to the medial prefrontal cortex, like lesions of the basal forebrain itself, eliminate the exaggerated autonomic reactions in anxiety-related contexts (see Berntson *et al.*, 1998).

The ascending pathways in Figure 3 are intended to be representative rather than exhaustive, and there are many important questions that remain in this area. It is increasingly apparent, however, that comprehensive models of cognitive processing or autonomic functions will require a deeper understanding of the reciprocal interactions between these functional domains. In contrast to the Jamesian view that somatovisceral feedback constitutes emotion, the ascending pathway of Figure 3 provides a route by which visceral afference may more subtly trigger or modulate cognitive/emotional processing, even in the absence of conscious perception of the visceral stimulus.

CONCLUSION

Classical views of the autonomic nervous system often focused on brainstem reflexes and the autonomic regulation of internal homeostasis. With the elucidation of higher neurobehavioral influences over autonomic outflow, and the important sensory functions of the ANS, these limited perspectives are no longer tenable. Beyond lower sensory and motor neurons, there is no clear distinction between central systems that regulate behavioral, autonomic, neuroendocrine, and immune processes. Moreover, it appears that the higher the level of neural organization, the greater is the integration among these response domains, culminating in the supreme integrative functions of cerebral cortical systems. Consequently, an understanding of cortical/cognitive processes and the systems and mechanisms that regulate this processing is a prerequisite for a comprehensive model of the autonomic nervous system and its central regulation.

CONTENTS

The basal forebrain is a complex of subcortical nuclei that project widely to cortical and limbic areas involved in cognitive function. Damage to the basal forebrain is associated with cognitive deficits. The contributions of particular neuroanatomical and neurochemical components of the basal forebrain to different aspects of cognitive function can be dissociated to some extent.

INTRODUCTION

The term 'basal forebrain' commonly refers to an extended continuum of subcortical neurons that projects to diverse limbic and neocortical areas implicated in various aspects of cognitive function. Damage to the basal forebrain region can result in global cognitive impairments. For instance, aneurysms of the anterior communicating artery that injure the basal forebrain are associated with amnesia and impairments in executive function. Cognitive deficits in both normal aging and age-related pathological conditions have also been associated with the basal forebrain. The severity of cognitive impairment observed in Alzheimer disease is correlated with the extent of deterioration of cholinergic neurons in the basal forebrain. A similar relationship between cognitive impairment and alterations in basal forebrain cholinergic neurons is seen in normal aging. For these reasons, cholinergic neurons have been central to most explanations of the cognitive effects of basal forebrain damage. Hypotheses regarding the involvement of the basal forebrain cholinergic system in global aspects of cognitive function have been gradually revised as more and more selective lesion methods have become available for experimental studies of this region (Wenk, 1997).

Attempts to identify the specific cognitive functions of basal forebrain cholinergic neurons have suggested that these neurons do not play a specific part in memory processing *per se*, or a general role in sustaining the function of their cortical targets. Instead, damage limited to basal forebrain cholinergic neurons produces highly restricted impairments in aspects of sensory information processing and attention.

ANATOMY AND CONNECTIONS OF THE BASAL FOREBRAIN

Cholinergic basal forebrain neurons are intermingled with a substantial population of noncholinergic neurons that share similar projection patterns (Gritti *et al.*, 1997). Estimates of the proportion of cortically projecting basal forebrain neurons that are cholinergic vary from study to study but are generally in the range 30–50 percent. Many noncholinergic neurons in the basal forebrain may be local circuit neurons, receiving cortical input and modulating activity of cortically projecting cholinergic and noncholinergic neurons (Zaborszky *et al.*, 1997).

The basal forebrain can be divided into four groups of cells: the medial septum, projecting primarily to the hippocampus; the vertical limb of the diagonal band of Broca, projecting primarily to the hippocampus and cingulate cortex; the horizontal limb of the diagonal band of Broca, projecting primarily to the olfactory bulb, piriform cortex and entorhinal cortex; and the nucleus basalis magnocellularis or substantia innominata, projecting primarily to the neocortex and amygdala (Figure 1). These cholinergic nuclei have also been designated Ch1 to Ch4 (Mesulam *et al.*, 1983); this nomenclature approximately corresponds to the above divisions. The organization of the basal forebrain is similar in the primate and in the rat, although subdivisions of the nucleus basalis can be identified reliably in the primate but not in the rat. Some areas of the basal forebrain are reciprocally connected with

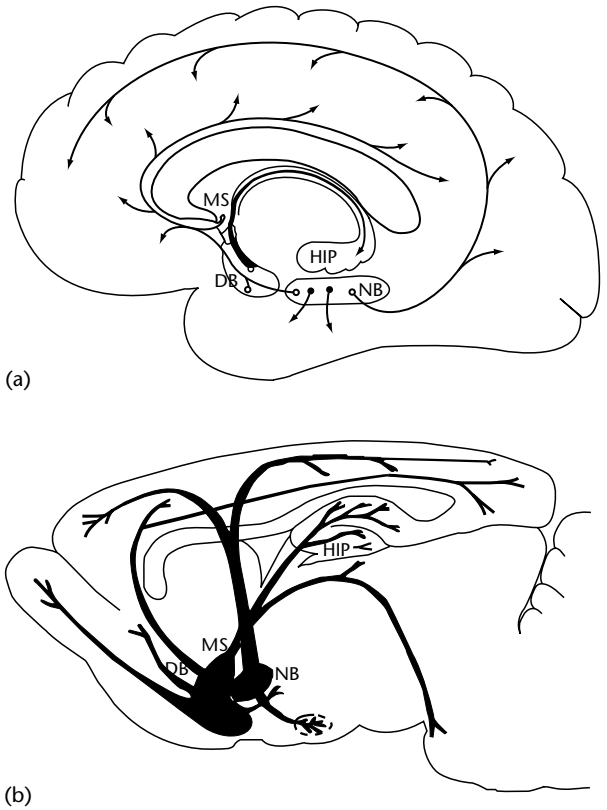

Figure 1. The basal forebrain cholinergic system, schematically represented in sagittal views of (a) human and (b) rat brain. The basal forebrain can be roughly divided into three major divisions (rostral to caudal): the medial septum (MS), projecting primarily to hippocampus (HIP); the diagonal band nuclei (DB), consisting of the vertical limb of the diagonal band of Broca, projecting to the hippocampus and cingulate cortex, and the horizontal limb of the diagonal band of Broca, projecting to the olfactory bulb and entorhinal cortex; and the nucleus basalis (NB), projecting to neocortex and amygdala. These cell groups share similar projection patterns in both species. The substantia innominata, which forms a less discrete nucleus in the rat than in the primate, sends cholinergic projections to the neocortex.

their targets; anatomical experiments in rats have shown that the medial septum and diagonal band project to the hippocampus and medial prefrontal cortex and receive projections back from these structures. Similarly, the nucleus basalis is reciprocally connected with the amygdala. The basal forebrain also receives inputs from the hypothalamus, as well as from the midbrain and upper pons (Wainer and Mesulam, 1990). Inhibitory projections from the nucleus accumbens to the basal forebrain may have a particular role in regulating cortical acetylcholine release (Sarter and Bruno, 2000).

INVOLVEMENT OF THE BASAL FOREBRAIN IN MEMORY

Considerable attention has been devoted to the magnocellular cholinergic neurons of the basal forebrain and their function in memory, because of the hypothesis that cholinergic dysfunction specifically is partially or wholly responsible for the memory deficits seen after damage to the basal forebrain (the 'cholinergic hypothesis'). Alzheimer disease involves loss of these neurons. Postmortem examinations of brains from people with Alzheimer disease have found a marked cell loss in the basal forebrain relative to the brains of healthy people. In Alzheimer disease there is a loss of choline acetyltransferase and acetylcholinesterase in the cortical targets of the basal forebrain. The enzyme choline acetyltransferase synthesizes acetylcholine; once released from the presynaptic terminal, acetylcholine is degraded by the enzyme acetylcholinesterase. Cognitive impairment in people with Alzheimer disease is correlated with the extent of cholinergic loss. These findings suggest that the loss of cholinergic transmission in the basal forebrain contributes to the mnemonic dysfunction observed in this disease (Collerton, 1986).

Additional support for the presumed role of the basal forebrain in memory dysfunction is derived from patients with amnesia resulting from an anterior communicating artery aneurysm. Infarcts associated with these aneurysms do not typically damage the traditional cerebral areas implicated in amnesia (i.e. medial temporal and diencephalic structures). Amnesic patients who sustained infarcts resulting in lesions confined to the basal forebrain with no evidence of diencephalic or medial temporal involvement have relatively intact immediate recall and intact implicit memory, but impaired delayed recall and an increased susceptibility to proactive interference. The increased susceptibility to proactive interference may be due to deficient attentional inhibitory mechanisms. These patients have also shown a reduced information processing speed, poor divided attention ability and increased distractibility (DeLuca and Diamond, 1995).

The findings in the above disorders suggest that the basal forebrain contributes to mnemonic dysfunction, motivating the development of animal models of basal forebrain damage to elucidate the exact role of the cholinergic basal forebrain system in mediating such dysfunction. In these models, the basal forebrain cholinergic system or its cholinergic targets are damaged and behavioral tests are performed to determine the consequent pattern of

mnemonic function. The validity of these models depends on the similarity of the cognitive processes being tested in animals and in humans, as well as on the anatomical homology of the basal forebrain in animals and humans.

To confirm the cholinergic hypothesis in an animal model, two challenges must be met: any memory deficits observed must be due to a specific impairment in memory processes, as opposed to disruption of other cognitive or noncognitive processes; and the deficits must not be attributable to destruction of other populations of noncholinergic neurons in the basal forebrain (Sarter and Bruno, 1997).

Most initial studies used stereotaxic placement of electrolytic or excitotoxic lesions in different regions of the basal forebrain in rats. Interpretation of these studies has been made difficult by the fact that electrolytic lesions damage mixed populations of neurons as well as passing fibers, and that excitotoxic lesions – produced, for example, by ibotenic acid, kainic acid, quisqualic acid or α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) – preserve the passing fibers but still damage mixed populations of neurons. Ibotenate and other excitotoxin-induced lesions of the nucleus basalis magnocellularis disrupt learning in working memory tasks (such as delayed alternation) and reference memory tasks (measuring spatial or conditional visual discrimination learning).

The cholinergic hypothesis was called into question, however, because lesions of the basal forebrain made with other excitotoxins (quisqualic acid and AMPA) resulted in greater destruction of cortically projecting cholinergic neurons of the nucleus basalis magnocellularis than that seen following ibotenate lesions, but induced only a few of the learning and memory deficits caused by ibotenate. Consequently, many of the deficits induced by ibotenate lesions of the basal forebrain cannot be attributed to a primary destruction of cholinergic neurons in the nucleus basalis magno cellularis (Everitt and Robbins, 1997).

Because these lesion techniques are not selective for cholinergic neurons and therefore the resulting behavioral deficits may be due in part to damage in some neighboring neuronal system, explicit tests of the cholinergic hypothesis require a neurotoxin specific for basal forebrain cholinergic neurons. The immunotoxin, 192 IgG-saporin, provides a route for directly targeting the toxin saporin to cholinergic neurons *in vivo* in the rat without damaging noncholinergic neurons at the lesion site. Immunotoxic lesions restricted to specific cholinergic nuclei of the basal forebrain have generally failed to produce mnemonic deficits. It is noteworthy that the more specific the cholinergic lesion, the less dramatic the effects on learning and memory (Everitt and Robbins, 1997; Baxter and Chiba, 1999). The studies with less specific excitotoxic lesions underscore the importance of careful validation that basal forebrain lesions intended to be specific to cholinergic neurons do actually spare noncholinergic neurons at the lesion site (for related discussion see Chappell *et al.*, 1998).

The foregoing experiments in rats suggesting a role for the basal forebrain in memory function but no specific role for cholinergic basal forebrain neurons are supported by experiments in nonhuman primates. These animals have a more spatially distinct nucleus basalis of Meynert, and comparisons of cognitive deficits between humans and monkeys are more plausible than between humans and rats. Voytko (1996) and her colleagues extensively and systematically investigated the effect of administration of ibotenic acid lesions placed stereotaxically into the basal forebrain cholinergic nuclei of Old World (macaque) monkeys. Their battery of tests (delayed nonmatching to sample, delayed response, simultaneous discrimination, and a visuospatial attention task) revealed no mnemonic deficits. There is some contradiction between the findings of ibotenic lesions of the basal forebrain nuclei in Old and New World monkeys. Ibotenate lesions to the nucleus basalis of Meynert led to impairments in retention of preoperatively learned visual discriminations and reversal learning of visual discriminations postoperatively in New World monkeys. This was accounted for by possible nonspecific damage in the lesions made in New World monkeys. Administration of the putative cholinergic toxin ME20.4 IgG-saporin to the basal forebrain nuclei of New World monkeys led to perceptual impairments on retention and acquisition of visual discriminations (Fine *et al.*, 1997), although sparing of noncholinergic neurons at the lesion site in these monkeys was not verified.

Aims to increase acetylcholine levels in the clefts of the cholinergic synapse with acetylcholinesterase inhibitors, or to directly replace acetylcholine with cholinomimetic drugs, have largely been unsuccessful in reversing cognitive deficits in people with Alzheimer disease. This may be because direct enhancement of acetylcholine levels may disrupt any remaining intact cholinergic transmission. An alternative approach, trans-synaptic modulation, describes the effects of changes in the activity of an afferent neuronal system on the excitability of its target neurons, e.g. the effects of afferents mediated by γ-aminobutyric acid (GABA), originating locally

or distally, on the cholinergic neurons of the basal forebrain. Another complementary, pharmacological strategy to treatment of cognitive deficits consequent to cholinergic loss would be to modulate the cholinergic system by trans-synaptic mechanisms, for example by affecting cholinergic transmission with GABA. This approach may be more effective in alleviating the cognitive deficits since this acts to amplify the endogenous physiological cholinergic signal (Sarter and Bruno, 1997). However, given that loss of cholinergic neurons does not seem to be a primary cause of memory impairment in these conditions, even pharmacological treatments aimed at enhancing function of remaining cholinergic neurons by trans-synaptic modulation might be expected to have little beneficial effect on memory.

In summary, the most recent and stringent tests of the cholinergic hypothesis in animal models have not supported an essential role for cholinergic involvement in learning and memory functions *per se*. In contrast, basal forebrain cholinergic neurons do appear to have an essential role in regulating attentional processing capacity.

INVOLVEMENT OF THE BASAL FOREBRAIN IN ATTENTION

Mechanisms of attention are thought to enable the efficient allocation of processing resources in order to respond to important events in the environment. There are different types of attentional processes: selective or focused attention targets attentional resources on a restricted number of sensory stimuli and excludes other sensory stimuli; sustained attention or vigilance reflects a state of readiness to detect and respond to unpredictable or rare events; and divided attention refers to simultaneous monitoring of several different channels of sensory information. Attention filters what sensory information is introduced into memory. The basal forebrain appears to regulate many of these attentional functions; recent studies of lesions of the cholinergic forebrain in rats and monkeys have suggested deficits in several different paradigms for measuring attention, including selective spatial, divided and sustained attention.

The five-choice serial reaction time task, based on a human test of continuous performance, measures sustained spatial attention in rats. In this task, rats are required to monitor the occurrence of a light stimulus in one of five locations. With this paradigm, excitotoxic lesions (e.g. ibotenate acid, quisqualic acid and AMPA) of the nucleus basalis magnocellularis (NBM) produce impairments in performance, which are ameliorated by increasing the duration of the stimuli. In support of the involvement of the cholinergic basal forebrain, this deficit is alleviated by an acetylcholinesterase inhibitor, physostigmine (Everitt and Robbins, 1997). A role for the NBM in attention has also been demonstrated in a temporal divided attention task, where at times rats are required to divide their attention between two simultaneous stimuli: rats with excitotoxic lesions of the NBM are specifically impaired in their ability to time two stimuli simultaneously (Olton *et al.*, 1988). In a cross-modal divided attention task, infusion of 192 IgG-saporin into the basal forebrain selectively increases the response latencies in a bimodal condition, without affecting the accuracy or the retrieval and execution of the stimulus–response action in either the visual or auditory modality (Turchi and Sarter, 1997).

Basal forebrain neurons, including the cholinergic neurons, receive direct contacts from GABA-mediated afferents and are inhibited by GABA. Like cholinergic lesions, infusions of a benzodiazepine receptor agonist into the basal forebrain impair the performance of rats tested in a sustained attention without altering the efficacy of perceptual processes. Infusion of the $GABA_A$ receptor agonist, muscimol, directly into the basal forebrain both decreases the activity of the cortically projecting NBM neurons and impairs accuracy on the five-choice task. Two-lever vigilance tasks present the rat with successive trials of changes in the intensity of continuously delivered auditory stimuli (e.g. white noise) or visual stimuli (e.g. illumination). One lever measures the 'hits' and the other lever measures the correct rejections. In two-lever vigilance tasks for rats, both 192 IgG-saporin lesions of the NBM and intra-NBM administration of $GABA_A$ benzodiazepine receptor agonists have impaired vigilance performance (Sarter and Bruno, 1997).

In a visuospatial attention task, Old World monkeys with basal forebrain lesions showed impairments in shifting attention (Voytko, 1996). A brief cue indicates the expected location of a target stimulus. The difference in response time to a target that appears at expected and unexpected locations is used as the measure of shifting of attention. A slower response time on invalid trials, in which the target appears at an unexpected location, compared with valid trials in which the target appears at the expected location, indicates that the subject has paid attention to the cue that is signaling the likely location of a target. Monkeys with basal forebrain lesions showed disproportionately longer response times on invalid trials, suggesting an

impairment in disengaging attention from the invalidly cued location. This was not due to a general impairment in motor skills, since the response to the target following the initiation of a response was comparable in monkeys with and without basal forebrain lesions. A similar result has been described in rats with selective lesions of cholinergic neurons in the NBM (Chiba *et al.*, 1999). It is important to note that this attentional impairment was selective; the monkeys with basal forebrain lesions in the study by Voytko were not impaired on tests of visual learning and memory, and rats with selective cholinergic lesions of the NBM were not impaired on a variety of cognitive tasks including tests of spatial learning and memory (reviewed by Baxter and Chiba, 1999).

Experiments that examine the regulation of attentional processing in associative learning paradigms have identified dissociable roles for rostral (septal) and caudal (NBM) regions of basal forebrain cholinergic neurons in these aspects of attention (reviewed by Baxter and Chiba, 1999). Increases in conditioned stimulus processing, brought about by violations of learned contingencies, require the integrity of cholinergic neurons in the NBM, but not cholinergic neurons in the medial septum or vertical limb of the diagonal band of Broca. Decreases in conditioned stimulus processing, which occur when conditioned stimuli are preexposed in the absence of reinforcement, or are consistent predictors of another event, require the integrity of cholinergic neurons in the latter structures, but not in the NBM.

The basal forebrain has reciprocal connections with the central nucleus of the amygdala, which has potential for widespread influences on cortical processing directly through projections to both lower-order and higher-order sensory areas and indirectly through projections to cholinergic neurons in the basal forebrain. Stimulation of the amygdala central nucleus has been found to influence basal forebrain electroencephalographic patterns consistent with acetylcholine release in rats and humans (Kapp *et al.*, 1994). Cortical acetylcholine release stimulated by the amygdala is thought to induce a state of cortical readiness for processing sensory information. This suggests that the basal forebrain cholinergic system might provide an output pathway for the regulation of attention and cortical information processing by the amygdala. Indeed, evidence from crossed-lesion studies suggests that projections from the central nucleus to the NBM are critical for producing increases in conditioned stimulus processing: disconnection of the NBM from the central nucleus of the amygdala by crossed unilateral lesions also disrupts the ability to increase attentional processing in response to a violation of expectancy (Baxter and Chiba, 1999).

Thus far, selective cholinergic lesions in the basal forebrain system appear to have a limited effect on measures of learning and memory, but rather impair attentional processing. It is assumed that attentional processes are involved in the primary stages in information processing, so it is remarkable that no dramatic effects in various learning and memory tasks have been observed following damage to basal forebrain cholinergic neurons. If attentional processes are impaired, then a performance deficit would be expected in most learning and memory tasks, but it appears that this is not the case after selective cholinergic lesions. However, the statement that basal forebrain damage impairs attention is an oversimplification. Instead, the effects of these lesions might be better characterized as producing an impairment in the ability to regulate attentional processing appropriately in response to task or environmental demands (Baxter and Chiba, 1999), rather than a reduction in the ability to attend to stimuli *per se*.

CONCLUSION

The basal forebrain is anatomically situated to regulate information processing in cortical and limbic structures involved in a wide array of cognitive functions. Indeed, extensive damage to the basal forebrain (to both cholinergic and noncholinergic components) results in a broad array of cognitive impairments. In contrast, damage limited to basal forebrain cholinergic neurons produces more restricted impairments in regulation of attentional processing. Hence, basal forebrain cholinergic neurons appear to have a selective role in regulating cortical information processing, rather than a generalized role in supporting the functions of their target areas. This apparently restricted function of basal forebrain cholinergic neurons suggests that a loss of these cells is probably not the core factor in producing cognitive deficits in conditions such as Alzheimer disease, or in the amnesia consequent to aneurysms in the basal forebrain.

The characterization of the function of basal forebrain cholinergic neurons as 'attentional' may fail to capture the array of functions performed by these neurons. These neurons are probably involved in other aspects of sensory processing and representational plasticity in primary sensory cortical areas (Baskerville *et al.*, 1997; Kilgard and Merzenich, 1998). The involvement of basal

forebrain cholinergic projections to other cortical areas in similar types of functions has not yet been investigated. Hence, a general operating principle for the role of these cholinergic neurons in cognition remains elusive, as does a role for the basal forebrain generally in cognitive function. The basal forebrain, particularly the cholinergic component, may be more broadly involved in gating cortical information processing and regulating aspects of conscious experience (Sarter and Bruno, 2000); hence abnormalities in basal forebrain function could contribute to a wide variety of cognitive impairments in both neurodegenerative disease and in psychopathology. These hypotheses represent a useful guiding principle for future studies of basal forebrain function, both in animal models and in human clinical populations.

Basal Ganglia

Introductory article

Lucy L Brown, Albert Einstein College of Medicine, Bronx, New York, USA
Samuel M Feldman, New York University, New York, USA

CONTENTS

Nuclei near the base of the brain integrate information from the entire cerebral cortex and serve a regulatory function for movement and cognition.

INTRODUCTION

The basal ganglia are a group of brain structures that regulate movement in mammals. Damage to these subcortical structures is the primary cause of involuntary, abnormally sequenced movements such as tremor, rigidity, athetosis, tics, chorea and ballism. However, the role of the basal ganglia goes well beyond the regulation of the sequencing of movements. They also have a major role in the learning of motor and cognitive skills. They control the expression of voluntary behaviors that are essential for normal mammalian interaction with an ever-changing and challenging environment. Unlike the spinal cord, which is necessary for withdrawal reflexes and the final stages of the movements we execute, the basal ganglia influence the selection and sequence of the final movement, and participate in adaptive motor control.

A neuroscientist's gag is: 'Why are the basal ganglia like the Dean's office?' Answer: 'Because they take up a lot of space and nobody knows what they do.' This old joke turns out to be surprisingly on target. A serious answer might be that they facilitate the global operations of a large 'institution', planning and making decisions based on many varied inputs. Such an executive role in brain function is difficult to analyze, and our knowledge about the function of these nuclei is still evolving. Accordingly, the descriptions of sensorimotor and cognitive functions of the basal ganglia that follow must be seen as descriptions of work in progress.

Anatomically, the basal ganglia are a collection of nuclei in the mammalian forebrain and midbrain. The forebrain nuclei include the caudate nucleus and putamen, the nucleus accumbens, the globus pallidus (internal and external segments) and the subthalamic nucleus. Two subunits of the substantia nigra, the pars reticulata and pars compacta, make up the midbrain component. Similar structures exist in other vertebrates, including reptiles, amphibians, birds and fish. Although the amygdala and other basal forebrain nuclei were once included in discussions of the basal ganglia, current concepts of anatomy and function restrict the definition now used.

Alternative designations are used for some of the basal ganglia nuclei. For example, in primates the caudate and putamen are anatomically distinct, but lower mammals such as the rat lack this dichotomy and have a single undifferentiated nucleus called the striatum. In the primate brain the putamen and globus pallidus are physically close and often hard to distinguish, and are referred to collectively as the lenticular nucleus.

The striatum receives its major synaptic input from the entire extent of the cerebral cortex. This diverse cortical input reflects the many functions in which the basal ganglia participate, ranging from sensorimotor feedback and motor control to spatial working memory. Both the anatomy and physiology suggest that the basal ganglia act collectively as a 'suppress and release' mechanism for a wide range of behaviors. Dysfunction of these mechanisms is seen in basal ganglia disorders; for example, people with Parkinson disease have difficulty initiating movements, while people with Huntington chorea cannot stop. These disorders are involuntary: people with Huntington chorea have little or no control over their flailing movements, nor can people with Parkinson disease voluntarily overcome their 'frozen' state. Thus, the suppress and release mechanism operates at the unconscious level.

ANATOMY AND CHEMOARCHITECTURE

Location and Gross Structure

The caudate–putamen and globus pallidus are situated on either side of the thalamus, beneath the mantle of the cerebral cortex. The corpus callosum and external capsule form a border around the caudate–putamen. In primates, the caudate and putamen are separated by the internal capsule, which contains axon projections between the cortex, brainstem and spinal cord. In the primate, the caudate has a head, body and tail. The head borders the anterior lateral ventricle while the body and tail follow the contour of the lateral ventricle into the temporal lobe (Figure 1). The nucleus accumbens is continuous with the caudate and putamen, extending anteriorly and downward to the inferior surface of the brain. The subthalamic nucleus, at the junction of the midbrain and forebrain, and substantia nigra, in the midbrain, are smaller than the caudate–putamen. The right basal ganglia control the left side of the body and vice versa. Accordingly, parkinsonian tremor of the left hand is evidence of pathological changes in the right basal ganglia.

Neuroanatomists have described connections of the basal ganglia in the mammal as loops that originate in different regions of the cortex, and project back to subregions of the originating cortex (Figure 2). For example, a sensorimotor loop has its origins in sensorimotor cortex. Excitatory sensorimotor cortex projections to striatum activate cells whose output to the globus pallidus is inhibitory. The pallidal neurons also have an inhibitory effect on their target neurons in the ventral thalamus,

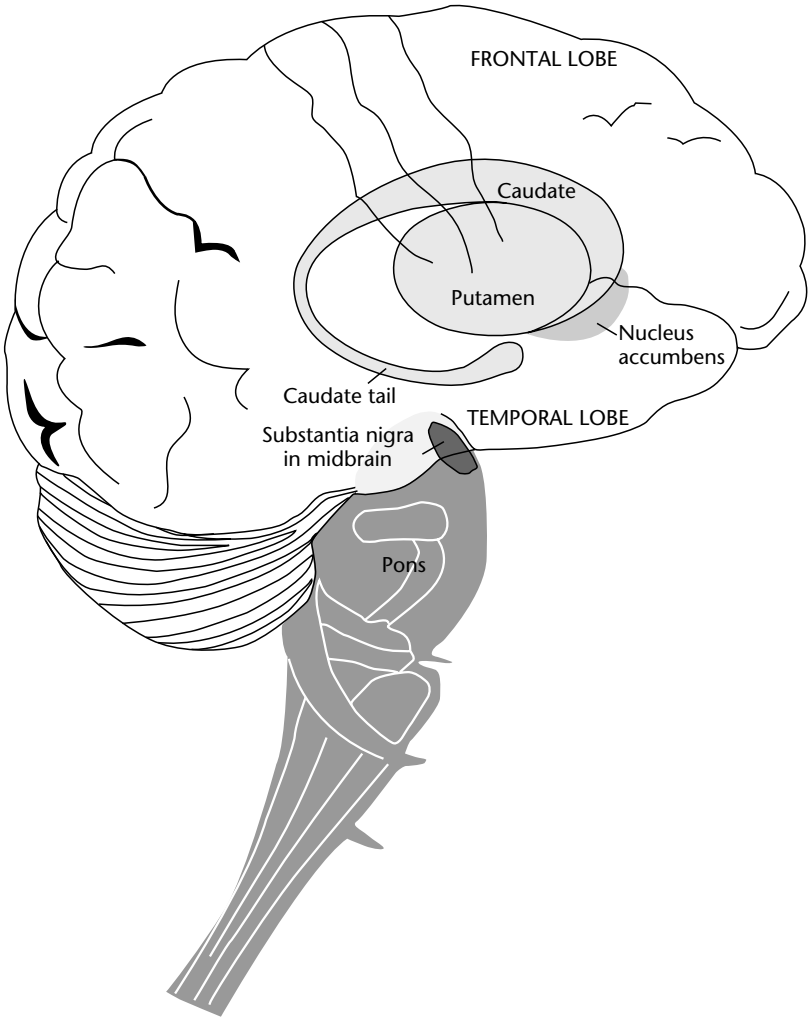

Figure 1. Sagittal (side) view of the human brain shows the central locations of the largest basal ganglia nuclei. The caudate, putamen, globus pallidus and nucleus accumbens are in the forebrain. The substantia nigra is in the midbrain while the subthalamic nucleus (not shown) is at the junction of the midbrain and forebrain.

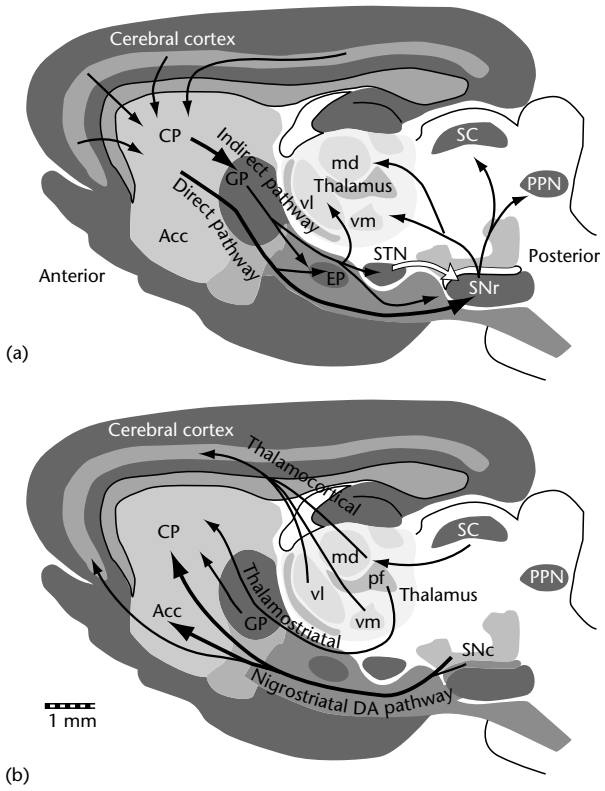

Figure 2. Nuclei and major pathways of the basal ganglia in the rat. The pathways exist also in primates. The view is sagittal, thus showing the extent of the basal ganglia from the forebrain to the midbrain. (a) Descending pathways. All of the cerebral cortex projects to the caudate–putamen (CP). The direct pathway projects to the internal segment of the globus pallidus, called the entopeduncular nucleus (EP) in rats, and to the substantia nigra reticulata before projecting out of the basal ganglia nuclei to the thalamus, superior colliculus and pedunculopontine nucleus. The indirect pathway projects to the subthalamic nucleus and globus pallidus externa (GP in rats) before going to the entopeduncular nucleus and substantia nigra and leaving the basal ganglia. (b) Feedback pathways. The substantia nigra compacta, which contains dopaminergic cells, sends an important projection called the nigrostriatal dopamine pathway to the caudate–putamen and nucleus accumbens. The thalamocortical projection completes the loop from cortex to basal ganglia to thalamus and back to cortex. Acc, nucleus accumbens; CP, caudate–putamen; DA, dopamine; EP, entopeduncular nucleus; GP, globus pallidus; md, mediodorsal nucleus; pf, parafascicular nucleus; PPN, pedunculopontine nucleus; SC, superior colliculus; SNc, substantia nigra compacta; SNr, substantia nigra reticulata; vl, ventrolateral nucleus; vm, ventromedial nucleus. Adapted from Gerfen and Wilson, 1999.

which in turn has an excitatory projection to the supplementary motor cortex, a region known to be involved in the planning of complex movements. The loop circuits are examples of brain regulatory systems that use inhibition of a tonic inhibitory drive as a gate to release normally suppressed output. Other important basal ganglia circuits include an oculomotor loop, which has a major output pathway to the superior colliculus, via the reticulata region of the substantia nigra, in addition to the cortical frontal eye fields, via the thalamus; a dorsolateral prefrontal cortex loop; and a so-called limbic loop.

In addition to the fundamental circuit described above, a critically important input to the striatum comes from the compacta region of the substantia nigra via the nigrostriatal tract (Figure 2). One of the major dopamine pathways in the brain, its integrity is essential for normal functioning of the basal ganglia. Parkinsonism is the direct result of interference with nigrostriatal transmission. Finally, complex and specialized interactions among basal ganglia structures involve the subthalamic nucleus through the 'indirect pathway' (Figure 2).

Chemoarchitecture

The basal ganglia are a collection of heterogeneous nuclei. The striatum contains small zones with a dense concentration of opioid receptors, called 'striosomes' or 'patches' (Figure 3), within a 'matrix' rich in cholinesterase. Many other neurally active substances (such as somatostatin, calbindin and substance P) and receptor proteins (such as the $GABA_A$ receptor) are unevenly distributed between the striosome and matrix compartments. Although the functional significance of this chemoarchitectonic heterogeneity is largely unknown, cells in the patch compartment are active following administration of some dopaminergic drugs, and may play a major part in regulation of dopamine in substantia nigra.

Other components of the basal ganglia have a distinctive complex of cell types, neurochemicals, receptor proteins and synaptic connections that interact in a highly structured fashion. For example, regions thought to have more cognitive than motor functions are rich in calbindin, a calcium binding protein, while those thought to regulate motor functions are calbindin-poor. In addition, the major target of the neostriatum, the globus pallidus, has two segments, internal and external, divided by different inputs; the external segment also has a much higher concentration of enkephalin. Finally, the substantia nigra has two components: reticulata

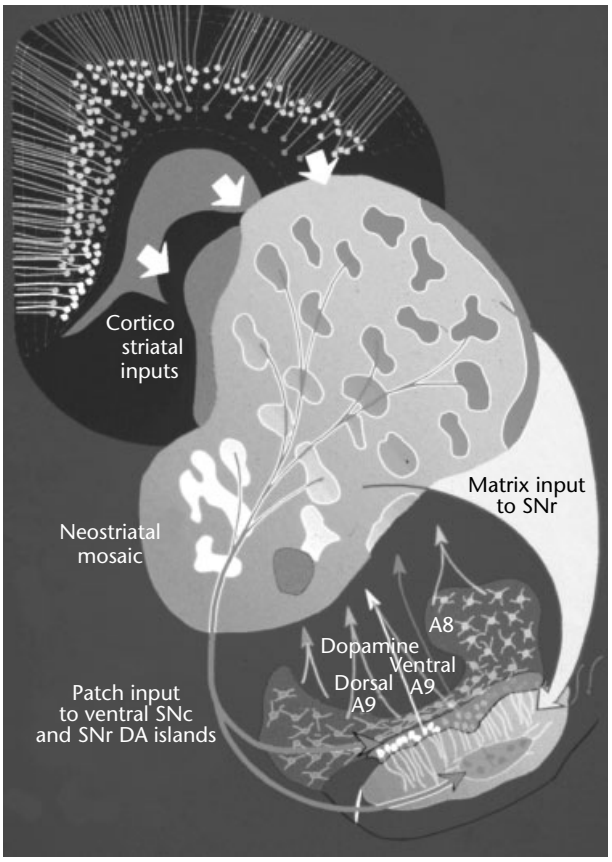

Figure 3. [*Figure is also reproduced in color section.*] The patch–matrix design of the striatum in the rat, seen in the right side of the rat cortex, striatum, nucleus accumbens and substantia nigra. The patches (red, orange and yellow zones), also called striosomes, are rich in an opioid receptor. The surrounding matrix is rich in acetylcholinesterase and calbindin. The anatomical connections of the patches and matrix are color-coded to show, for example, that the cells in the deep layers of lateral cortex project to the lateral patches in the striatum, which in turn project to the ventral substantia nigra compacta dopaminergic cells. SNr, substantia nigra reticulata; SNc, substantia nigra compacta; A9, nomenclature that refers to substantia nigra compacta cells; A10, refers to dopaminergic cells of the midbrain tegmentum that project to the nucleus accumbens. Diagram courtesy of C. Gerfen. >)

and compacta (Figure 3). The reticulata component contains GABA-mediated neurons, while compacta neurons are dopaminergic, their axons being the nigrostriatal pathway.

FUNCTIONS OF THE BASAL GANGLIA

Sensorimotor Functions

Tennis professionals and pianists practice constantly. Eventually their skills become unconscious habits, and during performance they do not think about them in any detail. Indeed, we all have large repertoires of highly practised motor skills (buttoning a shirt, riding a bicycle, driving a car) that require sensory feedback during learning, but are eventually executed without thought or verbalization. Consider the task of driving a car with a manual gear shift, in which each of the four limbs is simultaneously engaged in a different task! Evidence is currently accumulating that the basal ganglia have a critical role in regulation, learning and execution of such motor habits.

We know from animal studies that electrical stimulation of small areas of the caudate–putamen produces movement in localized body regions such as the tongue or contralateral wrist. Stimulation of larger areas produces contralateral head movements or turning, or flexion of the limbs. This reflects the fact that the output of the basal ganglia affects the elements of which the skilled behaviors are constructed. They play a critical part in innate motor sequences (e.g. grooming in rodents), voluntary movements (e.g. limb trajectory) and the sensory feedback that guides directional movement, all of which are essential for developing complex trained sequences or motor habits.

Injection of dopamine directly into the rat neostriatum produces contralateral turning, while small neostriatal lesions prevent the normal sequencing of movements seen during grooming. In rodents and subhuman primates, an abnormal increase in dopamine at synapses in the basal ganglia causes repetitive, stereotyped behaviors: uncontrolled, purposeless, repetitive movements. Rodents will continually chew or sniff, or move back and forth repetitively. In humans, stereotypies may be observed in following administration of dopaminergic drugs, including cocaine.

Note, however, that all of these affected elements of motor behavior are organized at the spinal cord and brainstem level. It is their release, suppression and timing that seem to be regulated by the basal ganglia. Rather than programming these behaviors directly, the basal ganglia apparently implement sequences of behavioral elements that achieve complex behavior.

Additional insight comes from electrophysiological studies. Striatal cells fire in relation to the serial order of innate grooming sequences in rodents, or to learned movement sequences in primates. Inactivating the globus pallidus neurons by cooling disrupts smooth performance of movements by causing continuous flexion of the limbs. Also, cells in the caudate–putamen and globus pallidus fire before or during a learned movement,

when a limb is passively moved, or when the animal produces a spontaneous, unlearned movement. Interestingly, cells do not fire in relation to the amplitude or speed of a movement. In addition, neurons in substantia nigra reticulata change their activity before and during an eye movement. The substantia nigra and superior colliculus are more involved in head and eye movements, while the globus pallidus appears to be involved in limb and trunk movements.

Note, again, that none of these functions is exclusive to the basal ganglia. Basal ganglionic damage may prevent a movement by compromising the release mechanism, even while other parts of the brain (e.g. cerebellum, cortex) retain both essential and redundant circuits for execution of the task. The result of such damage is serious disruption and even prevention of behavior. The basal ganglia can also influence muscle tension and extensor/flexor balance, which are largely controlled by the brainstem and spinal cord. Rather than acting as a motor control system, the basal ganglia and its related structures apparently function as a gating mechanism for innate and complex movement patterns that are organized at lower levels.

Cognitive Functions

Just as the basal ganglia have a role in the unconscious aspects of motor control, they also affect the unconscious aspects of cognition. Such processes are difficult to study and require subtle investigative approaches. Spatial working memory, one of the first cognitive functions of the basal ganglia to be recognized, is linked closely to similar functions of the cortex. Recall that the targets of basal ganglia projections are regions of the cortex involved in motor planning and higher-order cognitive functions, such as spatial working memory. Caudate–putamen lesions consistently produce deficits in spatial learning tasks, and imaging studies in humans show that learning a complex spatial task such as the Tower of London puzzle involves the caudate. In addition, cells of the basal ganglia are involved in detecting and evaluating the learned context of an environmental stimulus. They fire in relation to conditioned stimuli and also when a stimulus becomes relevant, which suggests that the basal ganglia may affect cognitive behavior on a global scale. For example, detecting a primary reward such as a sweet taste, or learning that money is rewarding, or expecting a reward, all profoundly affect our behavior and and its planning. In human brain-mapping studies, several categories of reward such as cash, the 'rush' and 'high' of cocaine, and verbal feedback, activate the caudate, putamen and nucleus accumbens. Activation in the nucleus accumbens tracks the value of a monetary reward during a gambling task, even when there is only a prospect of winning money. Thus, the anticipation of reward, a highly influential – and global – role in behavior is also represented in the basal ganglia.

Studies of people with basal ganglia disease add further insight. People with Parkinson disease experience attention deficits and difficulty in shifting mental set. They are poor at learning to predict probabilistic classifications, which are similar to unconscious, learned, motor habits. This involves unconscious memory and selection of a group of objects that are correct more often than not during a training series. People with globus pallidus lesions describe their mental life as empty; they have no spontaneous thoughts. In Tourette syndrome, people experience racing thoughts. People who suffer Huntington disease exhibit symptoms of obsessive–compulsive disorder prior to the onset of severe motor symptoms.

CONCLUSION

The basal ganglia are subcortical forebrain and midbrain nuclei that process information from the cortex to affect movement and cognition. Physiological and pathophysiological studies indicate that the basal ganglia influence stopping, starting and switching behaviors at the unconscious level; that they play a role in complex visuospatial tasks; and that they have access to learned motor and cognitive habits. An understanding of the normal functions of the basal ganglia nuclei remains unclear, perhaps because global, executive, decision-making processes are based on so many factors. 'Adaptive motor control' may be a good description of their functions, not only for motion, but also for strategic planning of movements and tasks.

Behavioral Neuropharmacological Methods

Introductory article

Roy A Wise, National Institute on Drug Abuse, Baltimore, Maryland, USA

CONTENTS

The neural systems responsible for cognitive function are segregated by anatomical and neurochemical specificity. Characterization of the effects of drugs on thought and action helps us to identify the basic functional units of neuronal and cognitive organization.

INTRODUCTION

Neuropharmacology deals with the 'chemical coding' of brain circuitry and the ability to influence and study this circuitry selectively, either through the use of drugs or in an effort to understand their action. Neurons are normally activated or inhibited by endogenous substances released from nerve cells and variously termed neurotransmitters, neuromodulators or neurohormones. These chemical messengers act at specialized receptor proteins embedded in the surface membranes of nerve cells. Because of peculiarities in their geometry, the receptors bind their appropriate messenger very selectively; transmitters and hormones fit their receptors in much the same way as a key fits a lock. Neuropharmacology deals with the activation or inhibition of neurons by chemicals, including exogenous substances – drugs – that can mimic, augment or block the functions of endogenous transmitters. Traditionally neuropharmacologists used electrophysiological recording techniques to measure the responses of single neurons to chemicals delivered systemically or locally. Behavioral neuropharmacology is the study of neurochemical control of brain function as it is reflected in behavior.

Behavioral neuropharmacological methods have key roles in the analysis of behavior. Much of behavior is dominated by neuropharmacological variables. The roles of hormones in stress and sexual behavior, the roles of nutrients and hormones in feeding and drinking behavior, the roles of endogenous opioids in control of pain, and the roles of drugs in addiction illustrate the importance of neuropharmacology in behavioral analysis. Behavioral neuropharmacology not only teaches us ways to control behavior; it contributes to our understanding of neuronal organization and function. The chemical selectivity of brain circuitry gives us major clues to the structure and function of the brain. As pointed out several decades ago by Donald Hebb, our best theories about the nature of cognition are always constrained by our current understanding of the structure and activity of the functional units of the brain.

MODIFYING NEUROTRANSMITTER SYSTEMS

The neurotransmitter systems of the brain can be selectively manipulated in several ways. The most direct ways involve drugs that bind to the receptors for endogenous neurotransmitters. Such drugs share the geometrical features that allow the neurotransmitter to bind to receptors on a target neuron. If the drug binds to the receptor for a given transmitter but does not trigger a transmitter-like action there, it is an antagonist of the transmitter, often termed a 'receptor blocker' because it physically blocks the access of the endogenous transmitter to its normal binding site. The effects of drugs on a neurotransmitter system are usually temporary.

If the drug's geometry is sufficiently similar to that of the transmitter it will not only bind to the receptor but also trigger the biological action of the transmitter; in such cases the drug is termed an 'agonist', because it mimics the transmitter action. Nicotine is an agonist at a subset of acetylcholine receptors; morphine is an agonist at receptors for endogenous 'opioid' peptide neurotransmitters. Phencyclidine is an antagonist at a subset of glutamate receptors.

Amphetamine and cocaine are termed 'indirect' monoamine agonists because although they do not

bind to monoamine receptors, they act at the transporter molecules that dispatch or take back up the monoamine transmitters. By reversing or blocking the reuptake mechanism, they elevate the synaptic concentrations of the three monoamine transmitters – dopamine, noradrenaline (norepinephrine), and serotonin. These drugs have the same behavioral effects as the transmitters because they increase the transmitter concentration in the local extracellular fluid. Injections of drugs often have more dramatic effects than injections of the transmitters themselves because the drugs are generally much more resistant than the transmitters to the normal deactivation mechanisms.

Neurotransmitter agonists and antagonists have varying degrees of selectivity for different receptors and different receptor subtypes. Cholinergic receptors (defined by their common sensitivity to the neurotransmitter acetylcholine) are of two major subtypes: nicotinic (binding and responding to nicotine but not to muscarine) and muscarinic (binding and responding to muscarine but not to nicotine). There are five or more variations of muscarinic receptors: five slightly different receptor molecules that each bind and respond to muscarine and acetylcholine. There are five known subtypes of dopamine receptor and 13 known subtypes of serotonin receptors. The selectivity of a given agonist or antagonist depends on sometimes subtle geometric peculiarities of the neurotransmitter, the drug and the receptor. One goal of neuropharmacology is to identify drugs that are highly selective for a given receptor molecule.

It is possible to cause permanent damage to single neurotransmitter systems or portions of single neurotransmitter systems by the use of neurotoxins. The substance 6-hydroxydopamine is a general neurotoxin if it is given in sufficient concentration. However, if given in low concentration, this molecule (which resembles dopamine) is taken up selectively by neurons that express and take up the closely related monoamines dopamine and noradrenaline. These neurons will concentrate the toxin intracellularly. Thus the toxin can be used to cause selective degeneration of dopaminergic and noradrenergic neurons. If a selective blocker for the noradrenergic uptake mechanism is given, the drug will be taken up and damage only dopamine systems. If the toxin is microinjected into a local brain region, it will damage only those dopaminergic or noradrenergic neurons found in that region. There are analogous neurotoxins for serotonergic neurons. Other toxins selectively damage noradrenergic systems; one substance, MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), is metabolized to a selective toxin for dopamine neurons by an enzyme found in monkeys but not in rats.

Another selective degeneration method involves coupling the general ribosome-inactivating protein saporin to an antibody that gives it selectivity for neurons of a given neurotransmitter type. Saporin-linked antibodies have been used successfully to destroy forebrain cholinergic neurons and, more recently, noradrenergic pathways. The linkage of saporin to other antibodies will allow it to be used to target other transmitter systems. Other neurotoxins, particularly excitatory amino acids, have little selectivity for particular neurotransmitter systems but, when injected locally, can be used to damage the cell bodies of a given region while sparing passing fiber systems.

In addition to neuropharmacological methods for selective modulation of neurotransmitter systems, new molecular biological approaches are rapidly being developed. The expression of receptors, enzymes or neurotransmitters can be blocked at the level of gene transcription by antisense oligonucleotides, and viral vectors can be used to insert genetic material that transiently increases expression of such gene products. There is thus an expanding range of methods for selective activation, blockade or destruction of particular neurotransmitter systems. Each of these methods can be used to study the behavioral role of a given neurotransmitter or the behavioral sensitivity to a given drug.

MEASURING NEUROTRANSMITTER ACTIVITY

The spontaneous activity of various neurotransmitter systems can be measured in several ways. Extracellular recordings of the electrophysiological activity of single neurons are useful when the cell type can be identified by anatomical location, firing patterns or sensitivity to different drugs. Unique firing patterns have been characterized from intracellular recordings in simplified preparations *in vitro* where a dye can be injected into the cell for subsequent identification of neurotransmitter type. Unfortunately, not all cell types have unique electrophysiological signatures, and the electrophysiological characteristics of some cell types differ considerably between conditions *in vitro* where identification is positive and conditions *in vivo* where it is not.

There are two approaches to measuring or estimating the concentrations of various neurochemicals in the extracellular fluid of a given brain

region. One involves sampling extracellular fluid from some local region and subjecting that fluid to bench-top assay. The extraction of extracellular fluid was originally accomplished with 'push-pull' cannulas where artificial cerebrospinal fluid was injected through one line and withdrawn through the other. Neurochemicals from the region mixed with the injected fluid and were withdrawn with it. This method is now infrequently used because it collects not only the transmitters but also the enzymes that continue to degrade them. In a more recent method the tips of push-pull cannulas are encapsulated in microdialysis tubing which allows the small neurotransmitters to diffuse into the perfusate, but blocks entry of the larger enzymes. This technique for collecting brain chemicals is termed 'microdialysis' (Figure 1).

When microdialysis samples are assayed, unambiguous identification of neurochemicals is possible. Microdialysis is currently used widely in conjunction with high-performance liquid chromatography to assay acetylcholine, glutamate, γ-aminobutyric acid (GABA) and the monoamine transmitters dopamine, noradrenaline (norepinephrine) and serotonin. The many neuropeptide transmitters tend to be released in very low concentrations, and are more difficult to assay with current methods. Mass spectrometric methods with much greater sensitivity are currently under development for this purpose.

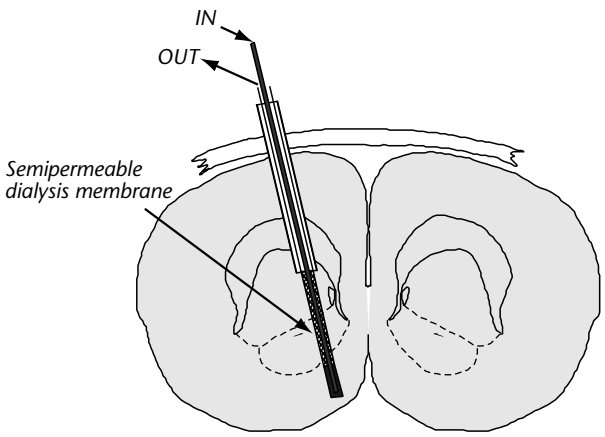

Figure 1. A microdialysis probe is inserted into a rat brain. The membrane portion of the probe is semipermeable, and (like a blood vessel) allows the exchange of brain chemicals between the artificial extracellular fluid which is perfused through it and the brain's extracellular fluid which surrounds it. The perfusing fluid is pumped slowly into the internal cannula, passes back up between the inner cannula and the membrane itself – where it absorbs neurotransmitters and other substances from the endogenous brain fluids – and is collected in a vial connected by flexible tubing to the outer cannula. The neutral perfusion fluid and the collected brain chemicals that it carries out of the brain are then analyzed to determine what neurotransmitters are being released under the conditions of testing.

The microdialysis approach allows confident identification of a given chemical species, but the temporal resolution is poor for behavioral studies. It often takes several minutes to collect detectable levels of a given transmitter, and it is not possible to identify peaks of neurotransmitter release within a given sampling period. Thus, even though it is clear which chemicals were released, it is difficult to determine precisely when they were released. A technique with greater temporal resolution is *in-vivo* voltammetry. Here a neurochemical assay is performed within the brain. Different chemicals oxidize at different voltages, and a voltage appropriate for the chemical of interest is applied locally. The voltage-specific oxidation of the chemical in question induces a measurable increment in the current flow between the electrodes. Fluctuations of these oxidation currents are used to estimate fluctuations in the concentration of the chemical of interest. Unfortunately, more than one chemical species may oxidize at a given voltage, and thus neurochemical resolution is not as good as in microdialysis.

Each of these methods is undergoing rapid refinement. The temporal resolution of microdialysis is being improved by development of more sensitive laboratory assays. The neurochemical resolution of voltammetry is being improved by development of different electrodes and by the use of pharmacological tools in conjunction with locally stimulated release of transmitters. The development of more precise methods for monitoring neurochemicals in freely moving animals is receiving active attention in several laboratories.

Another use for microdialysis is to infuse substances into local brain regions. Just as local neurochemicals diffuse from the brain across the dialysis membrane and into dialysis samples, neurochemicals in the dialysis fluid can diffuse into the brain. Drug infusion by dialysis is more localized and less stressful for local tissue than are bolus injections by the more traditional hydraulic pressure. If two dialysis probes are implanted in appropriate regions, it is possible to infuse a drug at one site and observe the consequences on behavior and on neurotransmitter release at the second site. Such studies begin to identify the connections between sites of drug action and help characterize the distal transmitter release caused by a drug.

THE STUDY OF COGNITION

The coding of information flow in the brain is both spatial and neurochemical. Our eventual understanding of the brain processes underlying various cognitive processes will require us not only to identify the portion of the brain that is sending and receiving relevant messages, but also which chemical messenger – among the dozens that can be found in most brain regions – is carrying the signals.

CONCLUSION

The realization that the circuits of the brain contain a wide range of chemical messengers, and that dozens of chemically coded messages can be transmitted simultaneously in the same brain region, has motivated the development of methods for distinguishing the neurochemical constituents of brain fluid, measuring their fluctuations during thought and action, and determining their consequences by microinfusing them into the brains of freely moving animals. Anatomists have come far in identifying the cells of different brain regions, the source of their inputs, and the targets of their outputs. They have also made great progress in identifying – through fluorescence and immunohistochemical techniques – the chemical messengers in various cell groups.

Neuropharmacologists build on such information to probe the functions of chemically distinct neuronal populations. Neuropharmacological methods help us to understand the effectiveness of various drugs in alleviating the symptoms of such conditions as schizophrenia, depression and Parkinson disease. Such methods are used increasingly to develop new drugs – with greater potency and fewer side effects – for the treatment of mood and thought disorders. Neuropharmacological methods also help us to understand basic brain function; they help us to parse and discover the syntax of the activity of the brain. Relative to the complexity of brain function, current neuropharmacological methods are still crude; none the less, the rate of technological advance is rapid and neuropharmacological methods have already given us major insights into the functional units of mood and movement.

Blindsight, Neural Basis of

Intermediate article

Carlo A Marzi, University of Verona, Verona, Italy

CONTENTS

Blindsight is the presence of unconscious visually guided behavior elicited by stimuli presented within the visual field loss of patients with damage to the primary visual cortex.

INTRODUCTION

The term 'blindsight' to describe the presence of unconscious visually guided behavior in people with a lesion of the primary visual cortex was coined by Weiskrantz *et al*. (1974) and should not be confused with the term 'residual vision', which defines conscious visually guided behavior following a visual cortical lesion. The essence of blindsight lies primarily in the lack of conscious awareness in the presence of an above-chance visual performance. The first demonstration of blindsight was the target localization by eye movements reported by Poeppel *et al*. (1973), followed by target localization by manual pointing and target detection (Weiskrantz *et al*., 1974). Many other functions have been since then tested with different success in humans and in nonhuman primates (Stoerig and Cowey, 1997). The importance of blindsight in neuroscience research is threefold. First, it has opened the way to the scientific investigation of conscious awareness, a topic before relegated to the domain of philosophy. Second, it has reconciled the discrepancy between human and nonhuman primates as far as the effect of the lesion of the primary visual cortex is concerned; lesions of the primary visual cortex in monkeys (or in cats), although severely impairing visual acuity, leave some visually guided behavior intact, while this is typically not the case in humans. Research has shown, however, that visually guided behavior in humans may persist following a primary visual cortex lesion, but it remains unconscious. Third, blindsight might be an initial stage in the return of vision; unfortunately, the correlation between presence of blindsight and successful rehabilitation of conscious visual function is not good. However, blindsight can improve with training and there is evidence of an increase in unconscious visual sensitivity over the years (Stoerig and Cowey, 1997). Whether this may lead to recovery of conscious vision is still an open question.

An important distinction is between direct and indirect methods of testing blindsight. The former include a forced-choice procedure similar to that used in animal testing, in which the person is asked to guess despite lack of stimulus awareness. In contrast, in the indirect procedure, the person does not have to guess but the presence of blindsight is inferred from the influence of unseen stimuli on the response to stimuli presented to the normally sighted hemifield.

LESION SITE

Unilateral complete lesions of the primary visual cortex (also known as striate cortex, area 17 in the Brodmann nomenclature, or area V1 in the jargon of electrophysiology) result in contralateral homonymous hemianopia: that is, the entire hemifield on the side opposite to the lesion is blind as assessed by clinical perimetric examination. Partial lesions, result in a scotoma which may affect various portions of the contralesional hemifield. Finally, bilateral complete lesions of the visual cortex result in cortical blindness that affects the whole visual field.

Which Regions Must Be Affected to Produce the Deficits?

Damage to visual centres other than V1 may result in a hemianopia but such lesions may not be compatible with blindsight when crucial centres are visually deafferented. This is the case with lesions of the optic tract, which funnels visual information not only to the geniculostriate system but also to the superior colliculus and other visual midbrain areas, or to thalamic areas such as the pulvinar

which relay visual information to cortical areas bypassing the primary visual cortex. When these areas are deafferented in addition to primary visual cortex, no blindsight is possible.

WHICH REGIONS MEDIATE SPARED FUNCTION?

There are two main candidates as centres mediating the spared unconscious functions characterizing blindsight: the superior colliculus and the extrastriate visual cortex. The superior colliculus (SC) projects indirectly through the thalamic pulvinar to extrastriate cortical areas such as V2, V3, V4 and V5 (also known as MT, see below) and to visually responsive temporal areas. Therefore, in the absence of V1, visual input can still activate these cortical areas. In addition, a small number of cells – mainly located in interlaminar zones of the dorsal lateral geniculate nucleus (dLGN) – project directly to extrastriate cortex, rather than to V1 like the majority of dLGN neurons. The difference between the relative contribution of these structures has been investigated by comparing the effects of lesions restricted to the primary visual cortex with the effects of lesions including the extrastriate cortex and those of loss of an entire hemisphere (Azzopardi *et al*., 2001). An intriguing conclusion emerging from those studies is that following hemispherectomy – that is, in the absence of both V1 and extrastriate cortex – the remaining SC and pulvinar cannot subserve voluntary responses such as those employed in the direct methods to test blindsight described above. In contrast, there are indications that some hemispherectomy patients can still show blindsight when tested with indirect methods, as reported by Tomaiuolo *et al*. (1997).

More evidence on the areas mediating blindsight comes from brain imaging studies in which visual stimuli are presented within the perimetrically blind area of the visual field. It has been shown with functional magnetic resonance imaging (fMRI) that, despite absence of activation of their lesioned V1, hemianopic patients show preserved responsiveness in area V5 with moving stimuli, and in areas V4 and V8 within the fusiform gyrus with colored images of objects (Goebel *et al*., 2001). The former is an area, or rather a complex of areas, which belong to the so-called dorsal system including a series of cortical regions mediating spatial perceptual and visuomotor functions. The area MT is named for its anatomical location in the monkey's middle temporal sulcus in the proximity of the junction of temporal, parietal and occipital lobes. It contains neurons selectively sensitive to the direction and velocity of motion stimuli. The human homolog of area MT is also known as area V5: its bilateral lesion results in a severe impairment in the detection of moving stimuli: see Zeki (1991) for a review.

In contrast to the dorsal stream, that is, a series of cortical regions, the ventral stream includes a host of cortical visually responsive areas whose neurons respond preferentially to forms, colors and natural objects. Areas within the fusiform gyrus (V4 and V8) belonging to this system have been found to be selectively activated by appropriate stimuli presented within the hemianopic field. It is important to consider that both the dorsal and the ventral system activations were not accompanied by conscious awareness of the stimuli. This shows that activation of extrastriate cortex *per se* is not sufficient to yield stimulus awareness.

WHICH FUNCTIONS ARE SPARED?

Blindsight functions can be divided into two categories: direct or voluntary responses usually elicited with a forced-choice procedure, and indirect responses usually tested by assessing the influence of unseen stimuli (presented to the hemianopic field) on stimuli presented to the normal hemifield.

Direct Response

Direct responses include basic functions such as simple detection of stationary or moving stimuli, spatial localization and discrimination of direction of motion, stimulus displacement, wavelength and orientation. The latter ability seems to be crucial for the apparent form discrimination exhibited by some people with blindsight. In fact, it has been shown that shape discrimination in the hemianopic field is impossible when orientation cues are eliminated. One interesting dissociation has been repeatedly described, namely that between action and perception. Some people who are unable to discriminate forms or objects because of cortical damage can none the less show reaching or grasping hand movements that are appropriate for the size and orientation of the stimuli presented. This means that information that is not available for conscious perception can be used for motor action on the same object.

Indirect Response

An example of this approach is the use of the redundant target effect (RTE), with bilateral stimuli

presented across the vertical meridian of the visual field. With this paradigm, simple manual reaction time in response to bilateral brief visual stimuli is typically faster than for unilateral single stimuli. It has been shown that this is the case even when one stimulus in the pair has been presented to the hemianopic hemifield of patients with a V1 lesion. Despite their claim of having seen only one stimulus they show an RTE with bilateral stimuli. The speeding up of reaction time by an unseen stimulus can thus be taken as indirect evidence of blindsight (Marzi *et al*., 1986). A similar implicit RTE has been found in patients with an hemianopia resulting from hemispherectomy performed as an extreme therapy for intractable epilepsy (Tomaiuolo *et al*., 1997). Another example of indirect approach is the demonstration that distractor signals in the blind half of the visual field could inhibit saccades toward targets in the intact visual field (Rafal *et al*., 1990).

RELEVANCE TO THEORIES OF CONSCIOUSNESS

One of the merits of research on blindsight is to have given impulse to a neuroscientific study of consciousness and to have aroused the interest of philosophers in the neural basis of conscious experience. A few years ago an experiment was attempted to answer this fundamental question (Sahraie *et al*., 1997). In an fMRI experiment on a blindsight patient extensively investigated in other studies (GY), stimulation of the blind hemifield yielded conscious or unconscious above-chance visual performance depending upon the velocity of motion stimuli. The patient was required to discriminate the direction of a moving stimulus; with slower stimuli, discrimination was as good as with faster stimuli but stimulus awareness was lost. The main thrust of the study was to provide evidence for a shift in the pattern of neural activation from cortical to subcortical neural structures associated with the change from conscious to unconscious vision. Notably, the superior colliculus was activated in the unconscious mode alone. These results confirm earlier views that blindsight may be mediated by subcortical structures. However, as pointed out by Searle (2000), they cannot be extended to consciousness in general because the patients only exhibit blindsight if they are already conscious. For a clue to the neural mechanisms of consciousness in general it is necessary to demonstrate that there are neural structures that are crucial for shifting from unconsciousness to a conscious state. So far, this evidence has not been provided.

OTHER POSSIBLE INTERPRETATIONS

In principle, blindsight effects could be the result of various spurious factors (Campion *et al*., 1983). One possibility is light-scattering: this possible source of artefact has been taken care of by minimizing the light intensity of the stimuli and, ingeniously, by introducing control trials in which stimuli are presented to the blind spot of the hemianopic hemifield, that is, to an area corresponding to a retinal zone without photoreceptors. Real blindsight cannot survive a blind spot presentation, and this is what has been found in the majority of cases; see for example Tomaiuolo *et al*. (1997).

Another possible source of spurious blindsight comes from a shift in the decision criteria adopted by the hemianopic patient in moving from clinical visual field assessment to experimental blindsight testing. In the former situation the patient may adopt a more conservative criterion and deny having seen something, despite some near-threshold residual vision. In contrast, under laboratory conditions, especially when using forced-choice procedures, the patient may adopt a more liberal criterion and performance might improve. A specific answer to this type of criticism has been provided by Azzopardi and Cowey (1997) who measured the sensitivity of a hemianopic patient independently of his response criterion. They found that, in contrast to normal control subjects, sensitivity was higher during the forced-choice task than during a procedure similar to that used in clinical visual field testing in which a conscious report is required ('Do you see the stimulus?'). This means that blindsight cannot be simply assimilated to normal near-threshold vision and that a mere shift of response criterion cannot explain it.

Finally, it has been proposed (Campion *et al*., 1983; Fendrich *et al*., 1992) that blindsight may be related to islands of spared visual cortex yielding correspondingly small areas of visual field preservation that can be documented only with special techniques (Fendrich *et al*., 1992). In contrast to this possibility, however, it has been found that two blindsight patients studied with fMRI did not show any activation of V1 (Goebel *et al*., 2001) and therefore it is unlikely that their blindsight might have been related to spared V1, although this might explain other cases. All in all, one can safely conclude that blindsight is a genuine phenomenon, but its investigation requires careful control of all possible sources of artefact.

Brain Asymmetry

Introductory article

Albert M Galaburda, Harvard Medical School, Boston, Massachusetts, USA
Glenn D Rosen, Harvard Medical School, Boston, Massachusetts, USA

CONTENTS

The two cerebral hemispheres are specialized for different functions. The discovery of anatomic asymmetries in the brain has given new light to our understanding of the cognitive differences between the left and right hemispheres.

INTRODUCTION

It is generally accepted that in humans the left hemisphere is specialized for the processing of some aspects of language while the right hemisphere dominates over many spatial, emotional and musical functions. The exact relationship between brain asymmetry and side differences in function, however, is not known. In fact, a century and a half after the initial discoveries of lateralization of language the neural basis for language is still not clearly understood, and as part of this incomplete knowledge the relationship between language lateralization and cerebral asymmetry is at best tentative. Moreover, the biological substrates underlying non-language-based functional lateralization is perhaps even less clear. That being said, there is a wealth of information concerning asymmetries in the brain, giving intriguing insights into cognitive function.

GROSS BRAIN ASYMMETRIES

Sylvian Fissure and Planum Temporale

Left–right asymmetries in the sylvian fissure (Figure 1) have been noted since the end of the nineteenth century. In general, the left sylvian fissure tends to be longer and have a flatter trajectory than its right hemisphere counterpart, which deviates dorsally at the posterior end. This obvious asymmetry led the neurologists Norman Geschwind and Walter Levitsky to examine the portion of the sylvian fissure subsumed by a structure known as the planum temporale in 100 autopsied human brains. The planum temporale, which contains several auditory association cortices, is thought on the left side to be an important portion of the language network of the left hemisphere (Figure 1(b)). Lesions affecting significant portions of the planum temporale, usually on the left side in right-handed people, often lead to Wernicke's aphasia. Geschwind and Levitsky found that 65% of the sample showed a longer left planum temporale, whereas the right planum was longer in only 11% and both plana were equal in the remaining 24%. The results were highly significant and were essentially confirmed by subsequent studies using both postmortem and *in vivo* imaging techniques. (*See* **Aphasia**; **Geschwind, Norman**)

Inferior Frontal Area

The inferior frontal area, composed of the pars opercularis, triangularis and orbitalis of the inferior frontal gyrus, the frontal operculum and the subcentral cortex, is complex, highly folded, and variable among individuals (Figure 1(a)). Asymmetries have been demonstrated in this part of the brain. The ascending limb of the sylvian fissure, which separates the pars opercularis posteriorly from the pars triangularis anteriorly, has been reported to be more often branched on the left side, giving off the diagonal sulcus. Others have found the pars opercularis to be more developed on the left, and still others have found greater surface area on the left side. Wada and colleagues, on the other hand, measured the surface portion of the pars opercularis together with part of the pars triangularis and found it to be larger on the right. (*See* **Frontal Cortex**)

Asymmetries in Fetal and Infant Brains

Gross anatomical asymmetries are present in the cerebral cortex before birth. Even though clearly cerebral dominance can be modified after birth

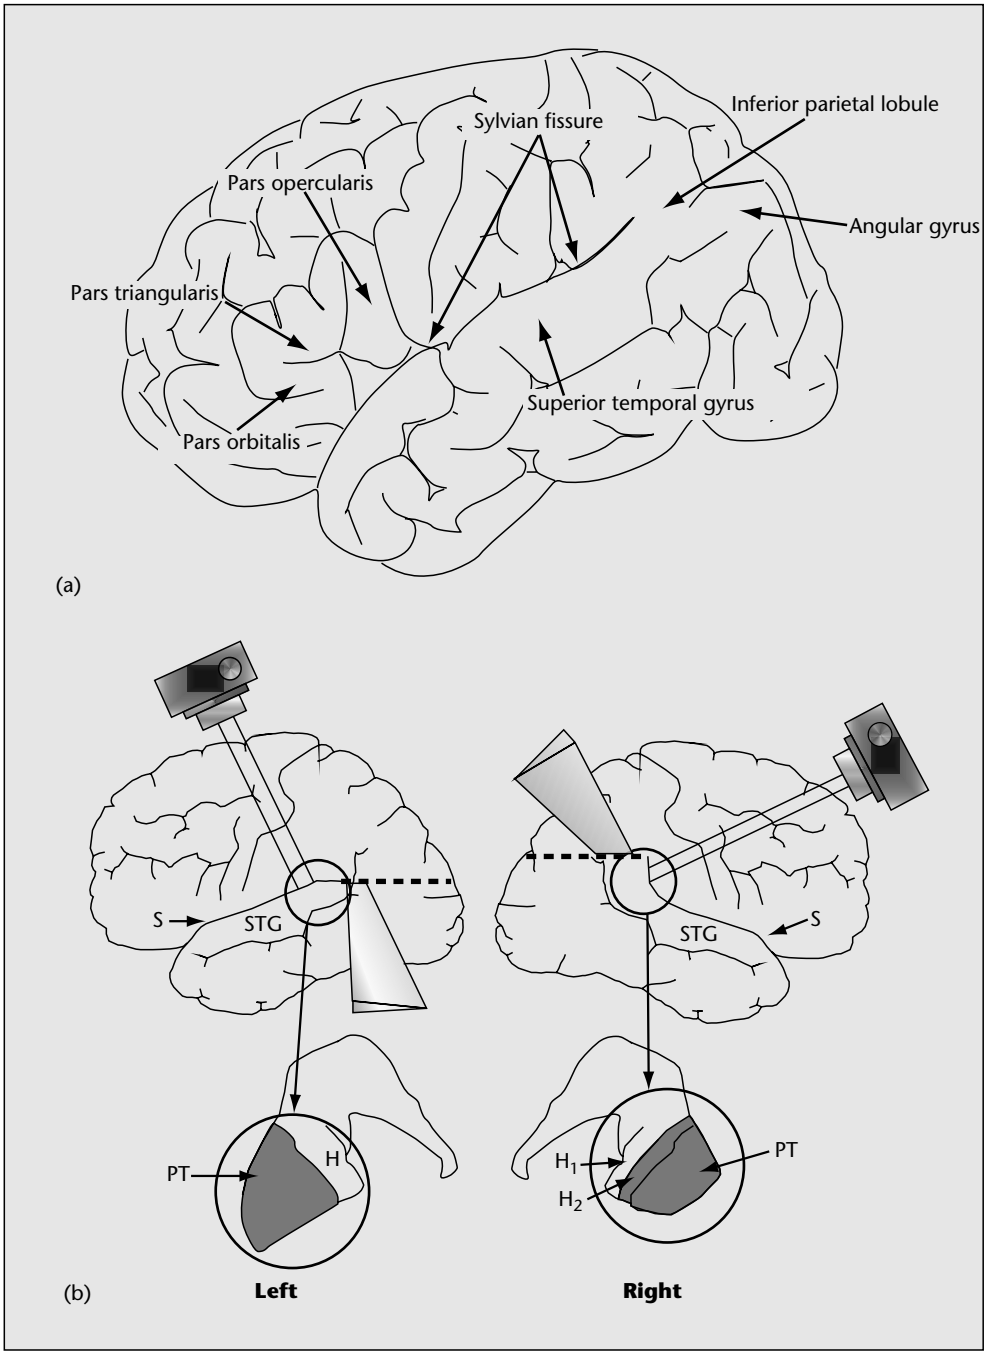

Figure 1. Locations of various structures in the human brain. (a) Lateral view of the left hemisphere identifying areas known to be asymmetric. (b) Lateral views of the right and left hemispheres: note the asymmetric patterns of the sylvian fissure (S), with the left fissure being longer and the right more angled posteriorly. To view the planum temporale (PT), a cut (dotted line) is made at the end of the sylvian fissure (encircled) exposing the superior surface of the superior temporal gyrus (STG). The resulting images are shown below. Here, the planum temporale is larger on the left than the right, and there are two Heschl's gyri (H) on the right side.

(e.g. recovery from early hemispheric injury and ability to switch handedness), the anatomical asymmetries that may underlie functional lateralization are fixed, at least in their gross design, before birth. This is not to say that recovery from early lesions is perfect at any age or that switching handedness leads to equivalent degrees of dexterity with the new hand. We do not know about this because controlled experiments cannot be performed in individual patients and variability in

the population gets in the way of interpreting the results. Thus, we cannot tell in advance how well language would have developed in the ordinary hemisphere before the lesion, or how good the right hand would have become without having had to switch to the left.

The sylvian fissures are visibly asymmetric from about the middle of the gestational period, demonstrating the pattern usually seen in the adult human. The planum temporale is also grossly asymmetric before the end of pregnancy. The study by Witelson and Pallie, which included 14 brains from newborns, found the planum temporale to be larger on the left side in 79% of the cases. Wada and colleagues made planimetric measurements of 100 adult and 100 newborn and fetal brains and found that the average ratio of the surface area of the right to left planum temporale was 67% in the younger brains and 55% in the adults. These authors also noted that the planum temporale asymmetry was visible beginning in the 29th week of gestation. Others have found that the right Heschl's gyrus (Figure 1(b)) was doubled on the right side in 54% of the cases and on the left in 18%.

ARCHITECTONIC ASYMMETRIES

Gross anatomical asymmetry reflects to a great extent asymmetries in underlying architectonic areas, which are subdivisions of cortex with specific cellular architecture, connectivity, and physiology. Cortical folding, however, may also be related to physical forces imposed by the skull during growth, and gross anatomical asymmetries may, therefore, reflect in part bony asymmetries unrelated to brain function. It is important, therefore, to ascertain whether asymmetry in the cerebral cortex can be demonstrated at a level that heralds functional differentiation more strictly than the gross anatomical level of lobes, gyri and sulci – the cytoarchitectonic level. It is possible with experience to draw architectonic borders around many cytoarchitectonic areas and to measure their volume in each hemisphere. This has shown asymmetries in several cortical areas implicated in language function. For instance, area Tpt, which is located on the posterior third of the superior temporal gyrus extending onto the planum temporale, is larger on the left side in the majority of brains. Asymmetry of area Tpt correlates positively with asymmetry of the planum temporale, and in some cases the left can be several times the size of the right. Damage to Tpt may result in problems with language comprehension.

The frontal operculum contains predominantly cytoarchitectonic areas 44 and 45, the former covering most of the pars opercularis and the latter mainly the pars triangularis (Figure 1(a)). Both of these cortices belong to the category of motor association cortex, with 44 being an inferior premotor cortex and 45 an inferior prefrontal cortex, and are concerned with speech production. Area 44, which was enhanced by special stains, was found to be of greater volume in six out of ten brains, nearly symmetrical in three, and larger on the right side in one brain from a collection of neurologically normal brains. There is no information regarding asymmetry of area 45.

A study of the inferior parietal lobule (Figure 1(a)) in 10 normal human brains, a region concerned with word meaning containing areas PF and PG, revealed a predominance of the left area PG in eight of those brains. Area PG (Brodmann's area 39) lies on the angular gyrus, is highly functionally multimodal, and is anatomically interposed between cortices dealing respectively with somesthetic, auditory and visual functions. Lesions of the angular gyrus, which often lead to anomic aphasia and acquired reading and writing deficits probably destroy the bulk of area PG. (*See* **Parietal Cortex**)

The same brains with leftward asymmetry of area PG also exhibited predominance of the left planum temporale and of the left area 44. However, a more dorsal parietal area, area PG, which is less clearly related to language and more likely to be related to hemispatial attention, tended to be larger on the right side, and asymmetry in this area did not correlate with asymmetry of the planum temporale or area PG. This finding could suggest that asymmetries in one region are correlated with asymmetries in another region as long as the two regions are functionally linked. Animal studies showed similar correlations of directional asymmetry between adjacent, visually related cortices.

ASYMMETRIES IN OTHER SPECIES

The cerebral cortex emerges for the first time in its six-layered organization in mammals. Asymmetries in structures other than cortex are present, however, in birds, fish and amphibians. In the case of birds, the asymmetries are mainly in the functional domain and consist of differential effects of neural lesions on the ability of birds to sing, with the left predominating. Slight left anatomical superiority of one of the song-relevant nuclei has also been demonstrated. Fish and amphibians often show asymmetries in the habenular nuclei, the functional significance of which is not clear.

In nonhuman primates, the types if not the degree of brain asymmetry are similar to those found in the human brain, which raises questions about what lateralized functions, if any, these structural asymmetries might serve. For instance, sylvian fissure asymmetries have been found in other primate brains. If one is permitted to attach significance to the sylvian asymmetry in the human *vis à vis* linguistic capacity, what then is the meaning of asymmetry in the same structure in the baboon, the orangutan and the chimpanzee? Adding fuel to the fire, recent reports suggest that the pattern of human planum temporale asymmetry is present in chimpanzees. This again has potentially important implications for the role of cortical asymmetry and language function.

Asymmetries have also been noted in fossil skulls. The best-known of these is the asymmetry in the Neanderthal fossil from La Chapelle-aux-Saints, about 60 000 years old, which showed a sylvian fissure asymmetry similar to that seen in modern humans. There was a suggestion of a comparable asymmetry in the endocast of Peking man, which dates from 500 000–600 000 years ago. Asymmetries in perisylvian cortex also appear to exist in australopithecines, *Homo habilis* and *Homo erectus*, which date to up to 3.5 million years. Again, as is the case in nonhuman primates, asymmetries in the sylvian fissure are found in individuals whose language capacity is in question. Whether these asymmetries represent linguistic capacities in early humans or some preadaptive behavior is likely to remain unknown. It will help to find out what it is about asymmetry of the modern human brain, if anything, that can explain linguistic capacity.

MECHANISMS OF CEREBRAL ASYMMETRY

The phrenological approach to neuropsychology suggests that the basis for cognitive capacity is size. For example, our brains are uniquely able to carry out complex cognitive tasks because they are bigger than the brains of other less cognitively gifted primates. Similarly, the left hemisphere is able to support language because some of the perisylvian cortices involved in language are larger than corresponding areas on the right. An alternative to the phrenological concept suggests that highly specialized functions may depend more on specificity of organization. Thus, building a phonologically competent brain area may require increasing the specificity of the brain substrate by customized reduction rather than just enlargement of its components. In this sense, an asymmetric language area would result from the pruning of one side rather than from the enlargement of the other.

We have gained some insight as to the underlying substrates of brain asymmetry through the use of an animal model. Rats, as it turns out, also exhibit brain asymmetry. While individual rats may exhibit a large degree of asymmetry (magnitude), there is no leftward or rightward directional bias of the population as a whole. Exploiting this distinction, researchers have begun to ask questions concerning what distinguishes a symmetric from an asymmetric brain, rather than what factors bias a population to one side or the other. Interestingly, Collins has convincingly demonstrated in mice that while magnitude of lateralization, in this case paw preference, is under genetic control, direction is not. Using rats, in combination with examination of human asymmetries, we can begin to gain a hold on the phrenologic debate outlined above.

Symmetry of cortical areas is associated with changes in the volume of architectonic areas – symmetric brain regions are larger than asymmetric ones. Further, side differences in overall volume are the result of different numbers and densities of some neurons. Also, with increasing asymmetry, the proportion of the targeted area receiving callosal connections diminishes. In other words, the more asymmetrical areas have relatively fewer callosal connections than similar areas that are more symmetric, suggesting that the one key component of anatomic asymmetry may be greater intrahemispheric – as opposed to interhemispheric – connectivity. Indirect evidence suggests, furthermore, that asymmetry is determined during the earliest stages of brain development.

CONCLUSION

The histological characteristics of symmetric and asymmetric cortical areas do not support the notion that cerebral dominance represents simply a case of storing functional areas in one hemisphere or the other, but rather that there are storage factors as well as factors of network size and detailed connectivity. Thus, cerebral dominance reflects variation in functional properties of symmetric and asymmetric cortical areas, which provides the species with desirable and sometimes problematic individual variation.

For the first time, it is possible to assess the normally functioning human brain with sophisticated methods that can address issues about localization and lateralization of function. With

improving anatomical imaging it will be possible to extract individual information rather than sample averages, which will be useful for studies on individual variation of localization and lateralization. This knowledge can then be applied to studies of variability in response to brain injury and of developmental variation in cognitive style, response to brain injury, and learning disorders. Brain Damage, Treatment and Recovery from

Intermediate article

Barbara A Wilson, MRC Cognition and Brain Sciences Unit, Cambridge, and the Oliver Zangwill Centre for Neuropsychological Rehabilitation, Ely, UK

CONTENTS

Natural recovery can and does occur in children and adults following brain injury. Rehabilitation can also result in improvements of functioning.

IS THERE RECOVERY FROM NONPROGRESSIVE DAMAGE?

The term 'recovery', when applied to nonprogressive brain damage, is interpreted in different ways by people according to their professional background, knowledge, expectations, and experience. Some will focus on biological repair of brain structures, others may regard survival rates as a measure of recovery, while others will be looking for signs of recovery of cognitive functions or motor skills. Some might argue that recovery can be thought of only in terms of the complete restoration of functions lost or impaired after brain injury. However, recovery in this sense is rarely achievable for the majority of brain-injured people. Others regard a good measure of recovery as resumption of normal life, even though there might be minor neurological and psychological deficits that do not disappear over time; this is certainly achievable for some people with nonprogressive brain damage. Yet another interpretation of recovery sees it as a diminution of impairments in behavioral or physiological functions over time; and experience suggests this is certainly true for the majority of people with brain injury. Observations by those involved in the treatment of brain injury suggest that recovery from nonprogressive brain damage typically involves partial recovery of function together with substitution of function, and can be operationally defined as complete or partial resolution of deficits incurred as a result of an insult to the brain.

People who sustain brain damage from a moderate or severe traumatic head injury (the most common cause of brain damage in people under the age of 25 years) usually undergo some – and often considerable – recovery. This is likely to be fairly rapid in the early weeks and months after the injury, followed by a slower recovery which can continue for many years. A typical pattern is an initial period of coma (the patient makes no verbal response, does not obey commands or open the eyes spontaneously or after stimulation), followed by posttraumatic amnesia (PTA), a period in which the patient is confused and disoriented, suffers from retrograde amnesia, and seems to lack the capacity to store and retrieve new information. The next stage is when the patient emerges from PTA, possibly with a number of motor, cognitive, and behavioral problems; these may resolve or partially resolve over time. Variations on this pattern may occur in other kinds of nonprogressive brain injury such as encephalitis (a viral infection of the brain), hypoxia (brain damage caused through shortage of oxygen), or cerebral vascular event.

A number of factors influence the extent of recovery, some of which we can do nothing about once the damage has occurred. These include the age of the person at the time of injury, the severity of damage, the location of damage, the status of undamaged areas of the brain, and the premorbid cognitive status of the brain. Other factors such as motivation, emotions, and the quality of rehabilitation programs available can be manipulated.

Age, often thought to be an important factor, has a less clear-cut influence than many believe. There appears to be a general belief that younger people recover better from injury to the brain than older people; this is known as the 'Kennard principle' after Kennard (1940), who showed that young primates with lesions in the motor and premotor cortex exhibited sparing and partial recovery

of motor function. Even Kennard, however, recognized that such sparing did not always occur and some problems became worse over time for certain younger individuals. Once severity, etiology and other demographic factors are taken into account, age is not always predictive of good outcome and younger people sustaining severe head injury often do worse than older people in terms of behavior problems and social deficits. Age, then, must be regarded as just one factor in the recovery process, to be considered alongside other factors such as whether the lesion is focal or diffuse, the severity of the injury, and the time since acquisition of the function under consideration: for example, someone who has only just learned to read is more likely to show reading deficits than someone who learned to read many years earlier.

One factor thought to interact with brain injury is level of 'cognitive reserve', suggesting that people with more education and higher intelligence may show less impairment than those with poor education and low intelligence. Most clinicians are aware of the fact that any injury of the same severity can produce profound damage in one patient and minimal damage in another. The concept of cognitive reserve has been used in studies of HIV (human immunodeficiency virus) infection and Alzheimer disease, and may also prove useful in understanding recovery from nonprogressive brain injury. A neurologist once said, 'It is not only the kind of head injury that matters but the kind of head.' Support for the idea of cognitive reserve comes from the field of language therapy, where severity of aphasia and site of lesion are not unfailing predictors of improvement.

Individuals with high intelligence and possibly superior education may process tasks in a more efficient way. Consequently, in cases of Alzheimer disease, task impairment may occur later in people with superior cognitive reserve than in those who are less intelligent and less well educated when both groups are matched for severity.

TREATMENT, REHABILITATION, AND OTHER FACTORS THAT INFLUENCE RECOVERY

Before considering intervention, one needs to have some understanding of the natural course of recovery from nonprogressive brain injury. This has been reported in a number of studies (Wilson, 1998). For example, a young girl developed meningococcal meningitis at the age of 14 months and, as a result, became prosopagnosic. When last seen at the age of 11 years and 7 months, there was no change in her prosopagnosia. Another study reported the case of a child who developed viral encephalitis at the age of 9 years, and was left with a visual object agnosia. When the girl was last seen at the age of 16 years, there had been a limited degree of recovery that the authors put down to her intact spatial abilities, which enabled her to compensate for her recognition difficulties. Scans using imaging techniques such as computerized tomography (CT) and magnetic resonance imaging (MRI) showed little change over time, leading the authors to believe that neural plasticity for visual processes is limited.

In contrast, a boy with Sturge–Weber syndrome showed dramatic recovery of language. The boy was mute until he underwent a left hemispherectomy at the age of 9 years. Language functioning then developed, and he was reported to have achieved clearly articulated speech with well-structured and appropriate language. At the age of 15 years he had the language skills appropriate for a child of 8–10 years. Possibly language skills are more likely to recover than other cognitive functions: children who develop hippocampal damage and consequent memory impairments early in life appear to show little, if any, improvement in memory.

These findings are confirmed in adults. Some people with language deficits go on to make a reasonable recovery, unlike those who sustain memory impairments. The patient HM, first reported by Scoville and Milner (1957), is perhaps the most famous amnesic patient in the world and has shown no recovery since his operation to relieve epilepsy in the 1950s. An amnesic musician who survived encephalitis, CW, also showed no recovery of memory functioning over a 10-year period. One study found that about two-thirds of memory-impaired people showed no change in memory functioning 5–10 years following discharge from a rehabilitation center, although most were compensating better.

As well as the nature of the cognitive deficit, the cause of the brain damage probably influences recovery. Thus people with head injuries often do better than people with other diagnoses: for example, a cohort of Second World War servicemen who sustained missile wounds to the brain showed considerable preservation of ability as a group despite some selective impairments related to the specific loci of the lesions. Most people with head injuries do not sustain penetrating wounds. Age and duration of coma are often found to be significant predictors of recovery from closed head injury (although recall the earlier caveats about

age). Different patterns of recovery are to be expected following severe head trauma, with some people doing well and others remaining in a minimally conscious state even after several years. In contrast to the results of head injury, people with bilateral surgical lesions, such as HM, and people with encephalitis such as CW, often show less recovery and little change over time. People with hypoxic brain damage also tend to show little improvement. On the other hand, recovery from a cerebrovascular event can be considerable for some people: Taub *et al*. (1993) showed it was possible to improve function in the hemiparetic upper limbs of stroke patients by preventing them using the corresponding unaffected limbs. After two weeks of training with the affected limbs (and immobilization of the unaffected ones), a significant improvement in motor functioning occurred.

According to some research, the recovery of stroke patients can be predicted by attentional skills. It is possible that restitution of functioning following stroke may be possible after small lesions while compensatory procedures are more likely to underlie recovery from larger lesions. We will return to this issue later. Meanwhile, note that in addition to natural recovery, treatment or rehabilitation of people with nonprogressive brain damage can also result in improvement of functioning.

Rehabilitation is a process whereby people disabled by injury or disease work together with professional staff, relatives and members of the wider community to achieve their optimum physical, psychological, social, and vocational wellbeing. Rehabilitation programs may work by teaching people to compensate for their problems, by helping them to learn more efficiently, or by achieving restoration (or partial restoration) of functioning through plasticity or regeneration. In clinical practice there appears to be a tendency to aim for restitution of function in the early days and weeks, with compensatory strategies coming into play when natural recovery stops or slows. Robertson (1999), however, believes that the choice of restitution or compensation as an aim depends on the extent (and possibly the location) of the lesion. He believes that restitution of function is achievable for some people with unilateral neglect, and states that 'there is growing evidence that restitution of basic function may be influenced by appropriate behavioural and cognitive inputs' (p. 691).

It is not clear whether such restitution is possible for other skills. The lack of change in memory function over time has already been mentioned. This may also be true for other cognitive functions, such as object recognition skills and spatial localization abilities. For such patients, compensation techniques taught during rehabilitation may offer the best hope of reducing everyday problems, and plenty of evidence exists to demonstrate that this is possible, as we shall see later.

EVIDENCE OF THE RECOVERY OF SENSORIMOTOR FUNCTIONS

Like other deficits, sensorimotor problems may show spontaneous recovery after nonprogressive brain damage. Zihl (2000) discusses spontaneous recovery of visual field disorders as well as recovery following training. He reports a finding that nearly a third of 41 patients with unilateral homonymous field loss showed recovery over an eight-month period. In several studies of people with cerebral blindness, only about 6% made a complete recovery but a further 67% showed some recovery of vision of varying degrees. Recovery tended to follow a particular pattern, with light perception recovering first, then perception of 'vague' contours with 'foggy vision', and finally perception of objects, faces, and surroundings. An interesting self-report of recovery of a visual field deficit following an occipital stroke is that of Bryan Kolb, a neuropsychologist (Kapur, 1997). Kolb kept a diary of his visual field deficit, his recovery, and his emotional reactions to this over a period of four years.

With regard to the recovery of motor functions, it has been found that the average patient receiving a program of focused stroke rehabilitation performed better than the majority of patients in control groups. The work of Taub *et al*. (1993) has already been mentioned, in which the unaffected upper limbs of hemiplegic stroke patients were immobilized for a period of two weeks while the patients were encouraged to use the affected limbs; considerable recovery was achieved. Furthermore, the recovery was maintained over the subsequent two-year period. Others have found that improvements in function could be obtained long after the natural recovery process was over and the hemiparetic limb had ceased to improve. Taub's team felt that temporary loss of use of a limb resulted in 'learned nonuse': the patients lost the habit of using the limb even though the underlying mechanisms enabling limb use had been repaired.

Some studies suggest that the incidence of visual, tactile, proprioceptive, and motor deficits is higher in patients whose stroke occurred in the right hemisphere rather than the left. This is thought to be due to a greater incidence of attentional deficits in patients with a right-sided injury, attention having an important role in influencing the function of

primary sensory and motor circuits, and consequently in recovering function within these circuits after a brain lesion. The functional recovery of 47 brain-damaged patients after a right-hemisphere injury was monitored over a two-year period, and it was found that sustained attention (assessed two months after the stroke using tasks from the Test of Everyday Attention) predicted motor recovery two years after the stroke. In addition, in comparison with a group of patients with left brain damage, those with right brain damage showed less functional ability and poorer attention skills.

Positron emission tomography (PET) has been used to look at the recovery of stroke patients. There appears to be considerable plasticity in the recovery of motor functions and this recovery is mediated by (a) recruitment of cortical areas in the undamaged hemisphere, and (b) extension of specialized areas adjacent to the site of the lesion. Another kind of imaging study looked at a 17-year-old girl who had sustained a unilateral brain injury at birth. Functional MRI revealed that the healthy hemisphere was controlling motor movements via direct ipsilateral corticospinal projections together with the contralateral cerebellum.

Relatively little has been written on the recovery of motor functioning following traumatic brain injury (TBI), although physical impairments are common resulting from both the brain damage and concomitant orthopedic trauma. It is believed that nearly half of people with TBI have physical problems, with about one quarter of these having orthopadic and/or muscular skeletal injuries as well as problems caused by the brain damage. A year after injury, however, most people with TBI are ambulant, and a study of Vietnam war veterans with penetrating head injuries and associated movement disorders found that at follow-up all were independent despite continuing mobility problems. It would appear that motor recovery after TBI follows, to a large extent, a developmental sequence.

EVIDENCE OF THE RECOVERY OF COGNITIVE FUNCTIONING

There appear to be four major approaches to cognitive rehabilitation: cognitive retraining through stimulation or exercises; strategies derived from cognitive–neuropsychological theoretical models; techniques combining methodologies and theories from a number of different fields, particularly behavioral psychology, neuropsychology, and cognitive psychology; and holistic approaches that address social and emotional problems alongside the cognitive ones. The nature of these approaches and an examination of their strengths and weaknesses are addressed in further detail by Wilson (1997).

There is increasing evidence that rehabilitation can improve cognitive functioning. In the field of memory disorders, the method of choice for reducing everyday problems is probably to teach compensatory approaches. Several publications show that people with memory impairments can function independently if they are able to use strategies to bypass their difficulties. Over a 10-year period, JC, a young man who became densely amnesic following a ruptured aneurysm on the left posterior cerebral artery, developed a sophisticated system of memory aids enabling him to live alone, hold down a job, and be totally independent despite remaining severely amnesic. The natural history of the development of his compensatory system shows that he began by writing on scraps of paper a few weeks after his stroke before gradually developing his highly successful system.

Another encouraging study describes the rehabilitation of a young woman who became amnesic following status epilepticus. She was taught to use a personal organizer (datebook), to refer to it regularly, and to monitor a number of daily events. Over a period of several weeks the young woman was able to learn the different sections of the datebook and use this to manage her life. After leaving the rehabilitation center, she worked in a voluntary capacity (still using her system) and eventually was taken on as a paid employee.

Even for people who are unable to return to work, memory compensations can assist independent living. One device that has been helpful to a number of people with memory impairment is a specifically designed alphanumeric pager worn on a belt, which sends out daily reminders. People with memory and/or planning problems all showed statistically significant improvements in achieving everyday target behaviors, such as taking medication, feeding the cat, and preparing meals, when using this pager, in comparison with a baseline period.

In addition to compensations in the form of external memory aids, techniques for improving learning in people with impaired memory are a major part of rehabilitation. It has been demonstrated that people with amnesia learn better if they are prevented from making mistakes during the learning process. Most of us can benefit from trial-and-error learning if we can remember our previous mistakes. People with amnesia, of course, cannot do this. Once a mistake has been made, it may be strengthened or reinforced or be

indistinguishable from the correct response. Consequently it is better to prevent the incorrect response being made in the first place. Several studies have applied the 'errorless learning' principle to teaching real-life tasks. Although a number of questions, both clinical and theoretical, remain to be answered about errorless learning, it appears to be more effective than trial-and-error learning when used to impart useful information to people with memory difficulties.

One group of people often considered difficult to treat are those with frontal lobe or executive deficits such as problems with planning, organization, and problem-solving. Even this group, however, have been helped by appropriate rehabilitation. Specific problem-solving training can help such people. Furthermore, the learning of patients with a dysexecutive syndrome and severe behavior problems can be enhanced through the provision of exaggerated feedback on their performance. A stroke patient with problems of attention, planning, distractibility, and perseverative behavior was able to overcome a number of her everyday problems through a combination of use of a pager and a checklist. More recently, a problem-solving strategy called Goal Management Training has been designed to help people with executive deficits and disorganized behavior manage their daily lives. This involves five stages, each corresponding to an important aspect of goal-directed behavior (e.g. 'define the main task', 'list the steps').

Several studies have demonstrated improvement of language functioning in both children and adults using training exercises presented through computer games. In one study children with language impairments had 8–16 hours of training over 20 days. This resulted in marked improvements of the children's ability to recognize sequences of nonspeech and speech stimuli. In another study, also using computer-based exercises, language comprehension improved with acoustically modified speech. Computer training was also carried out with 55 adults each of whom had sustained a left-hemisphere stroke resulting in aphasia. A reading treatment (visual matching and reading comprehension tasks) led to better results than computer stimulation (involving nonverbal tasks and games) or absence of treatment.

Numerous studies discuss the treatment of unilateral visual neglect, and a number of these discuss the rehabilitation of patients with visual disorders after brain injury. As with the studies quoted above, substantial evidence accrues to suggest that improvement of cognitive functioning can be achieved through rehabilitation.

MECHANISMS OF RECOVERY

The process of recovery from brain injury is not well understood and probably involves different biological processes. Changes seen in the first few minutes (for example after a mild head injury) presumably reflect the resolution of temporary dysfunction without accompanying structural damage. Recovery after several days is more likely to be due to resolution of temporary structural abnormalities such as edema or vascular disruption, or to the depression of metabolic enzyme activity.

Recovery after months or years is even less well understood. There are several ways this might be achieved, including regeneration, diaschisis, and plasticity. Regeneration in the central nervous system can occur and is more likely to do so early in life, although it does occur in adults. Thus the view held for many years that cerebral plasticity is severely restricted in the adult human brain is no longer credible. Although the limits of neurorehabilitation have been significantly influenced by the basic premise that brain cells can never regenerate, this is now known to be false and our horizons may well be extended. What is less clear is the extent to which regeneration can lead to functional gains in coping with real-life problems.

Diaschisis assumes that damage to a specific area of the brain can result in neural shock or disruption elsewhere in the brain. The secondary neural shock can be adjacent to the site of the primary insult or much further away. In either case, the shock follows a particular neural route. Similar to this, but not identical, is the idea of inhibition. In inhibition, however, the shock is more diffuse and affects the brain as a whole. Robertson and Murre (1999) interpret diaschisis as 'a weakening of synaptic connections between the damaged and undamaged sites, contingent on the reduced level of activity in the lesioned area' (p. 547). Because cells in the two areas are no longer firing together, synaptic connectivity between them is weakened and this results in the depression of functioning in the undamaged but partly disconnected remote site.

Plasticity implies anatomical reorganization based on the idea that undamaged areas of the brain can take on the functions subserved by a damaged area. Until recently this idea was discredited as an explanation for recovery in adults, although views are now changing. Robertson and Murre (1999), in a thought-provoking paper, suggest that plastic reorganization may occur initially because of a rapidly occurring alteration in synaptic activity taking place over seconds or minutes, followed by structural changes taking place over

days and weeks. The authors focus in particular on people who are likely to show recovery provided they have assistance and rehabilitation. According to Robertson and Murre, some individuals show autonomous recovery, others show little recovery even over a period of years, while others show reasonably good recovery provided they receive rehabilitation. They refer to this as a triage of spontaneous recovery, assisted recovery, and no recovery. Robertson and Murre believe that the strategy of choice for people in the 'no recovery' group is to teach compensatory approaches, and that the 'spontaneous recovery' group do not need rehabilitation as they will get better anyway. Consequently, they focus on the 'assisted recovery' group to address issues about brain plasticity. They also believe that the severity of the lesion relates to this triage, with mild lesions resulting in spontaneous recovery, moderate lesions benefiting from assisted recovery, and severe lesions necessitating the compensatory approach.

Although heuristically useful, this idea may be too simplistic. For example, people with mild lesions in the frontal lobes could be more disadvantaged in terms of recovery than people with severe lesions in the left anterior temporal lobe. The former group might have attention, planning, and organization problems precluding them from gaining the maximum benefit from the rehabilitation on offer, whereas the latter group with language problems could show considerable plasticity by transferring some of the language functions to the right hemisphere. Nevertheless, Robertson and Murre make some interesting arguments and present a model of self-repair in neural networks based on a connectionist model of recovery of function.

One technique that has potential to help us understand the nature of recovery is the employment of imaging techniques. Grady and Kapur (1999) suggest that imaging studies could enable us to measure specific changes occurring in the brain during recovery and allow us to determine whether recovery is the result of reorganization of functional interactions within an existing framework, recruitment of new areas into the network, or plasticity in regions surrounding the damaged area.

A few studies using imaging techniques to look at recovery following brain injury have been reported. Perhaps the first paper in this area reported on changes in regional cerebral blood flow (rCBF) following cognitive rehabilitation for people who had sustained encephalopathy after exposure to toxins. Later in 1997, PET was used to identify the neural correlates of stimulation procedures employed in language rehabilitation in people with dysphasia. Single photon emission computed tomography (SPECT) has been used to evaluate rCBF during recovery from brain injury. Specific changes in rCBF appeared to be related to (a) the location of the injury, and (b) strategies used in cognitive rehabilitation. Continued improvements in three patients were documented in rCBF, functional abilities, and cognitive skills up to 45 months following the injury.

The following year functional imaging was employed to monitor the effects of rehabilitation for unilateral neglect. The brain regions most active after recovery were almost identical to the areas active in control subjects engaged in the same tasks. This would appear to support the view that some rehabilitation methods repair the damaged network and do not simply benefit patients through compensation or behavioral change.

The use of imaging studies is certain to grow in research into recovery from brain injury. To what extent findings from such imaging studies will help us plan or improve rehabilitation remains an open question.

CONCLUSION

The human brain is capable of more plasticity than previously thought, since natural recovery can and does occur over time not only in children but also in adults. In addition to natural recovery there is increasing evidence that rehabilitation can result in improvements of both sensorimotor and cognitive functioning. Despite this, there is considerable variability in the nature and extent of such recovery and there are clearly limits to the amount of recovery and improvement possible in people with nonprogressive brain injury. We are now faced with a number of questions. What factors limit the recovery process? Can neurogenesis, for example, lead to cells that can survive in sufficient numbers and integrate in ways to improve everyday functioning? When should rehabilitation programs begin, during the spontaneous recovery process or later? How should we determine whether to aim for plasticity, regeneration, or compensation? Should we be influenced solely by the severity of the lesion, the cognitive function affected, the time after injury, or by all of these?

Brain Self-stimulation

Introductory article

Peter M Milner, McGill University, Montreal, Quebec, Canada

CONTENTS

Most vertebrates and some invertebrates learn to make responses that deliver electrical stimulation to parts of the nervous system. This provides a tool for studying the anatomy and neuropharmacology of reward mechanisms. Knowledge so gained has proved useful for understanding motivation and addiction.

INTRODUCTION

The observation that rats seek electrical stimulation of certain brain areas was made in 1953 by James Olds and Peter Milner, working in the laboratory of Donald Hebb at McGill University. The publication in 1949 of Hebb's influential book, *The Organization of Behavior*, brought a group of scientists to Hebb's laboratory, keen to explore his theories. James Olds was a postdoctoral fellow with a degree in social psychology from Harvard; I was a graduate student with a degree in communication engineering from Leeds University. A year before the discovery Seth Sharpless, a philosophy student from the University of Chicago, and I, seeking to improve on Hebb's account of motivation, performed a pilot study to test our notion that reward involved the recently discovered reticular activating system (RAS). Our experiments indicated, however, that RAS stimulation was punishing. As pain pathways pass through the RAS this outcome was not deemed sufficiently exciting to justify a change of thesis research.

When Olds arrived on the scene it fell to me to show him how to implant electrodes in the rat brain; Olds intended to implant his first practice electrode in the RAS. When the rat recovered from the operation he placed it on a large table and tested the effect of short bursts of stimulation. In the initial experiments the stimulation was a few volts of 60 Hz alternating current from a transformer connected to a power outlet. Most later experiments used brief (>1 s) trains of short (0.1–1.0 ms) rectangular current pulses of negative polarity. It was soon obvious that the rat found any place where it had been stimulated attractive. If removed from the place it would quickly return, sniffing and searching. Later tests, in which the rat learned to press a lever to deliver electric current to its brain, gave further reason to believe that the stimulation served as a reward.

This was very exciting. I immediately operated on another rat, using the same stereotaxic settings but, as before, without success. Suspecting that the rewarding electrode of the successful rat was not at the intended site we X-rayed its head, confirming our suspicion. Probably the dental cement holding the electrode to the skull had not set before the rat was released from the stereotaxic instrument. Unfortunately, when the rat finally came to autopsy, its brain was too badly damaged for precise localization of the electrode. Based largely on the x-ray, we estimated that the electrode was in the vicinity of the septal area, but after the relation of self-stimulation behavior to electrode site had been established by subsequent mapping studies, it became evident that the behavior exhibited by the first rat had been more similar to that of rats with hypothalamic electrodes than to rats with septal area electrodes. Before he embarked on a systematic search for reward areas in the brain, Olds designed an electrode that was held to the skull by screws rather than by dental cement.

MAJOR CHARACTERISTICS OF SELF-STIMULATION

The characteristics of self-stimulation depend greatly on the site of the electrode, owing in part to concomitant stimulation of paths not related to reward. Rewarding sites have been reported in many areas of the brains of most, if not all, vertebrates that have been tested, and even in some invertebrates. In mammals, stimulation is very rewarding in the vicinity of the medial forebrain bundle (MFB) where it passes through the lateral hypothalamus (LH), a nucleus at the base of the

brain involved in appetitive behaviors (Figure 1). Most rats with electrodes in that region quickly learn to press a lever for stimulation. Typically, after a few successful responses, they become excited and assail the lever vigorously, pausing momentarily at intervals to run in a tight circle. Some gnaw on the lever or other parts of the apparatus. If given the opportunity they may continue working at a high rate for as long as 24 h, without sleeping or eating.

Stimulation at some sites in the ventral midbrain (near the MFB) and the ventral pons elicits similar enthusiastic responding, but at most other reward sites, including parts of the frontal cortex, septal nuclei, basal ganglia, thalamus, and amygdala (too lateral to be shown in Figure 1), the results are less dramatic. At these sites, learning to bar-press may take several sessions, and responding is usually intermittent with long pauses. Sometimes the pressing is slow and deliberate and in some cases the rat recoils from the bar after pressing it, as if frightened or hurt, but nevertheless returns for more.

Stimulation at almost all reward sites appears to become aversive if the train lasts for more than a second or two, depending on its intensity. In most experiments the duration of each train of stimulation is determined by a timer, but if it is not, rats almost always release the lever within half a second. If stimulation is turned on automatically, rats will learn to press a lever to turn it off, so the effect is not due to stimulation-induced hyperactivity.

Rewarding brain stimulation can replace food or water reward in most animal learning experiments, but there are some differences. Rats with LH electrodes, for example, quickly learn to press a lever or run through a maze to receive stimulation, but they appear to forget equally quickly. They also show severe 'overnight decrement', initially ignoring, possibly even avoiding, the lever or goal-box for which they showed great enthusiasm the previous day. 'Priming' by a few bursts of stimulation delivered by the experimenter restores the motivation.

MECHANISMS OF SELF-STIMULATION

Quite soon after mapping the reward system, Olds discovered that self-stimulation was profoundly depressed by antipsychotic drugs. Subsequent discovery of dopamine fibers in the MFB led to the theory that stimulation fires these fibers, releasing dopamine in forebrain structures to reinforce synaptic connections. This theory was too simple to be the whole story. Dopamine fibers, which are all unmyelinated, are not easily fired by the short pulses of current commonly used for self-stimulation.

It was next postulated that the current fires myelinated fibers, which then synapse with dopamine neurons in the ventral tegmental area (VTA), thus indirectly increasing the delivery of dopamine to forebrain structures. However, such an increase has proved difficult to measure. Dopaminergic activity seems to increase mainly during unexpected

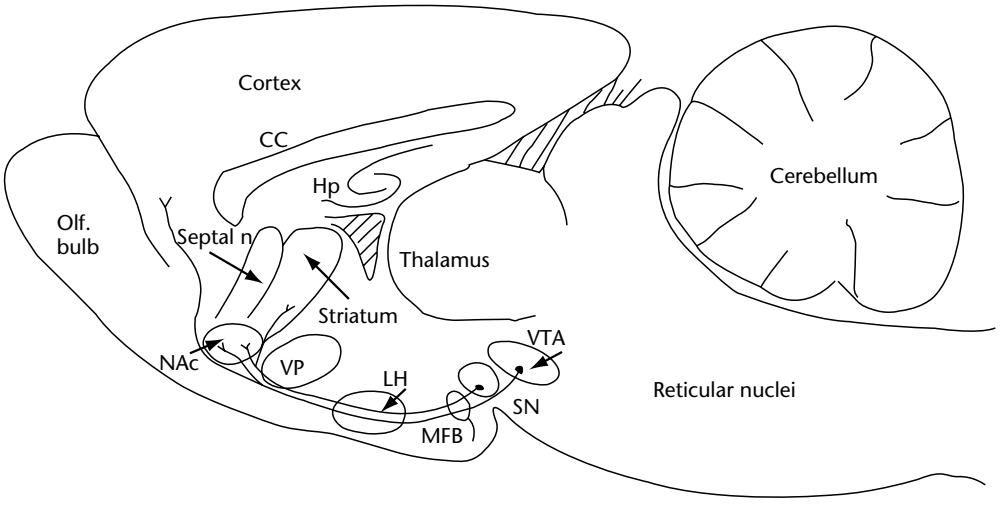

Figure 1. Longitudinal section of rat brain showing the locations of some brain-stimulation reward sites. CC, corpus callosum; Hp, hippocampus; LH, lateral hypothalamus; MFB, medial forebrain bundle; NAc, nucleus accumbens; Olf., olfactory; SN, substantia nigra; VP, ventral pallidum; VTA, ventral tegmental area.

events, which is of course when most learning takes place.

It certainly appears that dopamine is essential for brain stimulation reward from MFB sites; blocking its action in the accumbens nucleus by injecting a small quantity of a dopamine-blocking agent quickly diminishes self-stimulation. The accumbens is a nucleus that until the 1970s was considered part of the septal area, but its cell type and connections indicate that it is functionally part of the ventral striatum. It receives dopaminergic input via the MFB.

Using the fact that there is a rapid increase in the expression of the protein Fos in neurons when they are active, it has been found that self-stimulation of the LH or VTA activates neurons in many subcortical nuclei. Lesions indicate, however, that only a few of them play a vital role in self-stimulation. Some neurons are activated directly by the electrical current, others via synaptic connections from directly stimulated neurons. Some of the neurons that express Fos may be those involved in bar-pressing. An activated area that seems important for reward is the ventral pallidum, which lies just anterior to the LH. Some of its connections are to midbrain nuclei, including those that deliver dopamine to forebrain areas.

Signals from hunger, thirst, and other motivational states are delivered to the ventral part of the striatum, where they elicit appropriate response plans. It is there that incipient response activity can be either suppressed, or amplified to become an overt movement. The amplification circuit, which is modulated by dopamine, normally receives input from innately rewarding stimuli (such as water, or the smell of food) via the hypothalamus or the amygdala. The response suppressing system, which may also be modulated by dopamine, receives innately aversive input (pain or predator smell) mainly via the thalamus or the amygdala.

Innately neutral sensory input reaches the striatum via the cerebral cortex. In the striatum this input may acquire associations (by classical conditioning) with either the response amplifier or the response inhibitor, depending on which type of innate reinforcer influences the ventral striatum at the time. Thus an animal may at first be attracted only by the smell of food in a dish, but in time it is also attracted by the sight of the dish.

Rewarding brain stimulation is assumed to stimulate pathways that would normally be activated by innate rewards such as food, thereby triggering the response release mechanism in the striatum. As a consequence, sensory input and plans for motor activity that reach the striatum during rewarding stimulation acquire the ability to amplify and release a planned response.

It is generally assumed that brain self-stimulation has an effect similar to a conventional reward except that the modulatory effect of bodily need is bypassed. If an animal is not hungry, for example, the smell and taste of food do not amplify response plans, but self-stimulation, by acting directly on the reward system, is not greatly influenced by the intensity of bodily need. Self-stimulation has proved a useful tool for studying the basic mechanism of reward, providing direct access to the anatomical and physiological features of the system.

SELF-STIMULATION AND THE STUDY OF ADDICTION

Harmful addictions are the penalty we pay for an effective motivation system. Understanding the reward system in the brain is highly relevant to the way we approach the problems of drug abuse and other obsessive indulgences. At one time the most widely held view of drug dependency was that aversive after-effects of abused substances are alleviated by taking more of the substance, leading to a vicious spiral. Neither the sites of action nor the pharmacological processes involved were known. After the discovery of brain-stimulation reward, parallels were drawn between the behavior of the self-stimulating rat and that of addicts.

All creatures are in a sense addicted to certain essentials like air, water, heat, and food, all of which can be harmful in excess. Fortunately, protective regulators evolved along with the appetites. Automatic regulation of stimulants that act directly on the reward system is more difficult. Electrical stimulation has a similar direct effect on reward mechanisms, but with the advantage that it is easier to identify the brain structures involved, so that their connections and pharmacological properties may be studied.

When the importance of dopamine for self-stimulation was discovered, dopamine soon became a prime focus of investigations into drug abuse. It was pointed out that enhancers of dopaminergic action, such as amphetamine and cocaine, are addictive. Many dopaminergic neurons are sensitive to other abused substances such as opiates and nicotine.

The knowledge concerning the anatomy of reward systems was helpful in designing experiments to explore addictive processes; the techniques used for electrical stimulation were also

adapted for use in these experiments. Rats learn to press a lever to deliver many of the substances that are addictive to humans directly to a point in the brain via implanted cannulae. This makes it possible to determine or confirm the sites of action of a drug.

The dopamine theory of reward changed the direction of addiction research, but like most new theories it proved to be an oversimplification. Opiate receptors, for example, are widespread in the brain and almost certainly affect learning and other systems directly, as well as via dopamine. The mechanism by which dopamine itself influences reward is still not fully understood. Today the incentive for a great deal of the research on self-stimulation is the desire to resolve the problem of drug dependency. This quest, having been reoriented by the discovery of electrical self-stimulation, is now the tail that wags the dog.

SELF-STIMULATION AND THE STUDY OF COGNITION

Although philosophers used to draw a sharp distinction between knowledge and the will, behavior cannot be so clearly compartmentalized. Attention provides a strong link between motivation and perception, for example. Research on brain stimulation reward contributes to cognition by providing a better understanding of motivational mechanisms.

It is probably true to say that most perceptual research and theory during the twentieth century ignored attention. Sensory paths were treated as one-way streets from receptors to some internal representation of a stimulus in memory, or to the response mechanism. The basic function of sensory systems to extend the capacity of the motor system went unnoticed, or was forgotten.

Decisions to make a response are made on the basis of the kind of information we call motivational. Once the decision to act has been established, motor adjustments required to implement it are guided by the sort of stimuli that are most usually studied in perceptual experiments: the shape, color, distance and so on of objects. Of the very large number of stimuli usually present in the environment, the perceptual systems select for processing only those that pertain to the task in hand. In order to study the mechanism by which this is achieved it is necessary to understand how motivating stimuli influence response plans, and how these plans then interact with the reception and transmission of sensory signals.

Incentive learning is another example of the interplay between perceptual input and motivation. Important motivational paths meet sensory input in the striatum, suggesting that it is a place where stimuli that are not innately motivating may acquire value. Patterns of sensory input acquire the ability to release behavior or inhibit it. By the reverse process, motivational signals become associated with sensory patterns that are correlated with innately reinforcing events. Hunger becomes associated with the image of a food dish, for example. It is this image that determines the pattern of stimulation to which the sensory system is sensitized. In other words, reverse pathways in the sensory systems carry attentional facilitation. They can lower the perceptual threshold for goal-related stimuli and the motor threshold for intention-related actions. Thresholds for distracting stimuli are raised.

Cerebellum

Intermediate article

Frank A Middleton, State University of New York Upstate Medical University, Syracuse, New York, USA
Stephen I Helms Tillery, Arizona State University, Tempe, Arizona, USA

CONTENTS

The cerebellum ('little brain') contains more neurons than the rest of the entire nervous system, and its complex organization has been the subject of much research. Although it is not essential for cognitive thought processes, the cerebellum is clearly involved in the performance of some cognitive tasks and in the improvement of motor control.

INTRODUCTION

The human cerebellum is a fist-sized structure that sits in the back of the skull, located just behind the midbrain and below the cerebral hemispheres (Figure 1). It has been the subject of considerable scientific attention for much of the past two hundred years from researchers in such diverse fields as phrenology, psychiatry, evolutionary and comparative biology, neurology, genetics, and developmental biology. Cerebellum is translated literally as 'little brain' and indeed, despite its relatively small size, this single structure contains more neurons than the rest of the nervous system combined. While this feature alone might seem daunting at first glance, there are several aspects of cerebellar organization that have greatly simplified its study and led to its widespread use as a model system for addressing a large number of structural and functional issues in brain research.

ANATOMY

The cerebellum is often depicted as a composition of three basic elements: the cerebellar cortex (which consists of a granular layer, Purkinje layer and molecular layer), the deep cerebellar nuclei, and the large white-matter tracts that run between these structures and connect the cerebellum with other brain structures. In cerebellar cortex, five main types of neurons have been identified – the Purkinje, Golgi, granule, basket and stellate cells (Table 1, Figure 2) – as well as three minor classes of neurons – Lugaro, unipolar brush and pale cells (not shown). In the deep cerebellar nuclei, there are only two main types of neurons – projection neurons and local interneurons – although several minor classes have also been identified. In both the cortex and deep nuclei, the connections and neurochemical markers of these neurons have been well characterized (Table 1, Figure 2). In addition to these neuronal classifications, there are also three different types of nonneuronal cells in the cerebellum: radial (or Bergmann) glial cells in the Purkinje and molecular layers of cerebellar cortex; bushy astroglia in the granular layer; and oligodendrocytes in the white-matter layer between the cerebellar cortex and deep nuclei. Perhaps the most salient feature of cerebellar organization is the orderly arrangement of connections between all of these different cell types in the cerebellum (Figure 2). This circuitry was worked out by careful and time-consuming anatomical and electrophysiological mapping studies (see Ito, 1984). Because this basic circuitry exists throughout the entire cerebellum, researchers have been able to understand how the whole cerebellum works by studying only small parts of it.

Superimposed on the repetitive microcircuitry of the cerebellum are larger structural and functional subdivisions which have proved extremely useful for understanding cerebellar organization. At the gross anatomical level, the cerebellum is divided into multiple lobes or lobules, often smooth in appearance in smaller species but composed of numerous folds and fissures in more complex animals (Table 2, Figure 1). Each of these subdivisions contains essentially the same microcircuitry shown in Figure 2. The somewhat complicated nomenclature listed in Table 2 (and defined and described in detail by Larsell and Jansen, 1972) was actually developed as a simplifying scheme of the

Connections and microcircuitry of cerebellar structures. 5-HT, 5-hydroxytryptamine (serotonin); ACh, acetylcholine; DA, dopamine; GABA, gamma-aminobutyric acid; GLU, glutamate; NA, noradrenaline (norepinephrine). Plus and minus signs refer to excitatory and inhibitory projections, respectively.

transverse structural organization of the cerebellum that holds across all species of animals. However, the functional organization of the cerebellum as it is currently understood is simpler, and consists of different transverse 'zones' (see Jansen, 1972; Voogd, 1975). In the sagittal plane, the cerebellum can be divided into midline (vermal), intermediate (paravermal) and lateral (hemispheric) zones (Table 3, Figure 1). Each of these zones receives a certain type of functional input at the level of the cerebellar cortex and sends its output largely through a single deep nucleus. For example, most of the vermal zone is concerned with maintaining posture and balance and coordinating reflexes (including reflexive eye movements and some autonomic functions) and directs its output through the medial deep cerebellar nucleus. In a similar manner, most of the intermediate cerebellum is concerned with sensory and motor processing that facilitates and coordinates voluntary movement, and directs its output through the intermediate deep nuclei. Lastly, most of the lateral cerebellum (also called 'neocerebellum' by some investigators) appears to be concerned with the planning, generation and control of complex behavior and directs its output through the lateral deep nucleus (Table 3).

The cerebellum is known to be connected with a large variety of different brain regions, including the spinal cord, brainstem, vestibular and reticular nuclei, as well as several major nuclei that are known to be the site of synthesis of specific neurotransmitters, such as the raphe, ventral tegmental area, locus caeruleus, and pedunculopontine nuclei (Figures 1 and 2). The sole output structures of the cerebellum are the four deep cerebellar nuclei and the vestibular nuclei (Table 3). These nuclei send signals back to many of the same brain regions that provide input to the cerebellum. Not surprisingly, the area of the cerebellum that is reciprocally connected with these extracerebellar regions has often been shown to be involved in functions that are related to that structure. For example, vestibular signals from the inner ear regarding movement of the head are sent primarily to the vermis. The activity of neurons in certain parts of the vermis has been shown to be related to both these sensory signals and to the commands for movement that are sent from the cerebellum to the vestibuloocular system to help maintain orientation of the head and eyes while the body is in motion. A similar type of arrangement has been shown to exist for the connections between the cerebral cortex and cerebellum. Most of the cerebral cortex sends fibers to the pontine nuclei that are a source of input to the cerebellar cortex. In turn, the output nuclei of the cerebellum project back, via the thalamus, to many of the cortical areas from which they receive input. Defining the full scope of areas that participate in these types of reciprocal cerebellar loops has important implications for understanding the functions with which the cerebellum is most likely to be involved.

The precise nature of the input projection to the cerebellum depends on the structure from which it originated. Signals from the pontine nuclei, vestibular nuclei, trigeminal nuclei and spinal cord are conveyed to the cerebellum by mossy fiber projections to granule cells. Signals from the red nucleus are conveyed by a projection to the inferior olive, which sends climbing fibers to Purkinje cells (Figure 2). Within the cerebellum, a great deal of processing of these signals takes place using cerebellar microcircuitry. For many functions, this processing has been shown to improve the accuracy of the signals, so that the behavior or function that modulates the activity in the circuit is seen to improve. For this reason, the cerebellum has often been thought of as a type of external teaching device that improves the performance of any brain region participating in cerebellar feedback loops. In addition, the cerebellum has also been depicted as a

type of feedforward processor that integrates much of the low-level sensory information it receives into signals that help direct the activity of higher-level brain areas.

Three types of evidence are used to determine the functions that the cerebellum is involved in. First, anatomical data help define what areas of the brain participate in cerebellar loops, and thus what types of signals the cerebellum is likely to process. Second, physiological data from imaging studies and recordings of cerebellar cells have indicated which cerebellar regions and neurons are active during specific tasks. Finally, data from clinical, pathological and behavioral studies have revealed what the functional consequences of cerebellar damage are.

ROLE OF THE CEREBELLUM IN MOVEMENT

Theories about the role of the cerebellum as a component of the motor control system have a venerable history, dating back at least to the eighteenth century. In the nineteenth and early twentieth centuries, Flourens, Luciani and Holmes separately described the results of cerebellar damage (for a thorough review of these and later studies see Dow and Moruzzi, 1958). During the First World War, Holmes described several discrete movement disorders that resulted from gunshot wounds of the cerebellum, and attempted to characterize these disorders based on the site of damage. In so doing, Holmes essentially defined the classic

'cerebellar syndrome' that has guided much of the research on the cerebellum ever since.

Cerebellar Lesions and Motor Function

Following unilateral lesions limited to the lateral lobes of the cerebellum, Holmes and others noted the loss of muscle strength and tone, most often involving the arms (but occasionally the legs), along with ataxia, rebound disorder, oculomotor disorders, postural disorders and scanning speech. The most conspicuous of these symptoms is ataxia, a generalized disorder of coordinating and executing voluntary movements. In their attempts to coordinate movement, cerebellar patients often exhibit asynergia, or difficulty coordinating muscular actions, and decomposition of movement, in which normal complex movements become broken down into single movements involving single joints. In executing movements, patients with cerebellar damage suffer from dysmetria, poorly directed movements which often miss their targets, and deviations from the line of movement, where a movement path does not follow the shortest line between two points. Possibly related to dysmetria is intention tremor, or involuntary shaking of the reaching hand or limb as it performs an action. Examples of these types of problems are easily seen when people with cerebellar damage are asked to touch their nose with one of their fingers. At first, the movement becomes decomposed. To reach the finger to the nose requires coordinated movements of the shoulder, elbow and hand, but is nonetheless readily performed in one smooth motion by normal individuals. People with cerebellar damage, however, might perform this movement by first lifting the shoulder until the arm is horizontal, and then flexing the elbow separately to bring the hand close to the nose. Finally, when the finger approaches the nose, involuntary alternating contractions of the muscles in the hand and wrist cause the finger to successively undershoot and overshoot the nose. Interestingly, high levels of ethanol consumption produce a similar effect, probably due to its action on the cerebellum, forming the basis of the modern sobriety test.

Another specific problem of coordination often seen in people with cerebellar damage is dysdiadochokinesis, or difficulty in performing rapidly alternating movements, such as slapping the surface of a desk repeatedly first with the palm of the hand and then the back of the hand. In dysdiadochokinesis the movements of the affected limb slow down and decrease in amplitude.

Midline cerebellar lesions often also lead to oculomotor and postural disorders. Some of these may be analogous to the weakness and dysmetria of the limbs seen with lateral cerebellar lesions. For example, people with cerebellar damage often exhibit difficulty maintaining their gaze on moving objects, and may display nystagmus – continuous oscillations of the eyes as if they were watching a train pass. Speech is often also affected in cerebellar lesions, causing scanning speech in which articulation is difficult and often staccato. Importantly, however, none of the effects of cerebellar lesions on motor performance that have been described implies that the cerebellum is essential for the direct control of movement. Indeed, lesions of the cerebellum do not prevent the initiation of movement, but rather cause problems in the optimal regulation and performance of ongoing movement.

Another aspect of cerebellar organization revealed by Holmes's early work, and reinforced by many anatomical and physiological mapping studies, has been the realization that the functions of the cerebellum are somatotopically organized: that is, the regions of the cerebellum concerned with the sensation and movement of the arms, legs, eyes and face are largely separate from each other. This is true even though these body parts are each represented multiple times throughout the cerebellar cortex and deep nuclei.

Cerebellar Physiology

Knowledge of the effects of cerebellar damage formed a backdrop to the earliest physiological studies of the cerebellum. Research by Eccles and his colleagues (Eccles *et al*., 1967) and more recently by Rodolfo Llinas (Llinas and Sotelo, 1992) has dissected the basic physiology of the cerebellum and particularly the cerebellar cortex. Indeed, the basic firing properties of the major cell types in the cortex have been worked out in detail. The main output cell of the cerebellar cortex is the Purkinje cell; these distinctive cells are notable in that they fire two distinct types of action potentials, simple spikes and complex spikes (Thach, 1968). (*See* **Single Neuron Recording**)

Simple spikes are typical neuronal action potentials, in which the neuron's membrane voltage changes rapidly from about −50 mV to +50 mV, and then returns again to its resting membrane potential of about −50 mV. This entire cycle occurs in the space of less than 3 ms when the sum of a Purkinje cell's inputs from other sources, notably parallel fibers, exceeds a threshold voltage.

These simple spikes can occur at rates of up to $100\,s^{-1}$. Simple spikes are known to occur in a predictable fashion with a variety of volitional movements. The relations between behavior and simple spike discharge have been especially well characterized during arm movements, head and neck movements, smooth pursuit and vestibulooocular reflex eye movements, and during walking. Generally, the firing rates of Purkinje cells during movement can be related to specific aspects of the movement, such as velocity of joint rotation or eye movement, or direction of arm movement.

Complex spikes, on the other hand, are not typical at all. During a complex spike, the neuron's membrane voltage increases rapidly, but then stays at a high value for an extended period, lasting perhaps 20 ms or longer. While the membrane potential is depolarized, the neuron typically fires many action potentials. The complex spikes occur in a one-to-one relationship with the arrival of action potentials on the climbing fibers. Thus, a single action potential from the inferior olive produces a profound and long-lasting depolarization in the membrane potential of a Purkinje cell. Typically, complex spikes occur only once or twice per second. Complex spiking in Purkinje cells can often be reliably produced by application of stimuli to distinct patches of skin. Interestingly, during behavior, complex spiking can often be most readily related to the occurrence of unexpected stimuli. During walking, for example, if an unexpected obstacle prevents the swing of the leg, complex spikes are often seen in the lateral lobes.

Explaining the relations between simple spikes, complex spikes and behavior in terms of the operation that the cerebellum performs, however, has proved remarkably difficult. Two general types of models, not necessarily exclusive, have been proposed to describe the operations of the cerebellum in motor control: cerebellar learning hypotheses and cerebellar timing hypotheses. According to learning hypotheses, the cerebellum learns maps between input patterns and output patterns. The core idea, proposed independently by David Marr and James Albus around 1970, is that the strength of synapses between parallel fibers and Purkinje cells can be modified, and that the changes in the strength of those synapses are regulated by the action of climbing fibers. While evidence for this idea has proved both elusive and controversial (Bell *et al*., 1996), a great deal of cerebellar research has been inspired by this theory. Work by Masao Ito and colleagues (Ito, 1984) suggested that complex spikes induce a long-term change in the responsiveness of Purkinje cells to parallel fiber inputs, termed 'long-term depression' (LTD). While LTD is reliably produced in experimental situations, it is not clear whether it also occurs in more physiological conditions – see work by Bloedel and Kelley, in Llinas and Sotelo (1992). It also seems likely that the cerebellum plays a part in classical conditioning such as the nictitating membrane reflex, but the original idea that the engram for this conditioning lies in the cerebellum itself has not been borne out by all researchers (see Bell *et al*., 1996, and special issues of *Trends in Neurosciences* and *Trends in Cognitive Science* listed under 'Further Reading'). In contrast, there is accumulating evidence that the cerebellum is a critical storage site for the storage of the engram established during the learning of some operantly conditioned behaviors (see Milak *et al*., 1997). (*See* **Long-term Potentiation and Long-term Depression**)

Another idea consistent with the observations of asynergia and decomposition of movement is that the cerebellum participates in coordination by handling problems of timing. The core idea was initially proposed by Valentino Braitenberg, who noted that the parallel fibers stretching across a row of Purkinje cells looked something like a delay line, and proposed that this feature might enable the cerebellum to select the relative timing of output events. Research by Ivry and Keele has indeed shown that cerebellar patients often have difficulty judging and reproducing temporal intervals. More recently, evidence from several laboratories, notably the experimental work of Fred Miles and Steve Lisberger in eye movements and Jim Bloedel in limb movements, as well as the theoretical work of Chris Miall, has suggested that complex spikes might serve as a generalized error signal, reporting that in some way behavioral output is not meeting expected outcomes. Thus, the inferior olive would communicate an error signal to the cerebellar cortex that it needed to modify its output. The specific mechanism by which this signal leads to a change in the processing of information by the cerebellum is not yet clear, but it does seem to be consistent with a number of lines of evidence, including the error signal idea. (*See* **Time Perception and Timing, Neural Basis of**)

DOES THE CEREBELLUM PLAY A PART IN COGNITION?

The cerebellum has received a great deal of attention regarding its potential involvement in cognitive functions. In discussing this possibility, it is helpful to define precisely what is meant by the term 'cognition'. For many researchers, the term is

often operationally defined as an 'awareness' of behavior and the ability to voluntarily modify it. Using this definition, the evidence for the cerebellum's involvement in cognitive behavior is compelling. However, this involvement does not imply that the cerebellum is essential for that behavior. Animals and humans lacking a functioning cerebellum can interact meaningfully and demonstrate awareness of their behavior. Nonetheless, studies have shown that when the cerebellum is badly damaged, there are alterations in certain types of cognitive behavior that can be assessed with well-designed formal tests. When evaluating such studies, however, it is important to keep in mind the nature of the damage and the nature of the behavior being measured before reaching any conclusions. For example, it has been reported that individuals with localized cerebellar damage have deficits on many standardized intelligence and psychological tests. However, a close inspection of the results in some of these studies reveals that most of the tests that the cerebellar patients performed badly placed considerable demands on hand–eye coordination (visuomotor abilities) and the speed of responding, parameters that have little to do with formal cognitive processing. Thus, from these types of studies it is often not clear what type of cognitive deficits are present that are independent of motor deficits. In order for the cerebellum to be accepted as a true nodal point for normal cognitive processing, it is necessary to show that cerebellar damage can produce cognitive deficits without affecting motor performance. To date, very few studies have reported this type of finding for cerebellar patients.

Fiez and colleagues performed psychological testing on a patient with a localized lesion resulting from a small stroke in the lateral portion of one cerebellar hemisphere (Fiez *et al*., 1992). This patient had excellent scores on all standard intelligence and language measures. However, when he was given tasks to perform that involved rule-based learning, verbal association and planning, he showed deficits in the ability to improve his performance with practice, and mild deficits in the actual tasks themselves. Similar types of practice-related and performance deficits were also reported in studies of cerebellar patients by Jordan Grafman and colleagues (1992) at the National Institutes of Health. In addition, Akshoomoff and Courchesne (1992) studied a group of people with widespread cerebellar damage and concluded that one of the main consequences of cerebellar damage in humans was reduced verbal fluency and verbal association capacity, and impaired visuospatial skills. Finally, work by Ivry and Keele (1989) has shown that patients with lesions of the lateral cerebellum, but not the medial cerebellum, display impaired perception of temporal intervals. Thus, it appears that certain cognitive tasks do involve the cerebellum, particularly the lateral portions of it, and that improving the performance of these tasks, or detecting performance errors, requires the activity of an intact cerebellum. Moreover, in some cases the cognitive deficits appear to be present without considerable motor deficits. Therefore, it is possible that the deficits in verbal association, visuospatial skills, rule-based learning, planning and error detection form the core cognitive symptoms of cerebellar damage.

In addition to studies of cerebellar damage, perhaps the best evidence in support of the cerebellar involvement in cognitive function is derived from studies of cerebellar activation during cognitive tasks using brain imaging techniques such as positron emission tomography (PET) or functional magnetic resonance imaging (fMRI); for a review of this topic see Desmond and Fiez (1998). Importantly, with these approaches, it is possible to compare the activation seen during cognitive tasks with that seen during motor tasks, and thus reach more accurate conclusions regarding the patterns of activity one sees. In one of the early PET studies of cerebellar activation, Fiez and colleagues (1992) examined the potential cerebellar involvement in cognitive and language tasks. Participants in the study were asked to vocalize a verb after being presented with a noun; for example, given the noun 'dog', a participant might generate the verb 'bark'. These nouns were presented by auditory or visual means, and the levels of cerebellar activity during this task were compared with the activity seen during two types of control task. In the sensory control task, participants only looked at or listened to the noun, and in the motor control task for speech output, participants immediately repeated the noun they were presented with. In the motor control task, activation was confined to the midline cerebellar hemisphere and to motor and premotor areas of the cerebral cortex normally seen activated during speech. In the verb generation task, however, in addition to the areas activated during the motor control task, there was activation of the lateral cerebellar cortex and prefrontal regions of the cerebral cortex. Whether this additional activation was related to purely language functions or a working knowledge of the strategy involved in performing the task is not clear, and both are likely possibilities. This same task, however, was the one that the cerebellar

patient studied by Fiez and colleagues was found to be profoundly deficient on. In another imaging study, Decety *et al*. (1990) reported activation of the cerebellum in participants who were asked to imagine swinging a tennis racket, and to silently count the number of times they hit the ball. In comparison with people at rest, the people performing the mental imagery had a 10% increase in lateral cerebellar activity during silent counting and a 20% increase during the mental imagery condition. Finally, using fMRI, Kim *et al*. (1994) examined the activation of the lateral output nucleus of the cerebellum (the dentate) while participants sat in a scanner and either thought about ways to solve a difficult pegboard puzzle, or made visually guided movements of pegs in a pegboard. The participants had only mild increases in activity during the motor task, but displayed extensive activation of the dentate while mentally working out possible solutions to the puzzle. Taken together, these imaging studies show that whether or not observable movement takes place, there are regions of the cerebellum that display prominent activation during cognitive tasks, and that these areas appear to be different from those activated during simple motor tasks. This finding supports the idea that the cerebellum can process both cognitive and motor information using parallel circuits. (*See* **Planning: Neural and Psychological**; **Neuroimaging**)

ROLE OF THE CEREBELLUM IN COGNITIVE FUNCTION

The cerebellum is not essential for cognitive thought processes. However, the cerebellum is clearly involved in the performance of some cognitive tasks. The demonstration that cerebellar damage can alter affect behaviors that are known to rely on specific cognitive areas of the cerebral cortex suggests that the cerebellum must be communicating with these areas to exert its influence. In monkeys and cats, reciprocal cerebellar connections have been described with regions of the parietal cortex concerned with spatial orientation and attention and also areas of prefrontal cortex concerned with planning, rule-based learning, short-term working memory and verbal association. There are also reciprocal cerebellar connections with neuroendocrine areas of the brain, including parts of the hypothalamus. Together, these connections allow the possibility of direct cerebellar involvement in modulating limbic and autonomic functions as well as cognitive and motor functions. Such connections with primitive and highly advanced brain areas indicate that the cerebellar involvement in modulation of nonmotor function has a long-standing precedent and is not unique to humans. (*See* **Spatial Attention, Neural Basis of**; **Frontal Cortex**; **Hypothalamus**)

Although we know a great deal about the functions of the cerebellar microcircuitry and how it operates within the domain of vestibular, motor and sensory processing, we do not yet have any real insight into what the cerebellum might be doing during cognitive processing, or any idea at all how it utilizes the signals it receives from limbic, neuroendocrine and neurotransmitter synthesizing nuclei. We assume that the cerebellum does the same thing for cognitive tasks that it does for noncognitive tasks – namely, that it improves overall task performance by using its circuitry to fine-tune the speed, efficiency and accuracy of the response or planned response. However, one of the challenges of future research will be to show how this is achieved at the cellular, molecular and physiological levels for all types of behavior that fall under the influence of the 'little brain'.

Cerebral Commissures

Intermediate article

Alison Walter, McMaster University, Hamilton, Ontario, Canada

CONTENTS

The cerebral commissures house the fibers that interconnect the two hemispheres of the brain. The main fiber tract, namely the corpus callosum, varies greatly in size in the human brain. Factors such as sex of the individual and chronological age affect its size. Relationships exist between callosal size, degree of functional asymmetry and cognitive ability. The callosum may play a crucial role in the experience of conscious unity.

INTRODUCTION

With the increasing prominence of the neocortex in the mammalian brain, a system of neocortical commissures developed which provide a direct route for interhemispheric exchange of sensory and stored information. The importance of these commissures for cognitive function is now well established, but this issue has had a chequered history. As early as the eighteenth century, when neuroanatomists still did not know of the existence of neurons and their axons, the corpus callosum was believed by some to be the seat of the soul or the center of rationality or of higher thought. However, during the first half of the twentieth century, most authors considered the corpus callosum to have no function at all, except perhaps as a mechanical support for the cerebral cortex. There were exceptions, like Ramón y Cajal, who postulated that since memory centers for language are unilateral, but perceptual centers are present on both sides, the corpus callosum must be necessary to allow information to flow between the two hemispheres. By the 1960s, experimental research in animals and then studies of patients in whom the corpus callosum was surgically divided demonstrated the functional necessity of the callosum. Most recently of all, the role that the corpus callosum may play in the experience of human consciousness and personal identity is being reconsidered.

STRUCTURE

Gross Anatomy and Functional Topography

The corpus callosum (CC) is the main fiber tract connecting the cortical neurons between the two cerebral hemispheres. It is a major feature of the mammalian brain. The human CC is a large structure, about 7 cm in length from front to back, and it contains about 300 million fibers or axons. Axons from callosal neurons pass through the CC in a systematic pattern. Figure 1 is a photograph of a postmortem brain showing the CC and some anatomical regions. In general, the most anterior curved region of the CC, namely the genu, interconnects the prefrontal regions. The body of the CC interconnects the precentral and postcentral regions. The posteriormost part of the CC body, referred to as the isthmus due to its narrowing in height relative to the other regions, connects the posterior temporal and anterior parietal cortical regions between the hemispheres. The size of the isthmus has been particularly linked to the asymmetry in function between the two hemispheres, and to sex differences in CC anatomy (issues which will be discussed in more detail later). The posterior bulbous region is the splenium, which connects mainly occipital lobe cortex. The splenium has also been the subject of numerous studies concerning differences in CC size between the sexes.

Experimental research using methods of retrograde degeneration following cortical lesions and autoradiographic tracing techniques in monkeys have shown the specificity of the systematic pattern of the location where axons course through the CC to the opposite hemisphere (Figure 2). This topography is consistent with results obtained from neuropsychological studies of commissurotomized (split-brain) patients who underwent sectioning of

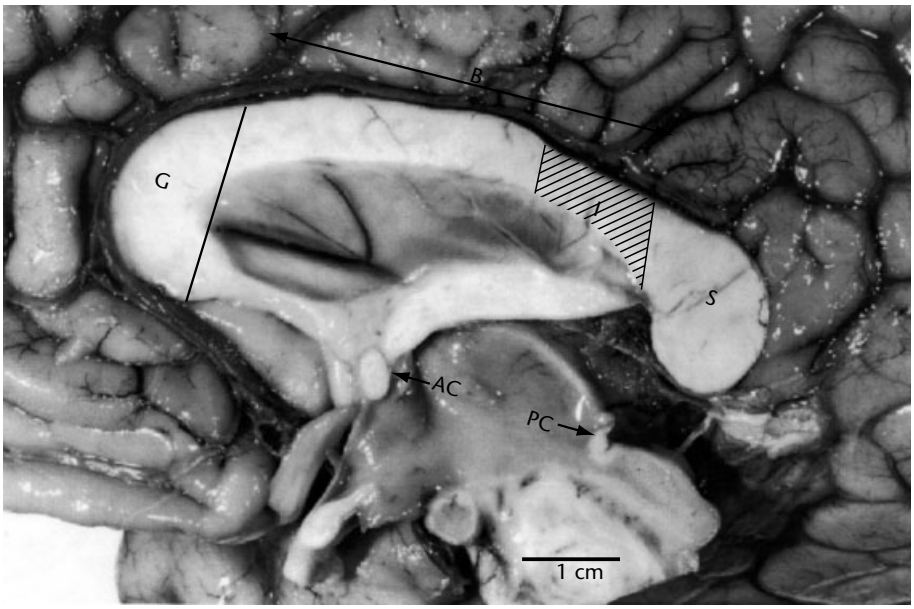

Figure 1. Photograph of the midsagittal view of an adult brain highlighting the three commissures, namely the corpus callosum (CC) and its main subregions [G, genu (most anterior region); B, body; I, isthmus (shaded); S, splenium] the anterior commissure (AC) and the posterior commissure (PC). Scale bar represents 1 cm.

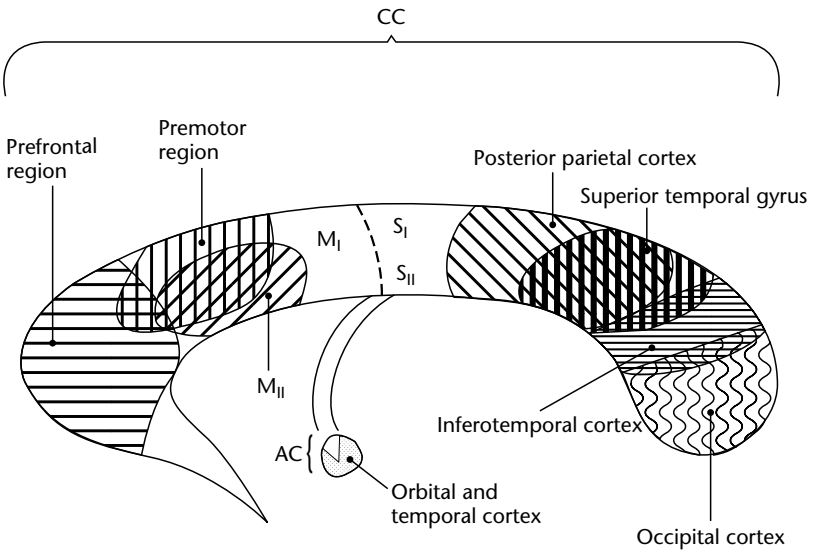

Figure 2. Diagrammatic representation of the midsagittal section of the corpus callosum (CC) and anterior commissure (AC) of the rhesus monkey, showing the topography of commissural fibers from different parts of the cerebral cortex. M_I, precentral motor region; M_{II}, supplementary motor region; S_I and S_{II}, postcentral somesthetic gyri. (Adapted from Pandya DN and Seltzer B (1986) The topography of commissural fibers. In: Leporé F, Ptito M and Jasper HH (eds) *Two Hemispheres – One Brain: Functions of the Corpus Callosum*, pp. 47–73. New York: Alan R. Liss.)

the CC for the relief of epilepsy that was uncontrollable by drug treatment. In some cases, the complete CC is not cut. Sectioning the posterior CC regions results in loss of transfer of visual or tactual information between the hemispheres. Sectioning only the anterior regions does not interfere with modality-specific cognition, but does interfere with more general cognitive functions such as semantic processing and aspects of memory (Sperry, 1974). The precise topography of the CC, as well as

the fractionation of cognition that study of the CC makes possible, are revealed by other clinical cases, such as those with callosal lesions. The latter indicated that the anterior to middle splenium is involved in the transfer of pictorial information from the language-nondominant hemisphere to the language-dominant side, and that the ventroposterior part is involved in the transfer of letter information.

Sex Differences
